Taylor, Frederick Winslow

The inscription "Frederick W. Taylor, Father of Scientific Management" appears on the grave marker of the U.S. inventor and engineer who introduced fundamental reforms in management practices. At a time when power-driven machines were beginning to have revolutionary effects in the countries of the West, he developed a means of improving the quality of industrial management by viewing it as an art based upon scientific principles. Universal in concept, his system, called scientific management, has influenced the development of virtually every country enjoying the benefits of modern industry.

By courtesy of the Smithsonian Institution, Washington, D.C.

Taylor.

Taylor was born in Philadelphia on March 20, 1856, the son of a lawyer. His early education included study at Germantown Academy and a European trip with his mother. Intending to follow his father's profession, he entered Phillips Exeter Academy in New Hampshire in 1872; he led his class scholastically and excelled in baseball as pitcher and team captain. After passing the entrance examination for Harvard, he was forced to abandon plans for matriculation, as his eyesight had deteriorated from night study. With sight restored in 1875, he was apprenticed to learn the trades of patternmaker and machinist at the Enterprise Hydraulic Works in Philadelphia.

Three years later he went to the Midvale Steel Company, where, starting as a machine shop labourer, he became successively shop clerk, machinist, gang boss, foreman, maintenance foreman, head of the drawing office, and chief engineer.

In 1881, at 25, he and a tennis partner won the National Doubles Championship; the same year he introduced time study at the Midvale plant. The profession of time study was founded on the success of this project, which also formed the basis for Taylor's subsequent theories of management science. Essentially, Taylor suggested that production efficiency in a shop or factory could be greatly enhanced by close observation of the individual worker and elimination of waste time and motion in his operation. Though the Taylor system provoked resentment and opposition from labour when carried to extremes, its value in rationalizing production was indisputable and its impact on the development of mass-production techniques immense.

Time and motion study

Studying at night, Taylor earned a degree in mechanical engineering from Stevens Institute of Technology in 1883. The following year he became chief engineer at Midvale and completed the design and construction of a novel machine shop. In 1884 he also married Louise Spooner. Taylor might have enjoyed a brilliant fulltime career as an inventor—he had more than 40 patents to his credit—but his interest in what was soon called scientific management led him to resign his post at Midvale and to become general manager of the Manufacturing Investment Company (1890–93), which in turn led him to develop a "new profession, that of consulting engineer in management." He served a long list of prominent firms ending with the Bethlehem Steel Corporation; while at Bethlehem, he developed high-speed steel and performed notable experiments in shoveling and pig-iron handling.

At 45 Taylor declared that he could no longer afford to work for money, and he retired, partly also for reasons of health. He continued, however, to devote time and money to promote the principles of scientific management through lectures at universities and professional societies. From 1904 to 1914, with his wife and three adopted children, Taylor lived in Philadelphia. For recreation, he grew roses, transplanted huge box trees in his garden, and, developing an enthusiasm for golf, built one of the first putting greens with natural ground contours. (His innovative putter with the shape of a capital Y was, however, banned by the U.S. Golf Association.)

The American Society of Mechanical Engineers elected him president in 1906, the same year that he was awarded an honorary doctor of science degree by the University of Pennsylvania. Many of his influential publications first appeared in the *Transactions* of that society, namely, "Notes on Belting" (1894); "A Piece-rate System" (1895); "Shop Management" (1903); and "On the Art of Cutting Metals" (1906). *The Principles of Scientific Management* was published commercially in 1911.

Taylor's fame increased after his testimony in 1912 at the Hearings Before a Special Committee of the House of Representatives to Investigate the Taylor and Other Systems of Shop Management. Considering himself a reformer, he continued expounding the ideals and principles of his system of management until his death from pneumonia on March 21, 1915, in Philadelphia, 18 days after his last lecture in Cleveland, Ohio.

BIBLIOGRAPHY. FRANK BARKLEY COPLEY, *Frederick W. Taylor: Father of Scientific Management*, 2 vol. (1923), is a comprehensive and historical portrayal of the ancestry, boyhood, education, career, and contributions to scientific management of Frederick Winslow Taylor.

(J.F.Me.)

Tchaikovsky, Peter Ilich

Among the most subjective of composers, Peter Ilich Tchaikovsky and his music are inseparable. His work is a manifestation, sometimes charming, often showy, and occasionally vulgar, of repressed feelings that became more and more despairing in later years and culminated in the composition of the *Sixth Symphony*, one of the greatest symphonic works of its time. Though unequal, his music shows a wealth of melodic inspiration and imagination and a flair for orchestration. Its lapses of taste are partly redeemed by enormous technical efficiency. Though his later work rejected conscious Russian nationalism, its underlying sentiment and character are as distinctively

Tchaikovsky, 1888.
Novosti Press Agency

Russian as that of the Russian nationalist composers. Tchaikovsky's success in bridging the gulf between the musician and the general public partly accounts for the exalted position he enjoys in the U.S.S.R.

Early life and education. Tchaikovsky was born on May 7 (April 25, old style), 1840, in Russia at Votkinsk (now in the Udmurt A.S.S.R), where his father was superintendent of government-owned mines. Because his mother was half French, and it was a customary practice among upper-class Russians of the period, he had a French governess. Tchaikovsky was musically precocious, but his interest in the subject was not actively encouraged because his parents considered that it had an unhealthy effect on an already neurotically excitable child. He adored his governess, but she was dismissed in 1848 when his father changed his post and moved to Moscow and then to St. Petersburg (Leningrad), where the boy entered the preparatory department of the School of Jurisprudence in 1850. There he was obviously disturbed by being treated as a "country bumpkin," but soon settled down happily.

His state of mind was more seriously affected in 1854 when he was 14 and his mother, whom he loved with all the ardour of an acutely introspective child, died of cholera. To alleviate the distress caused to him both by her death and by his easygoing father's comparative indifference to it, he composed a short waltz for piano and even thought of composing an opera. His abnormal love for his now-deceased mother and the ineffectualness of his father did nothing to hinder his latent homosexuality, and the disciplinary regime of the all-male School of Jurisprudence cannot have helped. There is, however, no evidence of his having given any active outlet to his secret desires. During these school days, desultory singing, piano and harmony lessons were all the musical education he received, complemented by increasingly numerous visits to the opera, which had a lasting influence on his musical taste.

Entry into the St. Petersburg Conservatory

He entered the newly founded St. Petersburg Conservatory of Music in 1862. His job as a clerk in the Ministry of Justice was hardly interesting enough to prevent his increasing absorption with music. A tale is told of his absentmindedly tearing pieces from an official document, munching at them steadily, and recovering his senses only to find that he had consumed them altogether. He soon left the government service and became a music student. His first orchestral score (composed, 1864), an overture based on Aleksandr Ostrovsky's play *The Storm*, is remarkable in showing many of the stylistic features later to be associated with his music and a youthful vulgarity that was not the only constituent in it to appal his primly Mendelssohnian teacher, Anton Rubinstein. Even so, he was offered in late 1865 a post as professor of harmony by Rubinstein's brother at the Moscow Conservatory.

Career. Tchaikovsky settled down comfortably in Moscow in January 1866, although he underwent a mental crisis as a consequence of overwork on his *Symphony No. 1 in G Minor (Winter Daydreams)*, Opus 13 (1866). His compositions of the late 1860s and early 1870s reveal a distinct affinity with the music of the nationalist group of composers in St. Petersburg, both in their treatment of folk song and in their harmonies deriving from a common link with Mikhail Glinka, the "father" of a Russian nationalist style. He corresponded with the leader of the group, Mily Balakirev, at whose suggestion he wrote a fantasy overture, *Romeo and Juliet* (1869). Tchaikovsky's intrinsic charm, testified to by many who knew him, is nowhere more apparent than in the nationalist comic opera *Vakula the Smith* (1874; first performed, 1876), which in its revised form, *Cherevichki (The Little Shoes)*, is of similar merit to another opera, *Sorochintsy Fair* (also based on one of Nikolay Gogol's Ukrainian tales), by the most original composer in the Petersburg group, Modest Mussorgsky. Tchaikovsky's opera, however, is much closer to Balakirev's own folkloric idiom than anything Mussorgsky ever wrote.

After a fleeting, but unsuccessful, love affair with Désirée Artôt, the prima donna of a visiting Italian opera company, he had only one further romantic relationship with a woman. In the mid-1870s, he had another nervous breakdown. One of the symptoms of this nadir in his life was almost hysterical activity in composition culminating in the *Symphony No. 4 in F Minor*, Opus 36 (1877), and the opera *Eugene Onegin* (1877–78) based on a poem by Pushkin, with whose heroine Tatyana he felt in such sympathy that when a former music student, Antonina Milyukova, became infatuated with him, threatening suicide should he reject her, he identified her in his mind with the cruelly spurned Tatyana and consented to marry her. He must have subconsciously known all along that an unconsummated marriage was hardly likely to be successful, but it was doubly unfortunate that his wife should have been a nymphomaniac who repelled him to such an extent that he made an abortive attempt at suicide. He now fully realized that in the eyes of society he was permanently to be a sexual outcast. He loved children but would never have any of his own. He was to live the rest of his life in frustration and loneliness alleviated only by occasional heavy drinking and by composition. Even the happy summers spent at his sister's house at Kamenka in the Ukraine were later spoiled by an overwhelming sense of guilt when he fell in love with her son, his young nephew "Bob" (Vladimir) Davydov.

Marriage

Meanwhile, he had begun late in 1876 an extraordinary correspondence with an admirer of his compositions, Nadezhda von Meck, a wealthy widow, who settled upon him an annuity sufficient to allow Tchaikovsky to give up his teaching post and devote himself entirely to composition. By her wish, the two never met. Their intimate correspondence was more revealing of her than of Tchaikovsky. Compelled by a necessity to be liked, he was always apt to write what he thought people wanted to read rather than what he really thought. The detailed program of his *Fourth Symphony*, which he made up especially for her, for example, is generally regarded with circumspection. He later averred that replying to her frequently effusive letters had become "irksome." All the same, this curious relationship apparently fulfilled a deeply felt psychological need for both, particularly for Tchaikovsky, whose wife, proving importunate even after a separation had been arranged, had to be bought off. The platonic relationship with Mme von Meck was much more to his taste.

Correspondence with Nadezhda von Meck

His attempts to justify to himself her generous annuity were the cause of his overproduction of the next few years, which included some of his drier compositions—the *Piano Sonata in G Major*, Opus 37 (1878), the orchestral *Suite No. 1 in D Minor*, Opus 43 (1878–79), music for the coronation of his patron the emperor Alexander III, and the first of his mature attempts to write a commercially successful opera, *The Maid of Orleans* (1878–79), for he never imagined that *Eugene Onegin* was dramatic enough in the "theatrical" sense to be a popular success. The years 1878 to 1881 also included

several major achievements: the sparkling *Violin Concerto in D Major*, Opus 35 (1878), and the popular *Serenade for Strings in C Major*, Opus 48 (1880); *Capriccio italien*, Opus 45 (1880), and the *1812 Overture*, Opus 49 (1880). *Onegin*, which was only a token success at its Moscow première, enjoyed great popularity in St. Petersburg because of the tsar's admiration. The *Manfred Symphony*, Opus 58, composed in 1885, not only called forth unstinted praise but showed in some of its histrionically despairing episodes the path that Tchaikovsky's life and music were to follow in the last years.

In 1885 he bought a house of his own at Maidanovo in the vicinity of Moscow, where he lived until the year before his death, when he moved into the house that is now the Tchaikovsky House Museum in the nearby town of Klin. He began to travel more in Russia, spending two particularly delightful vacations in the Caucasus, where he was enthusiastically feted at Tbilisi. He overcame an aversion to conducting, with successful performances of the newly revised *Vakula*, and in 1888 he undertook an important foreign tour, directing his own works in Leipzig (where he met the composers Johannes Brahms and Edvard Grieg), Hamburg, Berlin, Prague, Paris, and London. His music was well received everywhere.

The great foreign tour

This tour was the apex of Tchaikovsky's later life. From then on, in spite of the continuing success of many of his former compositions and the acclamation of new ones, including his second Pushkin opera, *The Queen of Spades*, and his favourite ballet, *The Sleeping Beauty* (first received coolly; both performed 1890), he was working his way toward another nervous breakdown. His major compositions, starting with *Symphony No. 5 in E Minor*, Opus 64 (1888), became more and more intense and emotional, filled with hysterical exaltation and neurotic despair.

Tchaikovsky went on further tours, including the United States and England, where he conducted his popular *Piano Concerto No. 1 in B Flat Minor*, Opus 23 (composed, 1874–75), in 1889 and his *Fourth Symphony* in 1893. In 1893 he was also awarded at Cambridge an honorary degree of doctor of music. These and other successes, including the tumultuous reception accorded to the suite he hastily made for concert performance from his *Nutcracker* ballet music (1892), did not alter the inexorable decline in his mental condition, which was aggravated in 1890 when Nadezhda von Meck suddenly ended both their correspondence and the annuity. From a financial standpoint, however, this hardly mattered because the royalties from *The Queen of Spades* covered the loss without difficulty, and he was by this time a recipient of a state pension. Tchaikovsky never forgave her for her behaviour, and the nature of the psychological wound it inflicted upon him can be judged by the fact that in the delirium of his last illness he repeated her name again and again in indignant tones.

His last work

Tchaikovsky completed his *Symphony No. 6 in B Minor*, Opus 74, which was his last and which he rightly regarded as a masterpiece, in August 1893. In October he conducted its first performance in St. Petersburg but was disappointed with its reception. Its novel slow finale could hardly have been expected to induce such applause as had greeted, only 1½ years before, the première of the lighter *Nutcracker* suite. Yet perversely, Tchaikovsky did expect it and was determined to make an issue of it with himself. Into this work, with its "secret" program, he had put his whole soul, and the public did not appreciate it. In spite of an epidemic of cholera in St. Petersburg and although he complained of feeling unwell, he drank a glass of unboiled water. He died of the disease on November 6. Whether or not he had already contracted the disease before he drank the water, the rumour was soon rife that he had really committed suicide as a result of the failure of his last symphony, whose very title, *Pathétique*, if nothing else, was enough to ensure instant notoriety in the context of the composer's mysterious death.

Assessment. No composer since Tchaikovsky has suffered more from changes of fashion or from the extremes of over- and undervaluation. On the one hand, he achieved an enormous popularity with a very wide audience, largely through his more emotional works; on the other, the almost hypnotic effect that he was able to induce led to serious questioning of his true musical quality. It appears plausible that time will add to, rather than diminish, his stature, if only because performances, recordings, and publications have disclosed that there are fine works of Tchaikovsky still to be discovered. He is certainly the greatest master of the classical ballet, demonstrated by *Swan Lake* (1877) and the symphonically conceived *Sleeping Beauty* (1890). The six symphonies may be variable in quality but all contain important music. The last three are deservedly famous, though to these should be added the neglected *Manfred Symphony*. The *First Piano Concerto* and the *Violin Concerto*, on the other hand, deserve a higher reputation than vehicles for virtuosity. Notable among his other orchestral works are the early *Romeo and Juliet Overture* and the exquisite *Serenade for Strings*. Of the operas, *Eugene Onegin* is a masterpiece and *The Queen of Spades* dramatically effective. His string quartets are excellent but his piano music is largely undistinguished. His numerous songs include several fine examples.

MAJOR WORKS

Theatre music

OPERAS: *Voyevoda* (first performed 1869); *Undine* (1869); *Oprichnik* (1874); *Vakula the Smith* (1876); *Eugene Onegin* (1879); *The Maid of Orleans* (1881); *Mazepa* (1884); *Cherevichki* (*The Little Shoes*, 1887; revised version of *Vakula the Smith*); *The Sorceress* (1887); *The Queen of Spades* (1890); *Iolanta* (1892).

BALLETS: *Swan Lake* (1877); *The Sleeping Beauty* (1890); *The Nutcracker* (1892).

Instrumental music

SYMPHONIES: Seven symphonies, including *No. 2 in C Minor* (*Little Russian*), op. 17 (composed 1872, revised 1879); *No. 3 in D Major*, op. 29 (1875); *No. 5 in E Minor*, op. 64 (1888); *No. 6 in B Minor* (*Pathétique*), op. 74 (1893); and the *Manfred*, op. 58, based on Byron's drama and unnumbered (1885).

SOLO AND ORCHESTRA (PIANO): Three concertos—*No. 1 in B Flat Minor*, op. 23 (1874–75); *No. 2 in G Major*, op. 44 (1879–80); and *No. 3 in E Flat Major*, op. 75 (1893; one movement only). (VIOLIN): *Concerto in D Major*, op. 35 (1878). (CELLO): *Variations on a Rococo Theme*, op. 33 (1876); *Pezzo capricioso*, op. 62 (1887).

OTHER ORCHESTRAL WORKS: Overture to Ostrovsky's play *The Storm*, op. 76 (1864); symphonic poem, *Fate*, op. 77 (1868); fantasy-overture, *Romeo and Juliet*, 3 versions (1869, 1870, and 1880); fantasy, *Francesca da Rimini*, op. 32 (1876); *Marche slave*, op. 31 (1876); *Serenade for Strings in C Major*, op. 48 (1880); *Capriccio italien*, op. 45 (1880); *1812 Overture*, op. 49 (1880); overture-fantasy, *Hamlet*, op. 67a (1888); suite from *The Nutcracker* ballet, op. 71a (1892); 3 orchestral suites.

Chamber music

Three string quartets; one trio; one sextet (*Souvenir de Florence*, op. 70; composed 1890–92); various pieces for violin and piano; various sets with the title "Pieces"; two sonatas.

Vocal music

SONGS: About 100 songs, including "Don Juan's Serenade," op. 38, no. 1 (1878); "Mid the Din of the Ball," op. 38, no. 3 (1878); "None but the Lonely Heart," op. 6, no. 6 (1869); "Why Did I Dream of You?" op. 28, no. 3 (1875).

VOCAL DUETS: Six duets (1880).

BIBLIOGRAPHY. Major catalogs of Tchaikovsky's compositions may be found in GERALD ABRAHAM, *Tchaikovsky* (1944); and (ed.), *Tchaikovsky: A Symposium* (1945); EDWIN EVANS, *Tchaikovsky*, rev. ed. (1966), shortly to be replaced by EDWARD GARDEN, *Tchaikovsky* (in prep.), with a select Russian bibliography. All Tchaikovsky's memorabilia, together with collections of correspondence and sketchbooks, may be found in the Tchaikovsky museum at Klin near Moscow. His complete correspondence is now in the process of being published. See *The Diaries of Tchaikovsky*, trans. with notes by WLADIMIR LAKOND (1945); ROSA NEWMARCH, *Tchaikovsky: His Life and Works*, rev. ed. (1908); and MODEST TCHAIKOVSKY, *The Life and Letters of Peter Ilich Tchaikovsky* (1905), an abbreviated and severely edited English version by ROSA NEWMARCH from the definitive Russian volume of 1900–02. A definitive modern biography is HERBERT WEINSTOCK, *Tchaikovsky* (1943).

(E.J.C.G.)

Teacher Education

While arrangements of one kind or another for the education of the young have existed at all times and in all societies, it is only recently that schools have emerged as distinctive institutions for this purpose on a mass scale, and teachers as a distinctive occupational category. Parents, elders, priests, and wise men have traditionally seen it as their duty to pass on their knowledge and skills to the next generation. As Aristotle put it, the surest sign of wisdom is a man's ability to teach what he knows. Knowing, doing, teaching, and learning were for many centuries, and in some societies are still today, indistinguishable from one another. For the most part the induction of the young into the ways of acting, feeling, thinking, and believing that are characteristic of their society has been an informal—if serious and important—process, accomplished chiefly by means of personal contact with full-fledged adults, by sharing in common activities, and by acquiring the myths, legends, and folk beliefs of the culture. Formal ceremonies, such as the puberty rite, marked the point at which it was assumed that a certain range of knowledge and skill had been mastered and that the individual could be admitted to full participation in tribal life. (Residual elements of such ceremonies remain in some modern arrangements; it has been seriously contended that the study of the Latin language in the Renaissance and post-Renaissance school can be interpreted as a form of puberty rite.) Even in the formally established schools of the Greek city-states and of the medieval world there was little separation between, on the one hand, the processes of organizing and setting down knowledge and, on the other, those of teaching this knowledge to others.

This does not mean that prior to the 19th century little attention was given to a training in teaching methods as distinct from "subjects." The great works of medieval scholasticism were essentially textbooks, designed to be used for the purpose of teaching. Today, as in the medieval world, methods of teaching and the organization of knowledge continue to be reciprocally influential. Nor are the problems that today surround the qualifications and certification of teachers wholly new. State, church, and local authorities everywhere have long recognized the importance of the teacher's work in maintaining or establishing particular patterns of social organization and systems of belief, just as radical and reformist politicians and thinkers have looked to the schools to disseminate their particular brands of truth. In medieval and post-Reformation Europe, for example, there was considerable concern with the qualifications and background of teachers, mainly but not entirely with reference to their religious beliefs. In 1559 Queen Elizabeth I of England issued an injunction that prohibited anyone from teaching without a license from his bishop, which was granted only after an examination of the applicant's "learning and dexterity in teaching," "sober and honest conversation," and "right understanding of God's true religion." Thus the certification of teachers and concern for their character and personal qualities are by no means new issues.

What is new for most societies—European, American, African, and Asian—is the attempt to provide a substantial period of formal education for everyone and not just for the small proportion of the population who will become political, social, and religious leaders or for those few who possess surplus time and money for the purpose. Universal literacy, already achieved in most European and American and many Asian societies, has become the goal of all. In an increasing proportion of countries every child now proceeds automatically to secondary education; many remain at school until 16 or 18 years of age, and large numbers go on to some form of postsecondary education and training. The scale and variety of educational provision that all this requires makes the supply, education, training, and certification of an adequate number of teachers a worldwide issue of education policy and practice. In developed and developing countries alike, no factor is of greater importance in relation to the quantity and quality of education; it is significant that a substantial proportion of the budget of the United Nations Educational, Scientific and Cultural Organization (UNESCO) is devoted to the improvement of teacher preparation.

The importance of teacher education

The term "teacher" in this article is used to mean those who work in schools providing education for pupils up to the age of 18. Thus, "teacher education" refers to the structures, institutions, and processes by means of which men and women are prepared for work in elementary and secondary schools. This includes preschool, kindergarten, elementary, and secondary institutions for children from the age of 2 or 3 to 18. (The education and training of lecturers and other staff members of technical colleges, polytechnics, universities, and other institutions of post-secondary education, both general and specialized, are treated in HIGHER EDUCATION.)

THE EVOLUTION OF TEACHER EDUCATION

Teacher education, as it exists today, can be divided into two stages, preservice and in-service. Preservice education includes all the stages of education and training that precede the teacher's entry to paid employment in a school. In-service training is the education and training that the teacher receives after the beginning of his career.

Early development. The earliest formal arrangements for teacher preparation, introduced in some of the German states during the early part of the 18th century, included both preservice and in-service training. A seminary or normal school for "young men who had already passed through an elementary, or even a superior school, and who were preparing to be teachers, by making additional attainments, and acquiring a knowledge of the human mind, and the principles of education as a science, and of its methods as an art" was set up in Halle in 1706. By the end of the century there were 30 such institutions in operation in Germany. Systematic training was linked to an equally systematic process of certification, control of teaching conditions, and in-service study. All public teachers were required to attend a series of meetings to extend their practical knowledge. Parochial conferences took place monthly in the winter, district conferences bimonthly in the summer, a circle conference twice a year, and a departmental conference annually. Each seminary was responsible for maintaining contact with all the teachers working within a six-mile radius, and some established "repetition courses" for experienced teachers who wanted to refresh and add to their knowledge.

The German normal school

Nineteenth-century developments in the United States, Britain, France, Belgium, and Japan owed much to the pattern that had been established in Germany. In France efforts were made after 1792 to set up a system of normal schools, and in 1808 Napoleon established the École Normale (later the École Normale Supérieure) to train teachers for the *lycées*. But it was not until after 1833 that a uniform system of *écoles normales* (initially only for male students) was created, and the normal-school systems of several countries date from the third decade of the century.

During the first 30 years of the 19th century, teacher preparation in the United States, Britain, and elsewhere was dominated by the monitorial methods introduced by Andrew Bell and Joseph Lancaster. In the simplest terms, the method involved a master instructing a number of senior pupils or "monitors," who then passed on their newly acquired knowledge to a larger number of pupils. Such methods were cheap, simple, and, it was widely believed, effective. They required a necessary emphasis upon facts, drill, repetition, mechanical learning, and ease of teaching. By 1820 there were 20 Lancastrian schools in the state of New York, where the system had official status until the middle of the century. With hindsight it is easy to condemn the monitorial system. At the time, when the supply of educated persons available and willing to teach in the elementary schools was severely limited, and when the public funds to employ them were in short supply, the system enabled a large number of children to achieve the minimum level of literacy on which future development could build. Just as the organization of knowledge characteristic of medieval times im-

Lancastrian schools

plied its own pattern of pedagogy, so the Lancastrian system embodied a distinctive approach to the process of teaching; one of the attractions of such systems is that they offer a built-in solution to the problem of reconciling what the teacher needs to know and the methods he should learn.

Among those who were unimpressed by the claims of the Lancastrian system was David Stow, who in 1834 founded the Glasgow Normal Seminary from which "trainers," as his graduates came to be called, went to schools in Scotland and many of the British colonial territories. In the United States, after an uncertain start, the Massachusetts Normal Schools founded by Horace Mann in the 1830s became a model for similar developments in Connecticut, Michigan, Rhode Island, Iowa, New Jersey, and Illinois. In England, churches and voluntary foundations were in process of establishing the first of the teacher training colleges. Australia began the organized preparation of teachers in the early 1850s. At this early stage certain issues were already emerging that were to remain alive for the next hundred years and that are to some extent still relevant today.

The needs of pupils and schools were beginning to advance beyond basic literacy. Human knowledge was becoming more diverse and scientific and was being organized into new disciplinary systems. Secondary education was expanding. The early inclusive pedagogic systems were falling into disfavour. The problem arose of reconciling the teacher's personal need for education with his professional need for classroom technique. There were other than purely pedagogic considerations involved; the inhibitions of class society in England, the demand for practicality in the United States, a fear of liberal agitation in France, the patriotic missionary role of the teacher in Japan—all tended to maintain an emphasis upon the practical techniques of school management and to limit the range and level of the elementary teacher's intellectual accomplishments to mastery of only such subject knowledge as was needed at the school level.

General education versus professional training

Some educators asserted that the curriculum of the normal school should be academic, on the ground that the future teacher needed nothing more than experience of conventional subjects soundly taught. Others argued that training should have a purely professional function, including only such subject knowledge as the teacher would need in his classroom work. Some advocates claimed that the liberal and professional elements could readily be harmonized or integrated. The work of Derwent Coleridge, principal of St. Mark's College, London, who admitted that he took his models not from the pedagogical seminaries of Germany but from the universities of Oxford and Cambridge, exemplified the attempt to introduce a larger element of general education into teacher preparation. Sir James Kay-Shuttleworth, founder of another London college, emphasized basic subject matter; he held that

> not merely the subjects of instruction, but also the methods of teaching the candidates, should be so ordered as to be in itself a preparation for their future vocation as teachers. On this account the oral instruction of classes in a Normal school is greatly to be preferred to any other mode.

In the United States, Horace Mann supported the value of a training in the "common branches" of knowledge, as a means of mental discipline. But the views of Derwent Coleridge, Kay-Shuttleworth, and Horace Mann, in common with those of many other educators of the time, reflected social as well as pedagogical considerations. Mann, it has been suggested, failed to recognize that the Prussian system that so impressed him was one that took lower class pupils and trained them as teachers of the lower classes—a system already under fire from German educators at the time that it was being used as a model for developments abroad.

Between 1870 and 1890, legislation was enacted in a number of countries to systematize and broaden the work of the normal schools. In Japan an ordinance of 1886 established higher normal schools providing a four-year course for boys and girls who had completed eight years of elementary education. A French law of 1879 established a nationwide system of colleges for training women primary teachers (*écoles normales d'institutrices*). In Russia a statute on teachers' seminaries was promulgated in 1870; within five years there were 34 such institutions, with nearly 2,000 students. A further statute in 1872 provided for institutes to train teachers for the new higher grade schools that were beginning to appear in the larger towns. In Scotland, the universities of Edinburgh and St. Andrews established chairs in education in 1876. In the United States a large number of universities had by 1895 set up education departments, and in some of them the preparation of teachers for work in the schools was beginning to be combined with systematic study and research in education processes.

Developments in American universities owed a great deal to the efforts of men such as Henry Barnard, who, as schools commissioner in Rhode Island from 1845 to 1849, stimulated a local interest in education that led to the creation of a department of education at Brown University. Barnard wrote an influential series of books on pedagogy and teacher education and later, as president of Columbia University, inspired Nicholas Murray Butler and others to found Teachers College in 1888. This soon became the foremost university school of education in the United States. It incorporated two schools as teaching laboratories, enrolling children from kindergarten to college age. As its "Announcement" of 1901 made clear, it was not restricted to any one level of professional preparation:

> The purpose of Teachers College is to afford opportunity, both theoretical and practical, for the training of teachers of both sexes for kindergartens and elementary and secondary schools, of principals, supervisors and superintendents of schools, and of specialists in various branches of school work, including normal schools and colleges.

Late 19th- and early 20th-century developments. Until about 1890 the "theoretical" elements in teacher preparation were of two kinds: the study of certain principles of teaching and school management, exemplified in the textbooks written by experienced schoolmen that were published in many countries during the second half of the 19th century; and instruction in "mental and moral philosophy," history of education, psychology, and pedagogics. Some of the most popular and influential works, such as Rosencrantz' *Philosophy of Education*, which was translated into English in the 1870s, made little distinction between philosophical and psychological data. But after 1890 psychology and sociology began to crystallize as more or less distinctive areas of study; students of education had a wider and more clearly structured range of disciplines to draw upon for their data and perspectives and to provide a "scientific" basis for their pedagogic principles.

Evolution of educational theory

In the middle years of the 19th century the ideas of the Swiss educator J.H. Pestalozzi and of the German Friedrich Froebel inspired the use of object teaching, defined in 1878 by Alexander Bain in his widely studied *Education as a Science* as the attempt

> to range over all the utilities of life, and all the processes of nature. It begins upon things familiar to the pupils, and enlarges the conceptions of these, by filling in unnoticed qualities. It proceeds to things that have to be learnt even in their primary aspect by description or diagram; and ends with the more abstruse operations of natural forces.

The work of these pioneers also led to a clearer recognition of the developmental needs and character of childhood. Later contributors to the corpus of ideas that underlie the processes of teacher education continued to provide philosophical, sociological, and psychological justification for particular views of the nature of education and of teaching, and also had a greater or lesser influence on the methods to be employed in classroom and school.

The work of the German philosopher Johann Friedrich Herbart (1776–1841) was of particular importance in this latter respect. Herbart wrote a number of pedagogical works during his teaching career at the universities of Göttingen and Königsberg. In the latter part of the 19th century, the study of education along Herbartian lines

became established in every European country, in America, and in Japan. Herbartianism offered a complete system—a philosophical theory, a set of educational aims, a rational psychology, and a pedagogy. Teaching, it held, should build on what the child already knows and should seek to inculcate, by the choice of appropriate materials, the highest moral character. It should be organized in accordance with the "five formal steps" of preparation, presentation, comparison, generalization, and application. The Herbartian doctrine rested as much upon the interpretation of his followers as upon the master's own works, and its influence was of relatively limited duration. Other ideas were coming to the fore, less direct and comprehensive than Herbart's but having greater impact upon the educational consciousness of the next half-century.

The influence of Darwinian evolutionary ideas upon pedagogy was very marked. To the extent that the evolutionary viewpoint emphasized the processes by which individuals become adapted to their environment, as in the teachings of the English philosopher Herbert Spencer, their influence was profoundly conservative. But evolutionary ideas were also embodied within the child development theories of the American psychologist G. Stanley Hall, who argued that the stages of individual growth recapitulated those of social evolution and therefore that the distinctive character and status of childhood must be respected. The American philosopher William James also included evolutionary notions in his psychology. James's emphasis, however, was not so much upon the processes by which individuals adapt as upon those through which they react creatively and positively with their circumstances, helping to shape and change these to meet their needs. James's formulation of associationism, the building up of useful habit systems, had implications for the study of learning that teacher educators were quick to recognize and that were made more significant by the later experiments of the American psychologist Edward L. Thorndike (1874–1949). Thorndike's work with animals stands at the beginning of a tradition that continues to the present day. The laws of learning that he formulated have for long been a staple of teacher training courses in many countries. Thorndike saw psychology as the basis of a genuinely scientific pedagogy, and claimed that "Just as the science and art of agriculture depend upon chemistry and botany, so the art of education depends upon physiology and psychology." He went on to argue, with a degree of confidence that rings strangely today, that

> A complete science of psychology would tell every fact about everyone's intellect and character and behavior, would tell the cause of every change in human nature, would tell the result which every educational force—every act of every person that changed any other or the agent himself—would have.

The greatest influence on teacher-training curricula in the United States and many other countries was exercised not by the experimental psychologists but by the pragmatist philosopher John Dewey. Dewey began with a conception of the nature of scientific method that he generalized into a specific pedagogical approach (popularized by others as the "project" method and, more recently, as inquiry-based learning). This he combined with a consideration of the nature of the child's interests and capacities for learning and life experience, the nature and claims of different types of subject matter, and the importance of democratic values in the social context of the school. Just as James's psychology gave back to the teacher and the school some of the influence on individual development that the interpreters of evolutionary adaptation had seemed to deny, so Dewey's notion of the school as the embodiment of community ideals and the spearhead of social reform lent a new importance to the processes of teacher education.

Conservative and progressive views

It is tempting to categorize these various perspectives as "conservative" or "progressive." The former stress the importance of subject matter and of standard methods of effective instruction: the need for regularity and order in the classroom and for means that will encourage children to apply themselves diligently to learning; the importance of the teacher as a subject-matter expert and as an exemplar of accepted morality; and the existence of objective standards of scholarship and achievement to which teachers and students alike should aspire. The progressives, on the other hand, emphasize a more child-centred approach, designed to build upon the natural interests and curiosity of the child: a flexible pattern of teaching and classroom organization recognizing individual differences in motivation, capacity, and learning style; a conception of the teacher as an organizer of children's learning rather than as an instructor; and the need to integrate the subject matter of different disciplines into topics and projects that have meaning in terms of the pupil's own experience.

Such conservative and progressive ideas have their roots in differing conceptions of the nature of man and society, of knowledge, and of the learning process. The differences are not new. The fortunes of the two perspectives tend to wax and wane in accordance with the times. Thus in the United States, fears of a loss of technological supremacy in the late 1950s encouraged conservative critics to point to the weaknesses of "child-centred" education. In the same way, anxieties about the meaninglessness of the education experienced by the poor, coupled with evidences of widespread alienation among the young, encouraged a revival of interest in progressive ideas in the early 1970s. Many educators, of course, do not fall into either the conservative or the progressive category but draw their ideas from various sources. There has been a tendency in many countries, however, for the curricula of teacher-preparing institutions to be identified with progressive educational ideas.

Many other ideas also influenced the curriculum and organization of teacher preparation during the last decade of the 19th and the first half of the 20th centuries. The dynamic psychology of Sigmund Freud and his early associates, the work of the Gestalt psychologists, the methods of measuring human abilities that were being developed in France, Great Britain, and the United States, the development of religious ideas in the Roman Catholic countries, the imposition of Marxist and Leninist ideologies in the Soviet Union—all of these in varying measure affected the normal schools, teachers' colleges and seminaries, and university departments of education. Such new ideas and systems of thought had their impact at three main levels.

The use of education in promotion of values

First, they influenced the nature of the social commitment that teacher-preparing institutions strove to instill in their students: commitment to the values of democracy and of opportunity in the United States, as exemplified in the writings of Dewey; to a sense of national purpose or patriotism, as in France, Germany, and Japan; to the pursuit of the socialist revolution, as in the post-tsarist Soviet Union; or to a religious outlook as manifested by Catholic doctrine in Italy, Spain, and Latin America.

Second, the philosophers, psychologists, and sociologists helped to redefine the teacher–pupil relationship. Whatever their differences of view, clear continuities are visible among them on such issues as the significance of the child's needs and interests, the weaknesses of the formal academic curriculum, and the nature of individual development.

Third, the new contributions affected the organization of learning through the measurement and assessment of abilities; the diagnosis of special learning problems; the placing of children in homogeneous age and ability groups by means of "tracking" and "streaming"; the emphasis on problem solving; and the project method. These changes, reflected both in the way in which teachers were trained and in the architecture and equipment of schools, transformed education for younger children in many countries during the first half of the 20th century.

Organization of teacher education in the 20th century. The educational doctrines that inspired, conceptualized, and legitimated this transformation themselves reflected other social, political, economic, demographic, and technological changes. Urbanization, the reduction of infant mortality, improvements in child health, the fact that families, individuals, and whole societies could afford

longer and better schooling, growth in the size of populations, greater capacity for control by central and local government, the availability of new kinds of educational apparatus and teaching aids—all these did much to shape the progress of teacher education during the decades after 1900.

Levels of teacher preparation

Among the countries of the world the arrangements for the preparation of teachers vary widely. In some countries "monitors" still receive short courses of training as their preparation to teach large classes of young children. In North America, and to an increasing extent in other developed countries, most teachers are university graduates who begin their teacher preparation after completing four to six years of secondary education. Between these extremes many other arrangements exist. At one level, which for present purposes might be called Normal School A, entry is prior to the usual age of completion of secondary education. Training is limited to the achievement of competence in teaching a range of the subjects taught at the primary level and does not last more than five years.

The second level, which may be called Normal School B, also begins prior to the age of completing secondary education, but usually after the "first certificate" at approximately age 16 or at the end of the period of compulsory schooling. This level provides combined courses of education and professional training, the former not necessarily limited to subjects taught at the primary level and extending beyond the usual age of completion of secondary education.

A third level, the college level, requires a full secondary education, usually ending at 18 but not necessarily with the same qualifications as are demanded of university entrants. Two- or three-year concurrent courses of general and professional education lead to the award of a teaching certificate, often valid for work in primary, intermediate, and lower secondary schools.

Finally, there is the university level, in which, after completing a full period of secondary education, the future teacher enters a multipurpose institution of higher education to follow three- to five-year courses of combined general education and professional training, the latter being either concurrent or consecutive, that lead to the award of a university degree and teaching qualification. Such qualification is considered valid for work at primary or secondary levels, or at both, according to the nature of the course followed.

Until the middle 1960s the normal-school pattern applied to students preparing for primary work in many European countries (Austria, Belgium, Spain, France, Italy, Iceland, The Netherlands, Switzerland, and Turkey), in Latin America, and in a number of Asian countries, although in many places there was more than one route to the attainment of qualified teacher status. The education and training of secondary school teachers was complicated by the general growth of secondary education for all. This encouraged the tendency to educate and train both primary and secondary teachers alongside one another in postsecondary colleges or in multipurpose universities. More recently there has been a widespread movement away from the types of training described here as Normal School A and B to the college and university patterns. But the fact that a country has adopted what has been called here the university pattern of training should not be taken to mean that all the institutions in which teachers are prepared are comparable to the pre-existing universities; some are devoted mainly to teacher preparation.

ISSUES AND PROBLEMS IN TEACHER EDUCATION

Elements of teacher education

In nearly all countries, courses of the Normal School B, college, and university categories contain three main elements. The first element is the study of one or more academic, cultural, or aesthetic subjects for the purpose both of continuing the student's own education and of providing him with knowledge to use in his subsequent teaching career. A second element is the study of educational principles, increasingly organized in terms of social science disciplines such as psychology, sociology, philosophy, and history. A third element consists of professional courses and school experience. Primary teachers may also receive instruction in the content and methods of subjects other than their own specialties that figure in the primary curriculum. In normal schools and colleges, and some universities, the three elements run parallel to one another, and the student is professionally committed from the outset of his course. Elsewhere, the study of educational processes and professional work (including school experience) may follow the completion of a period of academic study that the student has begun without any prior commitment to teaching as a career. There are still advanced countries where the possession of a university degree, without any qualification in education as such, is sufficient basis for the award of qualified teacher status. In England and Wales, for example, compulsory training for graduates, generally comprising two terms (six months) of professional and theoretical studies and a further three-month period of school experience, was scheduled to come into effect only in 1973.

General education. The sequencing, balance, content, and organization of general and specialist academic work, courses in education, and professional studies and teaching experience has been a subject of discussion since the earliest days of organized teacher education. The importance of the element of general education has been defended on various grounds. Sometimes such academic work may be highly specialized. Students in many colleges of education in England study only one principal subject, to which they devote about one-third of their total time, and teachers who graduate from universities have often pursued three-year courses for single-subject honours degrees. In the United States and elsewhere the academic element is broader, and the first two years of college or university work may embody a wide range of elective subjects from diverse disciplinary fields. Both patterns have their critics, the first because it produces narrow intellectual specialists, the second because it encourages dilettantism and inadequate depth. Where a pattern of electives is combined with a units/credits system, as in some universities in Japan and the United States, it is claimed that one result is an undesirable fragmentation of study and effort. In his influential *Education of American Teachers* (1963), James B. Conant recommended that half the course requirements of the four-year program of preparation for elementary teachers should be given over to general courses, a further quarter to an "area of concentration," and the remaining quarter to professional studies, including school experience. Prospective secondary teachers would spend still more time on the subjects they were preparing to teach, with less than 10 percent of their time devoted to practice teaching and special methods. Such a subject emphasis for secondary teachers can be found in many countries. In France the École Normale Supérieure still places freedom of study and the nurture of intellectual curiosity above questions of professional teacher training. Generally speaking, wherever there is a stress upon academic excellence and the achievement of high standards of scholarship, there is likely to be skepticism as to the claims of professional training for teaching. Oxford University had still not appointed a professor of education by the beginning of the 1970s.

In countries where technical or vocational education forms an important part of secondary school provision, there have sometimes been specialist institutions for the training of teachers for this work. Such teachers tend to have lower status than the secondary school staff who teach academic subjects, and efforts have been made to upgrade the position of the teacher of agricultural and industrial arts, home economics, and handicrafts. Nearly all the universities in England and Wales that now offer the bachelor of education degree for college of education students include technical subjects within their list of approved options.

The element of educational courses in the teacher preparation program has been the object of criticism from academic specialists, defenders of liberal culture, and practical-minded professional educators. The growing

range of speculation and empirical data generated by the burgeoning social sciences, philosophy, and history, have provided a rich ore from which those responsible for teacher preparation mined the materials they needed for the construction and legitimation of their pedagogic systems and principles. But such borrowing has done little to establish any very coherent system of educational ideas, or to provide the basis for a systematic theory of teaching adequate to sustain the variety and complexity of teacher preparation programs. In his *Evolution of American Educational Theory* (1964), C.J. Brauner was forced to conclude that

> middleman theorists, inexpert as scholars, had naïvely striven for some impossible synthesis that would be at once faithful to scholarship, useful to the practitioner, intelligible to the populace and thus comprehensive as a discipline, workable as a general method, and defensible as a social institution.

The study of educational principles. There has been much dispute as to whether the study of educational principles is to be seen as part of the liberal element in the course, contributing to the teacher's general education and personal development, or whether it is properly an adjunct to the professional sequence, serving to illuminate and enrich students' method courses and practical work. Where it was well done, the study of the philosophy, sociology, and history of education and of educational psychology clearly served both ends and also provided an introduction to a systematic exploration of human conduct and affairs that was both educationally defensible and important in its own right. But all too often it was not well done. As the field of the social sciences grew, it became increasingly difficult for those employed in teacher-preparing institutions to keep pace. In some places, student teachers could follow courses in psychology, sociology, and so on given by recognized authorities in their respective disciplines, and in all countries there were some prominent social scientists who themselves took a close and direct interest in educational matters. But, given the large number of institutions responsible for teacher preparation and the fact that the majority of their staff were necessarily recruited for their teaching competence rather than for their high academic qualifications, much of the teaching of educational principles tended to become out-of-date and secondhand.

In recent years there has been a revival of interest in the social sciences as an integral feature of teacher-education programs. This is partly a recognition of the popularity of studies of this kind among students, partly a reflection of their relevance in a time of rapid social and educational change, and partly a function of the larger supply of qualified social scientists available to teach them. There is now also becoming available a substantial volume of research material on problems such as the dynamics and correlates of children's learning, language development, differences in individual educability and response to teaching, and social class and educational opportunity. In his 1929 lecture, "The Sources of a Science of Education," John Dewey saw the elements of such a science being drawn out of other natural and social sciences, organized in relation to problems defined by the educational process. These hopes are now closer to realization.

Practical training. Professional and practical studies constitute the third major element in the teacher-preparation program. "Teaching practice" has always been important, initially carried out in the model or demonstration school attached to the normal school or college, later in the schools of the neighbourhood, and more recently in a variety of school, college, and community settings. The model and demonstration school was frequently criticized for the unreality of its teaching settings; some model schools attached to universities tended to become academically oriented and ceased to play an experimental role. But if there are advantages in practicing in more typical schools, there are also difficulties in relating the variety of experience thus attained to the purpose and content of the college course, particularly when there are discrepancies between the methods and approaches taught in the colleges and those that the student encounters in the school. In some countries, experienced teachers view the work of teacher-preparing institutions with a certain amount of disdain. It is sometimes claimed that college and university staff lack the recent, firsthand experience of schools that is needed if training is to be fully effective. Efforts have been made to reduce the separation between school and college; these include the transfer of college staff to periods of classroom teaching and of experienced teachers to college work, dual appointment to a college and to a school where the "teacher-tutor" assumes responsibility for supervision of the student's school-based work, the involvement of teachers' organizations in the determination of national policy on teacher education, the involvement of individual teachers in the government and committee work of teacher-preparing institutions, and the use of periods of school-based teacher education in which a tutor and group of student teachers are attached to a school or a number of schools for an extended period of observation, practical teaching, and theoretical study. Courses are also being devised in which periods of education, training, and paid employment in schools alternate with one another to make up a four- or five-year program.

Model schools

APPOINTMENT PROCEDURES AND PROBATIONARY REQUIREMENTS

Certification

Generally speaking, in federal countries such as the United States, Canada, and Australia, each state or province sets its own requirements for certification, which inevitably do much to shape the content and organization of the teacher-education programs. The variety of such regulations often means that teachers who have received their education and training in one province or state are not qualified to teach in schools elsewhere without satisfying additional requirements. In other countries, such as England and France, requirements are determined on a national basis. Responsibility for recommending the granting of qualified teacher status may, however, be delegated. In England this responsibility is exercised by regional consortia of colleges, local educational authorities, universities, and teacher interests known as area training organizations that were established after 1944.

There are likewise considerable variations among countries in the way in which teachers are appointed to their first posts after graduation from college or university. In a small number of countries, students have a completely free choice among all the schools of the type in which their training qualifies them to teach, and they make their applications directly to the school in which they wish to serve. A more common pattern is that of appointment to the service of a local, state, or provincial authority, which then places the teacher in a school where a suitable vacancy exists. In some places there is a tendency for beginning teachers to be placed in schools in more remote or less desirable areas. In countries that have universal military service, such as Israel, it is sometimes possible for trained teachers to satisfy military requirements by being drafted to a school of the government's choice.

Another aspect of the diversity of certification requirements is the extent to which teachers are permitted to undertake work in subjects other than those they specialized in at college or university. Generally speaking, where national and state rules exist they tend to be interpreted liberally during periods of teacher shortage and more stringently as the supply of teachers improves; it is often possible for a teacher to secure the additional qualifications required to undertake a greater variety of work by taking university summer sessions or other kinds of in-service courses.

IN-SERVICE TRAINING

Training on the job involves more than courses, conferences, and other organized study programs. Such efforts belong to a much broader system of communication whereby all those who are involved in the educational enterprise—teachers, administrators, research workers, curriculum-development specialists, teacher trainers—keep in touch with one another and with developments in their respective fields. One must therefore consider the

media that are available for in-service education as well as institutional arrangements by means of which such training is provided.

Learning materials

Printed matter forms the most obvious kind of communication medium among teachers. In all countries there are both general and specialist educational journals and newspapers; educational bodies of various kinds issue their own newsletters, broadsheets, and bulletins. The volume of material published in this form has increased enormously. In some countries books, journal articles, and research reports are systematically abstracted and distributed, and some schools have their own library and information services.

A second group of media for in-service training includes lectures and related types of face-to-face instruction and discussion. Greater use is now being made of seminars, working parties, discussions, and other group activities that require a higher level of individual participation. Alongside these methods, a beginning has been made with the use of case studies and simulation materials. Among the advantages of such techniques are the high degree of personal involvement they encourage, the "realism" of the problems dealt with, a reduction in the didactic element (especially important in work with senior staff), and the opportunities for questions of theory and principle to arise in the discussion of actual teaching and administrative incidents.

Multimedia approaches to in-service studies are encouraged by closed-circuit and broadcast television facilities within individual school systems and local areas. The work that professional and specialist associations have long performed in bringing teachers together for the discussion of issues of mutual concern is now being extended by such developments as the establishment of teachers' centres in Britain. These help to disseminate a wide range of new educational practices and ideas, including those that derive from the teacher-controlled Schools Council for Curriculum and Examinations. In North America, Australia, the United Kingdom, Germany, and some other European countries, credit-bearing courses are now available for teachers through broadcast television, radio, and correspondence tuition.

The use of a wider range of media has diversified the institutional settings in which in-service teacher education is provided. Universities, colleges, teachers' centres, and teachers' homes are now among the places where the teacher can pursue his education and seek to improve his qualifications. Given the larger number of teachers on the staffs of many schools, there is also scope for school-based in-service education. A new idea or principle may find more ready acceptance within a group of like-minded people than when it must make its way against the organizational conservatism of a particular school. Department discussions, staff working parties, and other forms of school-based meetings enable matters of curriculum and organization to be discussed in depth, facilitate the induction of younger members of the profession, and help to limit the isolation of the teacher within the classroom. School-based in-service education has the important merit of recognizing that there is a gap between the ideas, techniques, and approaches that teachers acquire as a result of their training and the application of these ideas and approaches within the social system of the school. With the growth of team teaching and interdisciplinary work, and the reinterpretation of the teacher's role as an organizer and manager of learning resources rather than a solo performer on the classroom stage, the importance of bridging this gap will become increasingly important.

FUTURE DEVELOPMENTS IN TEACHER EDUCATION

Coming decades are likely to see continuing development and change in teacher education. Postsecondary and higher education may soon reach between a third and a half of the population in many advanced countries. The teacher must adjust to new developments in educational technology, the growth of human knowledge, and the problem of creating a relevant and appropriate curriculum from the enormous range of material available. There will be new understanding of how children develop and learn. The patterns of authority in society will continue to change, and it is likely that there will be a greater recognition of the importance of moral and personal education in a world of pluralistic values and goals. All these factors will affect the ways in which teachers are educated and trained.

In all countries, whether or not any fundamental institutional changes are contemplated, there are evidences of radical change in the structure of ideas and assumptions that underlie the preparation of teachers. But it is unlikely that coming decades will see the introduction of any comprehensive pedagogical system resembling those of the 19th century. No single theory of learning or teaching is likely to satisfy the diversity of individual needs and societal arrangements.

BIBLIOGRAPHY. A useful recent review, on a comparative and international scale, is EDMUND J. KING, *The Education of Teachers* (1970). More detailed comparative perspectives are provided in GEORGE Z.F. BEREDAY and JOSEPH A. LAUWERYS (eds.), *The Education and Training of Teachers, The Yearbook of Education* (1963). J.B. CONANT, *The Education of American Teachers* (1963); and J.D. KOERNER, *The Miseducation of American Teachers* (1963), provide contrasting mid-century perspectives on teacher education in the United States. Similar contrasts for Great Britain may be found in contributions to W. TAYLOR (ed.), *Towards a Policy for the Education of Teachers* (1969). Historical developments for the U.S. are surveyed in W.S. MONROE, *Teaching Learning Theory and Teacher Education, 1890 to 1950* (1952); M.L. BORROWMAN, *The Liberal and the Technical in Teacher Education* (1956); and L.A. CREMIN, *The Transformation of the School: Progressivism in American Education, 1876–1956* (1961); and for England in R.W. RICH, *The Training of Teachers in England and Wales During the Nineteenth Century* (1933); and W. TAYLOR, *Society and the Education of Teachers* (1969). European provision for teacher education is reviewed in J. MAJAULT, *Teacher Training* (1965), in the Council of Europe series "Education in Europe." The Organization for Economic Cooperation and Development (OECD) issued between 1968 and 1970 a series of "Studies on Teachers," which cover all the western European countries, the United States, Canada, and Japan. Recommendations for the reform of teacher education in England and Wales are embodied in the *Report of the Committee of Inquiry on the Training of Teachers* (1972). Teacher education in developing countries is discussed in C. BEEBY, *The Quality of Education in Developing Countries* (1966); and PHILIP H. COOMBES, *The World Educational Crisis* (1967).

(W.Ta.)

Teaching Profession

Measured in terms of its members, teaching is the world's biggest profession. There are said to be about 20,000,000 teachers throughout the world. Though their roles and functions vary from country to country, the variations are generally greater within a country than they are between countries.

Because the nature of the activities that constitute teaching depends more on the age of the persons being taught than on any other one thing, it is useful to recognize three subgroups of teachers: primary-school, or elementary-school, teachers; secondary-school teachers; and university teachers—for whom UNESCO in 1967 estimated an approximate worldwide ratio of 62 percent, 30 percent, and 8 percent, respectively (the figures exclude China). The proportions differ by country and continents; in North America, for instance, they are 53, 29, and 18; in the Soviet Union, 71, 19, and 10; and in Africa, 77, 20, and 3.

Characteristics of the profession

The entire teaching corps, wherever its members may be located, shares most of the criteria of a profession, namely (1) a process of formal training; (2) a body of specialized knowledge; (3) a procedure for certifying, or validating, membership in the profession; and (4) a set of standards of performance—intellectual, practical, and ethical—that are defined and enforced by members of the profession. Teaching young children and even adolescents could hardly have been called a profession anywhere in the world before the 20th century. It was, instead, an art or a craft in which the relatively young and untrained women and men who held most of the positions "kept school" or "heard lessons" because they had been better

than average pupils themselves. They had learned the art solely by observing and imitating their own teachers. Only university professors and possibly a few teachers of elite secondary schools would have merited being called members of a profession in the sense that medical doctors, lawyers, or priests were professionals, and in some countries even today the primary school teacher may fairly be seen as a semiprofessional. The dividing line is unprecise. It is useful, therefore, to consider the following questions: (1) What is the status of the profession? (2) What kinds of work are done? (3) How is the profession organized?

THE STATUS OF TEACHERS

Teaching enjoys average to high status, depending in part on the amount of study required to prepare for employment. Since this ranges from a relatively brief time to many years, the levels of social and economic status span a wide range.

The economic status. *Salaries.* The salaries of elementary- and secondary-school teachers have generally been relatively low, at least in all the years before 1955, when in some countries they increased sharply. In industrialized nations at the beginning of the 20th century, teachers in this group were paid hardly more than semiskilled labourers. In Europe during these years they were relatively better off than they were in America, in part because many primary-school teachers in Europe were men, with families to support. In general, primary-school teachers who are women and have relatively little academic training for their jobs receive low salaries. In Brazil in 1957, for instance, the average annual salary of a teacher—usually a woman—in the official state primary-school system was the equivalent of about $850. It was even less, only $231, in the locally financed municipal schools. Since the school day in primary schools in Brazil is only three to five hours, teachers may, and generally must, take other jobs or look after their families and homes concurrently. The poorest countries, in any case, have continued with relatively low primary teachers' salaries down to the present time. In India, for example, poorly trained teachers in village schools are paid only one-tenth as much as teachers in select city schools; and even in commercially prosperous Japan, primary-school teachers are paid only about as much as a bank clerk, an office worker, or a salesperson in a department store.

The history of teachers' salaries in a developed country like the United States reflects two factors: (1) the effects of a rising level of training and (2) the effects of a teacher shortage and the impact of collective bargaining. Studies made by the National Education Association reveal that the average salary of elementary- and secondary-school teachers in American public schools was $3,010 in 1949–50, $4,350 in 1956–57, and $7,129 in 1966–67. The average salary of such teachers increased 57 percent between 1955 and 1964, while the average pay of factory employees was increasing only 40 percent in the same period. Interestingly, though, it was an increase in birthrates for the period 1946 to 1960 that crowded the schools and put the teachers in a good bargaining position for an escalation in salaries.

When salaries are too low for what teachers regard as necessities, they add other jobs. Men are more likely to do this than women. In 1965-66, male municipal schoolteachers in the United States derived 84 percent of their total income from their salaries as teachers; 7 percent from summer employment; and 6 percent from "moonlighting," or working at a second job, during the school year. Working at a second job is much more frequent in countries in which the school day is less than seven hours or the teaching load (for secondary-school teachers) less than about 25 classes a week. In Brazil and other Latin American countries, for example, where the average teaching load of a secondary-school teacher is about 12 classes a week, many teachers take two full teaching jobs, and some go beyond that to earn a living.

University salaries

The salaries of university teachers and others who teach in postsecondary institutions have traditionally been substantially higher than those of secondary-school teachers. This reflects the fact that university professors generally have spent more years in preparation for their work and are more highly selected. But in recent years university salaries have not increased as much as those of schoolteachers. Thus, again in the United States, the 1965-66 median salary of full-time teachers in four-year higher institutions was $9,081, only about 40 percent higher than the comparable figure for primary- and secondary-school teachers. Though these North American university salaries are the highest of their kind in the world, they fall below the average incomes of medical doctors, dentists, lawyers, and engineers. Salaries in higher education in Russia are higher, in relation to other comparable occupations, than American salaries. A teacher in a Russian pedagogical institute (which trains schoolteachers), for example, is paid slightly more than an engineer who has completed a university course.

Fringe benefits and other advantages. Vacations and leaves give a prized flexibility to teaching careers. One of the attractive things about teaching, for instance, may be the long annual vacation, usually in summer, which can be used for recreation, for further study or training, or for earning more money.

Leaves of absence are also more frequent than in other occupations. The sabbatical leave is a widespread practice among universities and is even available in some school systems. Formerly a fully paid leave for study or research every seventh year, it is now often reduced to a fully paid leave for a half year or half-salary for a full year. Maternity leave (without pay) is generally available to women teachers. Sick leave and short-term leave for personal needs are also often provided—with continuing salary for the teacher validly absent for a few days.

Other benefits are becoming quite common; some of them, such as pensions, have been in practice in Europe for many decades. Life-and-health insurance, another fringe benefit, is usually paid partly or wholly by the school system or the university.

Seniority rights, enjoyed by teachers in many school systems, give them preferential treatment in transfers to other schools and class assignments within their system.

Social and occupational status. According to a number of sociological surveys, university professors generally rank high in public estimation, comparable to medical doctors, lawyers, owners of large business and industrial establishments, bankers, and officials of national government. On a status scale ranging from 1 (high) to 7 (low), a university professor would be ranked 1 in most countries and 2 in some countries. A secondary-school teacher is generally ranked 2 or 3 on the same scale, sharing the level with journalists, clergymen, business managers, accountants, insurance agents, real-estate or land agents, and substantial landowners. A primary school teacher is generally ranked 3 or 4 on the seven-point scale, on the same level occupied by social workers, office managers, bank clerks, small independent farmers, and foremen.

Occupational status in the teaching profession is roughly related to the degree of selection involved in obtaining the teaching post and to the amount of training necessary to qualify for it. In a country with a selective university-preparatory secondary school, such as, for instance, the *lycée* in France, the grammar school in England, and the *Gymnasium* in Germany, the teacher must have the equivalent of a university education and must pass rigorous examinations or selective screening. This teacher has a higher occupational status than teachers in other branches of secondary education, such as industrial or commercial schools, which are less selective and require less training and accept lower examination standards of their teachers. Whenever a secondary-school system is divided into a number of branches or types of schools, the teachers and the public both make status distinctions among them.

Throughout the period from about 1850 to 1925, when schooling was becoming universal in the more developed countries, the elementary-school, or primary school, teacher had lower status than the teachers of the more advanced schools. Still, there was a good deal of variation between countries. In Germany, for example, the prima-

ry-school teachers were more frequently men than women, and the male *Volksschullehrer* had relatively high status. If he taught in a rural school, he usually had a comfortable house adjoining his school and was above peasant landowners in social status. If he taught in a city, he could look forward to becoming the head teacher or school director. The German schoolteachers had a series of about seven status positions, from the classroom teacher in the primary school to the department chairman in the *Gymnasium,* or academic secondary school. The four to six year primary school was followed by a set of middle schools that were related to the occupational destiny of the student, and the middle schools were followed by a variety of higher secondary schools, some leading to employment and some leading to the university. Teachers were ranked in this sequence. Many *Gymnasium* teachers —that is, teachers of college-preparatory schools—were scholars of some distinction, almost on the same status level as a university teacher. Oswald Spengler, for instance, with his broad-gauged historical writing (*The Decline of the West*) was a history teacher in a Hamburg *Gymnasium* and never a university professor.

In Japan, the evolution of the teaching profession has been somewhat similar to that in Germany. Both countries have more men than women teaching in elementary schools, and as late as 1964, only 22 percent of Japan's secondary-school teachers were women. Women were not encouraged to become teachers in Japan until after 1874, when the first Women's Normal School was founded. Both countries had several clearly marked status positions within a school level, depending on amount of training and on seniority. The moral stature of the Japanese teacher was regarded as an extremely important part of his qualification.

Status distinctions

Distinctions between primary- and secondary-school teaching die hard. In Europe and South America, for example, adolescent students training in normal schools to become primary-school teachers are generally addressed, referred to, and treated as children, while their counterparts in university preparatory schools are addressed as adults. Prospective primary-school teachers are normally called pupils and not students and are often addressed in the familiar forms of speech (*tu* or *Du* instead of *vous, usted,* or *Sie*) in contrast to university students.

In most modern countries, however, where the goal of universal schooling has been extended to the secondary level, distinctions in status between primary- and secondary-school teachers have been moderating. In such situations, secondary-school teaching becomes relatively less selective as additional teachers are sought for, at the same time that primary-school teachers are increasing their training level and, therefore, their salary and status levels. In a growing number of countries, including Germany, England, and the United States, primary-school teachers must now have as much university-level training as secondary-school teachers, and a single salary scale has been established, based on amount of training and years of experience. In 1964, for example, the average annual salary of primary-school teachers in the public schools of the United States was about 93 percent of that of secondary school teachers, indicating that the occupational status differential is being eliminated. France, on the other hand, still maintains two different systems of training and has different names for the primary-school teacher (*instituteur*) and the secondary-school teacher (*professeur*).

Whatever the status distinctions may be, the teaching profession in general is an important avenue of upward social mobility. Because teaching does not require capital, property, or family connection, it provides a good opportunity for the economic and social advancement of able and ambitious young people. A study of Chicago public-school teachers in 1964 indicated that approximately half of them had come from families of skilled, semiskilled, or unskilled workers (Robert J. Havighurst, *The Public Schools of Chicago: A Survey Report,* ch. 16, 1964). A study of the social origins of middle-school teachers in Brazil in 1963 showed that approximately half of them had moved up in social class as a result of becoming teachers (Robert J. Havighurst and Aparecida J. Gouveia, *Brazilian Secondary Education and Socio-Economic Development,* ch. 9, 1969).

Within the profession, the degree of status mobility is not great, at least in the primary and secondary schools. A classroom teacher is likely to remain a classroom teacher, unless he or she seeks out an administrative post or follows some specialty, such as curriculum work, counselling, or the teaching of handicapped pupils. In university teaching, on the other hand, there is a hierarchy of three or four steps within any institution and of prestige and salary among institutions. Thus a university teaching career in the United States normally leads from the rank of instructor or assistant professor to associate professor and to full professor; in Britain the titles are assistant lecturer, lecturer, senior lecturer or reader, and professor; similar rankings occur in other countries.

Geographical mobility of teachers. The high mobility of university teachers within their country has been noted. They also move from one country to another with relative ease, so that the profession of university teaching has a cosmopolitan character unique among the professions. Educators at this level belong to international professional organizations and tend to think of themselves as members of a worldwide profession.

For several reasons, there is less geographical mobility among primary- and secondary-school teachers. Because schoolteachers are licensed (whereas university teachers usually are not) they usually cannot secure a teaching job outside their own country, unless the receiving country has such a severe shortage of teachers that it seeks out immigrant teachers and gives them licenses to teach. Many African nations and India have, for this reason, a relatively large number of North American and European teachers. The language factor also interferes with geographical mobility.

Where there is a national system of state schools, as in France and England, teachers are licensed for the entire system and are able to move around from one locality to another more easily than they can in countries in which there are multiple school systems organized on state or provincial lines. In the United States, where each of the 50 states has its own licensing laws and standards, teachers tend to be held within the state (though some states do have "reciprocity" with each other).

Stereotype of the teacher. The aphorism attributed to George Bernard Shaw, "He who can, does; he who cannot, teaches," appears to have wide credence among intellectuals and educated groups. Schoolteaching is often seen as a refuge for mediocre people who are industrious but unimaginative and uncreative. Writing in the *Profession of Teaching* in 1901, a Boston educator, James P. Monroe, said:

> It is, indeed, the exceptional teacher—outside the faculties of colleges—who seriously looks upon himself as a professional man. The ordinary schoolmaster has little of the personal weight, of the sense of professional responsibility, of what may be called the corporate self-respect of the lawyer, the physician, or the engineer. The traditions of the teaching guild do not yet demand a wide education, a slow and laborious preparation, a careful and humble apprenticeship, such as are required for entrance into the really learned professions. A broad education and the poise of mind which follows it are the vital needs of a great majority of the public school teachers of today. They are ceaselessly complaining of a condition of things which is indeed grievous, but which is largely of their own creation. They demand high place without qualifying themselves to hold high place; they rebel at a not uncommon attitude of contempt or of contemptuous toleration on the part of the public, but do not purge themselves of the elements which excite that contempt; they accuse the parents and the public of indifference toward their work, but do little to render that work of such quality as to forbid indifference.

Over 60 years later a professor of education at Utrecht in The Netherlands, Martinus J. Langeveld, taking a rather ambivalent position, quoted the director of a Swiss teacher-training college, as saying, "The teaching profession is permeated with individuals who from youth upwards reveal the following characteristics: av-

erage drive for power, average ambition, and escapism [*Lebensscheu*]." Langeveld discerned an occupational type, or stereotype, characterized by lack of independence, social courage, limited social horizon, on the one hand, and industriousness, intellectual interest, achievement motivation, and love for teaching children, on the other.

Whether or not this has to be given credence, it hardly applies to university teachers; and the events of the 1960s seemed to be moving teachers toward much more social and political action as a group and toward greater personal initiative.

One stereotyped characteristic that does seem to be true for most, though not all, countries in the contemporary world is that it is a woman's profession. There is a preponderance of woman teachers, particularly on the elementary level. Of the 20,000,000 teachers in the world, a rough estimate is that two-thirds are women. Incomplete estimates for several countries and areas give the following percentages of woman teachers for the year 1965 or nearby years.

Percentage of Woman Teachers

	elementary level	secondary level	higher education
United States	87	51	22
Soviet Union	81	68	44
Japan	48	22	24
Australia-New Zealand	63	46	31
Western Europe	58	41	low*
Brazil	93	45	low*

*Official data are not available but it is known that the percentages are lower than other countries with the possible exception of the United States.

There is a good deal of variation in the sex ratio among teachers in European countries. In 1965 the percentage of primary-school teachers who were women in the United Kingdom, France, The Netherlands, and West Germany was 76, 66, 52, and 52, respectively. These percentages reflect the Central European tradition of male teachers in the rural village schools.

Building the profession in a new country. Since World War II it has been necessary to create or to rebuild the teaching profession in a new country, under varying conditions. Sometimes it was an old country becoming modern, such as India and China; sometimes it was a tribal society becoming a nation, as in central Africa; and in one case it was a religious society becoming a modern nation, as in Israel. In all such cases, the pattern of schools has been copied from older countries, but the teaching personnel have to be drawn from the human material available, and thus a wide variety of solutions to the problem of building the profession have been worked out.

In the case of Israel, there were 6,500 teachers in the school system in 1948 and 31,700 in 1963, while the school enrollment increased from 160,000 to 700,000. Since the nation was building a modern economy from a very small beginning, manpower was scarce, and especially educated manpower. This made it difficult for the state to secure male teachers, since educated men were in high demand for other more prestigious work. Consequently, the great majority of new teachers were women. The proportion of male teachers in the elementary and secondary schools was 49 percent in 1948 and 41 percent in 1963. The government has established a generous scholarship and loan program for prospective teachers and requires students who accept these stipends to teach at least five years. The Teachers' Association is the country's oldest trade union.

The evolution of the teaching profession in Hungary illustrates the problems of the teaching profession and their solution in a society that moves from capitalist to communist rule after war and revolution. In the period from 1945 to 1950, there was a serious shortage of teachers at all levels, due to wartime loss of life and to flight of teachers and professors to the West. Before World War II, most teachers were trained in institutions operated by the Catholic Church. For the first five years after 1945, there were strenuous attempts to recruit new teachers and to re-train experienced teachers so that they could serve the purposes of the new society. The retraining program consisted of a two-year part-time course of lectures that stressed a "progressive-Marxist" political and economic ideology. There were 10,000 elementary and secondary school teachers enrolled in this program in 1950.

The period from 1955 to 1967 saw a systematic upgrading of the training of elementary and secondary school teachers in Hungary, similar to what was being done in most countries. More university-level work was required. At the same time, recruiting was aimed at young people from the working class (50 percent of all university students were from peasant or working-class families during the decade of the 1950s). Secondary school entrance became more popular during the 1960s, and the numbers of secondary school teachers increased from 8,800 in 1960 to 12,300 in 1967, with a corresponding increase of school enrollment. By 1967 the supply of secondary school teachers exceeded demand. In that year, 614 positions were advertised, and 1,268 secondary school teachers were graduated from the universities. Salaries, however, are relatively low (in 1965 a rural teacher earned slightly less than an industrial or construction worker).

The teaching profession in the Soviet Union. As in all other modern countries, the length of preparation for elementary school and secondary school teaching in the Soviet Union has expanded since 1920. Most new teachers have had four years of work in a university or pedagogical institute after completing the basic ten-year school of general education. Competition is intense for places in the universities and pedagogical institutes. About 80 percent of teachers in elementary and secondary schools are women, the highest proportion in any major country.

Teachers are paid for a 20-hour week of actual teaching time in elementary schools, and 18 hours in secondary schools. They are paid extra for overtime work, which includes correcting papers in some subjects, holding conferences, and visiting parents. Many teachers earn up to twice the basic salary by extra hours of teaching. In rural areas, housing is furnished, including heating and lighting. After the age of 55, teachers may retire on a pension of 40 percent of the last salary received. They may draw the pension and continue to earn a regular salary if they wish to continue teaching.

University faculty members have a high status, comparable to that of other professional groups. Their salaries place them among the highest paid workers and they receive, in addition, payment for lectures, articles, and books.

FUNCTIONS AND ROLES OF TEACHERS

Broadly speaking, the function of a teacher is to help a client learn things, by imparting knowledge to him and by setting up a situation in which the client can and will learn effectively. But the teacher fills a complex set of roles, which vary from one society to another and from one educational level to another. Some of these roles are performed in the school or university, and some are performed in the community.

Roles in the school or university

- Mediator of learning
- Disciplinarian or controller of student behaviour
- Parent substitute
- Confidant to students
- Judge of achievement
- Organizer of curriculum
- Bureaucrat
- Scholar and research specialist
- Member of teachers' organization

Roles in the community

- Public servant
- Surrogate of middle class morality
- Expert in some area of knowledge or skills
- Community leader
- Agent of social change

In those areas in which teaching has not yet become a profession, the teacher may fill fewer of these roles. The

primary-school teacher in a simple agricultural society, for example, will fill only the first five of the school roles and the first and possibly the second of the community roles.

Some of the roles conflict; that is, the performance of one, that of disciplinarian, for example, tends to conflict with another, such as that of confidant to students, or the role of independent and creative scholar will tend to conflict with that of the bureaucrat. In the community, the role of surrogate of middle class morality tends to conflict with the role of agent of social change. In the presence of these role conflicts, the teacher must learn to balance, to know when and how vigorously to act in a particular role, and when to shift to another in a flexible way.

Role in curricular design. The family, the government, the church or religious authority, and the economic or business-industrial authority all have an interest in the development of children and youth, and all play a part, therefore, in setting up and controlling formal and many informal means of education. In the more developed societies, they employ teachers to do the work of education, and they work out with the teacher an understanding of what the teacher is expected to do. The more "professional" the teacher is, the more autonomy he demands and is given to teach within the concept of understood and mutually accepted goals and methods.

Teaching of skills, information, and attitudes

The elementary-school teacher must teach the basic mental skills—reading, writing, and arithmetic. Beyond this, the elementary-school teacher must teach facts and attitudes favourable to the nation or the church or any other institution supporting the school. Thus he must teach in a way that is favourable to Communism in the Soviet Union, to a mixed capitalist-socialist economy in Britain or the United States, to the French or Brazilian systems in France or Brazil, and so forth. In a society in which schools are directed by churches or religious groups, as in Spain, he must teach the relevant religious beliefs and attitudes.

In national and state systems of education, the legislature generally requires that certain subjects be taught so as to "improve" the citizenship or the morality or the health of the students. Many systems, for instance, require secondary schools to teach about the pitfalls of alcohol, drugs, and tobacco. A growing number of nations require teaching in favour of conservation of natural resources and protection of the physical environment against air and water pollution. Before World War II a central course required in the Japanese schools was "moral education." After the war, this was abolished by the American occupation forces on the grounds that it tended to inculcate a kind of authoritarianism and nationalistic ideology. With the ending of the military occupation, however, the Japanese government reintroduced a compulsory course in moral education, which became a source of major controversy between conservatives and progressives within the Japanese educational profession. The French school system also has a compulsory course in "civic morality."

Teaching freedom

Matters of curriculum and choice of textbooks and materials of instruction are determined in some countries with little or no participation of the individual teacher. Thus, in France, with a highly centralized national educational system, the course of instruction in the elementary schools is fixed by the Ministry of Education. In the United States, where each of the 50 states is its own authority, there is much more curricular variation. Some states require statewide adoption of textbooks, whereas others leave such matters to local decision. Many large city school systems have a curriculum department to set policy in such matters, and the individual teacher in a city school system or in certain state systems thus has relatively little power to decide what to teach. There is more flexibility at the secondary-school level than in the primary-school level. As for methods of teaching within the classroom, the individual teacher probably has more autonomy in the United States than in most European school systems.

The university teacher almost anywhere in the world has substantial autonomy in his choice of textbooks, of content to be covered in a particular course, and of methods of teaching. In general the only limits on the university teacher are set by the nature of his teaching assignment. If he is one of a number of teachers who teach a popular course, such as general chemistry or physics or history, which is taken by several hundred students and offered by several different instructors, he may have to use the same textbooks as those used by other instructors, and he may have to prepare his students for common examinations. On the other hand, in those courses that he alone gives, he has wide freedom to choose the content and methods of instruction.

In terms of the professional responsibility of teachers for what they teach, there is a major distinction between the university and elementary-secondary school systems. At the level of higher education, teachers have the power and the responsibility of defining the curriculum—its contents and its methods. This is the essence of academic freedom in higher education. The governing board of the university, whether it be a government or independent university, does not tell teachers what to teach or how to teach. There are, nevertheless, some external requirements operative on the university teacher. If he is preparing his students for examinations not under university control (civil service examinations, state bar and medical examinations, examinations for a certificate as a public accountant, or the like), his autonomy is limited by the necessity that his students be well prepared for these external examinations.

In contrast to the power of the university governing board, the board of an elementary- or secondary-school system has, but generally delegates to the school administration, the power to determine what is taught. The school administration, consisting of the superintendent, school directors, inspectors, and curriculum specialists, has effective power over the curriculum and brings the classroom teacher into the process as much or as little as it chooses. With the growth of teachers' unions and organizations, however, it appears that collective action by teachers is tending to increase the effective autonomy of the classroom teacher. Administrative and legislative prescriptions for the school curriculum are generally resisted in *principle* by the teaching profession; the profession presumes itself better able to decide what to teach and how to teach it.

The doctrine of in loco parentis. When minor children are entrusted by parents to a school, the parents delegate to the school certain responsibilities for their children, and the school has certain liabilities. In effect, the school and the teachers take some of the responsibility and some of the authority of the parents. The exact extent and nature of this responsibility and power vary from one society to another and from one school system to another. This is spelled out to some extent in the law, but much of it is determined by local custom and practice.

There is, of course, a relation between the age of the child on the one hand and the teacher's responsibility and liability for it on the other. The young child *must* obey the teacher, and the teacher may use the methods expected and tolerated in the community to control the child's behaviour. Furthermore, the child's physical safety is entrusted to the school and to the teacher, who thus become legally liable for the child's safety, insofar as negligence can be proved against them.

In the matter of corporal or physical punishment, local attitudes establish a wide range of expected and permissible behaviour on the part of the teacher. In most parts of the world, young children may be punished by a limited infliction of physical pain at the hands of the teacher or school principal, using a wooden ruler or a whip of one kind or another. But there are some systems and cities that explicitly bar a teacher from using corporal punishment. This seems most common in large cities; the teacher in a rural or small-city school is more apt to be expected to use physical measures for controlling pupil behaviour. As students become older, their behaviour is less apt to be controlled by physical measures, and they are more likely to be suspended from classes or expelled from school. This is the common last resort in the upper years of the secondary school and in the university.

Another facet of the doctrine of *in loco parentis* is seen

Relations between parents and teachers

in the relation between parents and teachers with respect to the promotion of pupils and to their counselling or guidance. Parent and teacher may be in conflict about the best procedures to use with a pupil. Shall this pupil be promoted from a fifth to a sixth year class or be "kept back" to repeat the year's work? This decision is generally seen as the responsibility of the school, though the parents may be brought in for consultation. If the parents object to the school's decision, what rights and powers do they have? May they see the school's records on their child? May they examine the pupil's examination papers or other school work? The answers to these questions are more fixed in some countries than in others, but in general, the school's authority is supported in these matters.

A more difficult problem is presented by a student, generally an adolescent, who is having serious problems with his school performance or with his school behaviour. He is sent to the school counsellor, who finds him in need of therapeutic counselling and proceeds to counsel him. Must the counsellor secure prior consent from the parents? Must the counsellor disclose to the parents what he learns about or from the student in confidence? Perhaps the counsellor concludes that a part of the student's difficulty is caused by his parents. Must the counsellor tell this to the parents? Is the counsellor intruding on the *privacy* of the parents by asking the student about his relations with them or by listening if the student volunteers such information? This is *terra incognita* for the teaching profession, and has become something of an issue in the places where personal counselling is regarded as part of the school's responsibility.

At the level of higher education, the doctrine of *in loco parentis* does not present as much of a problem for the teacher, since the student, even though he may be legally a minor, is presumed to be a more responsible person. But the university may have a problem in relation to the local police or city government. May university property—including classrooms in which teachers are trying to teach—be regarded as private property, with police and other outside persons barred unless they are explicitly asked for their help? The question (and others like it) has no clear and unequivocal answer.

Extramural activities of teachers. Traditionally, the schoolteacher has been a surrogate of middle class morality who serves the local community in various clerical or secretarial capacities because he or she can write legibly and spell accurately. Furthermore, the schoolteacher has often been expected to support the local religious group, if there is one, by teaching children, singing in the choir, and so forth. In other words, the teacher is seen as a useful minor civil servant, without deviant political or economic attitudes.

Though this may be true of most teachers in most countries, there are exceptions. In places where the community is polarized along religious or political lines, for instance, teachers generally have to take sides in local politics and cannot easily serve the whole community. Thus, in the small towns of France, the stereotype of schoolteacher is traditionally that of a man with leftist political leanings, always at war with the village priest. In the cities, schoolteachers are needed less to perform local community services and tend as teachers to be politically neutral or invisible.

University teachers are more likely to be leaders in local politics and local civic affairs. Since the university is expected to be a source of ideas as well as of information in controversial areas, university professors may perform this function by taking sides on political and economic issues. Also their expertness in the natural sciences makes them influential advisors on local and state problems of health, water supply, transportation, and the use and conservation of natural resources. When the university teacher does take sides on controversial economic or political issues, he may expect counterpressures to have him discharged, and his institution may or may not support him in the name of academic freedom.

As elementary- and secondary-school teachers have organized themselves for collective action, they have succeeded increasingly in protecting those of their group who do take unpopular positions on political and economic matters. In countries with two-party or multiparty political systems, teachers may now run for elective offices, and they and their organizations are likely to take sides on political issues. Thus the teacher at any educational level is increasingly free to take part in promoting social changes, and at least a few teachers are generally found in leadership roles in local and national politics.

Scholarship and the profession. Within the profession, prestige has traditionally gone to the productive scholar, the one who contributes to the growth of knowledge, literature, or art. Promotion in the university and fame in the world outside the university have gone to the person who does research or scholarly work—and publishes. The university is seen as an institution to discover new knowledge, as well as to pass on what is known, and these two functions are not necessarily tied together. The teacher of adolescents and of university undergraduates does not find that research or scholarly work makes him a better teacher. Only when he is teaching graduate students who themselves are being trained for scholarship does the university professor find himself working at the frontier of knowledge, with his students as apprentices.

Relation between research and teaching

The universities of the world have adapted to this situation in two ways. One is to assign some teachers a teaching role, with a heavy teaching load and recognition when they do a good job of teaching; the other is to give teachers a reduced teaching load and expect them to do research or writing. A second adaptation is to assign some staff members to full-time research with a few graduate students associated with them as apprentices and research assistants. In any case, it is the fact that the universities of the world, which claim the responsibility of advancing knowledge, do continue to judge their teachers more by their research and writing than by their teaching.

University teachers are also much in demand for consultation and advice to industry, business, government, and school systems. The best experts on problems of innovative development and on the conduct of industrial research and development are generally found in universities, and many teachers find as much as a quarter to a half of their time taken with consultation.

THE CAREER OF THE TEACHER

The professionalization of teaching. In the 19th century, systems of public education developed in order to meet the recognized need for universal literacy in an industrializing society. Teaching at this primary level was at first no more than a high-level domestic service, in which the teacher took over some of the child-rearing responsibility of the family. In some parts of the world, a year as a cadet teacher working under a more experienced teacher became the model for teacher training. Frequently, courses were added to the secondary school in the largest town of the county or province, for training classroom teachers. Even today in many countries, notably in Latin America, the training of teachers is still carried on largely in certain types of secondary schools, called "normal schools," which take students (mainly girls) at about age 15 or 16 for a two- or three-year course of study. In Europe and North America, the earlier normal schools or teachers colleges have since moved up to the postsecondary level of higher education. In any event, by the turn of the 20th century some rudiments of a teaching profession had begun to evolve. There was the beginning of a program of formal training; the emergence of a body of specialized knowledge called pedagogy; the imposition of an inchoate system of licensing or certification; and the recognition of a few minimal standards of performance to be defined, expanded, and enforced by the corps of teachers.

The combined efforts of educational reformers and teachers' organizations were required to fashion the beginnings of a profession. Men and women saw themselves becoming committed to a career in teaching and therefore sought to make this career more personally and socially satisfying. The Chicago Teachers' Federation, founded in 1897, for example, comprised a group of female primary-school teachers who were faced by an experimental pension system that was actuarially unsound and by

salaries that were very low. Margaret Haley, a dynamic 36-year-old Irish woman, was their leader, and in the 15 years after she helped found the Teachers' Federation, it brought a successful suit against the public utilities, forcing them to pay more taxes; forced the board of education to use the added tax income to increase teachers' salaries; affiliated with the Chicago Federation of Labor; sued the *Chicago Tribune* for revising its lease of school-owned land; and engineered the election of Chicago's woman superintendent of schools to the presidency of the National Education Association. Writing in 1915 in his publication, *The Daybook,* Carl Sandburg referred to her latest victory:

> Margaret Haley wins again! . . . For fifteen years, this one little woman has flung her clenched fists into the faces of contractors, school land leaseholders, tax dodgers and their politicians, fixers, go-betweens and stool pigeons. . . . Over the years the *Tribune*, the *News* and the ramified gang of manipulators who hate Margaret Haley have not been able to smutch her in the eyes of the decent men and women of this town who do their own thinking.

Tenure

Gradually, throughout the world, classroom teachers won "tenure" of their positions. In the early days, they were employed by the governing body of the school system on annual contracts; under such a system no teacher was assured of his job for the ensuing school year until he had received formal notice of his reappointment for the year. There then developed the practice of automatic renewal of the contract unless the teacher was notified by a certain date (usually three or four months before the beginning of the school year) that his services would *not* be needed. Finally, as school systems—local, state or provincial, and national—became more stabilized and organized, the rule of life tenure or tenure up to the age of retirement was adopted. Generally, under such a system, after two or three years of satisfactory service, a teacher achieves tenure and cannot be removed from his position except for specific reasons of incompetence or moral turpitude, and, even then, he has the right to a formal hearing on such charges.

This history of public-school teachers, involving a slow upgrading of teacher education combined with a struggle for professional recognition, has not been experienced by university teachers. Because higher education throughout the world has been limited to a selected few, it has correspondingly required relatively few teachers, and they seem to have emerged within the universities and to have been selected by the university authorities themselves. They frequently have constituted an inner circle or closed clique. There have, however, been a few instances of pressure by students and by civil government for improved professional standards. The South American University Reform of 1918, for instance, was started by students at the University of Córdoba in Argentina and was aimed at improving the low professional standards of teachers in Latin American universities.

The status and prestige of the university professor has been relatively high in most countries, and he has needed no politico-economic organization to fight for his professional status. Only in the late 20th century has there been a strong movement organized and led by university teachers to further upgrade or reform their profession. This movement has been particularly apparent in the United States, where the enormous extension of higher education has led to a growing teaching force and a consequent problem of maintaining professional standards. Since the 1950s the American Association of University Professors (AAUP) has pressed for higher salaries, by publishing various studies of salary levels that have singled out universities paying relatively low salaries. At the same time the AAUP has continued an aggressive campaign for academic freedom of the professor, by defining a code of professional ethics for the teacher and a procedure through which an institution must go if it proposes to discharge a professor.

Educational associations and teachers' unions. Professional groups all over the world have organized for collective action to do two quite different things. One objective of a professional organization is to improve the economic status and the working conditions of its members. A second broad objective is to improve the service that the profession performs for society. These two objectives may best be viewed separately, and it is not clear, a priori, to what extent they are mutually conflicting or mutually supportive.

Commencing in the latter half of the 19th century, elementary- and secondary-school teachers banded together to form societies of teachers in the various types of schools and in the various school subjects. Thus Germany and France with their stratified school systems had as many as five teachers' organizations that operated more or less independently of each other. By the middle of the 20th century, however, such organizations in European countries tended to coalesce into strong national organizations.

Professional associations. University teachers have generally organized themselves into associations for the improvement of scholarship and higher education. As a rule they have operated on the assumption that society will support them financially and morally if they do a good job of scholarly research, writing, and teaching. They accept as members scholars who are not actually teaching in higher institutions but are engaged in industrial, artistic, literary, or other work.

Every country has its national learned societies, which hold annual meetings, publish journals, and generally work for the improvement of scholarship. There are national organizations of classicists, foreign-language teachers, biologists, physical scientists, sociologists, psychologists, anthropologists, literature students, historians, and so forth. In addition there are interdisciplinary organizations, such as the Tavistock Institute of Human Relations (Britain) and the Social Science Research Council (U.S.). Selective prestige associations also exist to further the cause of the professions and to honour individual leaders. Some famous examples are the Académie Française, the Royal Academy (Britain), the National Academy of Sciences (U.S.), the Academy of Sciences of the U.S.S.R., and the Nippon Gakushiin (Japan).

International associations make the university teaching profession a worldwide force. There are international associations of scholars in chemistry, psychology, sociology, human development, gerontology, and other branches of scholarship. Special attempts have been made in recent years to bridge the gap separating the Communist bloc of nations from the European-North American bloc. International meetings have been held in Yugoslavia, Bulgaria, and Russia, and scholars from the Communist countries have been encouraged to attend conferences in non-Communist countries.

Teachers' unions and teachers' associations. In most countries there is one major teachers' organization to which all or nearly all teachers belong and pay dues. Sometimes membership is obligatory, sometimes voluntary. Thus there is the National Union of Teachers in England, the Japanese Teachers Union, the relatively young Fédération Générale d'Enseignement in France, and the Australian Teachers Union. In the Soviet Union, where much of the political and social life of the people is organized around unions, there are three teachers' unions —for preschool teachers, primary- and secondary-school teachers, and teachers in higher education. These unions in the U.S.S.R. provide pensions, vacation pay, and sick-leave pay and thus touch the welfare of teachers at many points. There are also professional societies for subject-matter specialists within the unions and subordinate to them.

The organizational complex is stable in some countries and changing in others. England, for example, has two different associations for male and female secondary-school teachers, two different associations for male and female headmasters of secondary schools, and a separate Association of Teachers in Technical Institutions. These associations are parallel to the National Union of Teachers, which is open to any qualified teacher from nursery school to university level. The National Union has no political affiliation but is politically powerful in its own right. France, in contrast, has a wide variety of teachers'

organizations, with various political leanings, but they do not get on well together and are politically less effective.

In the United States, there is a basic rivalry between the National Education Association, which includes teachers of various levels as well as administrators, and the American Federation of Teachers, a trade union that excludes administrators. Since about 1960 the NEA, a loose federation of local, state, and national organizations, has become more militant in working for the economic improvement of teachers and has tolerated strikes. This policy has resulted in a reorganization of the NEA into a looser federation, with classroom teachers operating quite separately from the associations of administrators. It has also brought the NEA into direct competition with the AFT, which is relatively strong in several large cities.

Although the classroom teachers' organizations began as agents for obtaining better salaries and working conditions, wherever they have succeeded substantially in this effort they have turned to the other activity—setting standards of performance and attempting to improve educational policy and practice. Faced with great difficulties in educating children in the slums and ghettoes of the big cities, the teachers' union in the U.S., for instance, has put into its collective bargaining agreements a statement of interest in, and responsibility for, educational policy and for the development of teaching methods and the training of teachers for those difficult positions.

The various national primary- and secondary-school teachers' associations have moved toward the formation of two loose international federations. One includes the national associations from the Communist bloc of countries—the World Federation of Teachers' Unions. The other, the World Confederation of Organizations of the Teaching Profession, was founded in 1952 and includes most of the national associations from the non-Communist bloc. They both compete for the allegiance of teachers' organizations in the uncommitted countries.

THE TEACHING PROFESSION AND CONTEMPORARY SOCIAL REVOLUTIONS

In almost every country with a free public voice, there are found today new militants urging professional associations to take sides in political controversies over problems that do not lie in their fields of professional competence. The argument in favour of militancy is that modern societies are engaged in a social revolution that is changing profoundly the nature of contemporary society, that this revolution will have profound effects on the teaching profession, and that teachers should assume responsibility for directing education toward constructive participation in the social revolution.

At the same time, the militants foresee a drastic change in the teaching profession. They see it as: (1) more critical of itself—new members are skeptical of many of what were once supposed to be established propositions of pedagogy and of science; (2) impatient for rapid change—the rate of social change of the past 50 years is presumed to be too slow; (3) adopting human welfare—the well-being of all people and especially of disadvantaged people—as the crowning objective of the profession; (4) looking to the consumer for guidance in the work of the profession—they believe in sharing power with students or clients in the shaping of education; and (5) becoming less concerned with formal professional standards, such as diplomas, licenses, and university degrees and turning more teaching responsibility over to teacher aides, using pupils as tutors, or admitting students to the university with little or no examination of their formal knowledge.

(R.J.H.)

Tea Production

Tea is made from the young leaves and leaf buds of the tea plant, a species of evergreen (*Camellia sinensis*). Ancient Chinese and Japanese legends refer to a beverage made from an infusion of dried tea leaves, the introduction of tea sometimes being attributed to the emperor Shen Nung about 2737 BC. Existing records credit the Chinese with originating tea cultivation, although it is possible that some tribes in Shan States in Burma, China, and Siam (Thailand) have used tea in some form as long as the Chinese. Lu Yu, writing in about AD 780, said that there were "a thousand and ten thousand" teas. He described the tea leaf, specifying that it must be plucked only during certain moons and in clear weather, and he explained how the leaf is manipulated in the hands, dried, and sealed. The China tea plant, brought to Japan about AD 800, was regarded as a medicine for 500 years, until green tea was developed and became a popular Japanese beverage.

China introduced tea to the world. The word tea comes from a Chinese ideogram pronounced "tay" in the Amoy dialect and came into English with that pronunciation, changing to its present form in the 18th century. Tea was introduced into Europe in the early 17th century, with the beginning of trade between Europe and the Far East. By 1715 the British East India Company, with a monopoly on overseas trade held over those British companies that were operating in Asia, was firmly established in Canton. The tea trade increased so rapidly that in 1805 England imported 7,500,000 pounds. In 1833, the Company, losing its legal monopoly, began to look for other sources of supply. The cultivation of tea in India began in 1834, with the planting of wild tea found growing in Assam in 1823. The tea produced was sold in London in 1839 and, with its acceptance, the modern tea industry began.

In the late 19th century China still supplied the bulk of the tea exported, with a peak figure in 1886 of 300,000,000 pounds, of which 170,000,000 were exported to Britain. India, which that year produced 90,000,000 pounds, soon moved into the lead of exporting countries. Ceylon followed India as a tea producer in 1867, after leaf disease caused the failure of its coffee plantations. Tea production began in Java in 1878. Tea is currently produced in about 30 countries, ranging from Soviet Georgia, latitude 42° N, to South Africa, latitude 29° S. The greatest producers are India, Sri Lanka (formerly Ceylon), and China, with Japan, eight African countries, Caucasia (Soviet Georgia, Turkey, and Iran), and South America responsible for the remaining production.

The table shows the distribution of tea planting, the amount produced in each area, and 1967 exports.

Tea Areas, Production and Export

country	area (000 ac)	production (000,000 lb)	export (000,000 lb)
China	...	600	70
Japan	121	187	4
India	868	672	471
Pakistan	100	65	0
Sri Lanka	599	496	477
Indonesia	164	89	59
Taiwan	88	54	42
Malaya and Vietnam	26	16	10
Africa	267	211	164
Caucasia	297	211	20
South America	89	45	39
Total	2,619	2,646	1,356

Habitat of the tea plant

The natural habitat of the tea plant is considered to be within the fan-shaped area between the Nāgāland, Manipur, and Lushai hills along the Assam-Burma frontier in the west; through to China, probably as far as Chekiang province in the east; and from this line south through the hills of Burma and Thailand into Vietnam. The east-west axis extends about 1,500 miles (2,400 kilometres) from longitude 95° to 120° E, and the north-south axis covers about 1,200 miles (1,920 kilometres), from the northern part of Burma, latitude 29° N, passing through Yunnan and Indochina, reaching latitude 11° N.

Tea growing. *Tea plant varieties.* The three main varieties of the tea plant, China, Assam, and Cambodia, each occur in their most distinct form at the extremes of the fan-shaped area. There are an infinite number of hybrids between the varieties; such crosses can be seen in almost any tea field.

The China variety, a multistemmed bush growing as high as 9 feet (2.75 metres), is a hardy plant able to withstand cold winters and has an economic life of at least 100 years. When grown at an altitude near that of Darjeeling and Ceylon, it produces teas with valuable flavour during the season's second flush or growth of new shoots.

The Assam variety, a single-stem tree ranging from 20 to 60 feet (6 to 18 metres) in height and including several subvarieties, has an economic life of 40 years with regular pruning and plucking. The tea planter recognizes five main subvarieties: the tender light-leaved Assam, the less tender dark-leaved Assam, the hardy Manipuri and Burma types, and the very large-leaved Lushai. In Upper Assam, the dark-leaved Assam plant, when its leaves are highly pubescent, produces very fine quality "golden tip" teas during its second flush. (The Chinese word *pekho*, meaning "white hair" or "down," refers to the "tip" in tea, which is correlated with quality.)

The Cambodia variety, a single-stem tree growing to about 16 feet (5 metres) in height, is not cultivated but has been naturally crossed with other varieties.

The mature leaves of the tea plant, differing in form according to variety, range from 1½ to 10 inches (3.80 to 25 centimetres) in length, the smallest being the China variety and the largest the Lushai subvariety. In harvesting, or plucking, the shoot removed usually includes the

bud and the two youngest leaves. The weight of 2,000 freshly plucked China bush shoots may be one pound (454 grams); the same number of Assam shoots may weigh two pounds (908 grams). Tea leaves may be serrated, bullate, or smooth; stiff or flabby; the leaf pose ranges from erect to pendant; and the degree of pubescence varies widely from plant to plant.

Cultivation. Three basic requirements must be considered in planning a tea estate: climate, soil acidity, and labour availability.

A suitable climate has a minimum annual rainfall of 45 to 50 inches (1,140 to 1,270 millimetres), with proper distribution. If there is a cool season, with average temperatures 20° F (11° C) or more below those of the warm season, the growth rate will decrease and a dormant period will follow, even when the cool season is the wetter one.

Tea soils must be acid; tea cannot be grown in alkaline soils. A desirable pH value is 5.8 to 5.4 or less. A crop of 1,500 pounds of tea per acre (1,650 kg/ha) requires 1.5 to 2 workers per acre (3.7 to 4.9/ha) to pluck the tea shoots and perform other fieldwork. Mechanical plucking has been tried, but because of its lack of selectivity, cannot replace hand plucking.

Scientific study of tea production began about 1890. Most tea-producing countries maintain scientific research stations to study every aspect of the subject, including seed production, clonal selection (for the propagation of single leaf cuttings), tea nursery management, transplanting, development of the bush and subsequent pruning and plucking, soil management and fertilizer use, and the ultimate replanting of the stand. Although procedures in all countries are related, appropriate details must be determined for each area. Since 1900, advancements in tea cultivation have increased the average yield per acre in Assam from 400 to 1,000 pounds, with many estates producing over 1,500 pounds.

The scientific study of tea

Single node cuttings growing in a tea vegetative propagation nursery, Kenya. The cuttings or clones are taken from a bush carefully selected for productivity, hardiness, and quality.

Pests and diseases. The tea plant is subject to attack from at least 150 insect species and 380 fungus diseases. In northeast India, where 125 pests and 190 fungi have been detected, losses from pests and diseases were recently estimated at 67,000,000 pounds (30,000,000 kilograms) of tea per annum. More than 100 pests and 40 diseases occur in the tea fields of Japan. Sri Lanka, where estates are close together or contiguous, has recorded many blights and suffered serious losses. Africa has little trouble with blights; the tea mosquito (*Helopeltis theivora*) is the only serious pest. Caucasia, with a climate similar to that of Japan, grows the China variety of plant and has no serious pests or blights.

Blight control has become highly developed. Northeast Indian scientists have issued a list of 40 approved proprietary pesticides. Some of these pesticides cannot be applied during the plucking season; others require that the two subsequent rounds of weekly pluckings be discarded.

Tea preparation. Hand methods for the preparation of tea shoots, consisting of the young leaves and terminal leaf bud, have their origin in antiquity. Tea is designated as black (fermented), green (unfermented), or oolong (semifermented), depending upon the process applied. Green tea is produced mainly in China, Japan, and Taiwan, but 98 percent of the international trade is in black tea.

When black tea is made by the small producer, the leaf is plucked on a clear day after the dew is gone, exposed to the sun and air for at least an hour, then lightly rolled on a table to develop a red colour and an aroma. The leaves are heated in a hot iron pan, rolled, heated several additional times, and finally dried in a basket over a charcoal fire. With China mechanizing its industry, China teas may retrieve their importance in the world markets.

In China, green tea is made by heating the freshly plucked leaf in an iron pan for a few minutes, causing the leaf to turn yellow, inactivating the enzymes, and killing the leaf. It is then hand rolled and given further roastings,

Chinese and Japanese green tea

which turn it to olive green and then to a bluish tint. In Japan, where most of the crop is made into green tea, the leaf is heated by steam, and modern machines perform the rolling and drying.

Oolong, semifermented tea, is prepared in South China and Taiwan from a special form of China plant, *chesima,* that gives this tea unique flavour. Preparation is similar to that followed in making China black tea. Both China and oolong teas are sometimes scented with flowers, such as jasmine.

Brick tea, made in China for export to inner Asia, is of little importance in world trade. It may consist of leaf, stalk, and even twigs, or mainly of tea dust and fannings (coarse tea dust). The bulk is softened with steam and then compressed into blocks or bricks.

In Burma, Thailand, and China, the tea leaf may be pickled and the product, which is called *leppet-so,* eaten as a vegetable.

Modern processing. When tea cultivation began in Assam, Chinese growers came to instruct the planters in leaf preparation. It was soon apparent that village hand methods were not suited to plantation work, and new processing methods were developed. In the new withering process, the leaves were spread on trays and left overnight, then rolled only once, and spread on the floor to ferment. Drying began in a hot iron pan and was finished on trays placed over a charcoal fire. Hand-rolling required the greatest amount of labour. The modern mechanical roller was developed in Assam in 1887. In the same year drying machines were produced in which the rolled, fermented leaf, spread on moving metal trays, was subjected to hot air currents. By 1890 the tea factory had replaced the tea house. The leaf, withered, or dehydrated, on racks for 18 hours, was then machine rolled for about an hour, fermented in a cool, humid room for three to four hours (including the rolling period); then dried by machine firing. Mechanical sorting or grading was carried out on wire mesh trays, ranging from 8- to 30-mesh. Six or more grades were produced, ranging in size from the unbroken orange pekoe to the smaller broken grades, fannings, and dust.

Tea leaf withering or wilting has always presented difficulties. Controlled loft withering was studied in Ceylon, but it was not until 1958 that trough withering was invented in the Congo. In the trough method conditioned air is forced through an 8-inch (20-centimetre) layer of leaf, producing an even wither. In the loft method the leaf is spread thinly, producing a wither that varies widely from rack to rack. In Assam 100 parts of fresh leaf may lose 30 parts of water during the wither, whereas in Sri Lanka the loss may be as much as 45 parts.

In Assam, where natural conditions often discourage withering, the loft is impractical; rolling frequently had to be performed on unwithered leaf prior to the invention of the trough. Unwithered leaf does not roll well, and in 1925 the "unorthodox" procedure was instituted, in which a Legg tobacco cutter was used to shred fresh leaf. This method makes a cut about 1/32 inch (0.08 centimetre) wide, distorting most of the leaf cells, and is followed by a short roll, a brief fermentation period, and firing.

The shredding and rolling process

A CTC (crushing, tearing, and curling) machine was invented in Assam in 1930. Normally withered leaf is given a short, light roll, then put through the machine. Two engraved metal rollers, one making 70 revolutions per minute (rpm) and the other, 700, distort the leaf in a fraction of a second. Other machines producing rapid and full leaf distortion have also been perfected. The unorthodox method is currently applied to 70 percent of the tea manufactured in northeast India, and the method is also prevalent in several other countries. The grades of tea produced are mainly dust and fannings, with some brokens.

The tea is machine fired, and on the following day it is sorted into grades. It is then stored in bins until a sufficient amount accumulates to make up an invoice of about 60 to 240 chests. Tea chests, made of three-ply wood and lined with aluminum foil and rice paper, hold 80 to 120 pounds (36 to 50 kilograms) of tea.

Tea bags. The tea bag, or tea ball, originally used over a century ago, regained its popularity in the 1950s. It is made of special paper and filled with the smaller sized grades of teas.

Instant or soluble teas. Green tea powders or soluble tea extracts have been used in Japan for many years. The tea industry is now developing and producing instant or powdered black teas. Instant teas offer greater convenience than ordinary leaf tea; they are easy and quick to infuse, leave no grouts for disposal, and can be used in vending machines. Instant tea powder may be produced by evaporating an ordinary infusion to dryness, but a more satisfactory and economical method is to distort and ferment tea leaf and then extract it, unfired. The resulting extract is evaporated to dryness at a low temperature, so that the resultant powder will produce an infusion with a bright, brisk liquor and the tea aroma. The evaporation may be carried out at a low temperature under reduced pressure, or the liquor may be spray-dried or freeze-dried. Infusions from the instant teas now available usually lack the character of a normal tea infusion but are improving as study continues.

Chemistry of tea. A freshly plucked tea shoot, consisting of two leaves and a bud, contains about 77 percent water and 23 percent solid matter. Half of the solid matter is insoluble in water; it is made up of crude fibre, cellulose, starches, proteins, etc. The remaining soluble half includes over 20 amino acids, about 30 polyphenolic bodies, 12 sugars, and 6 organic acids. The Assam variety of plant is richer in caffeine and polyphenolic bodies than the China plant.

The caffeine content of the tea shoot is highest in the terminal bud, where it may be 4 to 5 percent of the dry matter, and lowest in the stalk, where it may be 1.5 percent. Although caffeine does not play an active part in changes occurring during processing, it is one of the constituents, with theaflavins and thearubigins, that forms the "cream" or precipitate when a tea infusion cools.

The role of caffeine in tea

Two polyphenols of the flavanol group, *l*-epi gallo catechin and its gallate, are mainly involved in the changes that take place during fermentation. After the leaf is distorted, the tea leaf enzyme, a copper-protein compound, acts on these two substances, oxidizing them to orthoquinones. When the enzyme action ceases, the orthoquinones dimerize to form bis-flavanols and rapidly condense to theaflavins (yellow bodies) and then still further to thearubigins (red and brown bodies). Some of the last have strong tanning properties and precipitate leaf proteins that are lost to the tea infusion. Correct manufacture aims at getting a suitable ratio of theaflavins to thearubigins. In a good tea the ratio may be 1 to 12, in a poor tea, lacking briskness and brightness, it may be 1 to 20, and in a commercial blend it may be 1 to 16.

In orthodox teas as much as a quarter of the oxidizable polyphenols may remain unchanged, but in unorthodox teas practically all of them are changed.

The various aromas of tea are developed in the field and during each stage of manufacture. The 14 volatile compounds found in tea include methyl and ethyl alcohol, several aldehydes, and sulfur compounds.

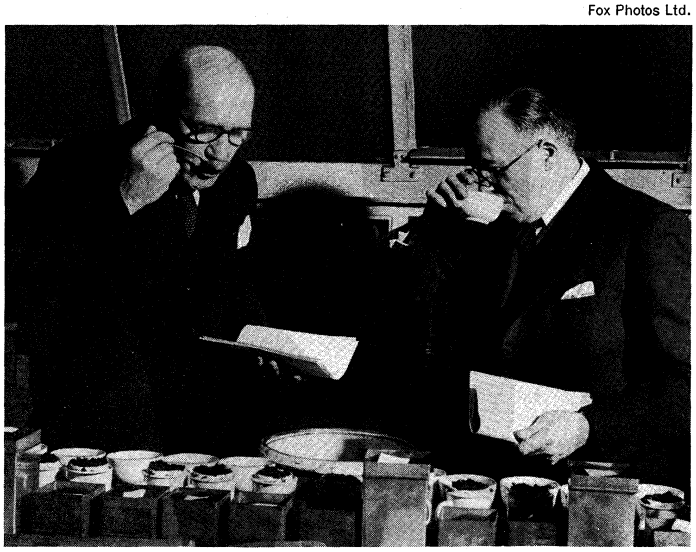
Pharmacology of tea. Although tea is consumed primarily for its caffeine content, the action of the caffeine is not apparent for some minutes, and the immediate comforting effect of the liquor is due to its warmth. A tea infusion provides only about 4 calories per cup but, with the addition of a tablespoon of milk (10 calories) and a lump of sugar (25 calories), it provides about 40 calories. In Great Britain, where six cups a day are average, tea may contribute 240 calories to the daily adult diet. Tea contains several of the B-complex vitamins, and six cups provide about 10 percent of the average daily adult requirement.

One pound of good tea (0.45 kilogram) may contain up to 245 grains (15.9 grams) of caffeine and is sufficient to make 200 cups of the beverage.

When an infusion is kept hot, changes in the thearubigins take place with a deterioration in quality. A tea infusion made with distilled water has a pH value of about 5. In areas where tap water is hard because of high lime con-

tent, a tea infusion made with the local water will have a high pH value (*e.g.*, 6.6 in London), producing changes in some of the constituents responsible for the bright orange colour and causing the liquor to look dull.

The tea trade. Although there has always been correlation between the planting and trading sections of the industry, a balance of supply and demand has never been achieved for long. Tea deteriorates and cannot be stockpiled for more than a few months. Because of these difficulties, many price slumps have occurred over the years, with serious slumps in 1866, 1879, 1896, 1920, and 1932, following which the International Tea Committee was formed by India, Ceylon, and the Dutch East Indies (Indonesia) to stabilize the market. In 1952, however, another slump developed, and by 1970 the expanding production in 30 leading tea-producing countries had brought another.



The world market and the International Tea Committee

Public auctions. The first London public tea auctions were held in 1834; current London auctions deal with teas from about 25 countries. Public auctions opened in Calcutta in 1861, in Colombo in 1883, in Cochin in 1947, in Chittagong in 1949, and in Nairobi in 1956. These centres deal with teas produced in their own countries or areas. There are also some local tea marts, and considerable amounts of tea are traded privately.

Tea tasting. Teas bought at auction are blended and packaged by the traders to suit their own markets. Each firm bases its bidding on information provided by a tea taster, who notes the appearance of the dry tea, the infused leaf, and the infusion; the aroma of both the dry tea and the infused leaf; and the taste and flavour of the infusion.

The tea taster's infusion is made from a weight of tea equal to that of a silver sixpence (1/10 ounce; 2.83 grams), which is infused in a China mug having ¼ pint capacity (0.12 litre) and fitted with a lid. Boiling water is poured on the tea and allowed to stand for five or six minutes; the resulting liquor is poured into a handleless cup, and the infused leaf is shaken from the mug onto the lid. The liquor, without additives, is tasted at a temperature of about 110° F (43° C), usually from a spoon, after which it is spat out. The special vocabulary of the tea taster includes about 120 terms.

Fox Photos Ltd.

London tea brokers tasting tea.

Tea blending. Teas to be used for a blend are selected for the quality, flavour, strength, and body of the liquors and the size, style, and density of the leaf. A proportion of neutral teas or "fillers" may be used to round off a blend and balance the price, and the blend may include four or five Assam teas, the same number of Ceylons, and a few Africans. China teas usually blend well only with Darjeelings and fine Ceylons.

Teas are blended by mixing the leaf in a machine consisting of a revolving drum fitted with veins. Satisfactory blending requires about 16 revolutions. The drum is half-filled with leaf, the charge ranging from 300 pounds (136 kilograms) to 5,000 pounds (2,265 kilograms) according to the size of the machine. The smallest drum may revolve at 20 revolutions per minute and the largest at three revolutions per minute.

BIBLIOGRAPHY. J.R. SEALY, *A Revision of the Genus Camellia*, sect. 6, designated "Thea" (1958), comprises five species, but only three of these are connected with the tea plant of commerce. INTERNATIONAL TEA COMMITTEE, *Bulletin of Statistics* (annual), gives current figures on production, export, consumption, tea stocks, and auction prices. E.A.H. ROBERTS, "Economic Significance of Flavonoid Compounds: Tea Fermentation," in T.A. GEISSMAN (ed.), *The Chemistry of Flavonoid Compounds*, ch. 16 (1962), discusses the properties of a tea infusion, which are based largely on flavonoid compounds. W.H. UKERS, *All About Tea*, 2 vol. (1935), deals with the historical, technological, scientific, commercial, social, and artistic aspects of tea production and includes extensive bibliographies. C.R. HARLER, *The Culture and Marketing of Tea*, 3rd ed. (1964), *Tea Growing* (1966), and *Tea Manufacture* (1963), are works discussing methods and current problems of the tea industry. C.J. HARRISON, *Indian Tea* (1953), deals with the development of tea production in India, where the modern tea industry originated. T. EDEN, *Tea* (1958), discusses tea production in Sri Lanka and in the newly developing African tea industry.

Technological Sciences

The technological sciences are a range of disciplines embracing the traditional engineering branches, the agricultural sciences, the modern disciplines relating to space, computers, and automation. From man's earliest emergence, technology has been one of the four environments within which he has lived—the others being the cosmic, the natural, and the social.

Technology has changed radically in quantity and quality over the millennia. For thousands of years science and technology constituted distinct traditions. Beginning sometime in the 19th century, they entered into a new and much closer relationship (see also TECHNOLOGY, HISTORY OF and TECHNOLOGY, CONCEPTIONS OF).

Emergence of the technological sciences. During the Renaissance in Europe, men of learning took new notice of the ancient crafts and advocated a closer relationship with them. The arts, it was suggested, could provide problems for science to solve, and the latter might provide laws and rules that would allow the former to progress more rapidly. Something of the sort began to happen in the 19th century, and a number of technological sciences —analogous to the physical sciences—began to appear and to develop competence; finally, they became indispensable for most progress in engineering.

The engineering disciplines. The rise of the technological sciences came only with the creation of a community of practitioners separate from either the body of inventors or that of scientists. The new group of specialists, who came to be called engineers, had, on the one hand, scientific training and a grasp of mathematics and, on the other, a commitment to and intimate knowledge of technology.

In some areas, such as strength of materials and hydraulics, engineering sciences evolved out of theoretical and experimental physics. In other cases, such as kinematics of mechanisms, the new science grew directly from traditional engineering practice. Either way, such fields were distinct from their antecedents and by the end of the 19th century formed a separate body of knowledge that allowed technological problems to be treated scientifically.

The problem of the strength of materials provides an example of this development. During the first decades of the 19th century, iron became a common material in the construction of buildings, bridges, and other structures. Its users accumulated practical experience, but scientifically collected data and theory were conspicuously lacking. Until rule of thumb was replaced by reliable formulas, material was wasted in overbuilding or lives were lost through underbuilding. Some development of this science was begun in the 18th century, but systematic experimen-

tation only began with Eaton Hodgkinson and Sir William Fairbairn of Great Britain in 1826. Fairbairn's *On the Application of Cast and Wrought Iron to Building Purposes* (1854) immediately became a classic among builders. In France such investigators as Emiland-Marie Gauthey and Claude-Louis-Marie Navier worked on similar problems. Their efforts were extended by mathematicians at the École Polytechnique in Paris (see below). In the United States, the strength of materials was scientifically investigated in 1830 by Alexander D. Bache, working for the Franklin Institute of Philadelphia on the causes of steam-boiler explosions. During the next half century there was a concerted effort to extend the competence and variety of such scientific investigations into practical engineering problems. In 1872, for example, the American Society of Civil Engineers successfully asked the U.S. Congress to appropriate funds for a testing machine to discover the properties of iron and steel. Such knowledge was increasingly necessary for the safe and efficient use of materials in the burgeoning economy of the late 19th century.

Neither individual scientists nor government agencies had the long-term commitment necessary to continue progress in the technological sciences. It was the engineering schools and their faculties that made the primary contributions to this task. Engineering education received its initial impetus in France. During the French Revolution the School of Bridges and Highways and the School of Mines were supplemented by the excellent and broader Polytechnic School (École Polytechnique; 1794), which had wide influence outside France, for example, on the new United States Military Academy at West Point (1802).

Engineering education

A new development was the founding, in 1824, of the Rensselaer Polytechnic Institute in Troy, New York, the first private engineering school. After the passage of the Morrill Land-Grant College Act (1862), by which the United States government granted land to state colleges to aid engineering and agricultural education, such schools as the Massachusetts Institute of Technology (1861) became prominent in the engineering sciences and the training of engineers. In Great Britain the universities of London and Glasgow began instruction in engineering in the 1840s, with other universities following.

Agricultural engineering. Agricultural engineering also had its origins in the 19th century. Here, too, it was hoped that the application of mathematics, the scientific method, and known scientific laws would produce improved implements. Thomas Jefferson, for example, tried to redesign the moldboard of the plow with the aid of mathematics. The difficulty of producing machines that would perform adequately under the wide range of conditions found on farms retarded machine development, however, as did the lack of a cheap, adequate, and flexible source of power. Mechanization was most advanced in the United States, where during the first decade of the 20th century, gasoline tractors began to break the power bottleneck. At this same time, in 1907, the American Society of Agricultural Engineers was founded by farm mechanics teachers. In 1909 the first department of agricultural engineering was established at the Iowa State College. By midcentury, 44 such departments were operating in the United States, and 40 additional institutions around the world granted degrees in agricultural engineering.

Agricultural science was not neglected. By the middle of the 19th century, soil chemistry, botany, genetics, and physiology were all being tried in an effort to improve agricultural practice. The leading scientist in this area was a German organic chemist, Justus von Liebig, who, after training in France, operated a famous laboratory at the University of Giessen. His classic work *Chemistry in its Applications to Agriculture and Physiology* (London, 1842) stirred wide response, and he trained students from many countries who then returned to their homes to apply the science. Many of them pressed for government support of agricultural education and agricultural experiment stations. When such institutional support was granted, agricultural science began to flourish. By the mid-20th century, agricultural innovation involved the efforts of both engineers and scientists, the former designing machines to handle particular crops and the latter redesigning the crops themselves to make them more amenable to machine culture.

The study of the history of technology. The history of technology, while only recently defined as a separate professional discipline, has roots in several older traditions, such as the search for priority of invention. Since patents are awarded only to the first inventor of a device, patent searches and court litigation necessarily include a historical survey of previous work in the field.

Patent searches

General historians have also given consideration to the history of technology. Especially since the 19th century, the progress of invention and industry has been considered a key index to the progress of civilization. Another scholarly source of writing has been the economic historians, especially those studying the Industrial Revolution, in which new devices obviously played an important role in economic change. Marxist scholars have had a special concern for the history of technology, concentrating on the development of implements of labour within the social structure of production. Finally, the history of technology has long been considered a branch of the history of science and has been cultivated along with that discipline.

Historians of technology continue to draw heavily upon other special and more general disciplines for data, insight, and techniques, especially on the discipline of history itself. Many important studies can only be undertaken by specialists in the physical, biological, or engineering sciences. Since technology is a social activity, all the social sciences—sociology, economics, psychology, political science, anthropology—are also pertinent to studies of its social origins and influence.

In several countries, especially the United States and Great Britain, industrial archaeology has developed as an important tool for discovering and recording technological remains—*e.g.*, dams, mill sites, quarries, and foundries, long buried or otherwise forgotten. The importance of this technique was perhaps first realized in 1962 by historians in Northern Ireland. In 1963 the British Ministry of Public Buildings and Works began an Industrial Monuments Survey, and in 1964 the British quarterly the *Journal of Industrial Archaeology* was established. Although such physical sites and the tools and machines associated with them are of critical importance in researching and writing the history of technology, the traditional narrative sources of social history (*e.g.*, the written word in the form of correspondence, diaries, and reports) remain the indispensable basis for most significant work in this field.

The history of technology is currently in a very flourishing condition. Either combined with the history of science or in separate courses, it is being taught at an increasing number of colleges both in Europe and the United States. The centre of professional training in the United States is Case Western Reserve University in Cleveland, Ohio. The Centre for the Study of the History of Technology, Bath University of Technology, Bath, England, was created in 1964. The previous year a department of history of science and technology was established at Imperial College of Science and Technology, London.

The major international organization in the field is the International Cooperation in History of Technology Committee (ICOHTEC), organized in 1965. In the United States the major organization is the Society for the History of Technology, incorporated in 1958. During the winter of 1959 the society began publication of *Technology and Culture*, an international quarterly devoted to the history of technology. Other national organizations include the Institute of History of Science and Technology, established within the framework of the Academy of Sciences of the Soviet Union and an outgrowth of the original Commission on the History of Science, Philosophy and Technology set up in 1921.

Organizations for historical studies

Outstanding among private institutions is the British organization the Newcomen Society for the Study of the

History of Engineering and Technology, which began publication of its *Transactions* in 1920. Other important serials include the German *Technik Geschichte*, begun in 1909, discontinued in 1941, and revived in 1965.

The study of the history of technology is facilitated by the existence of a number of excellent museums of science and technology. Major repositories include the Museo di Storia della Scienza in Florence, the Tekniska Museet in Stockholm, the Science Museum in London, the Conservatoire des Arts et Métiers in Paris, the Deutsches Museum in Munich, the Politekhnichesky Musey (Russian Polytechnic Museum) in Moscow, and the Smithsonian Institution in Washington, D.C.

BIBLIOGRAPHY. For general reference in this field, see MELVIN KRANZBERG and CARROLL W. PURSELL (eds.), *Technology in Western Civilization*, 2 vol. (1967). A longer work that gives relatively more emphasis to British achievements and less to the 20th century is CHARLES SINGER *et al.* (eds.), *A History of Technology*, 5 vol. (1954–58). Both of these contain extensive bibliographies, which should be supplemented by EUGENE S. FERGUSON, *Bibliography of the History of Technology* (1968). A very important effort to trace the rise of the engineering sciences is EDWIN LAYTON, "Mirror-Image Twins: The Communities of Science and Technology in 19th-Century America," *Technology and Culture*, 12:562–580 (1971). Histories of particular sciences include HUNTER ROUSE and SIMON INCE, *History of Hydraulics* (1957); EUGENE S. FERGUSON, "Kinematics of Mechanism from the Time of Watt" *Bull. U.S. Natn. Mus.*, no. 228 (1962); ISAAC TODHUNTER, *A History of the Theory of Elasticity*, 3 vol. (1893, reprinted 1960); STEPHEN P. TIMOSHENKO, *History of Strength of Materials* (1953); CYRIL STANLEY SMITH, *A History of Metallography* (1960); and FOREST R. MOULTON (ed.), *Liebig and After Liebig: An Analysis of the Progress in Agriculture Chemistry* (1942). Two yearbooks of the United States Department of Agriculture, both ed. by ALFRED STEFFERUD, survey American developments: *Power to Produce* (1960) and *After a Hundred Years* (1962).

Technology, Conceptions of

The systematic study of technology as a special branch of human activity is an essentially modern phenomenon, despite roots extending back to classical Greece. The term itself, a combination of the Greek *techne*, "art, craft," with *logos*, "word, speech," meant in Greece a discourse on the arts, both fine and applied. When it first appeared in English in the 17th century, it was used to mean a discussion of the applied arts only, and gradually these "arts" themselves came to be the object of the designation. By the early 20th century, the term was coming into general usage and embraced a growing range of means, processes, and ideas in addition to tools and machines. By the second half of the century, technology was defined by such phrases as "the means or activity by which man seeks to change or manipulate his environment." Even such broad definitions have been criticized by observers who point out the blurring line between scientific inquiry and technological activity.

More significant than the problem of definition has been the debate over the value of technology, a debate in which radically differing conceptions have been developed. To perceive the roots of these conflicting conceptions, a historical perspective is indispensable.

THE CHANGING VIEW OF TECHNOLOGY

Origins and nature of technology. "Man," said Benjamin Franklin, "is a tool-making animal." Franklin might have substituted "the" for "a"; man is man precisely because he makes tools. Animals occasionally use natural tools such as sticks or stones, and the creature that became man doubtless did the same for hundreds of millennia before the first giant step of fashioning his own tool. Even then it was an interminable time before he put such toolmaking on a regular basis, and still more aeons passed as he arrived at the successive stages of standardizing his simple stone choppers and pounders and of manufacturing them—that is, providing sites and assigning specialists to the work. A degree of specialization in toolmaking was achieved by the time of Neanderthal man (70,000 BC); more advanced tools, requiring assemblage of head and haft, were produced by Cro-Magnon *Homo sapiens* (40,000 BC), while the application of mechanical principles was achieved by pottery-making Neolithic man (20,000 BC) and by Metal Age man (10,000 BC).

Man, the toolmaker

Science and technology. With that step it might be said that the toolmaking animal introduced the great characteristic of modern technology, its relationship to science. This would be an exaggeration, however, for, until quite recently, science has remained largely divorced from technology, with each pursuing its separate path and maintaining its separate identity. Science in the classical world, East and West, belonged to the aristocratic philosophers and embodied all of knowledge, while technology was the possession of the working craftsmen. The separation was probably due less to the class division than to the fact that the speculative science of Aristotle and Ptolemy had little relevance for the technological problems of tanners, millers, silversmiths, and coopers. It was not until the lively social–economic interchange provoked by the commercial revolution of the Middle Ages that science and technology began to draw closer together. Roger Bacon, English savant of the 13th century, predicted mechanically powered ships and flying machines and was credited with the invention of gunpowder. The robust growth of technology, involving improvements in sailing ships, waterwheels, windmills, and firearms, could not fail to attract the interest of educated men. By the 16th century, Roger Bacon's namesake, Francis Bacon, was advocating experimental science, further suggesting that scientists study the methods of craftsmen and that craftsmen acquire more knowledge of science. Bacon organized a group whose purpose he described as "the knowledge of causes and the secret of things, and the enlarging of the bounds of human empire to the effecting of all things possible." Bacon, with Descartes and other contemporaries, for the first time saw man becoming the master of nature.

Yet the wedding of science and technology proposed by Francis Bacon was only slowly consummated. Over the next 200 years, carpenters and mechanics built iron bridges, steam engines, and textile machinery, but only during the course of the 19th century did technology gradually become based on science. The first scientist to become a major figure in technology emerged: Justus von Liebig, the German father of organic chemistry and inventor of synthetic fertilizer. More typically, the great 19th-century inventors built on the work of scientists: Edison, inventor of the first practical system of electrical lighting, on that of Faraday and Henry, early experimenters in electricity; Bell, inventor of the telephone, on that of Helmholtz; Marconi, inventor of radiotelegraphy, on that of Hertz and Maxwell. In the case of Edison, a significant further development took place: the union of science and technology was institutionalized. Scarcely anyone, even Edison, noticed the fact at the time, but the massive trial and error process by which he found the carbon filament for his electric light bulb resulted in the creation at Menlo Park, New Jersey, of the world's first research laboratory. Thus, the date of Edison's demonstration of the electric light, October 21, 1879, may also be taken as the birthday of modern technological research.

The first research laboratory

From this point forward the application not only of scientific knowledge but of scientific principles to technology grew. The engineering rationalism that Frederick W. Taylor applied to the organization of workers in mass production and the time and motion studies of Frank and Lillian Gilbreth were logically followed later in the 20th century by the invention of systems engineering, operations research, simulation studies, and mathematical models. These developments, added to the increased specialization and professionalization of technological work, brought technology to its highly efficient modern state.

Judged entirely on its own traditional grounds of evaluation—that is, in terms of efficiency—the result was admirable. Voices from other fields, however, were raising questions grounded in other modes of evaluation.

19th-century optimism: faith in progress. In the mid-19th century the non-technologists were almost unani-

mously enchanted by the wonders of the new man-made environment growing up around them. The London Exposition of 1851, with its arrays of machinery housed in the dazzling and truly innovative Crystal Palace, seemed the culmination of Francis Bacon's prophecy of "the effecting of all things possible" and the justification of Bacon's comfortably materialistic view that "Works themselves are of greater value than Assurances of the Truthfulness (of Theories) because they add to the Pleasures of Life." The new technology seemed to fit the new laissez-faire economics like a glove and to guarantee the rapid realization of the Utilitarian philosophers' ideal of "the greatest good for the greatest number." Even Marx and Engels, approaching from a radically different political orientation, saw in technology nothing but good, for in their eyes it produced an imperative toward socialist ownership and control of the means of production. Similarly, the American utopian Edward Bellamy, in his novel *Looking Backward*, foresaw a planned society in the year 2000 in which technology would play a conspicuously beneficent role.

The anti-technology trend. Yet, even in the midst of Victorian optimism, a few voices of dissent were heard, such as Emerson's ominous warning, "Things are in the saddle and ride mankind." Henry Adams, the introspective scion of one of America's most distinguished families, visiting the Paris Exhibition of 1900, experienced sensations very different from those of the admirers of the Crystal Palace. Describing his reactions in the third person in *The Education of Henry Adams*, he recorded that, to him:

> the dynamo became a symbol of infinity . . . As he grew accustomed to the great gallery of machines, he began to feel the forty-foot dynamos as a moral force, much as the early Christians felt the Cross . . . He could see only an absolute *fiat* in electricity, as in faith.

His companion Samuel P. Langley, secretary of the Smithsonian Institution and a noted experimenter in flight, could give him no comfort and in fact added a new and disturbing thought. The Curies' discovery of radioactivity had shown that physical matter could actually disintegrate, something theretofore unthinkable. As Adams put it, radium "denied its God, or, what was to Langley the same thing, denied the truth of his Science . . . The force was wholly new."

Adams had another thought, less mystically profound but extraordinarily perceptive for his time:

> The automobile, which since 1893 had become a nightmare at a hundred kilometres an hour, (was) almost as destructive as the electric tram which was only ten years older; and threatening to become as terrible as the locomotive steam engine . . . .

It was half a century before other intellectuals began to take up the anti-automobile theme.

Aldous Huxley's anti-utopia

Disenchantment with technology was first expressed in a dramatic and generalized way in a remarkable novel. *Brave New World*, by the British author Aldous Huxley, appearing in the midst of the Great Depression in 1932, contrasted sharply with Edward Bellamy's *Looking Backward*. Huxley pictured a society of the near future in which technology was entirely enthroned, keeping mankind in bodily comfort without knowledge of want or pain, but also without freedom, beauty, or creativity, and robbed at every turn of a unique personal existence. An echo of Huxley's viewpoint found unexpected artistic expression in the film *Modern Times*, in which Charlie Chaplin depicted the depersonalizing effect of the mass-production assembly line.

After World War II, technology came increasingly under fire for its specific wrongdoings. The outstanding contribution to this branch of anti-technology literature was *Silent Spring*, a magazine series and book by the American science writer Rachel Carson that had tremendous impact in the 1950s and 1960s, revealing the harmful effects on plant and animal life of the unrestricted use of pesticides such as DDT. Writers and politicians both in Europe and the United States joined in an anti-technology chorus that seemed to be reaching a crescendo at the very time that technology was achieving its most remarkable results in the purely technical sense, thus realizing the aphorism of the English essayist G.K. Chesterton that "Nothing fails like success."

The two thrusts of the anti-technology literature of the second half of the 20th century remained those of Henry Adams. On one level, the immediately discernible social defects of technological progress, such as automobile fatalities, air and water pollution, urban overcrowding, and excessive noise, were roundly assailed in the press and the political forum. On a deeper level, the theme of technological tyranny over man's individuality and traditional patterns of life was refined and broadened. Perhaps the outstanding contribution to the literature of this theme was *La Technique*, published in 1954 by Jacques Ellul, a professor at the University of Bordeaux. Defining technology as "the ensemble of practices by which one uses available resources in order to achieve certain valued ends," Ellul asserted that it had become so pervasive that man now lived in a milieu of technology rather than in his old milieu, nature. The new milieu he characterized as artificial, autonomous, self-determining, nihilistic (that is, not directed to ends, though proceeding by cause and effect), and, in fact, with means enjoying primacy over ends.

Technology, Ellul held, has become so powerful and ubiquitous that other social phenomena such as politics and economics are situated "in it" rather than influenced "by it." "Modern man's state of mind is completely dominated by technical values," Ellul wrote, "and his goals are represented only by such progress and happiness as is to be achieved through techniques." The individual, in other words, had come to be adapted to the technical milieu rather than the other way around.

While Ellul broadened and deepened the thrust of the more sophisticated anti-technology criticism, he dismissed the much talked-about immediate social problems created by technology. In this he followed Huxley, whose *Brave New World* was untroubled by air and water pollution. Ellul dismissed the social problems created by technology as fake, saying,

> We make too much of the disagreeable features of technical development . . . I am convinced that all such inconveniences will be done away with by the ongoing evolution of Technique itself and indeed, that it is only by means of such evolution that this can happen.

But the solution of such fake problems, he maintained, could do nothing to solve the basic problem he was describing, which he summarized in two questions:

First, is man able to remain master in a world of means —that is, a world in which technology's own imperatives determine social directions?

Second, can a new civilization appear that will encompass technology and still permit man to be free? Anticipating one line of response, he observed that technology has indeed freed man from many restrictions of time and space, but he added a searching question, "Is this what it means to be free?"

Accelerated rate of change. One of the principal elements of the context in which such critics as Ellul appeared in the last half of the 20th century was the rate of acceleration of technological advance. Illustrations abound, of which perhaps the most dramatic was the six and one-half years that passed between the disclosure of the fission of uranium in January 1939 and the detonation of the first atomic bomb at Alamogordo in July 1945. A distinctive feature of the progress from laboratory experiment to awesome realization was that scientists as well as laymen were unprepared for the result; in the words of the British scholar Ritchie Calder, "The safebreakers had forced the nuclear lock before the locksmiths knew how it worked."

The beginning of the atomic age

Many of the "safebreakers" were profoundly troubled by the fact. J. Robert Oppenheimer, who directed the work of the assembly of the bomb at Los Alamos, later opposed the decision to build the thermonuclear (fusion) bomb; but inevitably the decision was made and the more powerful bomb built, in the Soviet Union as well as the United States. In a lecture, Oppenheimer described the new accelerated pace of technology in these words:

> One thing that is new is the prevalence of newness, the changing scale and scope of change itself, so that the world alters as we walk in it, so that the years of man's life measure not some small growth or rearrangement or moderation of what he learned in childhood, but a great upheaval.

The information revolution, centring on the computer, for a time appeared almost more alarming than the bomb; the "electronic brain" seemed capable of replacing the human brain. Many computer limitations have since become obvious, though an entirely new type of computer, built as an analogue to the human nervous system, may presently raise new spectres along this line.

Yet, despite the admittedly headlong pace of modern technology, some qualification is in order on historical grounds. There have been times in man's past history in which technological innovation swept all or part of the world with extraordinary force; for example, the windmill in medieval Europe, the firearm in 16th-century Japan, and electric communication in the 19th century. Even granting technological acceleration, the present is not the first age to face the problem of rapid change.

A WORLD VIEW OF TECHNOLOGY'S PROMISE AND THREAT

One of the most striking aspects of modern conceptions of technology is the continuing deep division between the views of the developed and the underdeveloped nations. Broadly speaking, the anti-technology criticism on both the sophisticated and the popular level has come from the developed countries, while the underdeveloped and semi-developed nations have generally taken a favourable, often even an aggressively favourable, view.

Past and present benefits. That technology has produced incalculable material benefits for the developed nations is hardly in dispute, and that it has the potential for producing similar benefits for the underdeveloped nations may certainly be assumed. Even though Gandhi opposed the industrialization of India up to his death in 1948, his hope for a return to the pre-industrialized economy symbolized by the hand spinning wheel was so little shared by his countrymen that his successors have embraced modern technology as eagerly as all the other leaders of the underdeveloped world. Of all technology's successes, the outstanding one is probably the increase and stabilization of the food supply through the application of machinery and power, fertilizers and pesticides, hybridization, and processing techniques. These, reinforced by the medical–pharmaceutical–sanitation revolution, have brought rapid decreases in mortality rates and increases in life-spans. It is highly characteristic of the opposing world views that such obvious material benefits, longed for by humanity through the ages, have stimulated in the developed countries a considerable alarm over the resulting population increase. Among the many secondary but still important benefits much desired in the underdeveloped countries are the freeing of labour from the drudgery of the old-fashioned farm, the dramatic reduction in cost of manufactured commodities through mass-production techniques (sometimes to a tenth or twentieth of their former cost), the enormous improvement in literacy and educational levels, and the increased convenience and enrichment of life by the transportation–communications revolution.

Development of food supply

Promise for underdeveloped regions. The fact that the underdeveloped countries want to import technology from the developed countries and the fact that the developed countries see the export of their technology as in their own self-interest would seem to provide a congenial base for collaboration. Many problems have become obvious, several of which have to do with differing conceptions of technology's role. Two important principles have emerged: first, that the technology of the developed nations is not automatically ideal, or even always suitable, for the underdeveloped nations, and, second, that the underdeveloped nations need not necessarily pass through the same succession of stages that the vanguard of developed nations has undergone. The first principle is illustrated by the Malayan observer at a World Power Conference who passed by the giant atomic power station exhibit, explaining that he was looking for a little floating generator that could be used to harness a stream to provide light for illumination—"then we could read and learn about all these wonderful things they are talking about here." Largeness and complexity, the basic characteristics of so much of modern technology, are unsuited to most underdeveloped countries because the national markets are small, skilled labour is scarce, and the cost in foreign exchange is high. Simple, inexpensive machinery that can be operated and maintained by persons of little education is far more appropriate to these agrarian nations than computers and automated devices. A unit for producing methane gas from cow dung may be better, at least in the short run, than an atomic-power installation.

Dependence of new nations on the old

Yet the second principle, that the new nations should be assisted to avoid the hardships undergone by the old, is equally important in meeting what Adlai E. Stevenson called "the revolution of rising expectations." A Southeast Asian diplomat used this metaphor: while the developing nations must carry their own cross of technology, it need not be of the same weight as that borne by Europe and the United States in the 19th century; it can be of aluminum (a 20th-century material). Part of this conception, in the view of many, is the effort to export not the technology of the European–American past or even present but, rather, that of the future—that is, the newest ideas now emerging, such as emission-free engines.

Role of the scientist. The problem of the developing nations has had a stimulating effect on certain already apparent educational tendencies within the developed nations that have large implications for the problem of control of technology. Partly in response to a widely voiced criticism of the "two cultures" that seemed to separate educated Westerners into two intellectual classes, two broad, complementary trends had appeared by the 1970s: an added emphasis in the science and engineering curricula on humanities and social science and the education of humanities students in the history and philosophy of science and technology. A revealing study showed that the creative scientist knows more about the history of science than does his more routine-minded colleague; a reasonable inference is that the creative man knows better, from his study of history, what is truly novel and, therefore, worth pursuing.

The autonomy of technology. Such better educated scientists, engineers, and laymen are needed both to operate and to criticize the increasingly complex technological apparatus. In the past the technologist has not been expected to police his own technology, because he could control, and indeed could envision, only a small part of it. As a whole, the monster remained out of reach. In itself technology is fundamentally neutral, and even passive; in Lynn White's phrase, "Technology opens doors; it does not compel men to enter." Yet, from the beginning, the fact that technology exists in a social medium has imposed certain constraints. These were more affirmative than negative; that is, the social medium tended to push technology in certain directions rather than to keep it from going in certain others. Technology has never been wholly autonomous in the sense of being out of reach of the control of its human creators and operators. If there have been few important instances of moral constraints hampering technology, there have been many of technology itself creating a potential for moral decisions; for example, in the case of aid to the underdeveloped nations. It is also evident that technology's direction is itself often determined by political considerations with moral (or immoral) overtones.

It can be demonstrated that man exhibits resistance to inexorable changes in the milieu; for example, as Lynn White, an authority on medieval technology, has pointed out, the crank, which is used to convert reciprocal motion into rotary motion and vice versa, was slow to be invented and slow to disseminate. The reason seems to be that reciprocal motion is natural to living things, while rotary motion never occurs in them. Yet the crank became a universal part of man's technical apparatus. There is perhaps an important insight for the future here. "To use a crank," in White's words, "our tendons and muscles must

relate themselves to the motion of galaxies and electrons. From this inhuman adventure our race long recoiled."

The history of the crank may have significance for the future of 20th-century man. The distinguished German physicist Werner Heisenberg has made this prediction:

> Many of our technical apparatuses will perhaps in the future belong as inescapably to man as the snail's shell does to the snail or the spider's web to the spider . . . the apparatus would then be rather a part of our human organism.

An idea from which men at first tend to recoil may come to be accepted and even embraced. Humans may acquire, for example, through implanted electrodes, access to vast memory storage banks, enormously increasing their intellectual powers. Thus, a changing concept of technology may involve a changing concept of man himself. Yet even in Heisenberg's forecast, man remains the master.

Technology's continuing presence. Whatever justice lies in the views of Ellul, his predecessors, and his successors to come, no actual repudiation of technology appears to be possible. Technology seems destined to grow, in accordance with laws that man can in all likelihood discover only in retrospect. The need to exercise control over technology at once raises the question of who or what is to control the controllers. Yet some critics feel that this question may not be as formidable as Huxley and others have made out, because a planned technological society in which the planning would be limited to producing abundance and eliminating the need for drudgery might leave great scope for freedom and democracy. At least in a relatively short run, it would be fair to say that the momentous political–philosophical questions with which the world will grapple in the closing decades of the 20th century and the first decades of the 21st may be influenced by technology in a favourable as well as unfavourable sense. A few general principles in respect to technology's future have won broad acceptance: that the problem is global and cannot be adequately dealt with inside national borders; that institutions are needed to study technological problems, both technical and social; that both technologists and non-technologists must be given appropriate educational formulas; and that, by these means and whatever others are discovered, technology must be made man's servant. "In the final analysis," as Peter Drucker says, "this surely means mastery by man over himself, for if anyone is to blame, it is not the tool but the human maker and user." It is a poor carpenter, according to the adage, who blames his tools, and, just as it was naïve for the 19th-century Victorians to imagine that technology would bring paradise, it seems equally so for the 20th-century pessimists to make technology itself a scapegoat for man's shortcomings.

The global nature of the problem

One of man's shortcomings may be a common failure to appreciate the charm of technology. Novelist and social critic Arthur Koestler has pointed out that the traditionally humanities-educated Western man is reluctant to admit that a work of art is beyond his comprehension but will cheerfully confess that he does not understand how his radio or heating system works. Koestler characterizes such a modern man, isolated from a technological environment that he possesses without understanding, as "an urban barbarian." Despite its publicized shortcomings and its sometimes sinister hint of autonomy, technology is after all a human product, growing not only out of man's need to improve his material condition but out of his love of play and adventure. It is capable of furnishing a distinctively human pleasure at its workings and a human excitement at its unfolding. Man orbits the Earth and visits the Moon because, among other reasons, he finds the experiences thrilling.

The spirit of adventure that has been associated throughout history with man's association with technology will certainly be of value in confronting the massive challenges of the future. "The day before yesterday," wrote Gaston Berger, president of the *Encyclopédie Française*,

> we followed unconsciously what was called Nature; yesterday we tried conscientiously to conform to "nature," but today, our power having grown considerably, it behooves us sometimes to protect nature and sometimes to arrange it in ways which seem favourable. We have somehow become responsible for evolution . . . a reality is to be constructed and events awaited.

Technology, History of

If technology may be defined as the systematic study of techniques for making and doing things, then the history of technology is, in a sense, the history of man. Essentially, techniques are methods of creating new tools and products of tools, and the capacity for constructing such artifacts is a determining characteristic of manlike species. Other species make artifacts: bees build elaborate hives to deposit their honey, birds make nests, and beavers build dams. But these attributes are the result of patterns of instinctive behaviour and cannot be varied to suit rapidly changing circumstances. Man, in contrast with other species, does not possess highly developed instinctive reactions but does have the capacity to think systematically and creatively about techniques. He can, thus, innovate and consciously modify his environment in a way no other terrestrial species has achieved. An ape may on occasion use a stick to beat bananas from a tree: a man can fashion the stick into a cutting tool and remove a whole bunch of bananas. Somewhere at the point of transition between the two, the hominid, or the first manlike species, emerges. By virtue of his nature as a toolmaker, man is therefore a technologist from the beginning, and the history of technology encompasses the whole evolution of man.

In the process of using his rational faculties to devise techniques and modify his environment, man has attacked problems other than those of survival and the production of wealth with which the term technology is usually associated today. The technique of language, for example, involves the manipulation of sounds and symbols in a meaningful way, and similarly the techniques of artistic and ritual creativity represent other aspects of the technological incentive. This article does not include detailed consideration of these cultural and religious techniques, but it is valuable to establish their relationship at the outset because the history of technology reveals a profound interaction between the incentives and opportunities of technological innovation on the one hand and the sociocultural conditions of the human group within which they occur on the other.

Social involvement in technological advances. An awareness of this interaction is important in surveying the development of technology through successive civilizations. To simplify the relationship as much as possible, there are three points at which there must be some social involvement in technological innovation: social need, social resources, and a sympathetic social ethos. In default of any of these factors it is unlikely that a technological innovation will be widely adopted or be successful.

The sense of social need must be strongly felt, or people will not be prepared to devote resources to a technological innovation. The need may be for a more efficient cutting tool, a more powerful lifting device, a labour-saving machine, a means of utilizing new fuels, or a new source of energy. Or, military needs having always provided a stimulus to technological innovation, it may take the form of a requirement for better weapons. In modern societies, needs have been generated by advertising. Whatever the source of social need, it is essential that enough people be conscious of it to provide a market for an artifact or commodity that can meet the need.

Why some inventions fail

Social resources are similarly an indispensable prerequisite to a successful innovation. Many inventions have foundered because the social resources vital for their realization—the capital, materials, and skilled personnel—were not available. The notebooks of Leonardo da Vinci are full of ideas for helicopters, submarines, and airplanes, but few of these reached even the model stage because of deficient resources of one sort or the other. The resource of capital involves the existence of surplus productivity and an organization capable of directing the available wealth into channels in which the inventor can use it. The resource of materials involves the availability of appropriate metallurgical, ceramic, plastic, or textile substances that can perform whatever functions a new invention requires of them. The resource of skilled personnel implies the presence of technical skill capable of constructing new artifacts and devising novel processes. A society, in short, has to be well primed with suitable resources in order to sustain technological innovation.

A sympathetic social ethos implies an environment receptive to new ideas, one in which the dominant social groups are prepared to consider innovation seriously. Such receptivity may be limited to specific fields of innovation concerned—for example, with improvements in weapons or in navigational techniques—or it may take the form of a more generalized attitude of inquiry, as was the case among the industrial middle classes in Britain during the 18th century, who were willing to cultivate new ideas, and inventors, the breeders of such ideas. Whatever the psychological basis of inventive genius, there can be no doubt that the existence of socially important groups willing to encourage inventors and to use their ideas has been a crucial factor in the history of technology.

The rationality of technology

Social conditions are, thus, of the utmost importance in the development of new techniques, some of which will be considered below in more detail. It is worthwhile, however, to register another explanatory note. This concerns the rationality of technology. It has already been observed that technology involves the application of reason to techniques, and in the 20th century it has come to be regarded as almost axiomatic that technology is a rational activity stemming from the traditions of modern science. Nevertheless, it should be observed that technology, in the sense in which it is being used here, is much older than science, and also that techniques have tended to ossify over centuries of practice or to become diverted into such pararational exercises as alchemy. Some techniques became so complex, often depending upon processes of chemical change which were not understood even when they were widely practiced, that technology sometimes became itself a "mystery" or cult into which an apprentice had to be initiated like a priest into Holy Orders, and in which it was more important to copy an ancient formula than to innovate. The modern philosophy of progress cannot be read back into the history of technology; for most of its long existence technology has been virtually stagnant, mysterious, and even irrational. It is not fanciful to see some lingering fragments of this powerful technological tradition in the modern world, and there is more than an element of irrationality in the contemporary dilemma of a highly technological society contemplating the likelihood that it will use its sophisticated techniques in order to accomplish its own destruction. It is thus necessary to beware of overfacile identification of technology with the "progressive" forces in contemporary civilization.

On the other hand it is impossible to deny that there is a progressive element in technology, as it is clear from the most elementary survey that the acquisition of techniques is a cumulative matter in which each generation inherits a stock of techniques on which it can build if it chooses, and if social conditions permit. Over a long period of time the history of technology inevitably highlights the moments of innovation which show this cumulative quality as some societies advance, stage by stage, from comparatively primitive to more sophisticated techniques. But although this development has occurred and is still going on, it is not intrinsic to the nature of technology that such a process of accumulation should occur, and it has certainly not been an inevitable development. The fact that many societies have remained stagnant for long periods of time, even at quite developed stages of technological evolution, and that some have actually regressed and lost the accumulated techniques passed on to them, demonstrates the ambiguous nature of technology and the critical importance of its relationship with other social factors.

Modes of technological transmission. Another aspect of the cumulative character of technology which will require further investigation is the manner of transmission of technological innovations. This is an elusive problem, and it is necessary to accept the phenomenon of simultaneous or parallel invention in cases in which there is insufficient evidence to show the transmission of ideas in one direction or the other. The mechanics of technological transmission have been enormously improved in recent centuries by the printing press and other means of communication and also by the increased facility with which travellers have been able to visit the sources of innovation and to carry the ideas back to their own homes. Traditionally, however, the major mode of transmission has been through the movement of artifacts and craftsmen. Trade in artifacts has ensured their widespread distribution and encouraged imitation. Even more important, the migration of craftsmen—whether it be the itinerant metalworkers of early civilizations or the German rocket engineers whose expert knowledge was acquired by both the Soviet Union and the United States after World War II—has promoted the spread of new technologies.

Historical methodology

The evidence for such processes of technological transmission is a reminder that the material for the study of the history of technology comes from a variety of sources. Much of it relies, like any historical examination, on documentary matter, although this is sparse for the early civilizations because of the general lack of interest in technology on the part of scribes and chroniclers. For these societies, therefore, and for the many millennia of earlier unrecorded history in which slow but substantial technological advances were made, it is necessary to rely heavily upon archaeological evidence. Even in connection with the recent past, the historical understanding of the processes of rapid industrialization can be made deeper and more vivid by the study of "industrial archaeology." Much valuable material of this nature has been accumulated in museums in the last few decades, and even more remains in the place of its use for the observation of the field worker. The historian of technology must be prepared to use all these sources, and to call upon the skills of the archaeologist, the engineer, the architect, and other specialists as appropriate.

A highly compressed account of the history of technology such as this must adopt a rigorous methodological pattern if it is to do justice to the subject without grossly distorting it one way or another. The plan followed in the present article is primarily chronological, tracing the development of technology through phases which succeed each other in time. Obviously, the division between phases is to a large extent arbitrary. One factor in the weighting has been the enormous acceleration of Western technological development in recent centuries; Eastern technology is considered in this article in the main only as it relates to the development of modern technology.

Within each chronological phase a standard method has been adopted for surveying the technological experience and innovations. This begins with a brief review of the general social conditions of the period, and then goes on to consider the dominant materials and sources of power of the period, and their application to food production, manufacturing industry, building construction, transport and communications, military technology, and medical technology. In a final section the sociocultural consequences of technological change in the period are examined. This framework is modified according to the particular requirements of every period; new materials, for instance, occupy a substantial place in the earlier phases when new metals were being introduced but are compar-

atively unimportant in some of the later phases. But the general pattern, with a review of the primary materials and power sources followed by their application, sandwiched between a survey of social conditions and social consequences, is retained throughout. One key factor which does not fit easily into this pattern is that of the development of tools. It has seemed most convenient to relate these to the study of materials, rather than to any particular application, but it has not been possible to be completely consistent in this treatment.

The article follows this outline:

I. Technology in the ancient world
  The beginnings—Stone Age technology (to *c.* 3000 BC)
    Earliest communities
    The Neolithic Revolution
  The urban revolution (*c.* 3000–500 BC)

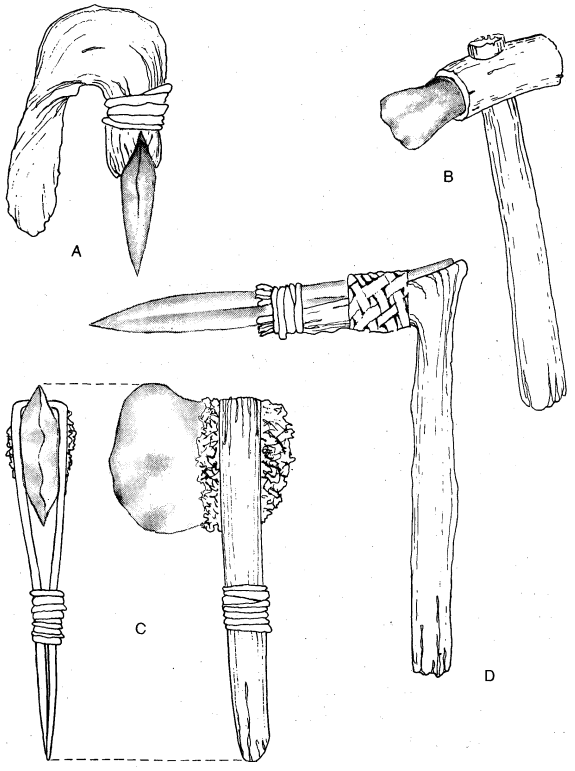
I. Technology in the ancient world

THE BEGINNINGS—STONE AGE TECHNOLOGY (TO C. 3000 BC)



The identification of the history of technology with the history of manlike species does not help in fixing a precise point for its origin, because the estimates of prehistorians and anthropologists concerning the emergence of human species vary so widely. The tendency has been for this time period to become increasingly extended as new excavations, especially in Central Africa, reveal evidence of progressively earlier human habitation. Suffice it to say here that over the long period of time before the dawn of recorded history there were few human beings on the face of the planet; that they did not, by reason of their simple way of life, leave many monuments or artifacts by which they might be recognized; and that there is not much chance of adding significantly to knowledge of human existence in this period, although assiduous excavation and new archaeological techniques may yet fill in some useful details.

Origins of technology

Earliest communities. What is known, therefore, may be summarized fairly briefly. For all except approximately the last 10,000 years, man has lived almost entirely in small nomadic communities, dependent for survival on his skill in gathering food by hunting and fishing and in avoiding predators. It is reasonable to suppose that most of these communities developed in tropical latitudes, especially in Africa, where climatic conditions are most favourable to a creature with such poor bodily protection as man. It is also reasonable to suppose that tribes of men moved out thence into the subtropical regions and eventually into the landmass of Eurasia, although their colonization of this region must have been severely limited by the successive periods of glaciation which rendered large parts of it inhospitable and even uninhabitable, even though man has shown remarkable versatility in adapting to such unfavourable conditions.

The Neolithic Revolution. Toward the end of the last Ice Age, some 15,000 to 20,000 years ago, a few of the

(C) Side and front views of ax with blade gripped in bend of withy, with attachment strengthened with hardened gum and lashing. (D) Adz with blade lashed in wooden sleeve which is attached to shouldered haft by band of plaited cane.

human communities which were most favoured by geography and climate began to make the transition from the long period of Paleolithic, or Old Stone Age, savagery to a more settled way of life depending on animal husbandry and agriculture. This period of transition, the Neolithic Period, or New Stone Age, led eventually to a marked rise in population, to a growth in the size of communities, and to the beginnings of town life. It is sometimes referred to as the Neolithic Revolution because the speed of technological innovation increased so greatly and the social and political organization of human groups underwent a corresponding increase in complexity. To understand the beginnings of human technology it is thus necessary to survey developments from the Old Stone Age through the New Stone Age down to the emergence of the first urban civilizations about 3000 BC.

Stone. The material that gives its name and a technological unity to these periods of prehistory is stone. Though it may be assumed that primitive man used other materials such as wood, bone, fur, leaves, and grasses before he mastered the use of stone, apart from bone antlers, presumably used as picks in flint mines and elsewhere, and other fragments of bone implements, none of these has survived. The stone tools of early man, on the other hand, have survived in surprising abundance, and over the many millennia of prehistory important advances in technique were made in the use of stone. Stones became tools only when they were shaped deliberately for specific purposes, and, for this to be done efficiently, suitable hard and fine-grained stones had to be found and means devised for shaping them and particularly for putting a cutting edge on them. Flint became a very popular stone for this purpose, although fine sandstones and certain volcanic rocks were also widely used. There is plenty of Paleolithic evidence of skill in flaking and polishing stones to make scraping and cutting tools. These early tools were held in the hand, but gradually ways of protecting the hand from sharp edges on the stone, at first by wrapping one end in fur or grass or setting it in a wooden handle, were devised. Much later, the technique of fixing the stone head to a haft converted these hand tools into more versatile tools and weapons.

The earliest tools

With the widening mastery of the material world in the Neolithic Period, other substances were brought into the service of man, such as clay for pottery and brick; and increasing competence in handling textile raw materials led to the creation of the first man-made fabrics to take the place of animal skins. About the same time, curiosity about the behaviour of metallic oxides in the presence of fire promoted one of the most significant technological innovations of all time and marked the succession from the Stone Age to the Metal Age.

Power. The use of fire was another basic technique mastered at some unknown time in the Old Stone Age. The discovery that the natural calamity of a forest fire could be tamed and controlled and the further discovery that a fire could be generated by persistent friction between two dry wooden surfaces were momentous. Fire was the most important contribution of prehistory to power technology, although little power was obtained directly from fire except as defense against wild animals. For the most part, prehistoric communities remained completely dependent upon manpower, but, as part of the transition to a more settled pattern of life in the New Stone Age, man began to derive some power from animals that had been domesticated. It also seems likely that by the end of prehistoric times the sail had emerged as a means of harnessing the wind for small boats, beginning a long sequence of developments in marine transport.

Tools and weapons. The basic tools of prehistoric man were determined by the materials at his disposal. But once the techniques of working stone had been acquired, he was resourceful in devising tools and weapons with points and barbs of flaked stone. Thus the stone-headed spear, the harpoon, and the arrow all came into widespread use. The spear was given increased impetus by the spear thrower, a notched pole that gave a sling effect. The bow and arrow were an even more effective combination, the use of which is clearly demonstrated in the earliest "documentary" evidence in the history of technology, the cave paintings of southern France and northern Spain which depict the bow being used in hunting. The ingenuity of these primitive hunters is shown also in their slings, throwing sticks (the boomerang of the Australian aborigines is a remarkable surviving example), blowguns, bird snares, fish and animal traps, and nets. These tools did not evolve uniformly as every primitive community developed only those instruments that were most suitable for its own specialized purposes, but all were in use by the end of Stone Age. In addition, the Neolithic Revolution had contributed some important new tools that were not primarily concerned with hunting. These were the first mechanical applications of rotary action in the shape of the potter's wheel, the bow drill, the pole lathe, and the wheel itself. It is not possible to be sure when these significant devices were invented, but their presence in the early urban civilizations suggests some continuity with the Late Neolithic Period. The potter's wheel, driven by kicks from the operator, and the wheels of early vehicles both gave continuous rotary movement in one direction. The drill and the lathe, on the other hand, were derived from the bow and had the effect of spinning the drill piece or the workpiece first in one direction and then in the other.

The bow and arrow

Developments in food production brought further refinements in tools. The processes of food production in Paleolithic times were simple, consisting of gathering, hunting, and fishing. If these methods proved inadequate to sustain a community, it moved to better hunting grounds or perished. With the onset of the Neolithic Revolution, new food-producing skills were devised to serve the needs of agriculture and animal husbandry. Digging sticks and the first crude plows, stone sickles, querns that ground grain by friction between two stones and, most complicated of all, irrigation techniques for keeping the ground watered and fertile; all these became well established in the great subtropical river valleys of Egypt and Mesopotamia in the millennia before 3000 BC.

Food production

Building techniques. Prehistoric building techniques also underwent significant developments in the Neolithic Revolution. Nothing is known of the building ability of Paleolithic man beyond a few fragments of stone shelters, but in the New Stone Age some impressive structures were erected, primarily tombs and burial mounds and other religious edifices, but also, towards the end of the period, showing a beginning in the use of sun-dried brick for domestic housing. In northern Europe, where the Neolithic transformation of primitive society began later than in the eastern Mediterranean societies and lasted longer, the huge stone monuments, of which Stonehenge in England is the outstanding example, still bear eloquent testimony to the technical skill, not to mention the imagination and mathematical competence, of the later Stone Age societies.

Manufacturing. Manufacturing industry had its origin in the New Stone Age, with the application of techniques for grinding corn (the quern), baking clay (pottery), spinning and weaving textiles, and also, it seems likely, in dyeing, fermenting, and distilling. Some evidence for all these processes can be derived from archaeological findings, and some of them at least were developing into specialized crafts by the time that the first urban civilizations appeared. In the same way, the early metalworkers were beginning to acquire the techniques of extracting and working the softer metals, gold, silver, copper and tin, which were to make their successors a select class of craftsmen. All these incipient fields of specialization, moreover, implied developing trade between different communities and regions, and again the archaeological evidence of the transfer of manufactured products in the later Stone Age is impressive. Flint arrowheads of particular types, for example, can be found widely dispersed over Europe, and the implication of a common source of manufacture for each is strong.

Such transmission suggests improving facilities for transport and communication. Paleolithic man presumably depended entirely on his own feet, and this remained the normal mode of transport throughout the Stone Age.

Domestication of animals undoubtedly brought some help here, however, with the ox, the donkey, and the camel, although difficulties in harnessing the horse long delayed its effective use. On water, the dugout canoe and the birch-bark canoe had demonstrated the potential of this means of transport, and, again, there is some evidence that the sail had already appeared by the end of the New Stone Age.

It is notable that the developments so far described in human prehistory took place over a long period of time, compared with the 5,000 years of recorded "history," and that they took place first in very small areas of the earth's surface and involved populations minute by modern standards. The Neolithic Revolution occurred first in those parts of the world with an unusual combination of qualities: a warm climate, encouraging rapid crop growth, and an annual cycle of flooding that made the fertility of the land in part at least naturally regenerative. On the Eurasian–African landmass such conditions occur only in Egypt, Mesopotamia, northern India, and some of the great river valleys of China. It was here, then, that men and women of the New Stone Age were stimulated to develop and apply new techniques of agriculture, animal husbandry, irrigation, and manufacture; and it was here that their enterprise was rewarded by increasing productivity, which encouraged the growth of population and triggered a succession of sociopolitical changes that converted the settled Neolithic communities into the first civilizations. Elsewhere, the stimulus to technological innovation was lacking or was unrewarded, so that these areas had to await the transmission of technical expertise from the more highly favoured areas. Herein is rooted the separation of the great world civilizations, for while the Egyptian and Mesopotamian civilizations spread their influence westward through the Mediterranean and Europe, those of India and China were limited by geographical barriers to their own hinterlands, which, although vast, were largely isolated from the mainstream of Western technological progress.

Effect of climatic conditions

THE URBAN REVOLUTION (C. 3000-500 BC)

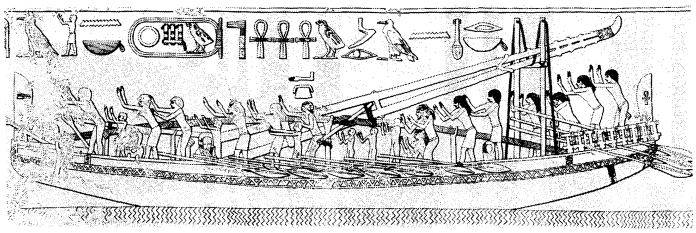
The technological change so far described took place very slowly over a long period of time, in response to only the most basic social needs, the search for food and shelter, and with few social resources available for any activity other than the fulfillment of these needs. About 5,000 years ago, however, a momentous cultural transition began to take place in a few well-favoured geographical situations. It generated new needs and resources and was accompanied by a significant increase in technological innovation. It was the beginning of the invention of the city.

Craftsmen and scientists. The accumulated agricultural skill of the New Stone Age had made possible a growth in population, and the larger population in turn created a need for the products of specialized craftsmen in a wide range of commodities. These craftsmen included a number of metalworkers, first those treating metals that could be easily obtained in metallic form and particularly the soft metals, such as gold and copper, which could be fashioned by beating. Then came the discovery of the possibility of extracting certain metals from the ores in which they generally occur. Probably the first such material to be used was the carbonate of copper known as malachite, then already in use as a cosmetic and easily reduced to copper in a strong fire. It is impossible to be precise about the time and place of this discovery, but its consequences were tremendous. It led to the search for other metallic ores, to the development of metallurgy, to the encouragement of trade in order to secure specific metals, and to the further development of specialist skills. It contributed substantially to the emergence of urban societies, relying heavily upon trade and manufacturing industries and thus to the rise of the first civilizations. The Stone Age gave way to the early Metal Age, and a new epoch in the story of mankind had begun.

Early extraction of metals

By fairly general consent, civilization consists of a large society with a common culture, settled communities, and sophisticated institutions, all of which presupposes a mastery of elementary literacy and numeration. Mastery of the civilized arts was a minority pursuit in the early civilizations, in all probability the carefully guarded possession of a priestly caste. But the existence of the skills, even in the hands of a small minority of the population, is significant because it made available a facility for recording and transmitting information that greatly enlarged the scope for innovation and speculative thought.

Hitherto, technology had existed without the benefit of science, but, by the time of the first Sumerian astronomers, who plotted the motion of the heavenly bodies with remarkable accuracy and based calculations about the calendar and irrigation systems upon their observations, the possibility of a creative relationship between science and technology had appeared. The first fruits of this relationship appeared in greatly improved abilities to measure land, weigh, and keep time, all practical techniques, essential to any complex society, and inconceivable without the literate skills and the beginnings of scientific observation. With the emergence of these skills in the 3rd millennium before Christ, the first civilizations arose in the valleys of the Nile and of the Tigris–Euphrates.



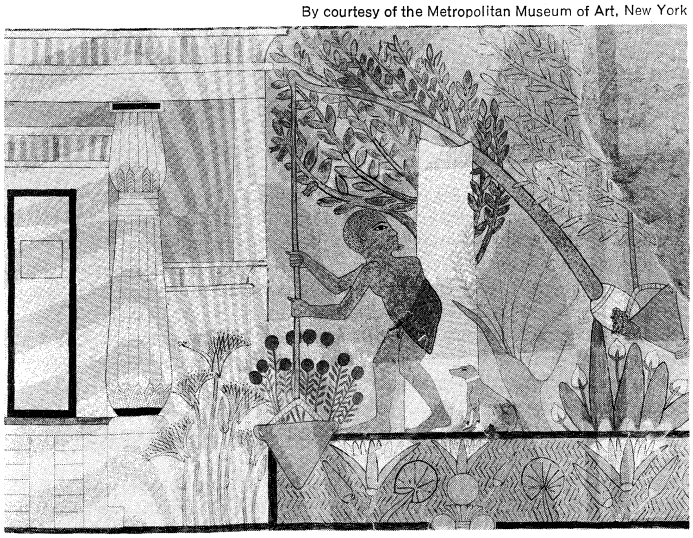
Copper and bronze. The fact that the era of the early civilizations coincides with the technological classification of the Copper and Bronze ages is a clue to the technological basis of these societies. The comparative softness of copper, gold, and silver made it inevitable that they should be the first to be worked, but archaeologists now seem to agree that there was no true "Copper Age," except perhaps for a short period at the beginning of Egyptian civilization, because the very softness of these metals limited their utility for everything except a decorative purpose or for use in coinage. Attention was thus given early to means of hardening copper in order to make satisfactory tools and weapons. The reduction of mixed metallic ores probably led to the discovery of alloying, whereby copper was fused with other metals to make bronze. Several bronzes were made, including some with proportions of lead, antimony, and arsenic, but by far the most popular and widespread was that created by copper with tin in proportions of about ten to one. This was a hard yellowish metal that, when molten, could be cast into the shape required. The bronzesmiths took over from the coppersmiths and goldsmiths the technique of heating the metal in a crucible over a strong fire and casting it into simple clay or stone molds to make ax or spear heads or other solid shapes. For more complicated shapes, such as hollow vessels or sculpture, they devised the so-called cire perdue technique in which the shape to be molded is formed in wax and set in clay, the wax then being melted and drained out to leave a cavity into which the molten metal is poured.

Discovery of alloying

Bronze became the most important material of the early civilizations, and elaborate arrangements were made to ensure a continuous supply of it. Metals were scarce in the alluvial river valleys where civilization developed and therefore had to be imported, involving complicated trading relationships and mining operations at great distances from the homeland. Tin presented a particularly severe problem, as it was in short supply throughout the Middle East. The Bronze Age civilizations were compelled to search far beyond their own frontiers for sources of the metal, and in the process knowledge of the civilized arts was gradually transmitted westwards along the developing Mediterranean trade routes.

In most aspects other than the use of metals, the transition from the technology of the New Stone Age to that of early civilizations was fairly gradual, although there was a general increase in competence as specialized skills became more clearly defined, and in techniques of building there were enormous increases in the scale of enterprises. There were no great innovations in power technology, but important improvements were made in the construction of furnaces and kilns in response to the requirements of the metalworkers and potters and of new craftsmen such as glassworkers. Also, the sailing ship assumed a definitive shape, progressing from a vessel with a small sail rigged in its bows and suitable only for sailing before the prevailing wind up the Nile River, into the substantial

The sailing ship



Drawing of an Egyptian seagoing ship, *c.* 2600 BC, based on vessels depicted in the bas-relief discovered in the pyramid of King Sahure at Abū Sīr, Cairo.

oceangoing ship of the later Egyptian dynasties, with a large rectangular sail rigged amidships. Egyptian and Phoenician ships of this type could sail before the wind and across the wind, but for making headway into the wind they had to resort to manpower. Nevertheless, they accomplished remarkable feats of navigation, sailing the length of the Mediterranean and even passing through the Pillars of Hercules into the Atlantic.

Irrigation. Techniques of food production also showed many improvements over Neolithic methods, including one outstanding innovation in the shape of systematic irrigation. The civilizations of Egypt and Mesopotamia depended heavily upon the two great river systems, the Nile and the Tigris–Euphrates, which both watered the ground with their annual floods and rejuvenated it with the rich alluvium they deposited. The Nile flooded with regularity each summer, and the civilizations building in its valley early learned the technique of basin irrigation, ponding back the floodwater for as long as possible after the river had receded, so that enriched soil could bring forth a harvest before the floods of the following season. In the Tigris–Euphrates Valley the irrigation problem was more complex, because the floods were less predictable, more fierce, and came earlier than those of the northward-flowing Nile. They also carried more alluvium, which tended to choke irrigation channels. The task of the Sumerian irrigation engineers was that of channelling water from the rivers during the summer months, impounding it, and distributing it to the fields in small installments. The Sumerian system eventually broke down because it led to an accumulation of salt in the soil, with a consequent loss of fertility. Both systems, however, depended on a high degree of social control, requiring skill in measuring and marking out the land and an intricate legal code to ensure justice in the distribution of precious water. Both systems, moreover, depended on intricate engineering in building dikes and embankments, canals and aqueducts (with lengthy stretches underground to prevent loss by evaporation), and the use of water-raising devices such as the shadoof, a balanced beam with a counterweight on one end and a bucket to lift the water on the other.

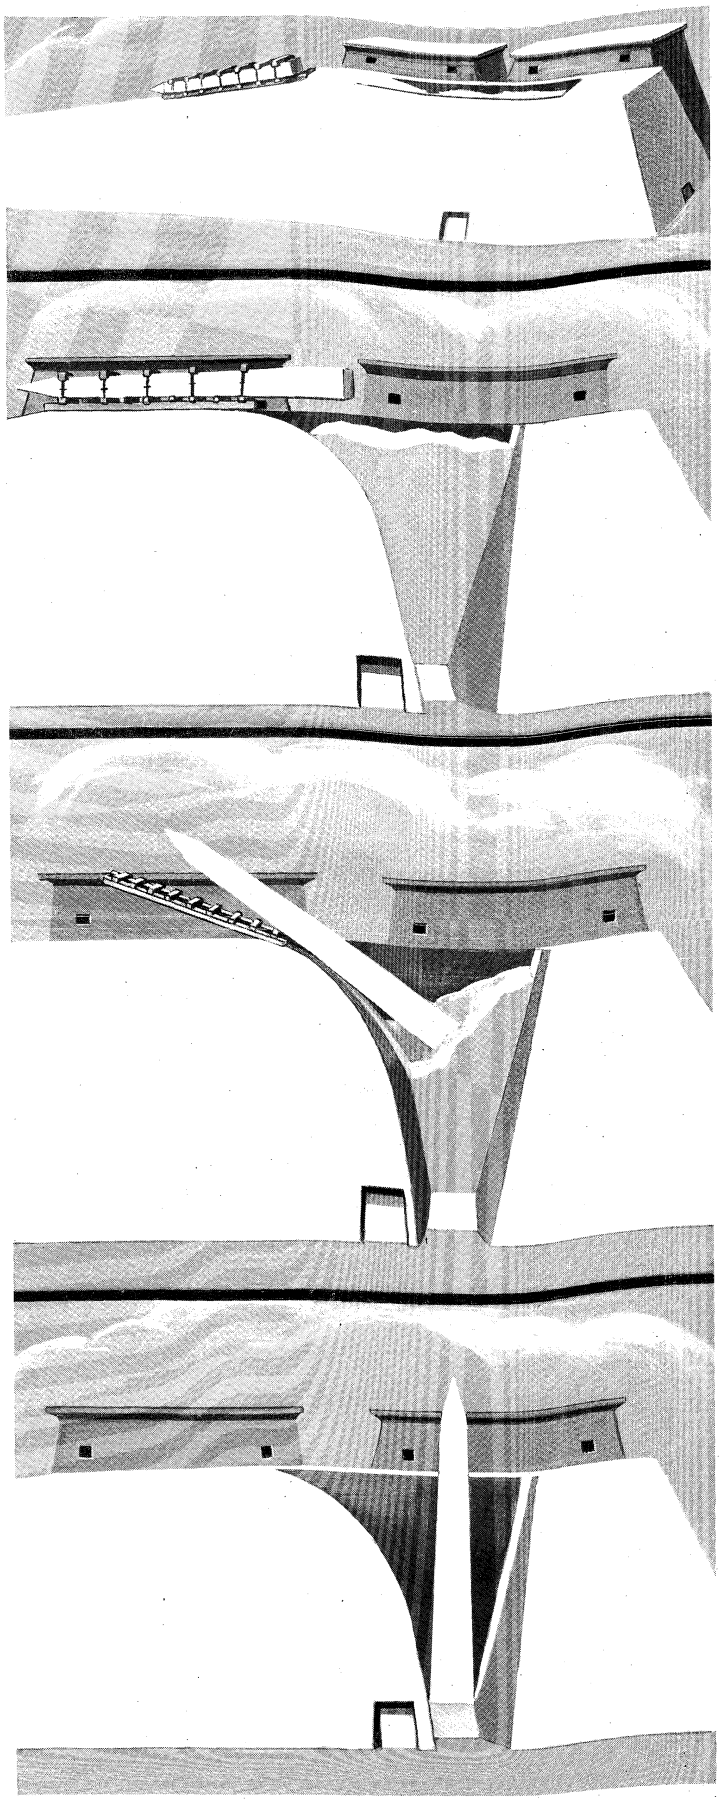
Urban manufacturing. Manufacturing industry in the early civilizations concentrated on such products as pottery, wines, oils, and cosmetics, which had begun to circulate along the incipient trade routes before the introduction of metals; these became the commodities traded for the metals. In pottery, the potter's wheel became widely used for spinning the clay into the desired shape, but the older technique of building it up by hand from rolls of clay remained in use for some purposes. In the production of wines and oils various forms of press were developed, while the development of cooking, brewing, and preservatives justified the assertion that the science of chemistry began in the kitchen. Cosmetics too were an offshoot of culinary art.

Transport was still primarily by animal, with the wheeled vehicle developing slowly to meet the divergent needs of agriculture, trade, and war. In the latter category, the chariot appeared as a weapon, even though its use was limited by the continuing difficulty of harnessing a horse. Military technology brought the development of metal plates for armour.



Wheeled vehicles

Building. In building technology there were developments comparable in importance to those in the field of metalworking, but their significance was in the scale of operations rather than in any particular innovation. The late Stone Age communities of Mesopotamia had already built extensively in sun-dried brick. Their successors continued the technique but extended it in scale to construct the massive brick temples called ziggurats. These were built on a square plan, with a core and facing of sun-dried mud bricks, the facing walls tapering slightly inward and broken by regular pilasters built into the brickwork, the whole structure ascending in two or three stages to a temple on the summit. Sumerians were also the first to build columns with brick, and this material from local clay provided the writing material for the scribes.

In Egypt, where clay was scarce but good building stone was plentiful, builders turned emphatically to stone, constructing the pyramids and temples which remain today as the outstanding monuments of Egyptian civilization. Stones were pulled on rollers and raised up the successive stages of the structure by ramps and by balanced levers adapted from the water-raising shadoof. The shaping of the stones was performed by skilled masons, and they were placed in position under the careful supervision of priest-architects who were clearly competent mathematicians and astronomers, as is evident from the precise astronomical alignments. It seems certain that the heavy labour of construction fell upon armies of slaves, which helps to explain both the achievements and limitations of early civilizations. Slaves were usually one of the fruits of military conquest, which presupposes a period of successful territorial expansion, although their status as a subject race could be perpetuated indefinitely. Slave populations provided a good and docile labour force for the major constructional works that have been described. On the other hand, the availability of slave labour discouraged technological innovation, a social fact that goes far toward explaining the comparative stagnation of mechanical invention in the ancient world.

Slave labour in building

Transmitting knowledge. In the ancient world, technological knowledge was transmitted by traders, who went out in search of tin and other commodities, and by craftsmen in metal, stone, leather, and the other media, who passed their skills to others by direct instruction or by providing models that challenged other craftsmen to copy them. This process of transmission by intermediary contact was occurring between the ancient civilizations and their neighbours to north and west during the 2nd millennium before Christ. The pace quickened in the subsequent millennium, distinct new civilizations arising in the Mediterranean, in Crete and Mycenae, in Troy and Carthage. Finally, the introduction of the technique of working iron caused another profound change in the capabilities and resources of human societies and ushered in the classical civilizations of Greece and Rome.

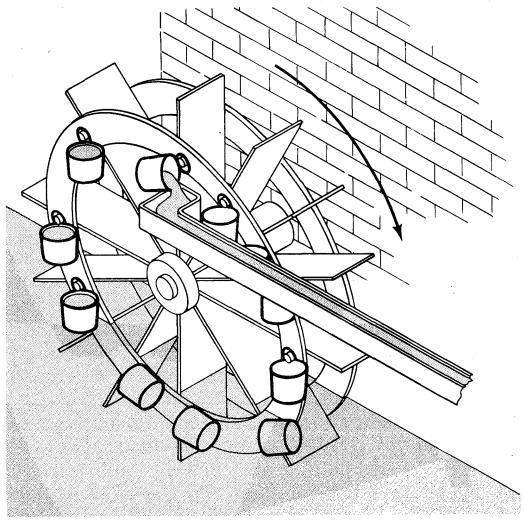
Erection of an obelisk; (top to bottom) obelisk hauled up ramp by sledge; partial removal of sledge; with all lashings removed, obelisk eased into surrounding sand; obelisk drawn upright on its pedestal.

TECHNOLOGICAL ACHIEVEMENTS OF GREECE AND ROME (500 BC–AD 500)

The contributions of Greece and Rome in philosophy and religion, political and legal institutions, poetry and drama, and in the realm of scientific speculations were in spectacular contrast with their relatively limited contributions in technology. Their mechanical innovation was not distinguished, and, even in the realms of military and construction engineering, in which they showed great ingenuity and aesthetic sensibility, their work represented more a consummation of earlier lines of development than a dramatic innovation. This apparent paradox of the classical period of the ancient world requires explanation, and the history of technology can provide some clues to the solution of the problem.

The mastery of iron. The outstanding technological factor of the Greco-Roman world was the mastery of iron, a technique derived from unknown metallurgists, probably in Asia Minor, about 1000 BC, and which spread far beyond the provincial frontiers of the Roman Empire. The use of the metal had become general in Greece and the Aegean islands by the dawn of the classical period about 500 BC, and it appears to have spread quickly westward thereafter. Iron ore, long a familiar material, had defied reduction into metallic form because of the great heat required in the furnace to perform the chemical transformation (about 1,535° C [2,795° F] compared with the 1,083° C [1,981° F] necessary for the reduction of copper from its ores). To reach this temperature, furnace construction had to be improved and ways devised to maintain the heat for several hours. Throughout the classical period, these conditions were achieved only on a small scale, in furnaces burning charcoal and using footbellows to intensify the heat, and even in these furnaces the heat was not sufficient to reduce the ore completely to molten metal. Instead, a small spongy ball of iron—called a bloom—was produced in the bottom of the furnace. This was extracted by breaking open the furnace and then consolidated by being hammered into bars of wrought iron, which could be shaped as required by further heating and hammering. Apart from its greater abundance, iron for most purposes provided a harder and stronger material than the earlier metals, although the inability to cast it into molds like bronze was an inconvenience. At an early date some smiths devised the cementation process for re-heating bars of iron between layers of charcoal to carburize the surface of the iron and thus to produce a coat of steel. Such case-hardened iron could be further heated, hammered, and tempered to make knife and sword blades of high quality. The very best steel in Roman times was Seric steel, brought into the Western world from India where it was produced in blocks a few inches in diameter by a crucible process; *i.e.*, melting the ingredients in an enclosed vessel to achieve purity and consistency in the chemical combination.

Improvements in metal furnaces



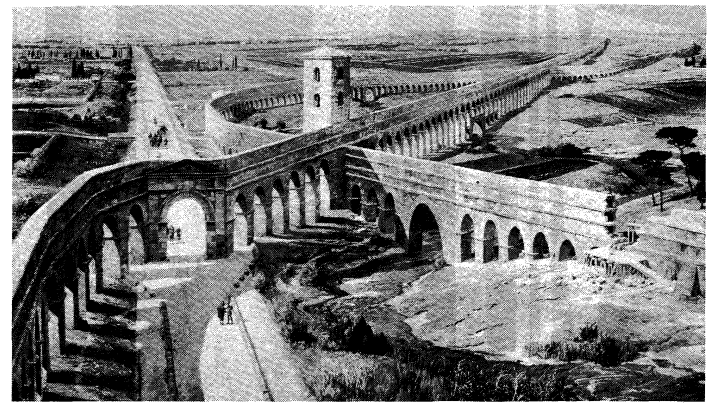
Mechanical contrivances. Though slight, the mechanical achievements of the Greco-Roman centuries were not without significance. In Archimedes the world had one of its great mechanical geniuses, who devised remarkable weapons to protect his native Syracuse from Roman invasion and applied his powerful mind to such basic mechanical contrivances as the screw, the pulley, and the lever. Alexandrian engineers, such as Ctesibius and Hero, were responsible for a wealth of ingenious mechanical contrivances including pumps, wind and hydraulic organs, compressed-air engines and screw-cutting machines. They also devised toys and automata such as the *aeolipile*, which may be regarded as the first successful steam turbine. Little practical use was found for these inventions, but the Alexandrian school marks an important transition from very simple mechanisms to the more complex devices that properly deserve to be considered as "machines." In a sense it provided a starting point for modern mechanical practice.

Introduction of rotary motion

Although they contributed few significant innovations, the Romans were responsible, through the application and development of available machines, for an important technological transformation involved in the widespread introduction of rotary motion. This was exemplified in the

use of the treadmill for powering cranes and other heavy lifting operations, the introduction of rotary water-raising devices for irrigation works (a scoop wheel powered by a treadmill), and the development of the waterwheel as a prime mover. The 1st-century Roman engineer Vitruvius gave an account of watermills, and by the end of the Roman era many were in operation.

Agriculture. Iron Age technology was applied to agriculture in the form of the iron (or iron-tipped) plowshare, which opened up the possibility of deeper plowing and of cultivating heavier soils than those normally worked in the Greco-Roman period. The construction of plows improved slowly during these centuries, but the moldboard for turning over the earth did not appear until the 11th century AD, so that the capacity of turning the sod depended more on the wrists of the plowman than on the strength of his draft team; this discouraged tackling heavy ground. The potentialities of the heavy plow were thus not fully exploited in the temperate areas of Europe until after the Roman period. Elsewhere, in the drier climates of North Africa and Spain, the Romans were responsible for extensive irrigation systems, using the Archimedean screw and the noria (an animal- or water-powered scoop wheel) to raise water.



The noria, used to raise water to a higher level. Arrow indicates direction of rotation of the wheel.

Building. Though many buildings of the Greeks survive as splendid monuments to the civilized communities that built them, as technological monuments they are of less significance. The Greeks adopted a form of column and lintel construction that had been used in Egypt for centuries and was derived from experience of timber construction. In no major sense did Greek building constitute a technological innovation. The Romans copied the Greek style for most ceremonial purposes, but in other respects they were important innovators in building technology. They made extensive use of fired brick and tile as well as stone, they developed a powerful cement that would set under water, and they explored the architectural possibilities of the arch, the vault, and the dome. They then applied these techniques in amphitheatres, aqueducts, tunnels, bridges, walls, lighthouses, and roads. Taken together, these constructional works may fairly be regarded as the primary technological achievement of the Romans.

Roman innovations

Other fields of technology. In manufacturing, transport, and military technology, the achievements of the Greco-Roman period are not remarkable. The major manufacturing crafts—pottery, glass, textiles, leather working, fine-metalworking, and so on—followed the lines of previous societies, albeit with important developments in style. Superbly decorated Athenian pottery, for example, was widely dispersed along the trade routes of the Mediterranean, and the Romans made good quality pottery available throughout their empire through the manufacture and trade of the standardized red Samian ware, originally from Greek Samos.

Transport. Transport, again, followed earlier precedents, the sailing ship emerging as a seagoing vessel with a carvel-built hull (that is, with planks meeting edge-to-edge rather than overlapping as in clinker-built designs), and a fully developed keel with stempost and sternpost. The Greek sailing ship was equipped with a square or rectangular sail to receive a following wind and one or more banks of oarsmen to propel the ship when the wind was contrary. The Greeks began to develop a specialized fighting ship, provided with a ram in the prows, and the cargo ship, dispensing with oarsmen and relying entirely upon the wind, was also well established by the early years of classical Greece. The Romans took over both forms, but without significant innovation. They gave much more attention to inland transport than to the sea, and constructed a remarkable network of carefully aligned and well-laid roads, often paved over long stretches, throughout the provinces of the empire. Along these strategic highways the legions marched rapidly to any crisis at which their presence was required. The roads also served for the development of trade, but their primary function was always military, as a vital means of keeping a vast empire in subjection.

Military technology. Roman military technology was inventive on occasion, as in the great siege catapults, depending on both torsion and tension power. But the standard equipment of the legionary was simple and conservative, consisting of an iron helmet and breastplate, with a short sword and an iron-tipped spear. As most of their opponents were also equipped with iron weapons and sometimes with superior devices, such as the Celtic chariots, the Roman military achievements depended more on organization and discipline than on technological superiority.

The Greco-Roman era was distinguished for the scientific activity of some of its greatest philosophers. In keeping with Greek speculative thought, however, this tended to be strongly conceptual so that it was in mathematics,

geometry, and other abstract studies that the main scientific achievements are to be found. Occasionally these had some practical significance, as in the study of perspective effects in building construction. Aristotle in many ways expressed the inquiring empiricism which has caused scientists to seek an explanation for their physical environment. In at least one field, that of medicine and its related subjects, Greek inquiry assumed a highly practical form, Hippocrates and Galen laying the foundations of modern medical science. But this was exceptional, and the normal Hellenic attitude was to pursue scientific enquiry in the realm of ideas without much thought of the possible technological consequences.

II. From the Middle Ages to 1750

MEDIEVAL ADVANCE (AD 500–1500)

The millennium between the collapse of the Western Roman Empire in the 5th century AD and the beginning of the colonial expansion of western Europe in the late 15th century has been known traditionally as the Middle Ages, and the first half of this period consists of the five centuries of the Dark Ages. We now know that the period was not as socially stagnant as this title suggests. In the first place, many of the institutions of the later empire survived the collapse and profoundly influenced the formation of the new civilization that developed in western Europe. The Christian Church was the outstanding institution of this type, but Roman conceptions of law and administration also continued to exert an influence long after the departure of the legions from the western provinces. Second, and more important, the Teutonic tribes who moved into a large part of western Europe did not come empty-handed, and in some respects their technology was superior to that of the Romans. It has already been observed that they were people of the Iron Age, and although much about the origins of the heavy plow remains obscure these tribes appear to have been the first people with sufficiently strong iron plowshares to undertake the systematic settlement of the forested lowlands of northern and western Europe, the heavy soils of which had frustrated the agricultural techniques of their predecessors.

Effect of the barbarian invasions

The invaders came thus as colonizers. They may have been regarded as "barbarians" by the Romanized inhabitants of western Europe who naturally resented their intrusion, and the effect of their invasion was certainly to disrupt trade, industry, and town life. But the newcomers also provided an element of innovation and vitality. About AD 1000 the conditions of comparative political stability necessary for the re-establishment of a vigorous commercial and urban life had been secured by the success of the kingdoms of the region in either absorbing or keeping out the last of the invaders from the East, and thereafter for 500 years the new civilization grew in strength and began to experiment in all aspects of human endeavour. Much of this process consisted of recovering the knowledge and achievements of the ancient world. The history of technology in the Middle Ages is thus largely the story of the preservation, recovery, and modification of earlier achievements. But by the end of the period the new Western civilization had begun to produce some remarkable technological innovations which were to be of the utmost significance.

Innovation. The word innovation raises a problem of great importance in the history of technology. Strictly, an innovation is something entirely new, but there is no such thing as an unprecedented technological innovation because it is impossible for an inventor to work in a vacuum and, however ingenious his invention, it must arise out of his own previous experience. The task of distinguishing an element of novelty in an invention remains a problem of patent law down to the present day, but the problem is made relatively easy by the possession of full documentary records covering previous inventions in many countries. In the millennium of the Middle Ages, however, few such records exist, and it is frequently difficult to explain how particular innovations were introduced to western Europe. The problem is especially perplexing because it is known that many inventions of the period had been developed independently and previously in other civilizations, and it is sometimes difficult if not impossible to know whether something is spontaneous innovation or an invention that had been transmitted by some as yet undiscovered route from those who had originated it in other societies.

The problem is important because it generates a conflict of interpretations about the transmission of technology. On the one hand there is the theory of the diffusionists, according to which all innovation has moved westward from the long-established civilizations of the ancient world, with Egypt and Mesopotamia as the two favourite candidates for the ultimate source of the process. On the other hand is the theory of spontaneous innovation, according to which the primary determinant of technological innovation is social need. Scholarship is as yet unable to solve the problem so far as technological advances of the Middle Ages are concerned because much information is missing. But it does seem likely that at least some of the key inventions of the period—the windmill and gunpowder are good examples—were developed spontaneously. It is quite certain, however, that others such as silk working were transmitted to the West, and, however original the contribution of Western civilization to technological innovation, there can be no doubt at all that in its early centuries at least it looked to the East for ideas and inspiration.

Theory of spontaneous innovation

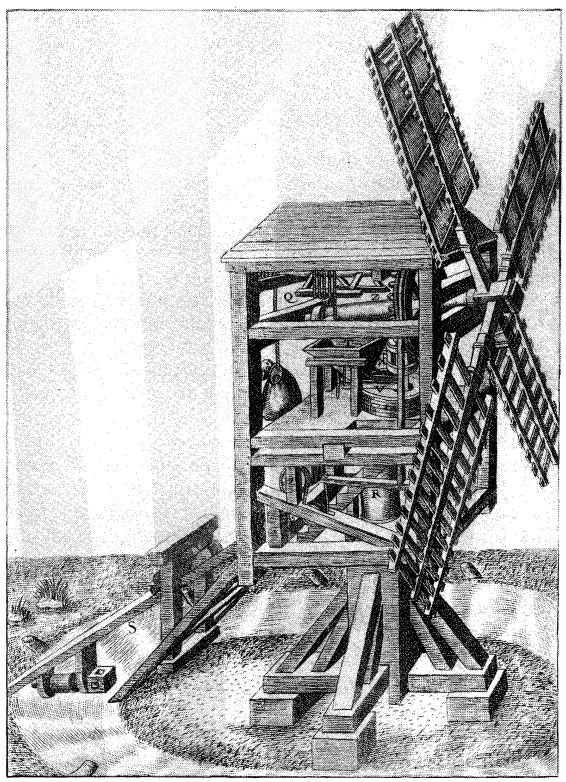
Byzantium. The immediate eastern neighbour of the new civilization of medieval Europe was Byzantium, the surviving bastion of the Roman Empire based on Constantinople, which endured for 1000 years after the collapse of the western half of the empire. Here the literature and traditions of Hellenic civilization were perpetuated, becoming increasingly available to the curiosity and greed of the West through the traders who arrived from Venice and elsewhere. Apart from the influence on Western architectural style of such Byzantine masterpieces as the great domed structure of Hagia Sophia, the technological contribution of Byzantium itself was probably slight, but it served to mediate between the West and other civilizations one or more stages removed, such as Islām, India, and China.

Islām. Islām had become a civilization of colossal expansive energy in the 7th century and had imposed a unity of religion and culture on much of southwest Asia and North Africa. From the point of view of technological dissemination, the importance of Islām lay in the Arab assimilation of the scientific and technological achievements of Hellenic civilization, to which it made significant additions, and the whole became available to the West through the Moors in Spain, the Arabs in Sicily and the Holy Land, and through commercial contacts with the Levant and North Africa.

Islām also provided a transmission belt for some of the technology of the ancient civilizations of East and South Asia, especially those of India and China. Chinese civilization had already developed a host of crafts and techniques which were still unknown in the West by AD 1000. Such techniques included silk working, gunpowder, iron casting, papermaking, the junk and dhow, kites, windmills, and porcelain. The fact that several of these techniques had become well established in the West by 1500 suggests that they were transmitted.

Chinese technology

Yet despite the acquisition of many techniques from the East, the Western world of 500–1500 was forced to solve most of its problems with little interference from outside. In doing so it transformed an agrarian society based upon a subsistence economy into a dynamic society with increased productivity sustaining trade, industry, and town life on a steadily growing scale. This was primarily a technological achievement, and one of considerable magnitude.



Power sources. The outstanding feature of this achievement was a revolution in the sources of power. With no large slave labour force to draw on, Europe experienced a labour shortage which stimulated a search for alternative sources of power and the introduction of labour-saving machinery. The first instrument of this power revolution was the horse. By the invention of the horseshoe,

the padded, rigid horsecollar, and the stirrup, all of which first appear in the West in the centuries of the Dark Ages, the horse was transformed from an ancillary beast of burden useful only for light duties into a highly versatile source of energy in peace and war. Once the horse could be harnessed to the heavy plow by means of the horsecollar, it became a more efficient beast of burden than the ox, and the introduction of the stirrup made the mounted warrior supreme in medieval warfare and initiated complex social changes to sustain the great expense of the knight, his armour, and his steed, in a society close to the subsistence line.

Water-power and wind power

Even more significant was the success of medieval technology in harnessing water and wind power. The Romans had pioneered the use of water power in the later empire, and some of their techniques probably survived. The type of watermill which flourished first in northern Europe, however, appears to have been the Norse mill, using a horizontally mounted waterwheel driving to a pair of grindstones directly without the intervention of gearing. Examples of this simple type of mill survive in Scandinavia and in the Shetlands; it also occurred in southern Europe where it was known as the Greek mill. It is possible that a proportion of the 5,624 mills recorded in the Domesday Book of England in 1086 were of this type, although it is probable that by this date the vertically mounted undershot wheel had established itself as more appropriate to the gentle landscape of England; the Norse mill requires a good head of water to turn the wheel at high speed in order to maintain an adequate grinding speed without gearing for the upper millstone (the practice of rotating the upper stone above a stationary bedstone became universal at an early date). Most of the Domesday watermills were used for grinding grain, but in the following centuries other important uses were devised in fulling cloth (shrinking and felting woollen fabrics), sawing wood, and crushing vegetable seeds for oil. Overshot wheels were also introduced where there was sufficient head of water, and the competence of the medieval millwrights in building mills and earthworks and in constructing increasingly elaborate trains of gearing grew correspondingly.

Post windmill with grinding machinery in mill housing, engraving from Agostino Ramelli's *Li diverse et artificiose macchine*, 1588.

Wind power in the shape of the sail had been harnessed from the dawn of civilization, but it was unknown in the form of the windmill in the West until the end of the 12th century. Present evidence suggests that the windmill developed spontaneously in the West despite precedents in Persia, but the question remains open. What is certain is that the windmill became widely used in Europe in the Middle Ages. Wind power is generally less reliable than waterpower, but where the latter is deficient wind power is an attractive substitute. Such conditions are found in areas that suffer from drought or from a shortage of surface water and also in low-lying areas where rivers offer little energy. Windmills have thus flourished in places such as Spain or the downlands of England on the one hand, and in the fenlands and polders of The Netherlands on the other hand. The first type of windmill to be widely adopted was the post-mill, in which the whole body of the mill pivots on a post and can be turned to face the sails into the wind. By the 15th century, however, many were adopting the tower-mill type of construction, in which the body of the mill remains stationary with only the cap moving to turn the sails into the wind. As with the watermill, the development of the windmill brought not only greater mechanical power but also greater knowledge of mechanical contrivances, which was applied in making clocks and other devices.

Origin of the windmill

Agriculture and crafts. With new sources of power at its disposal, medieval Europe was able greatly to increase productivity. This is abundantly apparent in agriculture, where the replacement of the ox by the faster-gaited horse and the introduction of new crops brought about a distinct improvement in the quantity and variety of food, with a consequent improvement in the diet and energy of the population. It was also apparent in the developing industries of the period, especially the woollen cloth industry in which the spinning wheel was introduced, partially mechanizing this important process, and the practice of using waterpower to drive fulling stocks (wooden hammers raised by cams on a driving shaft) had a profound effect on the location of the industry in England in the later centuries of the Middle Ages. The same principle was adapted to the paper industry late in the Middle Ages, the rag from which paper was derived being pulverized by hammers similar to fulling stocks.

Meanwhile, the traditional crafts flourished within the expanding towns where there was a growing market for the products of the rope makers, barrel makers (coopers), leatherworkers (curriers), and metalworkers (goldsmiths and silversmiths), to mention only a few of the more important crafts. New crafts such as that of the soapmakers developed in the towns. The technique of making soap appears to have been a Teutonic innovation of the Dark Ages, being unknown in the ancient civilizations. The process consists of decomposing animal or vegetable fats by boiling them with a strong alkali. Long before it became popular for personal cleansing, soap was a valuable industrial commodity for scouring textile fabrics. Its manufacture was one of the first industrial processes to make extensive use of coal as a fuel, and the development of the coal industry in northern Europe constitutes another important medieval innovation, no previous civilization having made any systematic attempt to exploit coal. The mining techniques remained primitive as long as coal was obtainable near the surface, but as the search for the mineral led to greater and greater depths the industry copied methods that had already evolved in the metallic mining industries of north and central Europe. The extent of this evolution was brilliantly summarized by Georgius Agricola in his *De re metallica*, published in 1556. This large, abundantly illustrated book shows techniques of shafting, pumping (by treadmill, animal power, and waterpower), and of conveying the ore won from the mines in trucks, which anticipated the development of the railways. It is impossible to date precisely the emergence of these important techniques, but the fact that they were well established when Agricola observed them suggests that they had a long ancestry.

Soap-making

Architecture. Relatively few structures survive from the Dark Ages, but the later centuries of the medieval

period were a great age of building. The Romanesque and Gothic architecture that produced the outstanding aesthetic contribution of the Middle Ages embodied significant technological innovations. The architect-engineers who had clearly studied classical building techniques, showed a readiness to depart from their models and thus to devise a style that was distinctively their own. Their solutions to the problems of constructing very tall masonry buildings while preserving as much natural light as possible were the cross-rib vault, the flying buttress, and the great window panels providing scope for the new craft of the glazier using coloured glass with startling effect.

Military technology. The same period saw the evolution of the fortified stronghold from the Anglo-Saxon motte-and-bailey, a timber tower encircled by a timber-and-earth wall, to the formidable, fully developed masonry castle that had become an anachronism by the end of the Middle Ages because of the development of artillery. Intrinsic to this innovation were the invention of gunpowder and the development of techniques for casting metals, especially iron. Gunpowder appeared in western Europe in the mid-13th century, although its formula had been known in the Far East long before that date. It consists of a mixture of carbon, sulfur, and saltpetre, of which the first two were available from charcoal and deposits of volcanic sulfur in Europe, whereas saltpetre had to be crystallized by a noxious process of boiling stable sweepings and other decaying refuse. The consolidation of these ingredients into an explosive powder had become an established yet hazardous industry by the close of the Middle Ages.

Gunpowder

The first effective cannon appear to have been made of wrought-iron bars strapped together, but although barrels continued to be made in this way for some purposes, the practice of casting cannon in bronze became widespread. The technique of casting in bronze had been known for several millennia, but the casting of cannon presented problems of size and reliability. It is likely that the bronzesmiths were able to draw on the experience of techniques devised by the bellfounders as an important adjunct to medieval church building, as the casting of a large bell posed similar problems of heating a substantial amount of metal and of pouring it into a suitable mold. Bronze, however, was an expensive metal to manufacture in bulk, so that the widespread use of cannon in war had to depend upon improvements in iron-casting techniques.

The manufacture of cast iron is the great metallurgical innovation of the Middle Ages. It must be remembered that from the beginning of the Iron Age until late in the Middle Ages the iron ore smelted in the available furnaces had not been completely reduced to its liquid form. In the 15th century, however, the development of the blast furnace achieved such a reduction, with the result that the molten metal could be poured directly into molds ready to receive it. The emergence of the blast furnace was the result of attempts to increase the size of the traditional blooms. Greater size made necessary the provision of a continuous blast of air, usually from bellows driven by a waterwheel, and the combination increased the internal temperature of the furnace so that the iron became molten. At first, the disk of cast iron left in the bottom of his furnace was regarded as undesirable waste by the iron manufacturer; it possessed properties completely unlike those of the wrought iron with which he was more familiar, being crystalline and brittle and thus of no use in the traditional iron forge. But the casting property of the new iron was soon discovered and turned to profit, particularly in the manufacture of cannon.

Transport. Medieval technology made few contributions to inland transport, though there was some experimentation in bridge building and in the construction of canals; lock gates were developed as early as 1180, when they were employed on the canal between Bruges (now in Belgium) and the sea. Roads remained indifferent where they existed at all, and vehicles were clumsy throughout the period. Wayfarers like Chaucer's pilgrims travelled on horseback, and this was to remain the best mode of inland transport for centuries to come.

Sea transport was a different story. Here the Middle Ages produced a decisive technological achievement: the creation of a reliable oceangoing ship depending entirely on wind power instead of a combination of wind and muscle. The vital steps in this evolution were, first, the combination of the traditional square sail, used with little modification from Egyptian times through the Roman Empire to the Viking long boats, with the triangular lateen sail developed in the Arab dhow and adopted in the Mediterranean, which gave it the "lateen" (Latin) association attributed to it by the northern seafarers. This combination allowed ships so equipped to sail close to the wind and thus to escape from dependence upon a following wind. Second, the adoption of the sternpost rudder gave greatly increased manoeuvrability, allowing ships to take full advantage of their improved sail power in tacking into a contrary wind. Third, the introduction of the magnetic compass provided a means of checking navigation on the open seas in any weather. The convergence of these improvements in the ships of the later Middle Ages, together with other improvements in construction and equipment—such as better barrels for carrying water, more reliable ropes, sails, and anchors, the availability of navigational charts (first recorded in use on board ship in 1270), and the astrolabe (for measuring the angle of the sun or a star above the horizon)—enabled mariners to become progressively more adventurous and thus led directly to the voyages of discovery that marked the end of the Middle Ages and the beginning of the expansion of Europe that has characterized modern times.

The lateen sail

Communications. While transport technology was preparing for these revolutionary developments, techniques of recording and communication were making no less momentous advances. The medieval interest in mechanical contrivances is well illustrated by the development of the mechanical clock, the oldest of which, driven by weights and controlled by a verge, an oscillating arm engaging with a gear wheel, and dated 1386, survives in Salisbury Cathedral, England. Clocks driven by springs had appeared by the mid-15th century, making it possible to construct more compact mechanisms and preparing the way for the portable clock. The problem of overcoming the diminishing power of the spring as it unwound was solved by the simple compensating mechanism of the fusee—a conical drum on the shaft that permitted the spring to exert an increasing moment, or tendency to increase motion, as its power declined. It has been argued that the medieval fascination with clocks reflects an increased sense of the importance of timekeeping in business and elsewhere, but it can be seen with equal justice as representing a new sense of inquiry into the possibilities and practical uses of mechanical devices.

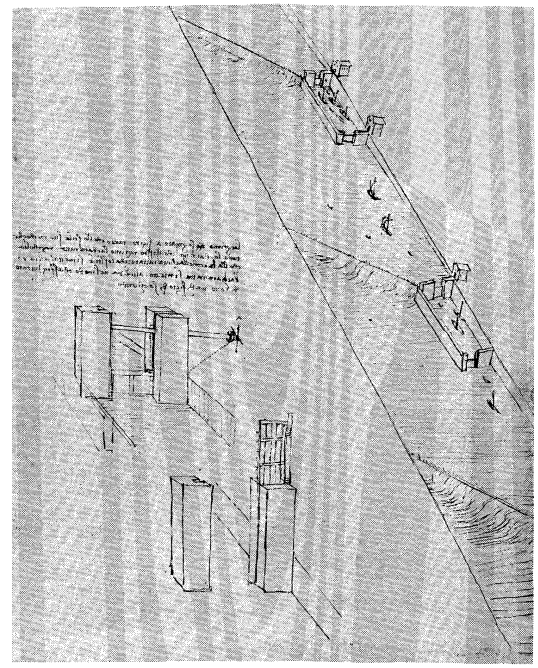
Even more significant than the invention of the mechanical clock was the 15th-century invention of printing with movable metal type. The details of this epochal invention are disappointingly obscure, but there is general agreement that the first large-scale printing workshop was that established at Mainz by Johannes Gutenberg, which was producing a sufficient quantity of accurate type to print a Vulgate Bible in 1448. It is clear, however, that this invention drew heavily upon long previous experience with block printing—using a single block to print a design or picture—and on developments in typecasting and ink making. It also made heavy demands on the paper industry, which had been established in Europe since the 12th century but which developed slowly until the invention of printing and the subsequent vogue for the printed word. The printing press itself, vital for securing a firm and even print over the whole page, was an adaptation of the screw press already familiar in the winepress and other applications. The printers found an enormous demand for their product, so that the technique spread rapidly and the printed word became an essential medium of political, social, religious, and scientific communication as well as a convenient means for the dissemination of news and information. By 1500 there were already almost 40,000 recorded editions of books printed in 14 European countries, with Germany and Italy accounting for two-thirds. Few single inventions have had such far-reaching consequences.

Printing with movable type

For all its isolation and intellectual deprivation, the new civilization that took shape in western Europe in the millennium 500 to 1500 achieved some astonishing feats of technological innovation. The intellectual curiosity which led to the foundation of the first universities in the 12th century and applied itself to the recovery of the ancient learning from whatever source it could be obtained was the mainspring also of the technological resourcefulness which encouraged the introduction of the windmill, the improvement and wider application of waterpower, the development of new industrial techniques, the invention of the mechanical clock and gunpowder, the evolution of the sailing ship, and the invention of large-scale printing. Such achievements could not have taken place within a static society. Technological innovation was both the cause and the effect of dynamic development. It is no coincidence that these achievements occurred within the context of a European society which was increasing in population and productivity, stimulating industrial and commercial activity, and expressing itself in the life of new towns and striking cultural activity. Medieval technology mirrored the aspiration of a new and dynamic civilization.

THE EMERGENCE OF WESTERN TECHNOLOGY (1500–1750)

The technological history of the Middle Ages was one of slow but substantial development. In the succeeding period the tempo of change increased markedly and was associated with profound social, political, religious, and intellectual upheavals in western Europe.



The emergence of the nation-state, the cleavage of the Christian Church by the Protestant Reformation, the Renaissance and its accompanying scientific revolution, and the overseas expansion of European states all had interactions with developing technology. The overseas expansion was made possible by the advance in naval technology which had opened up the ocean routes to Western navigators. The conversion of voyages of discovery into imperialism and colonization was made possible by the new firepower. The combination of light, manoeuvrable, ships with the firepower of iron cannon gave European adventurers a decisive advantage, enhanced by other technological assets.

Effect of the Protestant Reformation

The Reformation, not itself a factor of major significance to the history of technology, nevertheless had interactions with it; the capacity of the new printing presses to disseminate all points of view contributed to the religious upheavals, while the intellectual ferment provoked by the Reformation resulted in a rigorous assertion of the vocational character of work and thus stimulated industrial and commercial activity and technological innovation. It is an indication of the nature of this encouragement that so many of the inventors and scientists of the period were Calvinists, Puritans, and—in England—Dissenters.

The Renaissance. The Renaissance had more obviously technological content than the Reformation. The concept of "renaissance" is, however, elusive. As a "rebirth" of classical knowledge, since the scholars of the Middle Ages had already achieved a very full recovery of the literary legacy of the ancient world, the Renaissance marked rather a point of transition after which the posture of deference to the ancients began to be replaced by a consciously dynamic, progressive attitude. Even while they looked back to classical models, Renaissance men looked for ways of improving upon them. This attitude is outstandingly represented in the genius of Leonardo da Vinci. As an artist of original perception he was recognized by his contemporaries, but some of his most novel work is recorded in his notebooks and was virtually unknown in his own time. This included ingenious designs for submarines, airplanes, and helicopters and drawings of elaborate trains of gears and of the patterns of flow in liquids. The early 16th century was not yet ready for these novelties: they met no specific social need, and the resources necessary for their development were not available.

An often overlooked aspect of the Renaissance is the scientific revolution that accompanied it. As with the term Renaissance itself, the concept is complex, having to do with intellectual liberation from the ancient world. For centuries the authority of Aristotle in dynamics, of Ptolemy in astronomy, and of Galen in medicine had been taken for granted. Beginning in the 16th century their authority was challenged and overthrown, and scientists set out by observation and experiment to establish new explanatory models of the natural world. One distinctive characteristic of these models was that they were tentative, never receiving the authoritarian prestige long accorded to the ancient masters. Since this fundamental shift of emphasis, science has been committed to a progressive, forward-looking attitude and has come increasingly to seek practical applications for scientific research.

Technology performed science a service in this revolution by providing it with instruments which greatly enhanced its powers. The use of the telescope by Galileo to observe the moons of Jupiter was a dramatic example of this service, but the telescope was only one of many tools and instruments which proved valuable in navigation, map making, and laboratory experiments. More significant, however, were the services of the new sciences to technology, and by far the most important of these was the theoretical preparation for the invention of the steam engine.

The steam engine. The researches of a number of scientists, especially those of Robert Boyle of England with atmospheric pressure, of Otto von Guericke of Germany with a vacuum, and of the French Huguenot Denis Papin with pressure vessels, helped to equip practical technologists with the theoretical basis of steam power. Distressingly little is known about the manner in which this knowledge was assimilated by pioneers such as Thomas Savery and Thomas Newcomen, but it is inconceivable that they could have been ignorant of it. Savery took out a patent for a "new Invention for Raiseing of Water and occasioning Motion to all Sorts of Mill Work by the Impellent Force of Fire" in 1698 (No. 356). His apparatus depended on the condensation of steam in a vessel, creating a partial vacuum into which water was forced by atmospheric pressure.

Credit for the first commercially successful steam engine, however, must go to Newcomen, who erected his first machine near Dudley Castle in Staffordshire in 1712. It operated by atmospheric pressure on the top face of a piston in a cylinder, in the lower part of which steam was condensed to create a partial vacuum. The piston was connected to one end of a rocking beam, the other end of which carried the pumping rod in the mine shaft. New-

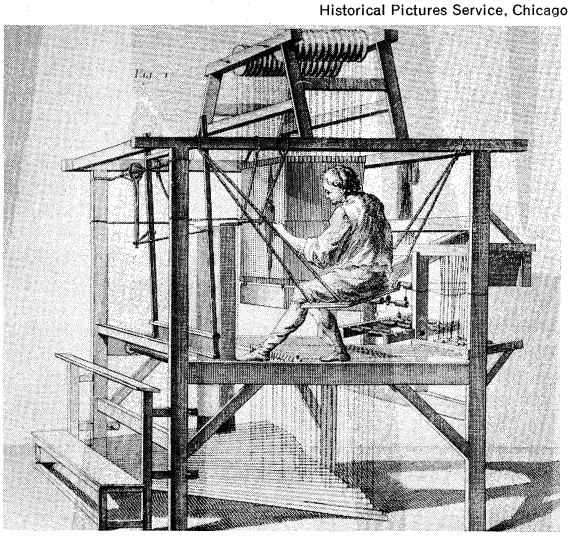
comen was a blacksmith in Dartmouth, Devon, and his engines were robust but unsophisticated. Their heavy fuel consumption made them uneconomical when used where coal was expensive, but in the British coal fields they performed an essential service by keeping deep mines clear of water and were extensively adopted for this purpose. In this way the early steam engines fulfilled one of the most pressing needs of British industry in the 18th century. Although waterpower and wind power remained the basic sources of power for industry, a new prime mover had thus appeared in the shape of the steam engine, with tremendous potential for further development as and when new applications could be found for it.

Metallurgy and mining. One cause of the rising demand for coal in Britain was the depletion of the woodland and supplies of charcoal, making manufacturers anxious to find a new source of fuel. Of particular importance were experiments of the iron industry in using coal instead of charcoal to smelt iron ore and to process cast iron into wrought iron and steel. The first success in these attempts came in 1709, when Abraham Darby, a Quaker ironfounder in Shropshire, used coke to reduce iron ore in his enlarged and improved blast furnace. Other processes, such as glass making, brick making, and the manufacture of pottery had already adopted coal as their staple fuel. Great technical improvements had taken place in all these processes. In ceramics, for instance, the long efforts of European manufacturers to imitate the hard, translucent quality of Chinese porcelain culminated in Meissen at the beginning of the 18th century and was subsequently discovered independently in Britain in the middle of the century. Stoneware, requiring a lower firing temperature than porcelain, had achieved great decorative distinction in the 17th century as a result of the Dutch success with opaque white tin glazes at their Delft potteries, and the process had been widely imitated.

In addition to mining for coal and iron, the period from 1500 to 1750 witnessed a steady expansion in other mining activities. The gold and silver mines of Saxony and Bohemia provided the inspiration for the treatise by Agricola, *De re metallica*, mentioned above, which distilled the cumulative experience of several centuries in mining and metalworking and became, with the help of some brilliant woodcuts and the printing press, a worldwide manual on mining practice. Queen Elizabeth I introduced German miners to England in order to develop the mineral resources of the country, and one result of this was the establishment of brass manufacture. This metal, an alloy of copper and zinc, had been known in the ancient world and in Eastern civilizations, but was not developed commercially in western Europe until the 17th century. Metallic zinc had still not been isolated, but brass was made successfully by alloying copper with calamine, an oxide of zinc mined in England in the Mendip Hills and elsewhere, and was worked up by hammering, annealing (a slow-cooling process to toughen the material), and wiredrawing into a wide range of household and industrial commodities. Other nonferrous metals such as tin and lead were sought out and exploited with increasing enterprise in this period, but as these frequently occurred at some distance from sources of coal, as in the case of the Cornish tin mines, the employment of Newcomen engines to assist in drainage was rarely economic, and this restricted the extent of the mining operations.



Brass manufacture

New commodities. Following the dramatic expansion of the European nations into the Indian Ocean and the New World, the commodities of these parts of the world found their way back into Europe in increasing volume. These commodities created new social habits and fashions and called for new techniques of manufacture. Tea became an important trade commodity but was soon replaced in volume and importance by the products of specially designed plantations such as sugar, tobacco, cotton, and cocoa. Sugar refining, depending on the crystallization of sugar from the syrupy molasses derived from the cane, became an important industry. So did tobacco processing, for smoking in clay pipes (produced in bulk at Delft and elsewhere) or for taking as snuff. Cotton had been known before as an Eastern plant, but its successful transplantation to the New World made much greater quantities available and stimulated the emergence of an important new textile industry.

The textile industry

The woollen cloth industry in Britain provided a model and precedent upon which the new cotton industry could build. Already in the Middle Ages, the processes of cloth manufacture had been partially mechanized with the introduction of fulling mills and the use of spinning wheels. But in the 18th century the industry remained almost entirely a domestic or cottage one, with most of the processing being performed in the homes of the workers, using comparatively simple tools that could be operated by hand or foot. The most complicated apparatus was the loom, but this could usually be worked by a single

Historical Pictures Service, Chicago

Drawloom, engraving from Diderot's *Encyclopédie*, 18th century.

weaver although the wider cloths required an assistant. It was a general practice to install the loom in an upstairs room with a long window giving maximum natural light. Weaving was regarded as a man's work, the women of the family being responsible for spinning. The weaver could use the yarn provided by up to a dozen "spinsters," and the balanced division of labour was preserved by the weaver assuming responsibility for supervising the cloth through the other processes, such as fulling. Pressures to increase the productivity of various operations had already produced some technical innova-

tions by the first half of the 18th century. The first attempts at devising a spinning machine, however, were not successful; and without this, John Kay's technically successful flying shuttle (a device for hitting the shuttle from one side of the loom to the other, dispensing with the need to pass it through by hand) did not fulfill an obvious need. It was not until the rapid rise of the cotton cloth industry that the old, balanced industrial system was seriously upset and that a new, mechanized system, organized on the basis of factory production, began to emerge.

Agriculture. Another major area that began to show signs of profound change in the 18th century was agriculture. Stimulated by greater commercial activity, the rising market for food caused by an increasing population aspiring to a higher standard of living and by the British aristocratic taste for improving estates to provide affluent and decorative country houses, the traditional agricultural system of Britain was transformed. It is important to note that this was a British development, as it is one of the indications of the increasing pressures of industrialization there even before the Industrial Revolution, while other European countries, with the exception of The Netherlands, from which several of the agricultural innovations in Britain were acquired, did little to encourage agricultural productivity. The nature of the transformation was complex, and it was not completed until well into the 19th century. It consisted partly of a legal re-allocation of land ownership, the "enclosure" movement, to make farms more compact and economical to operate. In part also it was brought about by the increased investment in farming improvements, because the landowners felt encouraged to invest money in their estates instead of merely drawing rents from them. Again, it consisted of using this money for technical improvements, taking the form of machinery—such as Jethro Tull's mechanical sower—of better drainage, of scientific methods of breeding to raise the quality of livestock, and of experimenting with new crops and systems of crop rotation. The process has often been described as an agricultural revolution, but it is preferable to regard it as an essential prelude to and part of the Industrial Revolution.

Construction. Construction techniques did not undergo any great change in the period 1500–1750. The practice of building in stone and brick became general, although timber remained an important building material for roofs and floors, and, in areas in which stone was in short supply, the half-timbered type of construction retained its popularity into the 17th century. Thereafter, however, the spread of brick and tile manufacturing provided a cheap and readily available subsititute, although it suffered an eclipse on aesthetic grounds in the 18th century when classical styles enjoyed a vogue and brick came to be regarded as inappropriate for facing such buildings. Brick making, however, had become an important industry for ordinary domestic building by then and, indeed, entered into the export trade as Dutch and Swedish ships regularly carried brick as ballast to the New World, providing a valuable building material for the early American settlements. Cast iron was beginning to be used in buildings, but only for decorative purposes. Glass was also beginning to become an important feature of buildings of all sorts, encouraging the development of an industry that still relied largely on ancient skills of fusing sand to make glass and blowing, molding, and cutting it into the shapes required.

Brick and tile manufacture

Land reclamation. More substantial constructional techniques were required in land drainage and military fortification, although again their importance is shown rather in their scale and complexity than in any novel features. The Dutch, wrestling with the sea for centuries, had devised extensive dikes; their techniques were borrowed by English land owners in the 17th century in an attempt to reclaim tracts of fenlands.

Military fortifications. In military fortification, the French strongholds designed by Sébastien de Vauban in the late 17th century demonstrated how warfare had adapted to the new weapons and, in particular, to heavy artillery. With earthen embankments to protect their salients, these star-shaped fortresses were virtually impregnable to the assault weapons of the day. Firearms remained cumbersome, with awkward firing devices and slow reloading. The quality of weapons improved somewhat with increasing skill by the gunsmiths.

Transport and communications. Like constructional techniques, transport and communications made substantial progress without any great technical innovations. Road building was greatly improved in France, and, with the completion of the Languedoc Canal between the Mediterranean and the Bay of Biscay in 1692, large-scale civil engineering achieved an oustanding success. The canal is 500 miles (240 kilometres) long, with a hundred locks, a tunnel, three major aqueducts, many culverts, and a large summit reservoir.

The Languedoc Canal

The sea remained the greatest highway of commerce, stimulating innovation in the sailing ship. The Elizabethan galleon with its great manoeuvrability and firepower, the Dutch herring *busses* and *fluitschips* with their commodious hulls and shallow draft, the versatile East Indiamen of both the Dutch and the British East India companies, and the mighty ships of the line produced for the French and British navies in the 18th century, indicate some of the main directions of evolution.

The needs of reliable navigation created a demand for better instruments. The quadrant was improved by conversion to the octant, using mirrors to align a star with the horizon and to measure its angle more accurately: with further refinements this evolved as the modern sextant. Even more significant was the ingenuity shown by scientists and instrument makers in the construction of a clock that would keep accurate time at sea: such a clock, by showing the time in Greenwich when it was noon aboard ship would show how far east or west of Greenwich the ship lay (longitude). A prize of £20,000 was offered by the British Board of Longitude for this purpose in 1714, but it was not awarded until 1762 when John Harrison's so-called No. 4 chronometer fulfilled all the requirements.

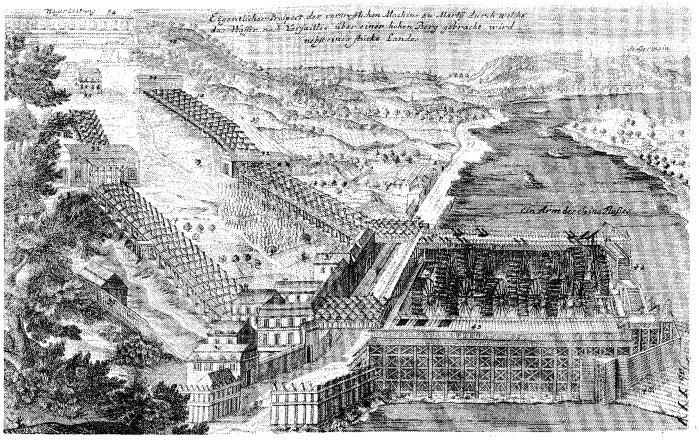
Chemistry. Robert Boyle's contribution to the theory of steam power has been mentioned, but Boyle's main claim to fame is as the "father of chemistry," in which field he was responsible for the recognition of an element as a material that cannot be resolved into other substances. It was not until the end of the 18th and the beginning of the 19th century, however, that the work of Antoine Lavoisier and John Dalton put modern chemical science on a firm theoretical basis. Chemistry was still struggling to free itself from the traditions of alchemy. Even alchemy was not without practical applications, for it promoted experiments with materials and led to the development of specialized laboratory equipment that was used in the manufacture of dyes, cosmetics, and certain pharmaceutical products. For the most part, pharmacy still relied upon recipes based on herbs and other natural products, but the systematic preparation of these eventually led to the discovery of useful new drugs.

The period from 1500 to 1750 witnessed the emergence of Western technology in the sense that the superior techniques of Western civilization enabled the nations that comprised it to expand their influence over the whole known world. Yet, with the exception of the steam engine, this was not an outstanding period of technological innovation. What was, perhaps, more important than any particular innovation was the evolution, however faltering and partial and limited to Britain in the first place, of a technique of innovation, or what has been called "the invention of invention." The creation of a political and social environment conducive to invention, the building up of vast commercial resources to support inventions likely to produce profitable results, the exploitation of mineral, agricultural, and raw material resources for industrial purposes, and, above all, the recognition of specific needs for invention and an unwillingness to be defeated by them, together produced a society ripe for an industrial revolution based on technological innovation. The technological achievements of the period 1500–1750, therefore, must be judged in part by their substantial contribution to the spectacular innovations of the following period.

Emergence of Western technology

III. The Industrial Revolution (1750–1900)

The term Industrial Revolution, like similar historical concepts, is more convenient than precise. It is convenient because history requires division into periods for purposes of understanding and instruction and because there were sufficient innovations at the turn of the 18th and 19th centuries to justify the choice of this as one of the periods. The term is imprecise, however, because the Industrial Revolution has no clearly defined beginning or end. Moreover, it is misleading if it carries the implication of a once-for-all change from a "pre-industrial" to a "post-industrial" society, because, as has been seen, the events of the traditional Industrial Revolution had been well prepared in a mounting tempo of industrial, commercial, and technological activity from about AD 1000 and led into a continuing acceleration of the processes of industrialization that is still proceeding in our own time. The term Industrial Revolution must thus be employed with some care. It is used below to describe an extraordinary quickening in the rate of growth and change, and more particularly, to describe the first 150 years of this period of time, as it will be convenient to pursue the developments of the present century separately.

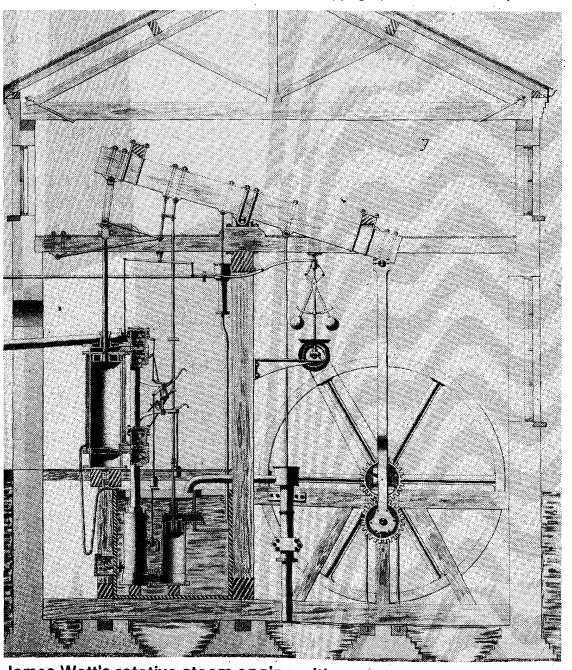


Spread of the Industrial Revolution

The Industrial Revolution, in this sense, has been a worldwide phenomenon, at least in so far as it has occurred in all those parts of the world, of which there are very few exceptions, where the influence of Western civilization has been felt. Beyond any doubt it occurred first in Britain, and its effects spread only gradually to continental Europe and North America. Equally clearly, the Industrial Revolution that eventually transformed these parts of the Western world surpassed in magnitude the achievements of Britain, and the process was carried further to change radically the socio-economic life of the Far East, Africa, Latin America, and Australasia. The reasons for this succession of events are complex, but they were implicit in the earlier account of the buildup toward rapid industrialization. Partly through good fortune and partly through conscious effort, Britain by the early 18th century came to possess the combination of social needs and social resources that provided the necessary preconditions of commercially successful innovation and a social system capable of sustaining and institutionalizing the processes of rapid technological change once they had started. This section will thus be concerned, in the first place, with events in Britain, although as the period develops it will be necessary to trace the way in which British technical achievements were diffused and superseded in other parts of the Western world.

POWER TECHNOLOGY

An outstanding feature of the Industrial Revolution has been the advance in power technology. At the beginning of this period, the major sources of power available to industry and any other potential consumer were animate energy and the power of wind and water, the only exception of any significance being the atmospheric steam engines which had been installed for pumping purposes, mainly in coal mines. It is to be emphasized that this use of steam power was exceptional and remained so for most industrial purposes until well into the 19th century. Steam did not simply replace other sources of power: it transformed them. The same sort of scientific inquiry that led to the development of the steam engine was also applied to the traditional sources of inanimate energy, with the result that both waterwheels and windmills improved in design and efficiency. A number of engineers contributed to the refinement of waterwheel construction, and by the middle of the 19th century new designs made possible increases in the speed of revolution of the waterwheel and thus prepared the way for the emergence of the water turbine, which is still an extremely efficient method of producing power.



Windmills. Meanwhile, British windmill construction was improved considerably by the refinements of sails and by the self-correcting device of the fantail, which kept the sails pointed into the wind. Spring sails replaced the traditional canvas rig of the windmill with the equivalent of a modern venetian blind, the shutters of which could be opened or closed, to let the wind pass through or to provide a surface for its pressure. Sail design was further improved with the "patent" sail in 1807. In mills equipped with these sails, the shutters were controlled on all the sails simultaneously by a lever inside the mill connected by rod linkages through the windshaft with the bar operating the movement of the shutters on each sweep. The control could be made more fully automatic by hanging weights on the lever in the mill to determine the maximum wind pressure beyond which the shutters would open and spill the wind. Conversely, counterweights could be attached to keep the shutters in the open position. With these and other modifications, British windmills adapted to the increasing demands on power technology. But the use of wind power declined sharply in the 19th century with the spread of steam and the increasing scale of power utilization. Windmills that had satisfactorily provided power for small-scale industrial processes were unable to compete with the production of large-scale steam-powered mills.

Waterwheels driven by the force of the river current activate a system of pumps to provide an inland water supply. Engraving from Jakob Leupold's *Theatrum Machinarum*, 1724–39.

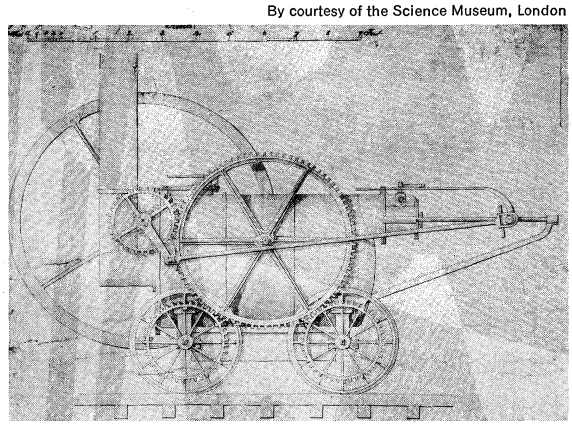
Steam engines. Although the qualification regarding older sources of power is important, steam became the characteristic and ubiquitous power source of the British Industrial Revolution. Little development took place in the Newcomen atmospheric engine until James Watt patented a separate condenser in 1769, but from that point

British Crown copyright, Science Museum, London

James Watt's rotative steam engine with sun-and-planet gear, original drawing, 1788. In the Science Museum, London.



Watt's separate condenser

onward the steam engine underwent almost continuous improvements for over a century. Watt's separate condenser was the outcome of his work on a model of a Newcomen engine which was being used in a University of Glasgow laboratory. Watt's inspiration was to separate the two actions of heating the cylinder with hot steam and cooling it to condense the steam for every stroke of the engine. By keeping the cylinder permanently hot and the condenser permanently cold, a great economy on energy used could be effected. This brilliantly simple idea could not be immediately incorporated in a full-scale engine because the engineering of such machines had hitherto been crude and defective. It needed the backing of a Birmingham industrialist, Matthew Boulton, with his resources of capital and technical competence, to convert the idea into a commercial success. Between 1775 and 1800, the period over which Watt's patents were extended, the Boulton and Watt partnership produced some 500 engines, which despite their high cost in relation to a Newcomen engine were eagerly acquired by the tin-mining industrialists of Cornwall and other power users who badly needed a more economic and reliable source of energy.

During the quarter of a century in which Boulton and Watt exercised their virtual monopoly over the manufacture of improved steam engines, they introduced many important refinements. Basically they converted the engine from a single-acting (*i.e.*, applying power only on the downward stroke of the piston) atmospheric pumping machine into a versatile prime mover that was double acting and could be applied to rotary motion, thus driving the wheels of industry. The rotary action engine was quickly adopted by British textile manufacturer Sir Richard Arkwright for use in a cotton mill, and although the ill-fated Albion Mill, at the southern end of Blackfriars Bridge in London, was burned down in 1791 when it had only been in use for five years and was still incomplete, it demonstrated the feasibility of applying steam power to large-scale grain milling. Many other industries followed in exploring the possibilities of steam power, and it soon became widely used.

Watt's patents had the temporary effect of restricting the development of high-pressure steam, necessary in such major power applications as the locomotive. This development came quickly once his patents lapsed in 1800. The Cornish engineer Richard Trevithick introduced higher steam pressures, achieving an unprecedented pressure of 145 pounds per square inch (ten kilograms per square centimetre) in 1802 with an experimental engine at Coalbrookdale, which worked safely and efficiently. Almost

By courtesy of the Science Museum, London

Trevithick steam locomotive, drawing by an unknown artist. In the Science Museum, London.

simultaneously, the versatile American engineer Oliver Evans built the first high-pressure steam engine in the United States, using, like Trevithick, a cylindrical boiler with an internal fire plate and flue. High-pressure steam engines rapidly became popular in America, partly as a result of Evans' initiative and partly because very few Watt-type low-pressure engines crossed the Atlantic. Trevithick quickly applied his engine to a locomotive vehicle, making the first successful steam locomotive for the Penydarren tramroad in South Wales in 1804. The success, however, was technological rather than commercial because the locomotive fractured the cast iron track of the tramway: the age of the railroad had to await further development both of the permanent way and of the locomotive.

First steam locomotive

Meanwhile, the stationary steam engine advanced steadily to meet an ever-widening market of industrial requirements. High-pressure steam led to the development of the large beam pumping engines with a complex sequence of valve actions, which became universally known as Cornish engines; their distinctive characteristic was the cutoff of steam injection before the stroke was complete in order to allow the steam to do work by expanding. These engines were used all over the world for heavy pumping duties, often being shipped out and installed by Cornish engineers. Trevithick himself spent many years improving pumping engines in Latin America. Cornish engines, however, were probably thickest on the ground in Cornwall itself, where they were used in large numbers in the tin and copper mining industries.

Another consequence of high-pressure steam was the practice of compounding, of using the steam twice or more at descending pressures before it was finally condensed or exhausted. The technique was first applied by Arthur Woolf, a Cornish mining engineer, who by 1811 had produced a very satisfactory and efficient compound beam engine with a high-pressure cylinder placed alongside the low-pressure cylinder, with both piston rods attached to the same pin of the parallel motion, which was a parallelogram of rods connecting the piston to the beam, patented by Watt in 1784. In 1845 John McNaught introduced an alternative form of compound beam engine, with the high-pressure cylinder on the opposite end of the beam from the low-pressure cylinder, and working with a shorter stroke. This became a very popular design. Various other methods of compounding steam engines were adopted and the practice became increasingly widespread, until in the second half of the 19th century triple- or quadruple-expansion engines were being used in industry and marine propulsion. By this time also the conventional beam-type vertical engine adopted by Newcomen and retained by Watt began to be replaced by horizontal-cylinder designs. Beam engines remained in use for some purposes until the eclipse of the reciprocating steam engine in the 20th century, and other types of vertical engine remained popular, but for both large and small duties the engine designs with horizontal cylinders became by far the most common.

A demand for power to generate electricity stimulated new thinking about the steam engine in the 1880s. The problem was that of achieving a sufficiently high speed of revolutions to make the dynamos function efficiently. Such speeds were beyond the range of the normal reciprocating engine (*i.e.*, with a piston moving backward and forward in a cylinder). Designers began to investigate the possibilities of radical modifications to the reciprocating engine to achieve the speeds desired, or of devising a steam engine working on a completely different principle. In the first category, one solution was to enclose the working parts of the engine and force a lubricant around them under pressure. The Willans engine design, for instance, was of this type and was widely adopted in early British power stations. Another important modification in the reciprocating design was the uniflow engine, which increased efficiency by exhausting steam from ports in the centre of the cylinder instead of requiring it to change its direction of flow in the cylinder with every movement of the piston. Full success in achieving a high-speed steam engine, however, depended on the steam turbine, a design of such novelty that it constituted a major technological innovation. This was invented by Sir Charles Parsons in 1884. By passing steam through the blades of a series of rotors of gradually increasing size (to allow for the expansion of the steam) the energy of the steam was converted to very rapid circular motion, which was ideal for generating electricity. Many refinements have since been made in turbine construction and the size of turbines has

Invention of the steam turbine

been vastly increased, but the basic principles remain the same and this method still provides the main source of electric power except in those areas in which the mountainous terrain permits the economic generation of hydroelectric power from water turbines. Even the most modern nuclear power plants use steam turbines because technology has not yet solved the problem of transforming nuclear energy directly into electricity. In marine propulsion, too, the steam turbine remains an important source of power despite competition from the internal-combustion engine.

Electricity. The development of electricity as a source of power preceded this conjunction with steam power late in the 19th century. The pioneering work had been done by an international collection of scientists including Benjamin Franklin of the U.S., Alessandro Volta of the University of Bologna, Italy, and Michael Faraday of Britain. It was the latter who had demonstrated the nature of the elusive relationship between electricity and magnetism in 1831, and his experiments provided the point of departure for both the mechanical generation of electric current, previously available only from chemical reactions within voltaic piles or batteries, and the utilization of such current in electric motors. Both the mechanical generator and the motor depend on the rotation of a continuous coil of conducting wire between the poles of a strong magnet: turning the coil produces a current in it, while passing a current through the coil causes it to turn. Both generators and motors underwent substantial development in the middle decades of the 19th century. In particular, French, German, Belgian, and Swiss engineers evolved the most satisfactory forms of armature (the coil of wire) and produced the dynamo which made the large-scale generation of electricty commercially feasible.

The next problem was that of finding a market. In Britain, with its now well-established tradition of steam power, coal, and coal gas, such a market was not immediately obvious. But in continental Europe and North America there was more scope for experiment. In the United States the inventive genius of Thomas Edison was applied to finding fresh uses for electricity, and his invention of the carbon-filament lamp showed how this form of energy could rival gas as a domestic illuminant. The problem here had been that electricity had been used successfully for large installations such as lighthouses in which arc lamps had been powered by generators on the premises, but no way of subdividing the electric light into many small units had been devised. The principle of the filament lamp was that a thin conductor could be made incandescent by an electric current provided that it was sealed in a vacuum which prevented it from burning out. The U.S. inventor Thomas A. Edison and the English chemist Sir Joseph Swan experimented with various materials for the filament and both chose a carbon substance. The result was a highly successful small lamp, which could be varied in size for any sort of requirement. It is relevant that the success of the carbon-filament lamp did not immediately mean the supersession of gas lighting. Coal gas had first been used for lighting by William Murdock at his home in Redruth, Cornwall, where he was the agent for the Boulton and Watt company, in 1792. When he moved to the headquarters of the firm at Soho in Birmingham in 1798, Matthew Boulton authorized him to experiment in lighting the buildings there by gas, and gas lighting was subsequently adopted by firms and towns all over Britain in the first half of the 19th century. Lighting was normally by a fishtail jet of burning gas, but under the stimulus of competition from electric lighting the quality of gas lighting was greatly improved by the invention of the gas mantle. Thus improved, gas lighting remained popular for some forms of street lighting until the middle of the present century.

Development of the electric light

Lighting alone could not provide an economical market for elecricity because its use was confined to the hours of darkness. Successful commercial generation depended upon the development of other uses for electricity, and particularly on electric traction. The popularity of urban electric tramways and the adoption of electric traction on subway systems such as the London Underground thus coincided with the widespread construction of generating equipment in the late 1880s and 1890s. The subsequent spread of this form of energy is one of the most remarkable technological success stories of the 20th century, but most of the basic techniques of generation, distribution, and utilization had been mastered by the end of the 19th century.

Internal-combustion engine. Electricity does not constitute a prime mover, for however important it may be as a form of energy it has to be derived from a mechanical generator powered by water, steam, or internal combustion. The internal-combustion engine is a prime mover, and it emerged in the 19th century as a result both of greater scientific understanding of the principles of thermodynamics and a search by engineers for a substitute for steam power in certain circumstances. In an internal-combustion engine the fuel is burned in the engine: the cannon provided an early model of a single-stroke engine; and several persons had experimented with gunpowder as a means of driving a piston in a cylinder. The major problem was that of finding a suitable fuel, and the secondary problem was that of igniting the fuel in an enclosed space to produce an action that could be easily and quickly repeated. The first problem was solved in the mid-19th century by the availability of town gas supplies, but the second problem proved more intractable as it was difficult to maintain ignition evenly. The first successful gas engine was made by Étienne Lenoir in Paris in 1859. It was modelled closely on a horizontal steam engine, with an explosive mixture of gas and air ignited by an electric spark on alternate sides of the piston when it was in midstroke position. Although technically operational, the running costs of the engine were high, and it was not until the refinement introduced by the German inventor Nikolaus Otto in 1878 that the gas engine became a commercial success. Otto adopted the four-stroke cycle of induction–compression–firing–exhaust that has been known by his name ever since. Gas engines became extensively used for small industrial establishments which could thus dispense with the upkeep of a boiler necessary in any steam plant, however small.

The Otto cycle

Petroleum. The economic potential for the internal-combustion engine lay in the need for a light locomotive engine. This could not be provided by the gas engine, depending on a piped supply of town gas, any more than by the steam engine, with its need for a cumbersome boiler; but, by using alternative fuels derived from oil, the internal-combustion engine took to wheels, with momentous consequences. Bituminous deposits had been known in Southwest Asia from antiquity and had been worked as building material, illuminants, and for medicinal products. The westward expansion of settlement in America, with many homesteads beyond the range of city gas supplies, promoted the exploitation of the easily available sources of crude oil for the manufacture of kerosene (paraffin). In 1859 the oil industry took on new significance when Edwin L. Drake bored successfully through 70 feet (21 metres) of rock to strike oil in Pennsylvania, thus inaugurating the search for and exploitation of the deep oil resources of the world. While world supplies of oil expanded dramatically, the main demand was at first for the kerosene, the middle fraction distilled from the raw material, which was used as the fuel in oil lamps. The most volatile fraction of the oil, petroleum, remained an embarrassing waste product until it was discovered that this could be burned in a light internal-combustion engine; the result was an ideal prime mover for vehicles. The way was prepared for this development by the success of oil engines burning cruder fractions of oil. Kerosene-burning oil engines, modelled closely on existing gas engines, had emerged in the 1870s, and by the late 1880s engines using the vapour of heavy oil in a jet of compressed air and working on the Otto cycle had become an attractive proposition for light duties in places too isolated to use town gas.

The diesel engine

The greatest refinements in the heavy-oil engine are associated with the work of Rudolf Diesel of Germany, who took out his first English patent in 1892. Working from thermodynamic principles of avoiding heat losses as

much as possible, Diesel devised an engine in which the very high compression of the air in the cylinder secured the spontaneous ignition of the oil when it was injected in a carefully determined quantity. This ensured high thermal efficiency, but it also made necessary a heavy structure because of the high compression maintained, and also a rather rough performance at low speeds compared with other oil engines. It was therefore not immediately suitable for locomotive purposes, but Diesel went on improving his engine and in the 20th century it became an important form of vehicular propulsion.

Meantime the light high-speed gasoline (petrol) engine predominated. The first applications of the new engine to locomotion were made in Germany, where Gottlieb Daimler and Carl Benz equipped the first motorcycle and the first motorcar respectively with engines of their own design in 1885. Benz's "horseless carriage" became the prototype of the modern automobile, the development and consequences of which can be more conveniently considered in relation to the revolution in transport.

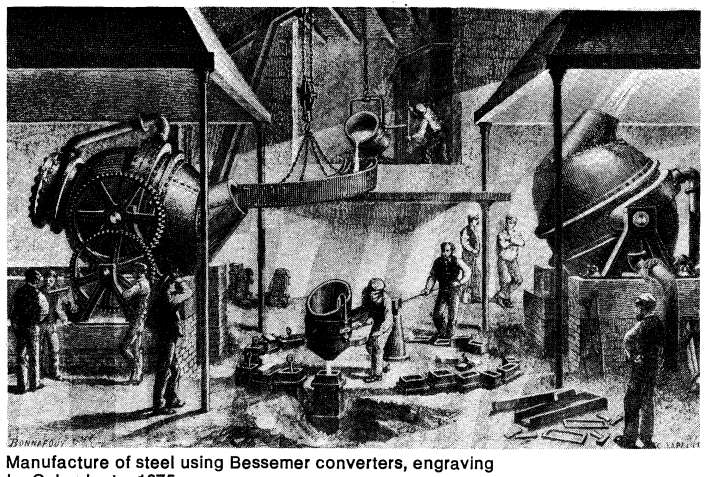
By the end of the 19th century, the internal-combustion engine was challenging the steam engine in many industrial and transport applications. It is notable that, whereas the pioneers of the steam engine had been almost all Britons, most of the innovators in internal combustion were continental Europeans and Americans. The transition, indeed, reflects the general change in international leadership in the Industrial Revolution, with Britain being gradually displaced from its position of unchallenged superiority in industrialization and technological innovation. A similar transition occurred in the theoretical understanding of heat engines: it was the work of the Frenchman Sadi Carnot and other scientific investigators which led to the new science of thermodynamics, rather than that of the British engineers who had most practical experience of the engines on which the science was based.

It should not be concluded, however, that British innovation in prime movers was confined to the steam engine, or even that steam and internal combustion represent the only significant developments in this field during the Industrial Revolution. Rather, the success of these machines stimulated speculation about alternative sources of power, and in at least one case achieved a success the full consequences of which were not fully developed. This

The hot-air engine

was the hot-air engine, for which a Scotsman, Robert Stirling, took out a patent in 1817. The hot-air engine depends for its power on the expansion and displacement of air inside a cylinder, heated by the external and continuous combustion of the fuel. Even before the exposition of the laws of thermodynamics, Stirling had devised a cycle of heat transfer that was ingenious and economical. Various constructional problems limited the size of hot-air engines to very small units, so that although they were widely used for driving fans and similar light duties before the availability of the electric motor, they did not assume great technological significance. But the economy and comparative cleanness of the hot-air engine were making it once more the subject of intensive research in the early 1970s.

The transformation of power technology in the Industrial Revolution had repercussions throughout industry and society. In the first place, the demand for fuel stimulated the coal industry, which had already grown rapidly by the beginning of the 18th century, into continuing expansion and innovation. The steam engine, which enormously increased the need for coal, contributed significantly toward obtaining it by providing more efficient mine pumps and, eventually, improved ventilating equipment. Other inventions such as that of the miners' safety lamp helped to improve working conditions, although the immediate consequence of its introduction in 1816 was to persuade mine owners to work dangerous seams, which had hitherto been regarded as inaccessible. The principle of the lamp was that the flame from the wick of an oil lamp was enclosed within a cylinder of wire gauze through which insufficient heat passed to ignite the explosive gas (firedamp) outside. It was subsequently improved, but remained a vital source of light in coal mines until the advent of electric battery lamps. With these improvements, together with the simultaneous revolution in the transport system, British coal production increased steadily throughout the 19th century. The other important fuel for the new prime movers was oil, and the rapid expansion of oil production has already been mentioned. In the hands of John D. Rockefeller and his Standard Oil organization it grew into a vast undertaking in the United States after the end of the Civil War, but the oil-extraction industry was not so well organized elsewhere until the 20th century.



DEVELOPMENT OF INDUSTRIES

Metallurgy. Another industry that interacted intimately with the power revolution was that concerned with metallurgy and the metal trades. The development of iron and steel techniques was one of the outstanding British achievements of the Industrial Revolution. The essential characteristic of this achievement was that by converting the iron and steel industry from dependence upon charcoal to coal as a fuel it enormously increased the production of these metals. It also provided another incentive to coal production and made available the materials that were indispensable for the construction of steam engines and every other sophisticated form of machine. The transformation that began with a coke-smelting process in 1709 was carried further by the development of crucible steel in 1744 and by the puddling and rolling process to produce wrought iron in 1784. The first development led to high quality cast steel by fusion of the ingredients (wrought iron and charcoal, in carefully measured proportions) in sealed ceramic crucibles that could be heated in a coal-fired furnace. The second applied the principle of the reverberatory furnace, whereby the hot gases passed over the surface of the metal being heated rather than through it, thus greatly reducing the risk of contamination by impurities in the coal fuels, and the discovery that by puddling, or stirring, the molten metal and by passing it hot from the furnace to be hammered and rolled, the metal could be consolidated and the conversion of cast iron to wrought iron made completely effective.

Use of coal in iron and steel industry

Iron and steel. The result of this series of innovations was that the British iron and steel industry was freed from its reliance upon the forests as a source of charcoal and was encouraged to move toward the major coal fields. Abundant cheap iron thus became an outstanding feature of the early stages of the Industrial Revolution in Britain. Cast iron was available for bridge construction, for the framework of fireproof factories, and for other civil-engineering purposes such as Thomas Telford's dramatic cast-iron aqueducts. Wrought iron was available for all manner of mechanical devices requiring strength and precision. Steel remained a comparatively rare metal until the second half of the 19th century, when the situation was transformed by the Bessemer and Siemens processes for manufacturing steel in bulk. Henry Bessemer

The Bettmann Archive

Manufacture of steel using Bessemer converters, engraving by C. Laplante, 1875.

The Bessemer converter

took out the patent for his converter in 1856. It consisted of a large vessel charged with molten iron, through which cold air was blown. There was a spectacular reaction resulting from the combination of impurities in the iron with oxygen in the air, and when this subsided it left mild steel in the converter. Bessemer was virtually a professional inventor with little previous knowledge of the iron and steel industry; his process was closely paralleled by that of the American iron manufacturer William Kelly, who was prevented by bankruptcy from taking advantage of his invention. Meanwhile, the Siemens–Martin open-hearth process was introduced in 1863, utilizing the hot waste gases of cheap fuel to heat a regenerative furnace, with the initial heat transferred to the gases circulating round the large hearth in which the reactions within the molten metal could be carefully controlled to produce steel of the quality required. The open-hearth process was gradually refined and by the end of the 19th century had overtaken the Bessemer process in the amount of steel produced. The effect of both these processes was to make steel available in bulk instead of small-scale ingots of cast crucible steel, and henceforward steel steadily replaced wrought iron as the major commodity of the iron and steel industry.

Low-grade ores. The transition to cheap steel did not take place without technical problems, one of the most difficult of which was the fact that most of the easily available low-grade iron ores in the world contain a proportion of phosphorus, which proved difficult to eliminate but which ruined any steel produced from it. The problem was solved by the British scientists S.G. Thomas and Percy Gilchrist, who invented the basic slag process, the principle of which was that by lining the furnace or converter with an alkaline material the phosphorus could be made to combine with it to produce a basic slag, which turned out to be an important by-product in the nascent artificial-fertilizer industry. The most important effect of this innovation was to make the extensive phosphoric ores of Lorraine and elsewhere available for exploitation. Among other things, therefore, it contributed significantly to the rise of the German heavy iron and steel industry in the Ruhr. Other improvements were made in British steel production in the late 19th century, particulary in the discovery of alloys for specialized purposes, but these contributed more to the quality than the quantity of steel and did not affect the shift away from Britain to continental Europe and North America of dominance in this industry. British production continued to increase, but by 1900 it had been overtaken by that of the United States and Germany.

Mechanical engineering. Closely linked with the iron and steel industry was the rise of mechanical engineering, brought about by the demand for steam engines and other large machines, and taking shape for the first time in the Soho workshop of Boulton and Watt in Birmingham, where the skills of the precision engineer, developed in manufacturing scientific instruments and small arms, were first applied to the construction of large industrial machinery. The engineering workshops that matured in the 19th century played a vital part in the increasing mechanization of industry and transport. Not only did they deliver the looms, locomotives, and other hardware in steadily growing quantities, but they also transformed the machine tools on which these machines were made. The lathe became an all-metal, power-driven machine with a completely rigid base and a slide-rest to hold the cutting tool, capable of more sustained and vastly more accurate work than the hand or foot operated wooden-framed lathes which preceded it. Drilling and slotting machines, milling and planing machines, and a steam hammer invented by James Nasmyth, an inverted vertical steam engine with the hammer on the lower end of the piston rod, were among the machines devised or improved from earlier woodworking models by the new mechanical engineering industry. After the middle of the 19th century, specialization within the industry became more pronounced, as some manufacturers concentrated on vehicle production while others devoted themselves to the particular needs of industries such as coal mining, paper-making, and sugar refining. This movement toward greater specialization was accelerated by the establishment of mechanical engineering in the other industrial nations, especially in Germany, where electrical engineering and other new skills made rapid progress, and in the United States, where labour shortages encouraged the development of standardization and mass-production techniques in fields as widely separated as agricultural machinery, small arms, typewriters, and sewing machines. Even before the coming of the bicycle, the automobile, and the airplane, therefore, the pattern of the modern engineering industry had been clearly established. The dramatic increases in engineering precision, represented by the machine designed by British mechanical engineer Sir Joseph Whitworth in 1856 for measuring to an accuracy of 0.00001 of an inch (even though such refinement was not necessary in everyday workshop practice), and the corresponding increase in the productive capacity of the engineering industry, acted as a continuing encouragement to further mechanical innovation.

Improvements in machine tools

Textiles. The industry that, probably more than any other, gave its character to the British Industrial Revolution was the cotton-textile industry. The traditional dates of the Industrial Revolution bracket the period in which the processes of cotton manufacture in Britain were transformed from those of a small-scale domestic industry scattered over the towns and villages of the South Pennines into those of a large-scale, concentrated, power-driven, mechanized, factory-organized, urban industry. The transformation was undoubtedly dramatic both to contemporaries and to posterity, and there is no doubting its immense significance in the overall pattern of British industrialization. But its importance in the history of technology should not be exaggerated. Certainly there were many interesting mechanical improvements, at least at the beginning of the transformation. The development of the spinning wheel into the spinning jenny, and the use of rollers and moving trolleys to mechanize spinning in the shape of the frame and the mule, respectively, initiated a drastic rise in the productivity of the industry. But it could be maintained that these were secondary innovations in the sense that there were precedents for them in the experiments of the previous generation; that in any case the first British textile factory was the Derby silk mill built by the Lombe brothers in 1719; and that the most far-reaching innovation in cotton manufacture was the introduction of steam power to drive carding machines, spinning machines, power looms, and printing machines. This, however, is probably to overstate the case, and the cotton innovators should not be deprived of credit for their enterprise and ingenuity in transforming the British cotton industry and making it the model for subsequent exercises in industrialization. Not only was it copied, belatedly and slowly, by the woollen-cloth industry in Britain, but wherever other nations sought to industrialize they tried to acquire the expertise of British cotton industrialists and artisans and British cotton machinery.

Importance of the British cotton industry

One of the important consequences of the rapid rise of the British cotton industry was the dynamic stimulus which it gave to other processes and industries. The rising demand for raw cotton, for example, encouraged the plantation economy of the Southern states of the U.S. and the introduction of the cotton gin, an important contrivance for separating mechanically the cotton wool from the seeds and stem of the plant.

Chemicals. In Britain, it brought a sudden increase of interest in the chemical industry, because one formidable bottleneck in the production of textiles was the long time taken by natural bleaching techniques, relying on sunlight, rain, sour milk, and urine. The modern chemical industry was virtually called into being to develop more rapid bleaching techniques for the British cotton industry. Its first success came in the middle of the 18th century, when John Roebuck invented the method of mass producing sulfuric acid in lead chambers. The acid was used directly in bleaching, but it was also used in the production of more effective chlorine bleaches, and in the manufacture of bleaching powder, a process perfected by Charles Tennant at his St. Rollox factory in

Glasgow in 1799. This effectively met the requirements of the cotton-textile industry, and thereafter the chemical industry turned its attention to the needs of other industries, and particularly to the increasing demand for alkali in soap, glass, and a range of other manufacturing processes. The result was the successful establishment of the Leblanc soda process, invented by Nicolas Leblanc in France in 1791, for manufacturing sodium carbonate (soda) on a large scale; this remained the main alkali process in Britain until the end of the 19th century, even though the Belgian Solvay process, considerably more economical, was replacing it elsewhere.

Innovation in the chemical industry shifted, in the middle of the 19th century, from the heavy chemical processes to organic chemistry. The stimulus here was less a specific industrial demand than the pioneering work of a group of German scientists on the nature of coal and its derivatives. Following their work, W.H. Perkin, at the Royal College of Chemistry in London, produced the first artificial dye from aniline in 1856. In the same period, the middle third of the 19th century, work on the qualities of cellulosic materials was leading to the development of high explosives such as nitrocellulose, nitroglycerine, and dynamite, while experiments with the solidification and extrusion of cellulosic liquids were producing the first plastics, such as celluloid, and the first artificial fibres, so-called artificial silk, or rayon. By the end of the century all these processes had become the bases for large chemical industries.

An important by-product of the expanding chemical industry was the manufacture of a widening range of medicinal and pharmaceutical materials as medical knowledge increased and drugs began to play a constructive part in therapy. The period of the Industrial Revolution witnessed the first real progress in medical services since the ancient civilizations. Great advances in the sciences of anatomy and physiology had had remarkably little impact on medical practice. In 18th-century Britain, however, hospital provision increased in quantity although not invariably in quality, while a significant start was made in immunizing people against smallpox culminating in Edward Jenner's vaccination process of 1796, by which protection from the disease was provided by administering a dose of the much less virulent but related disease of cowpox. But it took many decades of use and further smallpox epidemics to secure its widespread adoption and thus to make it effective in controlling the disease. By this time Louis Pasteur and others had established the bacteriological origin of many common diseases and thereby helped to promote movements for better public health and immunization against many virulent diseases such as typhoid fever and diphtheria. Parallel improvements in anesthetics (beginning with Sir Humphry Davy's discovery of nitrous oxide, or "laughing gas," in 1799) and antiseptics were making possible elaborate surgery, and by the end of the century X-rays and radiology were placing powerful new tools at the disposal of medical technology, while the use of synthetic drugs such as barbitone, cocaine, quinine, and aspirin (acetylsalicylic acid) had become established.

Improvements in control of disease

Agriculture. The agricultural improvements of the 18th century had been promoted by people whose industrial and commercial interests made them willing to experiment with new machines and processes to improve the productivity of their estates. Under the same sort of stimuli, agricultural improvement continued into the 19th century and was extended to food processing in Britain and elsewhere. The steam engine was not readily adapted for agricultural purposes, yet ways were found of harnessing it to threshing machines and even to plowing by means of a cable pulling the plow across a field between powerful traction engines. In the United States mechanization of agriculture began later than in Britain, but because of the comparative labour shortage it proceeded more quickly and more thoroughly. The McCormick reaper and the combine harvester were both developed in the United States, as were barbed wire and the food-packing and canning industries, Chicago becoming the world-famous centre for these processes. The introduction of refrigeration techniques in the second half of the 19th century made it possible to convey meat from Australia and Argentina to European markets, and the same markets encouraged the growth of dairy farming and market gardening, with distant producers such as New Zealand able to send their butter in refrigerated ships to wherever in the world it could be sold.

Civil engineering. As far as large civil-engineering works were concerned, the heavy work of moving earth continued to depend throughout this period on human labour organized by building contractors. But the use of gunpowder, dynamite, and steam diggers helped to reduce this dependence increasingly toward the end of the 19th century, and the introduction of compressed air and hydraulic tools also contributed to the lightening of drudgery. The latter two inventions were important in other respects, such as in mining engineering and in the operation of lifts, lock gates, and cranes. The use of a tunnelling shield, to allow a tunnel to be driven through soft or uncertain rock strata, was pioneered by the French émigré engineer Marc Brunel in the construction of the first tunnel underneath the Thames River in London, (1826–42), and the technique was adopted elsewhere. The iron bell or caisson was introduced for working below water level in order to lay foundations for bridges or other structures, and bridge building made great advances with the perfecting of the suspension bridge by the British engineers Thomas Telford and Isambard Kingdom Brunel and the German-American engineer John Roebling and the development of the truss bridge, first in timber, then in iron. Wrought iron gradually replaced cast iron as a bridge-building material, although several distinguished cast-iron bridges survive, such as that erected at Ironbridge in Shropshire between 1776 and 1779, which has been fittingly described as the "Stonehenge of the Industrial Revolution." The sections were cast at the Coalbrookdale furnace nearby and assembled by mortising and wedging on the model of a timber construction, without the use of bolts or rivets. The design was quickly superseded in other cast-iron bridges, but the bridge still stands as the first important structural use of cast iron. Cast iron became very important in the framing of large buildings, the elegant Crystal Palace of 1851 being an outstanding example. This was designed by the ingenious gardener-turned-architect Sir Joseph Paxton on the model of a greenhouse that he had built on the Chatsworth estate of the Duke of Devonshire. Its cast-iron beams were manufactured by three different firms and tested for size and strength on the site. By the end of the 19th century, however, steel was beginning to replace cast iron as well as wrought iron, and the new technique of reinforced concrete was being introduced. In water-supply and sewage-disposal works, civil engineering achieved some monumental successes, especially in the design of dams, which improved considerably in the period, and in long-distance piping and pumping.

Advances in bridge construction

Transport and communications. Transport and communications provide an example of a revolution within the Industrial Revolution, so completely were the modes transformed in the period 1750–1900. The first improvements in Britain came in roads and canals in the second half of the 18th century. Although of great economic importance, these were not of much significance in the history of technology, as good roads and canals had existed in continental Europe for at least a century before their adoption in Britain. A network of hard-surfaced roads was built in France in the 17th and early 18th centuries and copied in Germany. A notable improvement was introduced in road construction by Pierre Trésaguet of France in the later 18th century, in separating the hard-stone wearing surface from the rubble substrata and taking care to provide ample drainage. Nevertheless, by the beginning of the 19th century British engineers were beginning to innovate in both road- and canal-building techniques, with J.L. McAdam's cheap and long-wearing road surface of compacted stones and Thomas Telford's well-engineered canals. The outstanding innovation in transport, however, was the application of steam power, which occurred in three forms.

Steam locomotive. First was the evolution of the railroad: the combination of the steam locomotive and a permanent travel way of metal rails. Experiments in this conjunction in the first quarter of the 19th century culminated in the Stockton and Darlington Railway, opened in 1825, and a further five years of experience with steam locomotives led to the Liverpool and Manchester Railway, which, when it opened in 1830, constituted the first fully timetabled railway service with scheduled freight and passenger traffic relying entirely on the steam locomotive for traction. This railway was designed by George Stephenson, and the locomotives were the work of Stephenson and his son Robert, the first being the famous "Rocket," which won a competition held by the proprietors of the railway at Rainhill, outside Liverpool, in 1829. The opening of the Liverpool and Manchester line may fairly be regarded as the inauguration of the Railway Era, which continued until World War I. During this time railways were built across all the countries and continents of the world, opening up vast areas to the markets of industrial society. Locomotives increased rapidly in size and power, but the essential principles remained the same as those established by the Stephensons in the early 1830s: horizontal cylinders mounted beneath a multitubular boiler with a firebox at the rear and a tender carrying supplies of water and fuel. This was the form developed from the "Rocket," which had diagonal cylinders, being itself a stage in the transition from the vertical cylinders, often encased by the boiler, which had been typical of the earliest locomotives (except Trevithick's Penydarren engine, which had a horizontal cylinder). Meanwhile, the construction of the permanent way underwent a corresponding improvement on that which had been common on the preceding tramroads: wrought iron, and eventually steel, rails replaced the cast-iron rails which cracked easily under a steam locomotive, and well-aligned track with easy gradients and substantial supporting civil-engineering works became a commonplace of the railroads of the world.

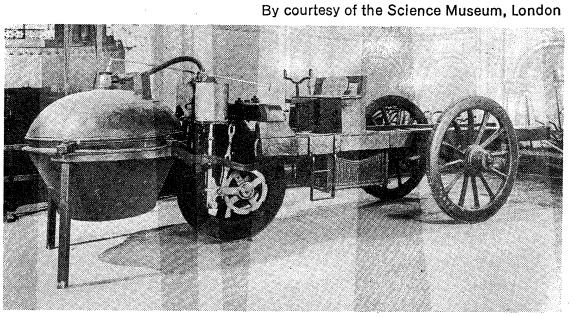
Beginning of the Railway Era

Road locomotive. The second form in which steam power was applied to transport was that of the road locomotive. There is no technical reason why this should not have enjoyed a success equal to that of the railway engine, but its development was so constricted by the unsuitability of most roads and by the jealousy of other road users that it only achieved general utility for heavy traction work and such duties as road rolling. The steam traction engine, which could be readily adapted from road haulage to power farm machines, was nevertheless a distinguished product of 19th-century steam technology.

Steamboats and ships. The third application was much more important, for it transformed marine transport. The first attempts to use a steam engine to power a boat were made on the Seine in France in 1775, and several experimental steamships were built by William Symington in Britain at the turn of the 19th century. The first commercial success in steam propulsion for a ship, however, was that of the American Robert Fulton, whose paddle steamer "Clermont" plied between New York and Albany in 1807, equipped with a Boulton and Watt engine of the modified beam or side-lever type, with two beams placed alongside the base of the engine in order to lower the centre of gravity. A similar engine was installed in the Glasgow-built "Comet," which was put in service on the Clyde in 1812 and was the first successful steamship in Europe. All the early steamships were paddle-driven, and all were small vessels suitable only for ferry and packet duties because it was long thought that the fuel requirements of a steamship would be so large as to preclude long-distance cargo carrying. The further development of the steamship was thus delayed until the 1830s, when I.K. Brunel began to apply his ingenious and innovating mind to the problems of steamship construction. His three great steamships each marked a leap forward in technique. The "Great Western" (launched 1837), the first built specifically for oceanic service in the North Atlantic, demonstrated that the proportion of space required for fuel decreased as the total volume of the ship increased. The "Great Britain" (launched 1843) was the first large iron ship in the world and the first to be screw propelled; its miraculous return to the port of Bristol in 1970, after a long working life and abandonment to the elements, is a remarkable testimony to the strength of its construction. The "Great Eastern" (launched 1858), with its total of 18,918 tons (17,162,400 kilograms), was by far the largest ship built in the 19th century. With a double iron hull and two sets of engines driving both a screw and paddles, this leviathan was never an economic success, but it admirably demonstrated the technical possibilities of the large iron steamship. By the end of the century, steam was well on the way to displacing the sailing ship on all the main trade routes of the world.

Robert Fulton's "Clermont"

Printing and photography. Communications were equally transformed in the 19th century. The steam engine helped to mechanize and thus to speed up the processes of papermaking and of printing, the latter being achieved by the introduction of the high-speed rotary press and the Linotype machine for casting type and setting it in justified lines (*i.e.*, with even right-hand margins). Printing, indeed, had to undergo a technological revolution comparable to the 15th-century invention of movable type to be able to supply the greatly increasing market for the printed word. Another important process which was to make a vital contribution to modern printing was discovered and developed in the 19th century: photography. The first photograph was taken in 1826 by the French physicist J.-N. Niepce, using a pewter plate coated with a form of bitumen that hardened on exposure. His partner L.-J.-M. Daguerre and the Englishman W.H. Fox Talbot adopted silver compounds to give light sensitivity, and the technique developed rapidly in the middle decades of the century. By the 1890s George Eastman in the United States was manufacturing cameras and celluloid photographic film for a popular market, and the first experiments with the cinema were beginning to attract attention.



Telegraphs and telephones. The great innovations in communications technology, however, derived from electricity. The first was the electric telegraph, invented or at least made into a practical proposition for use on the developing British railway system by two British inventors, Sir William Cooke and Sir Charles Wheatstone, who collaborated on the work and took out a joint patent in 1837. Almost simultaneously, the American inventor Samuel F.B. Morse devised the signalling code that was subsequently adopted all over the world. In the next quarter of a century the continents of the world were linked telegraphically by transoceanic cables, and the main political and commercial centres were brought into instantaneous communication. The telegraph system also played an important part in the opening up of the American West by providing rapid aid in the maintenance of law and order. The electric telegraph was followed by the telephone, invented by Alexander Graham Bell in 1876 and quickly adopted for short-range oral communication in the cities of America, and at a somewhat more leisurely pace by those of Europe. About the same time, theoretical work on the electromagnetic properties of light and other radiation was beginning to produce astonishing experimental results, and the possibilities of wireless telegraphy began to be explored. By the end of the century, Guglielmo Marconi had transmitted messages over many miles in Britain and was preparing the apparatus with which he made the first transatlantic radio communication on December 12, 1901. The world was thus being drawn inexorably into a closer community by the spread of instantaneous communication.

Morse Code

Military technology. One area of technology was not dramatically influenced by the application of steam or electricity by the end of the 19th century: military technology. Although the size of armies increased between 1750 and 1900, there were few major innovations in techniques, except at sea where naval architecture rather reluctantly accepted the advent of the iron steamship and devoted itself to matching ever-increasing firepower with the strength of the armour plating on the hulls. The quality of artillery and of firearms improved with the new high explosives which became available in the middle of

the 19th century, but experiments such as the three-wheeled iron gun carriage, invented by the French army engineer Nicolas Cugnot in 1769, which counts as the

Nicolas Cugnot's steam carriage, showing (left) the boiler and (right of boiler) the vertical cylinders, 1770. In the Science Museum, London.

first steam-powered road vehicle, did not give rise to any confidence that steam could be profitably used in battle. Railroads and the electric telegraph were put to effective military use, but in general it is fair to say that the 19th century put remarkably little of its tremendous and innovative technological effort into devices for war.

In the course of its dynamic development between 1750 and 1900 important things happened to technology itself. In the first place, it became self-conscious. This change is sometimes characterized as one from a craft-based technology to one based on science, but this is an oversimplification. What occurred was rather an increasing awareness of technology as a socially important function. It is apparent in the growing volume of treatises on technological subjects from the 16th century onward, and in the rapid development of patent legislation to protect the interests of technological innovators. It is apparent also in the development of technical education, uneven at first, being confined to the French polytechnics and spreading thence to Germany and North America, but reaching even Britain, which had been most opposed to its formal recognition as part of the structure of education, by the end of the 19th century. Again, it is apparent in the growth of professional associations for engineers and for other specialized groups of technologists.

Increasing awareness of technology

Second, by becoming self-conscious, technology attracted attention in a way it had never done before, and vociferous factions grew up to praise it as the mainspring of social progress and the development of democracy, or to criticize it as the bane of modern man, responsible for the harsh discipline of the "dark Satanic mills" and the tyranny of the machine and the squalor of urban life. It was clear by the end of the 19th century that technology was an important feature in industrial society and that it was likely to become more so. Whatever was to happen in the future, technology had come of age and had to be taken seriously as a formative factor of the utmost significance in the continuing development of civilization.

IV. The 20th century

TECHNOLOGY FROM 1900 TO 1945

Recent history is notoriously difficult to write, because of the mass of material and the problem of distinguishing the significant from the insignificant among events that have virtually the power of contemporary experience. In respect to the recent history of technology, however, one fact stands out clearly: despite the immense achievements of technology by 1900, the following seven decades witnessed more advance over a wide range of activities than the whole of previously recorded history. The airplane, the rocket and interplanetary probes, electronics, atomic power, antibiotics, insecticides, and a host of new materials have all been invented and developed to create an unparalleled social situation, full of possibilities and dangers, which would have been virtually unimaginable before the present century.

In venturing to interpret the events of the present century it will be convenient to separate the years before 1945 from those which have followed. The years 1900 to 1945 were dominated by the two world wars, while those since 1945 have been preoccupied by the need to avoid another major war. The dividing point is one of outstanding social and technological significance: the detonation of the first atomic bomb at Alamogordo, New Mexico, in July 1945.

There have been profound political changes in the 20th century related to technological capacity and leadership. It may be an exaggeration to regard the 20th century as "the American century," but the rise of the United States as a superstate has been sufficiently rapid and dramatic to excuse the hyperbole. It has been a rise based upon tremendous natural resources exploited to secure increased productivity through widespread industrialization, and the success of the United States in achieving this objective has been tested and demonstrated in the two world wars. Technological leadership passed from Britain and the European nations to the United States in the course of these wars. This is not to say that the springs of innovation went dry in Europe: many important inventions of the 20th century originated there. But it has been the United States that has had the capacity to assimilate innovations and to take full advantage from them at times when other nations have been deficient in one or other of the vital social resources without which a brilliant invention cannot be converted into a commercial success. As with Britain in the Industrial Revolution, the technological vitality of the United States in the 20th century has been demonstrated less by any particular innovations than by its ability to adopt new ideas from whatever source they come.

The two world wars were themselves the most important instruments of technological as well as political change in the 20th century. The rapid evolution of the airplane is a striking illustration of this process, while the appearance of the tank in the first conflict and of the atomic bomb in the second show the same signs of response to an urgent military stimulus. It has been said that World War I was a chemists' war, on the basis of the immense importance of high explosives and poison gas. In other respects the two wars hastened the development of technology by extending the institutional apparatus for the encouragement of innovation by both the state and private industry. This process went further in some countries than in others, but there were no major belligerent nations which could resist entirely the need to support and coordinate their scientific–technological effort. The wars were thus responsible for speeding the transformation from "little science," with research still largely restricted to small-scale efforts by a few isolated scientists, to "big science," with the emphasis on large research teams sponsored by governments and corporations, working collectively on the development and application of new techniques. While the extent of this transformation must not be overstated, and recent research has tended to stress the continuing need for the independent inventor at least in the stimulation of innovation, there can be little doubt that the change in the scale of technological enterprises has had far-reaching consequences. It has been one of the most momentous transformations of the 20th century, for it has altered the quality of industrial and social organization. In the process it has assured technology, for the first time in its long history, a position of importance and even honour in social esteem.

The world wars and their effect

Fuel and power. There were no fundamental innovations in fuel and power before the breakthrough of 1945, but there were several significant developments in techniques that had originated in the previous century. An outstanding development of this type was the internal-combustion engine, which was continuously improved to meet the needs of road vehicles and airplanes. The high-compression engine burning heavy-oil fuels, invented by Rudolf Diesel in the 1890s, was developed to serve as a submarine power unit in World War I and was subsequently adapted to heavy road haulage duties and to agricultural tractors. Moreover, the sort of development that had transformed the reciprocating steam engine into the steam turbine occurred with the internal-combustion engine, the gas turbine replacing the reciprocating engine

Developments in engine design

for specialized purposes such as aero-engines, in which a high power-to-weight ratio is important. Admittedly, this adaptation had not proceeded very far by 1945, although the first jet-powered aircraft were in service by the end of the war. The theory of the gas turbine, however, had been understood since the 1920s at least, and in 1929 Sir Frank Whittle, then taking a flying instructor's course with the Royal Air Force, combined it with the principle of jet propulsion in the engine for which he took out a patent in the following year. But the construction of a satisfactory gas-turbine engine was delayed for a decade by the lack of resources, and particularly by the need to develop new metal alloys which could withstand the high temperatures generated in the engine. This problem was solved by the development of a nickel-chromium alloy, and with the gradual solution of the other problems work went on in both Germany and Britain to seize a military advantage by applying the jet engine to combat aircraft.

Gas-turbine engine. The principle of the gas turbine is that of compressing and burning air and fuel in a combustion chamber and using the exhaust jet from this process to provide the reaction which propels the engine forward. In its turbopropellor form, which developed only after World War II, the exhaust drives a shaft carrying a normal airscrew (propeller). Compression is achieved in a gas-turbine engine by admitting air through a turbine rotor. In the so-called ramjet engine, intended to operate at high speeds, the momentum of the engine through the air achieves adequate compression, but this form of the engine is still in its experimental stages. The gas turbine has been the subject of experiments in road, rail, and marine transport, but for all purposes except that of air transport its advantages have not so far been such as to make it a viable rival to traditional reciprocating engines.

Petroleum. As far as fuel is concerned, the gas turbine burns mainly the middle fractions (kerosene, or paraffin) of refined oil, but the general tendency of its widespread application has been to increase still further the dependence of the industrialized nations on the producers of crude oil, which has become a raw material of immense economic value and international political significance. The refining of this material has itself undergone important technological development. Until the present century, it consisted of a fairly simple batch process whereby oil was heated until it vaporized, when the various fractions were distilled separately. Apart from improvements in the design of the stills and the introduction of continuous-flow production, the first big advance came in 1913 with the introduction of thermal cracking. This process took the lower fractions after distillation and subjected them to heat under pressure, thus cracking the heavy molecules into lighter molecules and so increasing the yield of the most valuable fuel, petrol or gasoline. The discovery of this ability to tailor the products of crude oil to suit the market marks the true beginning of the petrochemical industry. It received a further boost in 1937, with the introduction of catalytic cracking. By the use of various catalysts in the process means were devised for still further manipulating the molecules of the hydrocarbon raw material. The development of modern plastics has followed directly on this (see below *Plastics*). So efficient had the processes of utilization become that by the end of World War II the petrochemical industry had virtually eliminated all waste materials.

Petroleum cracking

Electricity. All the principles of generating electricity had been worked out in the 19th century, but by the end of that century these had only just begun to produce electricity on a large scale. The 20th century has witnessed a colossal expansion of electrical power generation and distribution. The general pattern has been toward ever-larger units of production, using steam from coal- or oil-fired boilers. Economies of scale and the greater physical efficiency achieved as higher steam temperatures and pressures were attained both reinforced this tendency. United States experience indicates the trend: in the first decade of the century a generating unit with a capacity of 25,000 kilowatts with pressures up to 200–300 pounds per square inch at 400°–500° F (about 200°–265° C) was considered large, but by 1930 the largest unit was 208,000 kilowatts, with pressures of 1,200 pounds per square inch at a temperature of 725° F, while the amount of fuel necessary to produce a kilowatt-hour of electricity and the price to the consumer had fallen dramatically. As the market for electricity increased, so did the distance over which it was transmitted, and the efficiency of transmission required higher and higher voltages. The small direct-current generators of early urban power systems were abandoned in favour of alternating-current systems, which could be adapted more readily to high voltages. Transmission over a line of 155 miles (250 kilometres) was established in California in 1908 at 110,000 volts; Hoover Dam in the 1930s used a line of 300 miles (480 kilometres) at 287,000 volts. The latter case may serve as a reminder that hydroelectric power, using a fall of water to drive water turbines, has been developed to generate electricity where the climate and topography make it possible to combine production with convenient transmission to a market. Remarkable levels of efficiency have been achieved in modern plants. One important consequence of the ever-expanding consumption of electricity in the industrialized countries has been the linking of local systems to provide vast power grids, or pools, within which power can be shifted easily to meet changing local needs for current.

Alternating current

Atomic power. Until 1945, electricity and the internal-combustion engine were the dominant sources of power for industry and transport in the 20th century, although in some parts of the industrialized world steam power and even older prime movers remained important. Early research in nuclear physics was more scientific than technological, stirring little general interest. In fact, from the work of Ernest Rutherford, Albert Einstein, and others to the first successful experiments in splitting heavy atoms in Germany in 1938, no particular thought was given to engineering potential. The war led to the Manhattan Project to produce the fission bomb that was first exploded at Alamogordo. Only in its final stages did even this program become a matter of technology, when the problems of building large reactors and handling radioactive materials had to be solved; and at this point it also became an economic and political matter, because very heavy capital expenditure was involved. Thus, in this crucial event of the mid-20th century, the convergence of science, technology, economics, and politics finally took place.

Industry and innovation. There have been technological innovations of great significance in many aspects of industrial production during the 20th century. It is worth observing, in the first place, that the basic matter of industrial organization has become one of self-conscious innovation, with organizations setting out to increase their productivity by improved techniques. Methods of work study, first systematically examined in the United States at the end of the 19th century, were widely applied in United States and European industrial organizations in the first half of the 20th century, evolving rapidly into scientific management and the modern studies of industrial administration, organization and method, and particular managerial techniques. The object of these exercises has been to make industry more efficient and thus to increase productivity and profits, and there can be no doubt that they have been remarkably successful, if not quite as successful as some of their advocates have maintained. Without this superior industrial organization it would not have been possible to convert the comparatively small workshops of the 19th century into the giant engineering establishments of the 20th with their mass-production and assembly-line techniques. The rationalization of production, so characteristic of industry in the present century, may thus be legitimately regarded as the result of the application of new techniques which form part of the history of technology since 1900.

Studies of work and industrial organization

Improvements in iron and steel. Another field of industrial innovation in the present century has been the production of new materials. As far as volume of consumption goes, man still lives in the Iron Age, with the utilization of iron exceeding that of any other material.

But this dominance of iron has been modified in three ways: by the skill of metallurgists in alloying iron with other metals; by the spread of materials such as glass and concrete in building; and by the appearance and widespread use of entirely new materials, particularly plastics. Alloys had already begun to become important in the iron and steel industry in the 19th century (apart from steel itself, which is an alloy of iron and carbon); self-hardening tungsten steel had been first produced in 1868, and manganese steel, possessing toughness rather than hardness, in 1887. Manganese steel is also non-magnetic, which suggests great possibilities for its use in the electric-power industry. In the 20th century steel alloys multiplied. Silicon steel was found to be useful because, unlike manganese steel, it is highly magnetic. In 1913 the first stainless steels were made in England by alloying steel with chromium, and the Krupp works in Germany produced stainless steel in 1914 with 18 percent chromium and 8 percent nickel. The importance of a nickel–chromium alloy in the development of the gas-turbine engine in the 1930s has already been noted. Many other alloys also came into widespread use for specialized purposes.

Building materials. Methods of producing traditional materials like glass and concrete on a larger scale have also supplied alternatives to iron, especially in building; in the form of reinforced concrete they have supplemented structural iron. Most of the entirely new materials have been nonmetallic, although at least one new metal, aluminum, has reached proportions of large-scale industrial significance in the 20th century. The ores of this metal are among the most abundant in the crust of the Earth, but before the provision of plentiful cheap electricity made it feasible to use an electrolytic process on an industrial scale, the metal was extracted only with great difficulty. The strength of aluminum, compared weight for weight with steel, has made it a valuable material in aircraft construction, and many other industrial and domestic uses have been found for it. In 1900 world production of aluminum was 3,000 tons, about half of which was made using cheap electric power from Niagara Falls. Production has since risen rapidly.

Importance of aluminum

Electrolytic processes had already been used in the preparation of other metals. At the beginning of the 19th century, Davy had pioneered the process by isolating potassium, sodium, barium, calcium, and strontium, although there was little commercial exploitation of these processes. By the beginning of the 20th century, significant amounts of magnesium were being prepared electrolytically at high temperatures, and the electric furnace made possible the production of calcium carbide by the reaction of calcium and carbon. This material provided a useful step in the processing of synthetic resins and thus of plastics.

Plastics. The quality of plasticity is one that had been used to great effect in the crafts of metallurgy and ceramics. The use of the word plastics as a collective noun, however, refers not so much to the traditional materials employed in these crafts as to new substances produced by chemical reactions and molded or pressed to take a permanent rigid shape. The first material to be manufactured artificially in this way was Parkesine, developed by the British inventor Alexander Parkes from a mixture of chloroform and castor oil which produced "a substance hard as horn, but as flexible as leather, capable of being cast or stamped, painted, dyed or carved . . ." The words are from a guide to the Great Exhibition of 1862 in London, at which Parkesine won a bronze medal for its inventor. It was soon followed by other plastics, but apart from Celluloid, a cellulose nitrate composition using camphor as a solvent and produced in solid form (as imitation horn for billiard balls) and in sheets (for men's collars and photographic film), these had little commercial success until the 20th century.

The early plastics had relied upon the large molecules in cellulose, usually derived from wood pulp. However, Leo H. Baekeland, a Belgian-U.S. inventor, took out his patent for Bakelite in 1909, based on the reaction between formaldehyde and phenolic materials, and by fusing these in powder form at high temperatures he was able to produce a plastic that was hard, infusible, and chemically resistant (the type known as thermosetting plastic). As a nonconductor of electricity it proved to be exceptionally useful for all sorts of electrical appliances. The success of Bakelite gave a great impetus to the plastics industry, to the study of coal-tar derivatives and other hydrocarbon compounds, and to the theoretical understanding of the structure of complex molecules. This activity led to new dyestuffs and detergents, but it also led to the successful manipulation of molecules to produce materials with particular qualities such as hardness and flexibility. Techniques were devised, often requiring catalysts and elaborate equipment, to secure these polymers—that is, complex molecules produced by the aggregation of simpler structures. Linear polymers give strong fibres, surface polymers have been useful in paints, and mass polymers have formed solid plastics.

Chemical advances in plastics

Synthetic fibres. The possibility of creating artificial fibres was another 19th-century discovery which did not become commercially significant until the 20th century, when it developed alongside the solid plastics with which it was closely related. The first artificial textiles had been made from rayon, a silklike material produced by extruding a solution of nitrocellulose dissolved in acetic acid into a coagulating bath of alcohol, and various other cellulosic materials were used in this way. But later research exploited the polymerization techniques being used in solid plastics, and culminated in the production of nylon just before the outbreak of World War II. Nylon consists of long chains of carbon-based molecules, giving fibres of unprecedented strength and flexibility. It is formed by melting the component materials and extruding them, the strength of the fibre being greatly increased by stretching it when cold. Nylon was developed with the women's stocking market in mind, but the conditions of war gave it an opportunity to demonstrate its versatility and reliability in such things as parachute cord. This and other synthetic fibres became generally available only after the war.

Synthetic rubber. The chemical industry in the 20th century has thus put a wide range of new materials at the disposal of society. It has also succeeded in replacing natural sources of some materials: an important example of this has been the manufacture of artificial rubber to meet a world demand far in excess of that which could be met by the existing rubber plantations. This technique was pioneered in Germany during World War I. Here, as in other materials such as high explosives and dyestuffs, the consistent German investment in scientific and technical education paid dividends, for advances in all these fields of chemical manufacturing were prepared by careful research in the laboratory.

Pharmaceuticals and medical technology. An even more dramatic result of the growth in chemical knowledge has been the expansion of the modern pharmaceutical industry. The science of pharmacy emerged slowly from the traditional empiricism of the herbalist, but by the end of the 19th century there had been some solid achievements in the analysis of existing drugs and in the preparation of new ones. The discovery in 1856 of the first aniline dye had been occasioned by a vain attempt to synthesize quinine from coal-tar derivatives. Greater success came in the following decades with the production of the first synthetic antifever drugs and pain-killing compounds, culminating in 1899 in the development of salicylic acid into acetylsalicylic acid, which as aspirin is still the most widely used drug. Progress was being made simultaneously with the sulfonal hypnotics and the barbiturate group of drugs, and early in the 20th century Paul Ehrlich of Germany successfully developed an organic compound containing arsenic (No. 606, denoting how many tests he had made, but better known as Salvarsan) which was effective against syphilis. The significance of this discovery, in 1910, was that it was the first drug devised to overwhelm an invading micro-organism without offending the host. In 1932 the discovery that Prontosil, a red dye developed by the German synthetic-dyestuff industry, was an effective drug against streptococcal infections (leading to blood poisoning) introduced the

Penicillin and antibiotics

important sulfa drugs. Alexander Fleming's discovery of penicillin in 1928 was not immediately followed up, because it proved very difficult to isolate the drug in a stable form from the mold in which it was formed. But the stimulus of World War II gave a fresh urgency to research in this field, and successful production of the first of the antibiotics began in 1943. These drugs work by preventing the growth of pathogenic organisms. All these pharmaceutical advances demonstrate an intimate relationship with chemical technology.

Other branches of medical technology made significant progress. Anesthetics and antiseptics had been developed in the 19th century, opening up new possibilities for complex surgery; techniques of blood transfusion, examination by X-rays (discovered in 1895), radio therapy (following demonstration of the therapeutic effects of ultraviolet light in 1893), the discovery of radium in 1898, and orthopedic surgery for bone disorders all developed rapidly. The techniques of immunology similarly advanced, with the development of vaccines effective against typhoid and the other fever diseases.

Food and agriculture. The increasing chemical understanding of drugs and micro-organisms was applied with outstanding success to the study of food. The analysis of the relationship between certain types of food and human physical performance led to the definition of vitamins ("vital amino acids") in 1911 and to their classification into three types in 1919, with subsequent additions and subdivisions. It was realized that the presence of these materials was necessary for a healthy diet, and eating habits and public-health programs were adjusted accordingly. The importance of trace elements, very minor constituents, was also discovered and investigated, beginning in 1895 with the realization that goitre was caused by a deficiency of iodine.

As well as improving in quality, the quantity of food produced in the 20th century increased rapidly as a result of the intensive application of modern technology. The greater scale and complexity of urban life created a pressure for increased production and a greater variety of foodstuffs, and the resources of the internal-combustion engine, electricity, and chemical technology were called upon to achieve these objectives. The main service of the internal-combustion engine was in the shape of the tractor, which became the almost universal agent of mobile power on the farm in the industrialized countries. The same engines powered other machines such as combine harvesters, which became common in the United States in the early 20th century, although their use was less widespread in the more labour-intensive farms of Europe, especially before World War II. Synthetic fertilizers, an important product of the chemical industry, became popular in most types of arable farming, and other chemicals appeared toward the end of the period that performed something of an agrarian revolution as pesticides and herbicides. Once again, it was World War II which gave a powerful boost to this development. Despite problems of pollution by residue that developed later, the marketing of DDT as a highly effective insecticide in 1944 was a particularly significant achievement of chemical technology. Food processing and packaging also made advances, with the introduction of dehydration techniques such as vacuum-contact drying in the 1930s, but the 19th-century innovations of canning and refrigeration remained the dominant techniques of preservation.

Farm machinery

Civil engineering. Important development occurred in civil engineering in the first half of the 20th century, although there were few striking innovations. Advancing techniques for massive construction, such as skyscrapers, bridges, and dams, produced many spectacular achievements all over the world, but especially in the United States. The city of New York acquired its characteristic skyline, built upon the exploitation of steel frames and reinforced-concrete techniques. Conventional methods of building in brick and masonry had reached the limits of feasibility in the 1800s with office blocks up to 16 stories high, and the future lay with the skeleton frame or cage construction pioneered in the 1880s in Chicago. The vital ingredients for the new tall buildings or skyscrapers that followed were abundant cheap steel for columns, beams, and trusses, and efficient passenger elevators. The availability of these and the demand for more and more office space in the thriving cities of Chicago and New York caused the boom in skyscraper building that continued until 1932, when the Empire State Building, with its total height of 1,250 feet (378 metres) and 102 stories, achieved a limit only recently exceeded and demonstrated the strength of its structure by sustaining the crash impact of a B-25 bomber in July 1945 with only minor damage to the building. The Depression brought a halt to skyscraper building from 1932 until after the war.

Skyscraper construction

Concrete, and more especially reinforced concrete (that is, concrete set around a framework or mesh of steel), played an important part in the construction of the later skyscrapers, and this material also led to the introduction of more imaginative structural forms in buildings and to the development of prefabrication techniques. The use of large concrete members in bridges and other structures has been made possible by the technique of prestressing: by stretching the reinforcing material, often in the form of high-tension piano wire, it has been possible to introduce tensions into the concrete opposite to those of the external loading, and in this way the members can be made stronger and lighter. The technique was particularly applicable in bridge building. The construction of large-span bridges received a setback, however, with the dramatic collapse of the Tacoma Narrows (Washington) Suspension Bridge in the United States in 1940, four months after it was completed. This led to a reassessment of wind effects on the loading of large suspension bridges and to significant improvements in subsequent designs. Massive use of concrete has produced spectacular high arch dams, in which the weight of water is transmitted in part to the abutments by the curve of the concrete wall, rather than depending upon the sheer bulk of impervious material as in a conventional gravity or embankment dam.

Transportation. Some of the outstanding achievements of the 20th century are provided by transportation history. In most fields there was a switch from steam power, supreme in the previous century, to internal combustion and electricity. Steam, however, retained its superiority in marine transport, with the steam turbine providing power for a new generation of large ocean liners beginning with the Cunard "Mauretania," developing 70,000 horsepower and a speed of 27 knots (27 nautical miles, or 50 kilometres, per hour) in 1906, and continuing throughout the period, culminating in the "Queen Elizabeth," launched in 1938, with about 200,000 horsepower and a speed of 28.5 knots. Even here, however, there was increasing competition from large diesel-powered motor vessels. Most smaller ships adopted this form of propulsion and even the steamships accepted the convenience of oil-burning boilers in place of the cumbersome coal burners with their large bunkers.

Advent of the modern ocean liner

On land, steam fought a long rear-guard action, but the enormous popularity of the automobile deprived the railways of much of their most lucrative traffic and forced them to seek economies in conversion to diesel engines or electric traction, although these developments had not spread widely in Europe by the outbreak of World War II. Meanwhile, the automobile stimulated prodigious feats of production. Henry Ford led the way in the adoption of assembly-line mass production; his spectacularly successful Model T, the "Tin Lizzie," was manufactured in this way first in 1913, and by 1923 production had risen to nearly 2,000,000 a year. Despite this and similar successes in other countries, the first half of the 20th century was not a period of great technological innovation in the motorcar, which retained the main design features given to it in the last decade of the 19th century. For all the refinements (for example, the self-starter) and multitudinous varieties, the major fact of the automobile in this period was its quantity.

Unlike the automobile, to which its development was intimately related, the airplane is entirely a product of the 20th century. This is not to say that experiments with flying machines had not taken place earlier. Throughout

the 19th century, to go back no further, investigations into aerodynamic effects were carried out by inventors such as Sir George Cayley in England, leading to the successful glider flights of Otto Lilienthal and others. Several designers perceived that the internal-combustion engine promised to provide the light, compact power unit that was a prerequisite of powered flight, and on December 17, 1903, Wilbur and Orville Wright in their "Flyer I" at the Kill Devil Hills in North Carolina achieved sustained, controlled, powered flight, one of the great "firsts" in the history of technology. The "Flyer I" was a propeller-driven adaptation of the biplane gliders that the Wright brothers had built and learned to fly in the previous years. They had devised a system of three-dimension control through elevator, rudder, and a wing-warping technique that served until the introduction of ailerons. Within a few years the brothers were flying with complete confidence, astonishing the European pioneers of flight when they crossed the Atlantic to give demonstrations in 1908. Within a matter of months of this revelation, however, the European designers had assimilated the lesson and were pushing ahead the principles of aircraft construction. World War I gave a great impetus to this technological development, transforming small-scale scattered aircraft manufacture into a major industry in all the main belligerent nations, and transforming the airplane itself from a fragile construction in wood and glue into a robust machine capable of startling aerobatic feats.

The Wright brothers' flight

The end of the war brought a setback to this new industry, but the airplane had evolved sufficiently to reveal its potential as a medium of civil transport, and during the interwar years the transcontinental air routes were established and provided a market for large, comfortable, and safe aircraft. By the outbreak of World War II, metal-framed-and-skinned aircraft had become general, and the cantilevered monoplane structure had replaced the biplane for most purposes. War again provided a powerful stimulus to aircraft designers; engine performance was especially improved. The gas turbine received its first practical application. Other novel features of these years included the helicopter, deriving lift from its rotating wings, or rotors, and the German V-1 flying bomb, a pilotless aircraft.

The war also stimulated the use of gliders for the transport of troops, the use of parachutes for escape from aircraft and for attack by paratroops, and the use of gas-filled balloons for anti-aircraft barrages. The balloon had been used for pioneer aeronautical experiments in the 19th century, but its practical uses had been hampered by the lack of control over its movements. The application of the internal-combustion engine to a rigid-frame balloon airship by Ferdinand von Zeppelin had temporarily made a weapon of war in 1915, although experience soon proved that it could not survive in competition with the airplane. The apparently promising prospects of the dirigible (that is, manoeuvrable) airship in civil transport between the wars were ended by a series of disasters, the worst of which was the destruction of the "Hindenburg" in New Jersey in 1937. Since then the airplane has been unchallenged in the field of air transport.

Communications. The spectacular transport revolution of the 20th century has been accompanied by a communications revolution quite as dramatic, although technologically springing from different roots. In part, well established media of communication like printing have participated in this revolution, although most of the significant changes here such as the typewriter, the Linotype for casting and setting complete lines of print, and the high-speed power-driven rotary press were achievements of the 19th century. Photography was also a proved and familiar technique by the end of the 19th century, but cinematography was new and did not become generally available until after World War I, when it became enormously popular.

The rise of electronics

The real novelties in communications in the 20th century came in electronics. The scientific examination of the relationship between light waves and electromagnetic waves had already revealed the possibility of transmitting electromagnetic signals between widely separated points, and on December 12, 1901, Guglielmo Marconi succeeded in transmitting the first wireless message across the Atlantic. Early equipment was crude, but within a few years striking progress was made in improving the means of transmitting and receiving coded messages. Particularly important was the development of the thermionic valve, a device for rectifying (that is, converting a high-frequency oscillating signal into a unidirectional current capable of registering as a sound) and amplifying an electromagnetic impulse. This was essentially a development from the carbon-filament electric light bulb. It had been observed that an ordinary vacuum bulb with a carbon filament with use acquired a black coating on the inside (the Edison effect, after Edison's observation of 1883), and this was correctly attributed to a stream of electrons radiated by the hot filament. In 1904, Sir John Ambrose Fleming of Britain discovered that by placing a metal cylinder around the filament in the bulb and by connecting the cylinder (the plate) to a third terminal, a current could be rectified so that it could be detected by a telephone receiver. This was known as the diode, and two years later, in 1906, Lee De Forest of the United States made the significant improvement which became known as the triode by introducing a third electrode (the grid) between the filament and the plate. The outstanding feature of this refinement was its ability to amplify a signal. Its application made possible by the 1920s the widespread introduction of live-voice broadcasting in Europe and America, with a consequent boom in the production of wirelesses and other equipment.

This, however, was only one of the results derived from the application of the thermionic valve. The idea of harnessing the flow of electrons was applied in the electron microscope, radar (a detection device depending on the capacity of some radio waves to be reflected by solid objects), the electronic computer, and in the cathode-ray tube of the television set. The first experiments in the transmission of pictures had been greeted with ridicule. Working on his own in Britain, John Logie Baird in the 1920s demonstrated a mechanical scanner able to convert an image into a series of electronic impulses that could then be reassembled on a viewing screen as a pattern of light and shade. Baird's system, however, was rejected in favour of a method of electronic scanning developed in the United States by Philo Farnsworth and Vladimir Zworykin with the powerful backing of the Radio Corporation of America, which operated much more rapidly and gave a more satisfactory image. By the outbreak of World War II, television services were being introduced in several nations, although the war suspended their extension for a decade. The emergence of television as a universal medium of mass communication is thus a phenomenon of the postwar years. But already by 1945 the cinema and the radio had demonstrated the power of the mass media in communicating news, propaganda, commercial advertisements, and entertainment.

Military technology. It has been necessary to refer repeatedly to the effects of the two world wars in promoting all kinds of innovation. It should be observed also that technological innovations have transformed the character of war itself by the introduction of new mechanical and chemical devices. One weapon developed during World War II deserves a special mention. The principle of rocket propulsion was well known earlier, and its possibilities as a means of achieving speeds sufficient to escape from the earth's gravitational pull had been pointed out by such pioneers as the Russian Konstantin Tsiolkovsky and the American Robert H. Goddard. The latter built experimental liquid-fuelled rockets in 1926. Simultaneously, a group of German and Romanian pioneers, including Hermann Oberth, was working along the same lines, and it was this team that was taken over by the German war effort in the 1930s and given the resources to develop a rocket capable of delivering a warhead hundreds of miles away. At the Peenemünde base on the island of Usedom in the Baltic, Wernher von Braun and his team created the V-2. Fully fuelled, it weighed 14 tons; it was 40

Development of rockets

German V-2 rocket on its launch vehicle.
Bilderdienst im Suddeutschen Verlag

feet (12 metres) long and was propelled by burning a mixture of alcohol and liquid oxygen. Reaching a height of over 100 miles (160 kilometres), the V-2 marked the beginning of the Space Age, and members of its design team were instrumental in both the Soviet and United States space programs after the war.

Technology had a tremendous social impact in the period 1900–45. The automobile and electric power, for instance, radically changed both the scale and the quality of 20th-century life, promoting a process of rapid urbanization and a virtual revolution in living through mass production of household goods and appliances. The rapid development of the airplane, the cinema, and radio made the world seem suddenly smaller and more accessible. The development of modern pharmaceutics, medicine, antibiotics, pesticides, and the many products of the chemical industry further transformed the life of most people. In the years following 1945 the constructive and creative opportunities of modern technology could be exploited, although the process has not been without its problems.

SPACE AGE TECHNOLOGY (1945–70)

The years since the end of World War II have been spent under the shadow of the atomic bomb, even though this weapon has not been used in war since August 1945. Nuclear weapons have undergone momentous development, first with the achievement of the technique of hydrogen fusion (1950), and second with their combination with long-range rockets. This new military technology has had an incalculable effect on international relations, for it has contributed to the polarization of world power blocs while enforcing a caution, if not discipline, in the conduct of international affairs which was sadly absent earlier in the 20th century.

The fact of nuclear power is by no means the only technological novelty of the post-1945 years. So striking, indeed, have been the advances in engineering, chemicals, medical technology, transport and communications, that some commentators have written, somewhat misleadingly, of the "second Industrial Revolution" to describe the changes in these years. The rapid development of electronic engineering has created a new world of computer technology, remote control, miniaturization, and instant communication, which has transformed almost every department of industry and administration and reached into every household. Even more expressive of the character of the period has been the leap over the threshold of extraterrestrial exploration. The techniques of rocketry, first applied in weapons, were developed to provide launch vehicles for satellites, lunar and planetary probes, and eventually, in 1969, to set the first men on the Moon and to bring them home safely again. This astonishing technological achievement was stimulated in part by the international ideological rivalry already mentioned, as only the Soviet Union and the United States had both the resources and the will to support the huge programs of expenditure that the achievement required. It justifies the description of this period, however, as that of "Space Age technology."

Power. The great power innovation of this period has been the harnessing of nuclear energy. The first atomic bombs represented only a comparatively crude form of nuclear fission, releasing all the energy of the radioactive material immediately and explosively. But it was quickly appreciated that the energy released within a critical atomic pile, a mass of graphite absorbing the neutrons released from radioactive material inserted into it, could generate heat which in turn could create steam to drive turbines and thus convert the nuclear energy into usable electricity. Atomic power stations have been built on this principle in the advanced industrial nations, and the system is still undergoing refinement, although so far atomic energy has not vindicated the high hopes placed in it as an economic source of electricity and presents formidable problems of waste disposal and maintenance. Nevertheless, it seems probable that the effort devoted to experiments on more direct ways of controlling nuclear fission will eventually produce results in power engineering. Meanwhile, nuclear physics has been probing the even more promising possibilities of harnessing the power of nuclear fusion, of creating the conditions in which simple atoms of hydrogen combine, with a vast release of energy, to form heavier atoms. This is the process that occurs in the stars, but so far it has only been created artificially by triggering off a fusion reaction with the intense heat generated momentarily by an atomic-fission explosion. This is the mechanism of the hydrogen bomb. So far scientists have devised no way of harnessing this process so that continuous, controlled energy can be obtained from it, although researches into plasma physics, generating a point of intense heat within a stream of electrons imprisoned in a strong magnetic field, hold out some hopes that such means will be discovered in the not-too-distant future.

The harnessing of nuclear energy

Alternatives to fossil fuels. It may well become a matter of urgency, before the end of the present century, that some means of extracting usable power from nuclear fusion be acquired. At the present rate of consumption, the world's resources of mineral fuels, and of the available radioactive materials used in the present nuclear-power stations, will be exhausted within a period of perhaps a few decades. While pressure on coal reserves has slackened slightly, demands for fuel oil and natural gas have increased at a prodigious rate and the exhaustion of these reserves cannot be long delayed. The most attractive alternative is thus a form of energy derived from a controlled fusion reaction that would use hydrogen from seawater, a virtually limitless source, and that would not create a significant problem of waste disposal. Other sources of energy that may provide alternatives to mineral fuels include various forms of solar cell, deriving power from the sun by a chemical or physical reaction such as that of photosynthesis. Solar cells of this kind are already in regular use on satellites and space probes, where the flow of energy out from the sun (the solar wind) can be harnessed without interference from the atmosphere or the rotation of the earth. Unless such alternative sources fulfill their promise of more general application, industrial civilization will face a major crisis of energy starvation within the 21st century.

Solar cells

Wankel engine. While new sources of energy hold out some hope for the future, the heavy consumption of oil fuels has been steadily increasing in the last quarter century as oil-burning engines and boilers have become ever more widespread. The conventional internal-combustion engine is still the reciprocating engine used in most automobiles, although the more efficient Wankel rotary engine is beginning to displace it. In this engine, a three-sided inner rotor moves within an outer rotor or casing, forming chambers within which the four-stroke cycle can be performed without conventional valves. Although there had been many previous ideas for rotary-piston engines, the first to work satisfactorily as a light internal-combustion engine was that invented in 1954 by Felix

Wankel of West Germany. This was introduced as a gasoline engine for automobiles in 1968, and its advantages regarding weight, economy, compactness, and smooth running make it very attractive, especially to manufacturers not too heavily committed to the traditional reciprocating engine.

Gas turbine. The gas turbine has undergone substantial development since its first successful operational use at the end of World War II. The high power-to-weight ratio of this type of engine made it ideal for aircraft propulsion, so that in either the pure jet or turboprop form it was generally adopted for all large aircraft, both military and civil, by the 1960s. The immediate effect of the adoption of jet propulsion was a spectacular increase in aircraft speeds, the first piloted airplane exceeding the speed of sound in level flight being the American Bell X-1 in 1947, and by the late 1960s supersonic flight was becoming a practicable, though controversial, proposition for civil-airline users. Ever-larger and more powerful gas turbines have been designed to meet the requirements of airlines and military strategy, and increasing attention has been given to refinements to reduce the noise and increase the efficiency of this type of engine. Meanwhile, the gas turbine has been installed as a power unit in ships, railroad engines, and automobiles, but in none of these uses has it proceeded far beyond the experimental stage.

Use of the gas turbine in aircraft

Materials. The Space Age has spawned important new materials, and uncovered new uses for old materials. A vast range of applications has been found for plastics that have been manufactured in many different forms with widely varied characteristics. Glass fibre has been molded in rigid shapes to provide motor-car bodies and hulls for small ships. Carbon fibre has demonstrated remarkable properties that promise to provide an alternative to metals for high-temperature turbine blades. Research on ceramics has produced materials resistant to high temperatures suitable for heat shields on spacecraft. The demand for iron and its alloys and for the nonferrous metals has remained high. The modern world has found extensive new uses for the latter, copper for electricity conductors, tin for protecting less resistant metals in the form of tinplate, lead as a shield in nuclear-power installations, and silver in photography. In most of these cases the development began before the 20th century, but the continuing increase in demand for these metals is affecting their prices in the world commodity markets.

Automation and the computer. Both old and new materials are used increasingly in the engineering industry, which has been transformed since the end of World War II by the introduction of control engineering with automation and computerized techniques. The vital piece of equipment has been the computer, and especially the electronic digital computer, a 20th-century invention the theory of which was expounded by the English mathematician and inventor Charles Babbage in the 1830s. The essence of this machine is the use of electronic devices to record electric impulses coded in the very simple binary system, using only two symbols, but other devices such as punched cards and tape for storing and feeding information have been important supplementary features. By virtue of the very high speeds at which such equipment can operate, even the most complicated calculations can be converted into the binary system and performed in a very short space of time.

The Mark I digital computer was at work at Harvard University in 1944, and after the war the possibility of using it for a wide range of industrial, administrative, and scientific applications was quickly realized. The early computers, however, were large and expensive machines, and their general application was delayed until the invention of the transistor revolutionized computer technology. The transistor is another of the key inventions of the Space Age. The product of research on the physics of solids, and particularly of those materials such as germanium and silicon known as semiconductors, the transistor was invented at Bell Telephone Laboratories in the United States in 1948. It was discovered that crystals of semiconductors, which have the capacity to conduct electricity in some conditions and not in others, could be made to perform the functions of a thermionic valve but in a shape that was much smaller, more reliable, and more versatile. The result has been the replacement of the cumbersome and fragile heat-producing thermionic valve by the small and strong transistor in a wide range of electronic equipment. Most especially, this conversion has made possible the construction of much more powerful computers while making them more compact and less expensive. Indeed, so small can effective transistors be that they have made possible the new skills of miniaturization and microminiaturization, whereby complicated electronic circuits can be printed on minute pieces of metal and incorporated in large numbers in computers. By the late 1950s the computer was in office use in industries and other organizations.

Semiconductor devices

These techniques have seemed to hold out the prospect of completely automated factories, with computer-controlled machines performing every stage in the production process. The fact that this consummation was not rapidly achieved on a large scale may be an indication of the power of social factors rather than of the inadequacy of the technology, for there is no reason to doubt that the computer is capable of very much greater development in the future. So powerful, it seems, can this instrument become, that some commentators have likened it to the human brain, and there is no doubt that human analogies have been important in its development.

The chemical industry provides some of the most striking examples of fully automated, computer-controlled manufacture. The characteristics of flow production, in contrast to the unit production of most engineering establishments, lend themselves ideally to automatic control from a central computer monitoring the information fed back to it and making adjustments accordingly. Many large petrochemical plants producing fuel and raw materials for manufacturing industries are now run in this way, with the residual human function that of maintaining the machines and of providing the initial instructions. The same sort of influences can be seen even in the old established chemical processes, although not to the same extent: in the ceramics industry, in which continuous firing has replaced the traditional batch-production kilns; in the paper industry, in which mounting demand for paper and board has encouraged the installation of larger and faster machines; and in the glass industry, in which the float-glass process for making large sheets of glass on a surface of molten tin requires close mechanical control.

Automated chemical production

Even in medicine and the life sciences the computer has provided a powerful tool of research and supervision. It is now possible to monitor complicated operations and treatment. Surgery has made great advances in the Space Age. The introduction of transplant techniques has attracted worldwide publicity and interest, but perhaps of greater long-term significance has been the research in microbiology, with the aid of modern techniques and instruments, that has begun to unlock the mysteries of cell formation and reproduction through the self-replicating properties of the DNA molecules present in all living substances, and thus to explore the nature of life itself.

Food production. Food production has also been subject to technological innovation, such as accelerated freeze-drying and irradiation as methods of preservation, as well as the increasing mechanization of farming throughout the world. The widespread use of new pesticides and herbicides has in some cases reached the point of abuse, causing worldwide concern. Despite such problems, farming has been transformed in response to the demand for more food; scientific farming, with its careful breeding, controlled feeding, and mechanized handling, has become commonplace. New food-producing techniques such as aquiculture and hydroponics, for farming the sea and the seabed and for creating self-contained cycles of food production without soil respectively, are being explored, either to increase the world supply of food or to devise ways of sustaining closed communities such as may one day venture forth from the earth on the adventure of interplanetary exploration.

Civil engineering. One industry which has not been deeply influenced by new control-engineering techniques

is civil engineering, in which the nature of the tasks involved makes dependence on a large labour force still essential, whether it be in constructing a skyscraper, a new highway, or a tunnel. Nevertheless, some important new techniques have appeared since 1945, notably the use of heavy earth-moving and excavating machines such as the bulldozer and the tower crane. The use of prefabricated parts according to a predetermined system of construction has become widespread. In the construction of housing units, often in large blocks of apartments or flats, such systems are particularly relevant because they make for standardization and economy in plumbing, heating, and kitchen equipment. The revolution in home equipment that had begun before World War II has continued apace since, with a proliferation of electrical equipment.

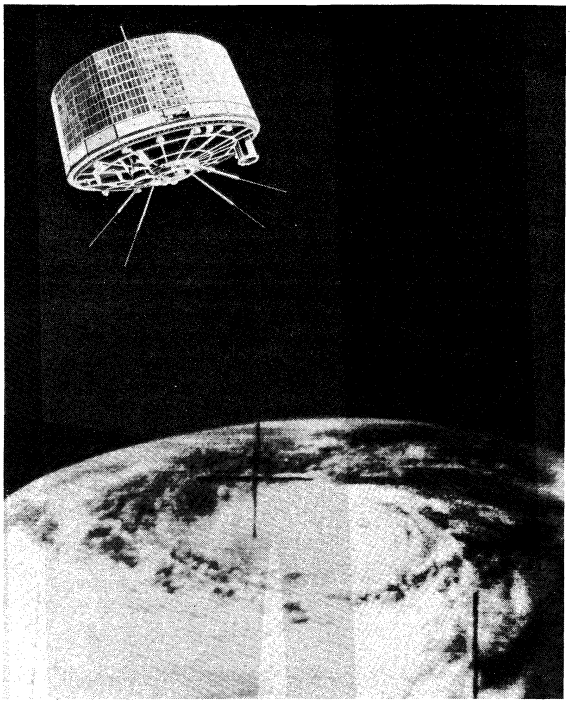
Prefabricated buildings

Transport and communications. Many of these changes have been facilitated by improvements in transport and communications. The transport developments have, for the most part, continued those well established in the earlier part of the century. The automobile has proceeded in its phenomenal growth in popularity, causing radical changes in many of the patterns of life, although the basic design of the motorcar has remained unchanged. The airplane, benefitting from jet propulsion and a number of lesser technical advances, has made spectacular gains at the expense of both the ocean liner and the railroad. The growing popularity of air transport, however, has brought problems of crowded airspace, noise, and airfield siting.

World War II helped bring about a shift to air transport, with direct passenger flights across the Atlantic introduced immediately after the war. The first generation of transatlantic airliners were the aircraft developed by war experience from the Douglas DC-3 and the pioneering types of the 1930s incorporating all-metal construction with stressed skin, wing flaps and slots, retractable landing gear, and other advances. The coming of the big jet-powered civil transport in the 1950s kept pace with the rising demand for air services, but accentuated the social problems of air transport. The solution to these problems may lie partly in the development of vertical takeoff and landing techniques, a concept successfully pioneered by the British military aircraft, the Hawker Siddeley Harrier. Longer term solutions may be provided by the development of air-cushion vehicles derived from the Hovercraft, in use in the English Channel and elsewhere, and one of the outstanding technological innovations of the period since 1945. The central feature of this machine is a down-blast of air which creates an air cushion on which the craft rides without direct contact with the sea or ground below it. The remarkable versatility of the air-cushion machine is beyond doubt, but it has proved difficult to find very many transportation needs that it can fulfill better than any craft already available. Despite these difficulties, it seems likely that this type of vehicle will have an important future. It should be remembered, however, that all the machines mentioned so far, automobiles, airplanes, and Hovercraft, use oil fuels, and it is possible that the exhaustion of these will turn attention increasingly to alternative sources of power, and particularly to electric traction (electric railroads and autos), in which field there have been promising developments such as the linear-induction motor.

The Hovercraft

In communications, also, the dominant lines of development continue those which were established before or during World War II. In particular, the rapid growth of television services, with their immense impact as media of mass communication, has built on foundations laid in the 1920s and 1930s, while the universal adoption of radar on ships and airplanes has followed the invention of a device to give early warning of aerial attack. But in certain features the development of communications in the Space Age has produced important innovations. The transistor, so significant for computers and control engineering, has also made a large contribution to communications technology. Second, the establishment of space satellites, considered to be a remote theoretical possibility in the 1940s, had become part of the accepted technological scene in the 1960s, and these have played a dramatic part in telephone and television communication as well as in relaying meteorological pictures and information. Third, the development of magnetic tape as a means of recording sound and, more recently, vision, has provided a highly flexible and useful mode of communication. Fourth, new printing techniques have developed. In phototypesetting, a photographic image is substituted for the conventional metal type. In xerography, a dry copying process, an ink powder is attracted to the image to be copied by static electricity and then fused by heating. Fifth, new optical devices such as zoom lenses have increased the power of cameras and correspondingly improved the quality of film available to the cinema and television. Sixth, new physical techniques such as those which produced the laser (light amplification by stimulated emission of radiation) are making available an immensely powerful means of communication over long distances, although these are still in their experimental stages. The seventh and final communications innovation is the use of radio waves to explore the structure of the universe by means of the radio telescope and its derivative, the X-ray telescope. This technique was pioneered after World War II and has since become a vital instrument of satellite control and space research. Radio telescopes have also been directed toward the Sun's closest neighbours in space in the hope of detecting electromagnetic signals from other intelligent species in the universe.



New uses of radio waves

Military technology. Military technology in the Space Age has been concerned with the radical restructuring of strategy caused by the invention of nuclear weapons and the means of delivering them by intercontinental ballistic missiles. Apart from these major features and the elaborate electronic systems which purport to give an early warning of missile attack, the main emphasis of military reorganization has been on high manoeuvrability through helicopter transport and a variety of armed vehicles. Such forces have been deployed in wars in Korea and Vietnam, and the latter has also seen the widespread use of napalm bombs and chemical defoliants to remove the cover provided by jungle foliage. At sea, World War II marked the demise of the heavily armoured battleship. The only large ships to survive in the navies of the world are aircraft carriers. The emphasis now is on electronic detection and the support of nuclear-powered submarines equipped with missiles carrying nuclear warheads. The only major use of nuclear power since 1945, other than generating large-scale electric energy, has been in the power plants of ships, and particularly the breed of missile-carrying submarines capable of cruising for extended periods below sea level.

Space exploration. The rocket, which has played a crucial part in the revolution of military technology since the end of World War II, has acquired a more constructive significance in the space programs of the Soviet Union and the United States. The first spectacular step was Sputnik 1, a sphere with an instrument package of 184 pounds (83 kilograms), launched into space by the Soviet Union on October 4, 1957, to become the first artificial satellite. The feat precipitated the so-called space race, in which achievements soon followed each other in rapid succession. They may be conveniently grouped in four chronological although overlapping stages. In the first stage, the emphasis was on increasing the thrust of rockets capable of putting satellites into orbit and on exploring the possible uses of satellites in communications, in weather observation, in monitoring military information, and in topographical and geological surveying. The second stage was that of the manned space program. This began with the successful orbit of the Earth by the Soviet cosmonaut Yury Gagarin on April 12, 1961, in the space vehicle Vostok 1. This flight demonstrated mastery of the complex problems of weightlessness and of safe re-entry into the atmosphere of the Earth. It was followed by a series of Soviet and United States space flights in which the techniques of space rendezvous and docking were acquired, flights up to a fortnight were achieved, and men "walked" in space outside their craft.

Manned space flights

The third stage of space exploration was the lunar program, beginning with approaches to the Moon and going

U.S. weather satellite orbiting the Earth.
By courtesy of National Aeronautics and Space Administration

on through automatic surveys of its surface to manned landings. Again, the first achievement was Soviet: Lunik 1, launched on January 2, 1959, became the first artificial body to escape the gravitational field of the Earth, fly past the Moon, and enter an orbit around the Sun as an artificial planet. Lunik 2 impacted on the Moon on September 13, 1959, to be followed by Lunik 3, launched on October 4, 1959, which went round the Moon and sent back the first photographs of the side turned permanently away from the Earth. The first soft landing on the Moon was made by Lunik 9 on February 3, 1966; this craft carried cameras which transmitted the first photographs taken on the surface of the Moon. By this time, however, excellent close-range photographs had been secured by the United States Ranger 7, 8, and 9, which crashed into the Moon in the second half of 1964 and the first part of 1965; and between 1966 and 1967 the series of five Lunar Orbiters photographed almost the entire surface of the Moon from a low orbit in a search for suitable landing places. The United States Surveyor 1 soft-landed on the Moon on June 2, 1966, and this and following Surveyors acquired much useful information about the lunar surface. Meanwhile, the size and power of launching rockets climbed steadily, and by the late 1960s the enormous Saturn V rocket, standing 353 feet (108 metres) high and weighing 2,725 tons (92,472,000 kilograms) at lift-off, made possible the United States three-man Apollo series which climaxed on July 20, 1969, when Neil Armstrong and Edwin Aldrin clambered out of the Lunar Module of their Apollo 11 spacecraft onto the surface of the Moon. The manned lunar exploration begun thus continued with a widening range of experiments and achievements.

Space probes

The fourth stage of space exploration has been that which has looked out beyond the Earth and its immediate satellite, the Moon, to the possibilities of planetary exploration. The two closest planetary neighbours of the Earth, Venus and Mars, were the first to receive attention. The United States space probe Mariner 2 was launched on August 27, 1962, and passed by Venus the following December, relaying back information about that planet which indicated that it was hotter and less hospitable than had been expected. These findings were confirmed by the Soviet Venera 3 which crash-landed on the planet on March 1, 1966, and by Venera 4, which made the first soft-landing on October 18, 1967. Meanwhile, Mariner 4, launched on November 28, 1964, passed within about 6,000 miles (9,700 kilometres) of Mars after a journey of 228 days and sent back photographs which showed with startling clarity that the surface of Mars closely resembles that of the Moon. Further photographs were taken from space probes in 1969 and 1971, but the frequency of these attempts is limited to the few weeks every two years or so when the two planets are in a favourable relationship to each other. Serious thought is now being given to the possibility of extending space exploration beyond the orbits of the nearest planets to the giant planets of Jupiter and beyond. With existing technology much useful information could be gathered, but the cost is extraordinarily high, especially in the launching stages when an enormous amount of fuel and equipment is consumed without any attempt at recovering the launch vehicle.

At the dawn of the Space Age it is possible to perceive only dimly its scope and possibilities. But it is relevant to observe that the history of technology has brought the world to a point in time at which man, equipped with unprecedented powers of self-destruction, stands on the threshold of extraterrestrial exploration. Only the gradual accumulation of skills over many millennia, the acceleration in the processes of industrialization in the last 200 years, the diffusion of these processes over the whole earth, and the vast increase in investment in technology, both in hardware and in social forms of investment such as technical education, could have created the situation which modern civilization reached in the 1970s. Many problems attended the rush of technological advance, and it is appropriate to conclude with a brief survey of these problems.

TECHNOLOGY AND THE ENVIRONMENT

Technology confronts modern civilization with a challenge to make a decision, or rather, a series of decisions, about how the enormous power now available to society will be used. The need to control the development of technology by regulating its application to creative social objectives makes it ever more necessary to define these objectives while the problems presented by rapid technological growth can still be solved.

These problems, and the social objectives related to them, may be considered under four broad headings. First is the nuclear problem, of controlling the application of nuclear technology. Second is the population problem, arising out of the population explosion to which 20th-century medical technology has made such a momentous contribution. A third is the complex of social difficulties created by the impact of technology on life in town and countryside, bringing about an upheaval of traditional social and educational systems. Finally, there is the ecological problem, brought on by advanced technology causing the pollution of the environment and disturbing the balance of natural forces of regeneration.

Nuclear technology. The solution to the first problem, of controlling nuclear technology, is generally thought to be political in essence. Its root is the anarchy of national self-government, for as long as the world remains divided into a multiplicity of nation-states, or even into two power blocs, each committed to the defense of its own sovereign power to do what it chooses, nuclear weapons merely replace older weapons by which such nation-states have been maintained. The availability of a nuclear armoury, indeed, has brought home the weaknesses of a world political system based upon independent nation-states, though it has not made it any easier to overcome them. Here, as elsewhere, technology is a tool which can be used creatively or destructively. But the manner of its use depends utterly on human decisions, and in this matter of nuclear self-control the decisions are those of governments.

Nuclear weapons and international politics

Population problem. Assuming that the nuclear threat can be averted, world civilization will have to come to grips with the population problem long before the end of the present century if life is to be tolerable on the planet Earth in the next century. The problem can be tackled in two ways, both drawing on the resources of modern technology. On the one hand, efforts may be made to limit the rate of population increase. Medical technology, which, through new drugs and other techniques, has provided a

powerful impulse to the increase of population, also offers means of controlling this increase through contraceptive devices and through painless sterilization procedures. Again, technology is a tool that is neutral in respect to moral issues about its own use, but it would be futile to deny that artificial population control is inhibited by powerful moral constraints and taboos. Some reconciliation of these conflicts is essential, however, if stability in world population is to be satisfactorily achieved. On the other hand, even the most optimistic program of population control can only hope to achieve a slight reduction in the rate of increase by the end of the 20th century, so that a second approach to the population problem must be made simultaneously in the shape of an enormous effort to increase the world's production of food. Technology has much to contribute here, both in raising the productivity of existing sources of food supply and in creating new sources by making the deserts fertile and by farming systematically the riches of the oceans. There is enough work here to keep engineers and food technologists busy for many generations.

Social difficulties. An operative solution to these first two problems will bring to the fore secondary social problems associated with a way of life based upon large-scale technology. These are already clearly visible in the advanced industrial countries, but they are likely to become more widespread. The cities of many industrial nations are already afflicted by urban blight, as the traditional centres are deserted by the middle class and left to socially disfavoured and impoverished groups, with a consequent loss of social order.

Urban decay

This decay of megalopolis has been caused largely by the automobile and electricity, which made possible the rapid expansion of towns and then contributed to their depopulation. Another consequence has been the increase of urban sprawl around cities, and the spoiling of the neighbouring countryside as traditional rural communities have been overwhelmed. At another level, social dislocation has been prompted by technology through the pressure for education. Technical education has long been recognized as an essential feature of any advanced industrial nation. Such education, however, requires a high level of literacy and numeracy, so that industrial survival has come to be equated with an elaborate system of national education.

Ecological problems. The fourth and final problem area of modern technological society is the ecological problem of preserving a healthy environmental balance. Though man has been damaging the environment for centuries by overcutting trees and farming too intensively, and though some protective measures, such as the establishment of national forests and wildlife sanctuaries, were taken decades ago, great increases in population and in the level of industrialization have caused a public crisis. Thus the great public concern with pollution in the advanced nations is both overdue and welcome. Once more, however, it needs to be said that the fault for this waste-making abuse of technology lies with man himself rather than with the tools he uses. For all his intelligence, man behaves in communities with a thoughtlessness for his environment that is potentially suicidal. It is debatable, then, whether technology is a blessing or a bane. The history of technology has led from the earliest technological achievements of man the toolmaker to the crossroads at which the species now stands, in the last third of the 20th century, confronted by a choice, that of self-destruction or a millennium of adventurous growth and expansion, reaching out to colonize the universe, unlocking the secrets of controlled nuclear fusion as a source of power, exploiting exotic sources of food, and creating a healthy and well-regulated environment.

BIBLIOGRAPHY. The best general work is still CHARLES SINGER *et al.*, *A History of Technology*, 5 vol. (1954–58); the single-volume companion study, T.K. DERRY and T.I. WILLIAMS, *A Short History of Technology* (1960), is a valuable summary. Both are confined to western technology and its antecedents, and both stop at the year 1900. M. KRANZBERG and CARROLL W. PURSELL, JR., *Technology in Western Civilization*, 2 vol. (1967), brings the story into the mid-20th century. Good specialized works include: V.G. CHILDE, *What Happened in History* (1942), a classic study of man's mastery of his environment in prehistory; H. HODGES, *Technology in the Ancient World* (1970); L.T. WHITE, JR., *Medieval Technology and Social Change* (1962); A.P. USHER, *A History of Mechanical Inventions*, 2nd ed. (1954); and J. JEWKES, D. SAWERS, and R. STILLERMAN, *The Sources of Invention*, 2nd ed. (1969). F. KLEMM, *Technik: Eine Geschichte ihrer Probleme* (1954; Eng. trans., *A History of Western Technology*, 1959), is a useful selection of documents. The economic and social implications of technological development are explored in W.H.G. ARMYTAGE, *A Social History of Engineering*, 2nd ed. (1970); DAVID S. LANDES, *The Unbound Prometheus* (1970); and S. LILLEY, *Men, Machines and History* (1948). LEWIS MUMFORD, *Technics and Civilization* (1934), remains a very stimulating essay on this theme. R.J. FORBES, *Man, the Maker* (1958), is a good general review of the history of technology; and R.A. BUCHANAN, *Technology and Social Progress* (1965), may also be found useful as an introductory text. EUGENE S. FERGUSON, *Bibliography of the History of Technology* (1968), is a comprehensive and thorough study. The two outstanding sources of periodical literature are: *Technology and Culture*, the quarterly journal of the Society for the History of Technology, published since 1959; and the *Transactions* of the Newcomen Society for the Study of the History of Engineering and Technology, published annually since 1920 except for some irregular volumes during and immediately after World War II.

(R.A.Bu.)

Tecumseh

Tecumseh, chief of the North American Indian tribe of the Shawnees, a gifted orator and magnanimous military leader and the determined advocate of an Indian confederation, has been regarded as an outstanding representative of his people. He urged the Indians to substitute intertribal alliance for intertribal warfare and to restore the integrity of their own culture by freeing themselves from the alien influence of the white man's culture. He tried to save for his people their ancient lands, which at that time—the late 18th and early 19th centuries—were being seized with impunity by whites or bartered off by chiefs for petty annuities that provided for their own comfort but left only meagre amounts for the tribesmen. Tecumseh's cause failed, but his vision and zeal put him among the great leaders of primitive peoples who have tried to protect their homelands and their culture against the inexorable advance of civilization.

In appearance Tecumseh was straight, slim, and muscular; he stood about five feet, 10 inches, with proud bearing and intent hazel eyes. Of light, copper colouring, as were most Shawnees, he has been described erroneously at times as part white. He was capable of withstanding long, exhausting journeys on foot, by canoe, and by pony. Fierce in battle, he was suave and urbane in conversation. He shunned the garments of the whites, dressing in unadorned buckskin, with a tomahawk and silver-hilted hunting knife thrust through his belt.

Early life and training

Tecumseh was born in 1768 in the Indian village of Old Piqua, near present-day Springfield, Ohio. His father was killed by whites in 1774. His mother, a Muskogee (Creek Confederacy), instilled in the boy a spirit of vengeance and bitter hatred of the whites. When he was seven years old, she left him to accompany part of the tribe to Missouri and then passed into obscurity. Tecumseh was reared by an elder sister, Tecumapease, who trained him in the strict Shawnee code of honesty; an elder brother Cheeseekau taught him woodcraft and hunting. He was adopted by the Shawnee chief Blackfish and grew to young manhood with several white foster brothers whom Blackfish had captured. Among them was the famous frontiersman Daniel Boone, who was captured in Kentucky but who escaped after a short time.

Murder, massacre, and invasion of Shawnee land and the destruction of their crops deepened the hatred for whites instilled in Tecumseh by his mother. When he was about 14 years old, during the U.S. War of Independence, he accompanied Blackfish in combined British and Indian attacks on Americans. As hostile as he was toward whites, however, about a year later Tecumseh rebuked his fellow Shawnees for the cruelty they themselves practiced, and it was then that he discovered that words could be as

powerful as weapons. He had accompanied one of the predatory Shawnee raids on the flatboats that were bringing encroaching white settlers down the Ohio River; he had seen a white man tied to a stake and burned. Horrified, he had showered his fellow tribesmen with such abuse that they never tortured a prisoner in his presence again. On a later occasion, he denounced and personally subdued his warriors when he found them beginning to slaughter captured prisoners, risking his life by hurling the attackers to the ground.

After the war Tecumseh for a number of years was a marauder, fighting small actions against the whites in the Northwest and assisting the Cherokees in the South. He saw his brother Cheeseekau killed in an unsuccessful raid near Nashville, Tennessee, in September 1792. Though he was the youngest of the Shawnee band, he was chosen leader, fought a number of small actions in the South, and made an acquaintance with the Creeks that helped him later to form an alliance with them. At the call of Bluejacket, the Shawnee chief who was collecting a force to meet a U.S. army under Maj. Gen. Anthony Wayne, he returned to Ohio, where he directed the unsuccessful attack on Ft. Recovery in June 1794. On August 20, he led part of Bluejacket's force when it was decisively defeated by Wayne at Fallen Timbers. There he saw another older brother, Sauwaseekau, killed.

When the leading chiefs of the Old Northwest gathered at Wayne's call at Greenville, in Ohio, Tecumseh held aloof; and when the Treaty of Greenville was negotiated in August 1795, he refused to recognize it and roundly attacked the "peace" chiefs who signed away land that he contended they did not own. Land, he said, was like the air and water, the common possession of all Indians. This doctrine of communal ownership of the land became the cornerstone of his policy.

Break with the "peace" chiefs

Partly because of his superb oratory, which the whites compared with that of the young Henry Clay, the rising political leader in Kentucky, Tecumseh became the spokesman for the Indians in great councils at Urbana (1799) and Chillicothe (1804) in Ohio that undertook to settle grievances. For a time he studied treaties, spoke at councils, and lived peacefully in Ohio and Indiana.

About 1808 Tecumseh settled in Indiana with his brother Tenskwatawa, called "the Prophet" because he claimed to have had a revelation from the "Master of Life." There the brothers sought to induce the Indians to discard white customs and goods (particularly whiskey, which was making drunkards of many Indians and destroying entire tribes) and to abjure intertribal wars for unity against the white invader. The code of the Prophet had a mysticism that appealed to the Indians, and many became converts.

Organizer of Indian confederation

With inexhaustible energy, Tecumseh began to form an Indian confederation to resist white pressure. He made long journeys in a vast territory, from the Ozarks to New York and from Iowa to Florida, gaining recruits (particularly among the tribes of the Creek Confederacy, to which his mother's tribe belonged). The tide of settlers had pushed game from the Indians' hunting grounds, and, as a result, the Indian economy had broken down.

In 1811, while Tecumseh was in the South, William Henry Harrison, governor of the Indiana Territory, marched up the Wabash River and camped near the brothers' settlement. The Prophet unwisely attacked Harrison's camp and was so decisively defeated in the ensuing Battle of Tippecanoe that his followers dispersed, and he, having lost his prestige, fled to Canada and ceased to be a factor in Tecumseh's plans.

Seeing the approach of war (the War of 1812) between the Americans and British, Tecumseh assembled his followers and joined the British forces at Ft. Malden on the Canadian side of the Detroit River. There he brought together perhaps the most formidable force ever commanded by a North American Indian, an accomplishment that was a decisive factor in the capture of Detroit and of 2,500 United States soldiers (1812).

Fired with the promise of triumph after the fall of Detroit, Tecumseh departed on another long journey to arouse the tribes, which resulted in the uprising of the Alabama Creeks in response to his oratory, though the Chickasaws, Choctaws, and Cherokees rebuffed him. He returned north and joined the British Gen. Henry A. Procter in his invasion of Ohio. Together they besieged Ft. Meigs, held by William Henry Harrison, on the Maumee River above Toledo, where by a stratagem Tecumseh intercepted and destroyed a brigade of Kentuckians under Col. William Dudley, coming to Harrison's relief. He and Procter failed to capture the fort, however, and were put on the defensive by Oliver Hazard Perry's decisive victory over the British fleet on Lake Erie (September 10, 1813). Harrison thereupon invaded Canada. Tecumseh with his Indians reluctantly accompanied the retiring British, whom Harrison pursued to the Thames River, in present-day southern Ontario. There, on October 5, 1813, the British and Indians were routed and Harrison won control of the Northwest. Tecumseh, directing most of the fighting, was killed. His body was carried from the field and buried secretly in a grave that has never been discovered. Nor has it ever been determined who killed Tecumseh. Tecumseh's death marked the end of Indian resistance in the Ohio Valley and in most of the lower Midwest and South, and soon thereafter the depleted tribes were transported beyond the Mississippi.

Teeth and Gums, Human

In man there are two dentitions, or sets of teeth. The first of these, the primary, or deciduous, dentition, is functional from shortly after birth to about the time of puberty, by which time it has been entirely replaced by the permanent dentition. The process of replacement takes place in an orderly progression between the ages of seven and 12 years, so that the permanent dentition is completed between 18–20 years, with the appearance of the third permanent molars, the so-called wisdom teeth.

Each tooth has three parts, the root, the neck, and the crown. The root is the part of the tooth that is attached to the tooth-bearing bone—the alveolar processes—of the jaws by a fibrous ligament called the periodontal ligament or membrane. The crown is that portion of the tooth that projects into the mouth. Between the root and the crown is the neck, the portion of the tooth that is embraced by the fleshy gum tissue, a specialized area of mucous membrane that lines the mouth cavity.

Tooth form and function. Man has 20 deciduous and 32 permanent teeth. In each jaw there are four incisors, two canines, and four molars belonging to the deciduous dentition. The permanent dentition is made up of four incisors, two canines, four premolars, and six molars in each jaw. The deciduous molars are succeeded by premolars; the permanent molars have no deciduous predecessors.

Incisors and canines are used for cutting (incising), while premolars and molars are used for crushing and grinding food. The forms of the teeth reflect their functions: the incisor crowns having cutting edges, and premolars and molars a series of elevations, or cusps, used for breaking up particles of food. Human dentition is unique in the relatively small size of the canines. The number of roots (fangs) for each tooth varies from one for incisors and canines to three for upper molars.

The development of teeth. Each tooth is the product of a tooth germ, or bud, which grows out of the lining of the developing oral cavity. The tooth germ is a cap, called an enamel organ, over a collection of cells called the dental papilla or primary pulp. Both enamel organ and papilla are surrounded by a fibrous tissue sac, the dental follicle, attaching each germ to the overlying gum.

Origin of enamel, dentin, and cement

From the enamel organ there develops the specialized hard enamel that covers the crown of the tooth; from the dental papilla develops another hard tissue, dentin, that surrounds the pulp of the tooth. From the follicle originate both cement (or cementum), another calcified tissue covering the root area of each tooth, and the periodontal membrane.

Around each developing tooth the alveolar bone forms a bony socket to which the tooth becomes attached by the periodontal membrane. As each tooth develops and its hard tissue elements, enamel, dentin, and cement, commence to calcify, the tooth erupts towards and into the mouth cavity. During eruption the remains of the enamel organ unite with the outer layer or epithelium of the overlying gum to form an attachment between the gum and the surface of the tooth.

There is still uncertainty regarding all the factors involved in tooth eruption.

During replacement of deciduous teeth by permanent teeth, the overlying bone and the greater part of the root area of each deciduous tooth is resorbed and a fresh socket is produced for the succeeding permanent tooth.

The structure of teeth. Enamel, the hardest tissue produced by the body, is the product of a special layer of cells, the ameloblasts, situated at the inner surface of the enamel organ adjacent to the dental papilla. The ameloblasts produce a substance filled with tiny fibres, or fibrils; inorganic salts derived from the blood are deposited in this matrix as minute crystals. Enamel is formed as a series of adjacent prisms or rods, each growing toward the outer surface of the tooth. After each prism is fully formed, there is no further deposition. If enamel is destroyed or worn away with use, it cannot be replaced or repaired. Enamel formation depends on an adequate supply of inorganic substances in the diet and on certain hormones and vitamins. Starvation or severe malnutrition and certain diseases interfere with its formation. Poorly calcified teeth are more liable to decay.

Dentin is the product of special cells, odontoblasts, derived from the tooth pulp. As dentin develops at the expense of the pulp, projections of odontoblasts come to occupy narrow tubes (dentinal tubules) in the dentin. Unlike enamel, dentin is capable of continuous formation (secondary dentin), especially in response to stimulation after loss of enamel or decay, and the tubules may become closed by further calcification. Dentin is less highly mineralized and more elastic than enamel.

Cement is formed by specialized cells of the dental follicle, cementoblasts, in layers upon the surface of the roots of teeth. It provides anchorage for the fibre bundles of the periodontal membrane. It is similar in its composition and structure to bone and is more capable of repair than any other calcified dental tissue.

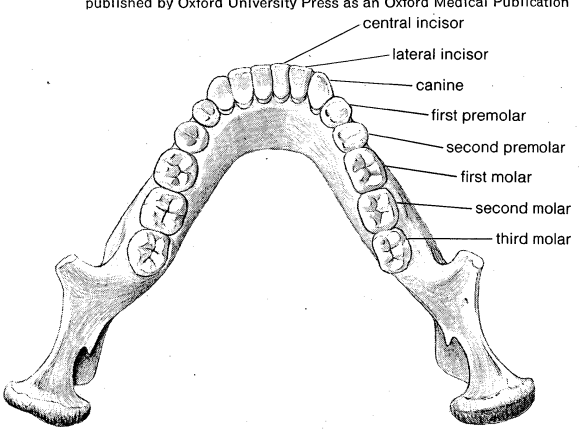

Figure 1: Lower jaw and its permanent teeth.

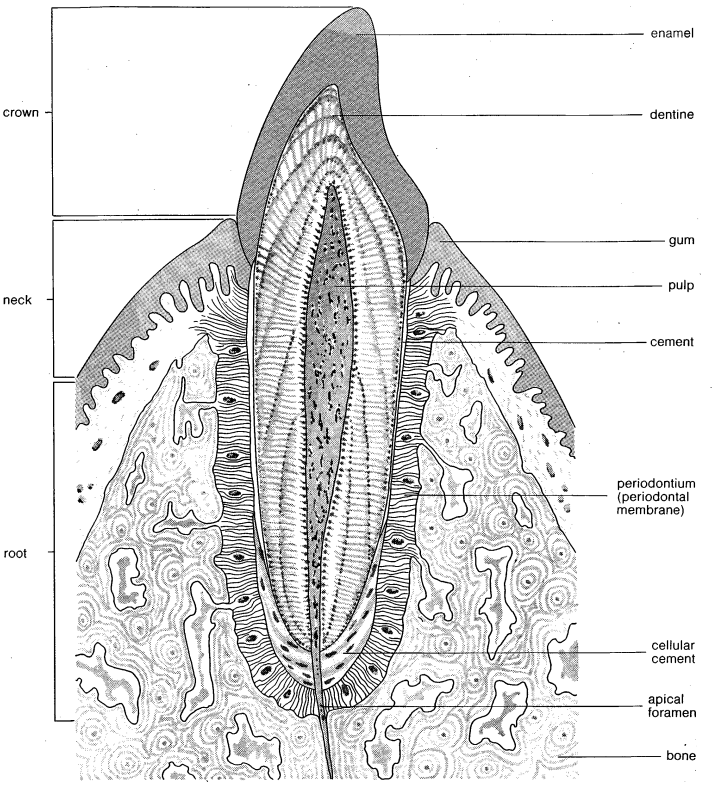

Figure 2: Vertical section through a tooth showing its parts and surrounding tissues.
Adapted from *Cunningham's Textbook of Anatomy* edited by G.J. Romanes and published by Oxford University Press as an Oxford Medical Publication

The pulp of a tooth occupies a central pulp cavity connecting through root canals with the tooth surface at the apex of each root. Pulp cavities decrease with age because of the deposition of secondary dentin. Pulp consists of cells, a delicate framework of fibres, blood vessels, and nerves that respond with toothache to damage to pulp and dentin. With age, the pulp becomes more fibrous and less cellular, vascular, and sensitive. It provides nutrition for the adjacent dentin, but a fully formed tooth can remain functional when its pulp is removed.

Periodontal membrane

The periodontal membrane consists of bundles of fibrous tissue that hold each tooth in its socket. Other fibre bundles attach the gum tissue to the tooth and adjacent teeth to one another. The periodontal membrane contains blood vessels and sensory nerve endings for pain, touch, and proprioceptive sensation (sensation arising from stimuli within rather than outside the body), the latter providing the central nervous system with the feedback information necessary for coordinated muscle activity in complex activities such as mastication and swallowing. The ability of the periodontal membrane to repair itself is an essential factor in tooth transplantation.

Development and structure of gum tissue. Before the erupting teeth enter the mouth cavity, gum pads develop (slight elevations of the overlying oral mucous membrane). When tooth eruption is complete the gum embraces the neck region of each tooth. Gum is attached to the adjacent alveolar bone and to the cement of each tooth by fibre bundles. It is also attached to the tooth enamel.

Diseases of teeth and gums. *Variations in number and shape of teeth.* Complete congenital absence of teeth (anodontia) is a rare condition. Congenital absence of individual teeth is uncommon in the deciduous dentition and more frequent in the permanent dentition. The teeth most often absent (as confirmed by X-ray examination) are upper lateral incisors, lower premolars, and third permanent molars.

Teeth over and above the normal number (supernumerary teeth) are also more common in the permanent denti-

tion. They are most often found in the upper incisor region, the premolar region, and the permanent molar series. In some cases they resemble normal teeth; more often they are abnormal in form, usually peg shaped.

Variations in the shape of teeth may be the result of genetic abnormalities, often associated with some degree of mental disturbance, or of abnormal development due to malnutrition or disease.

Irregularity of the teeth resulting in deformed dental arches (the curves formed by the upper and lower rows of teeth) and abnormality of relationship between the teeth in opposing jaws (malocclusion) is frequent in modern civilized societies. In the less severe forms one or more teeth may be out of alignment though the jaws are in normal relation to one another. In more serious forms the jaws are themselves out of alignment. Treatment consists of moving the teeth by the use of special fixed or removable appliances. Sometimes teeth are extracted to provide space for the remaining teeth. In more serious cases surgery may be necessary.

Pulp abscesses and gumboils

Infection of pulp. Infection of the pulp of a tooth usually results from rapidly penetrating and neglected dental caries (see below) or wear of tooth substance (attrition) leading to exposure of dentin or even of the pulp cavity. Inflammation of the pulp, owing to the rigidity of its limiting walls and the resultant strangulation of blood vessels, is liable to produce abscess formation or death of pulp tissue. Pulp abscesses tend to spread to the tissues around the root tips and from these spread through the alveolar bone, opening into the mouth cavity (gumboil) or into the deeper regions of the mouth and face. Such infection may enter the bloodstream and set up secondary abscesses or destruction of tissue in various body organs including the valves of the heart.

Tumours. Tumours of dental tissues vary from extra cusps or roots to complex growths involving a multiplicity of dental tissues (odontomas), which may on rare occasions become malignant.

Dental decay. Dental decay (caries), along with gum infection (gingivitis), is by far the most frequent of dental diseases; perhaps, apart from the common cold, the most frequent disease in contemporary society.

It is generally accepted that tooth decay is due to the destruction of the dental calcified tissues, especially enamel or dentin, by acids produced locally in the mouth by bacterial fermentation of sugar and starchy food debris. Caries usually commences on surface enamel, especially in pits and fissures and between adjacent teeth. From enamel the process of decay spreads to the underlying dentin, and may finally involve the tooth pulp. Dentin may respond by the formation of secondary dentin in the pulp chamber and by the obliteration of its tubule.

Poorly calcified teeth are more vulnerable to caries. It has been demonstrated that dental decay, especially in deciduous teeth, can be greatly reduced by the addition of fluorides to drinking water.

Although the above outline of caries causation is generally accepted, there remain unexplained features and alternative theories, as would be expected in a disease that does not easily fit into any particular pathological classification. Treatment is by removal of decayed tissue and replacement by inert filling substances.

Diseases of gums. The most frequent of gum diseases is gingivitis. Gingivitis, or inflammation of the gum, usually commences at or close to the gum margins, often between adjacent teeth. Pockets form between the gum and the adjacent teeth, sometimes penetrating deeply into the tissues. This leads to further infection, with inflammation and bleeding from the ulcerated gums. Deeper penetration produces destruction of alveolar bone and involvement of the periodontal membrane, leading to loosening and loss of teeth. When the teeth are lost or extracted the condition clears up.

Predisposing factors are poor oral hygiene, some abnormal relationship of gum to underlying bone, excessive masticatory load on individual teeth, badly fitting partial dentures or corrective appliances, obscure hormonal conditions, and lack of certain vitamins, especially vitamin C (lack of this vitamin results in scurvy).

The most common forms of gingivitis are not related to any particular group of micro-organisms, but some more severe types are due to specific infection (*e.g.*, Vincent's gingivitis, or trench mouth), producing marked ulceration of the gums. Certain poisons, including lead, bismuth, and mercury, are excreted in the oral cavity and especially in relation to the gums, leading to a special form of gingivitis.

Treatment of gingivitis

Effective treatment of gum infection once it becomes established may involve surgery followed by strict oral hygiene.

Other gum conditions include atrophy (lack of gum substance), hyperplasia (excess of gum tissue), and local overgrowth of tissue (epulis). Malignant tumours arising directly from gum tissue are rare, although deeply seated malignant tumours may involve the gums and adjacent structures, with resultant loosening of teeth.

Research. Recently there has been considerable addition to existing knowledge of the structure of dental tissues, especially of enamel and dentin. In this process use of the electron microscope has made a useful contribution. There has also been a steady accumulation of information regarding the development of teeth and growth of the skull. Much work remains to be done regarding the causation of dental abnormalities and of the two major diseases of the oral cavity, dental caries and gingivitis.

Another stimulating field of research is that of oral neurophysiology, the functional relationship between the processes that take place in the mouth and the nervous system.

SYMONS, *Introduction to Dental Anatomy*, 6th ed. (1971); and H.H. STONES, *Oral and Dental Diseases*, 5th ed. by E.D. FARMER and F.E. LAWTON (1966).

(J.H.S.)

Tehrān

Tehrān (Teheran) is the capital city of both the country and the Central *ostān* (province) of Iran. It is situated on the southern slopes of the Elburz Mountains, which separate it from the Caspian Sea 62 miles (100 kilometres) to the north. The city lies at an altitude of about 3,800 feet (1,200 metres) above sea level between the Jājrūd and the Karaj rivers, which flow down from the mountains. To the south extends the Central Plateau of Iran.

The name Tehrān is derived from the Old Persian words *teh*, "warm," and *ran*, "place." In order to escape the heat, many of the city's inhabitants go to summer resorts, such as Shemiran, in the mountains ten miles to the north. About 44 miles to the northeast rises the snow-covered peak of Mt. Dāmavēnd, which figures in Persian legends; the mountain is an inactive volcano 18,624 feet (5,678 metres) high. Tehrān has a metropolitan area of 109 square miles (282 square kilometres) and a population in the early 1970s of over 3,000,000. It is the residence of the *shāh* of Iran. (For an associated physical feature, see ELBURZ MOUNTAINS.)

History. Tehrān is the successor to the ancient Iranian capital of Rey, which was destroyed by the Mongols in AD 1220; traces of Rey—where the conqueror Alexander the Great (*q.v.*) halted while pursuing Darius III, king of Persia, in 330 BC—are still to be found almost four miles south of Tehrān.

The village of Tehrān is believed to have been a suburb of Rey in the 4th century. An observer who visited it at the beginning of the 13th century, just before the destruction of Rey, described it as a considerable town with 12 districts; all dwellings were then built underground, and there were many gardens. The town was then reported to be in a state of civil discord, although the government of the day chose to be lenient in dealing with the inhabitants. After the fall of Rey, many of the inhabitants who escaped the massacre took refuge in Tehrān. The first European to mention Tehrān was Don Ruy Gonzales de Clavijo, ambassador of the King of Castile to the court of Timur (Tamerlane), who visited the town in 1404.

In 1553 and 1554, Shāh Ṭahmāsp I of the Safavīd dy-

The rise of the city

nasty of Persia provided Tehrān with a bazaar and built a wall around it; the wall had four gates and 114 towers.

An English writer, Thomas Herbert, author of "Travels in Persia" (published in 1634), visited Tehrān in 1628–29 and estimated the number of houses at 3,000; he described the city as being very hot, with many orchards and "lovely women." The *shāh* Ḥoseyn, of the Safavīd dynasty, held court in Tehrān in 1720, a short while before his defeat by invading Afghans. Karīm Khān Zand, who ruled Iran from 1758 to 1779, considered making Tehrān his capital but instead chose Shīrāz, in southern Iran.

Tehrān became prominent after its capture (1785) by Āghā Moḥammad Khān, the founder of the Qājār dynasty (1779 to 1925), who made the city his capital in 1788 because the tribe to which he belonged lived in the vicinity. Since that date Tehrān has been uninterruptedly the capital of Iran. After the deposition of the last of the Qājārs in 1925, the city experienced a period of great expansion under Reza Shah Pahlavi (1925 to 1941). In 1943 the World War II leaders of the Allies, representing the United States, the United Kingdom, and the Soviet Union, met at the Teheran Conference, at which, among other decisions, they guaranteed the independence of Iran. The reign of the *shāhanshāh* ("king of kings") Mohammad Reza Pahlavi (since 1941) has been marked by a rapid and increasing modernization of the city; his queen, Farah, with her interest in architecture, has been entrusted by the *shāhanshāh* with the formulation of plans for a greater Tehrān to house more than 5,000,000 people.

The city. The city, as mentioned, stands at a mean altitude of 3,800 feet on ground that rises gently northward toward Shemiran. Shemiran itself is inhabited by many wealthy people; surrounded by magnificent mountain scenery, it attracts thousands of city dwellers during the hot summer months.

In contrast to the fashionable districts in the northern part of the city, the old town and the bazaar are to the south. Firdowsī Square, at the junction of Shah Reza Avenue and Firdowsī Street, forms the city's centre, which was formerly Sepah Square (Maidan-e Sepah), but the population centre is still Sepah Square with the bazaar located on its southern side.

The centre of Tehrān's modern district lies to the north of Shah Reza Street. The growth of the city can also be observed along the two roads connecting it with Shemiran. Modern villas, attractive buildings, and the private houses along the highways in the suburbs of Tajrīsh, Darband, Qolhak, and Niavaran, surrounded by ancient trees, complete the scene.

Area and population. Tehrān—which in the early 19th century had a municipal area of two square miles and a population of 120,000—in 1970 had a municipal area of 83 square miles and a population of over 3,300,000. The population has grown rapidly in recent years. Numbering only 540,000 in 1939, it increased to 2,000,000 in 1960. Planners estimate that the municipal area will have increased to 250 square miles and the population to 5,000,000 before the end of the 20th century. In 1970 the rate of population growth was 26 per thousand per year, and the population density was 39,759 per square mile. About half of the population lives in about one-third of the city's area in the south and southeast.

Population growth

The main factor causing population increase has been the expansion of Iran's economy, partly the result of the exploitation of oil. Tehrān, as the capital city, has attracted industry, commerce, and banking, as well as hundreds of thousands of workers who have flocked there, especially from the northern and northwestern provinces.

Climate. Tehrān experiences warm summers and relatively cool winters. High and low mean monthly temperatures are 84° F (29° C) in July and 39° F (4° C) in January. The average annual rainfall is about eight inches; rain usually falls from November to the end of May, and snow also occurs from December to the end of February. Air pollution is worsening each year as a result of the increase in motor traffic and the increased use of oil fuel by industry.

Transport. Tehrān is a focus for road, rail, and air transport. Three paved roads run northward, one runs to the west, two to the south, and one to the east. The Iranian state railway has lines running north, northwest, south, and east from Tehrān; Tehrān is also linked to the trans-Europe railway system via Turkey.

Tehrān is linked by air to major cities in Europe and Asia and to states in the Persian Gulf. Domestic air services also link the capital to major Iranian towns. There is an international airport at Mehrābād, six miles west of Firdowsī Square; two smaller airports—at Qal'eh Morghī and Daushan-Tapeh—are used by small aircraft. A second international airport, capable of handling giant aircraft, is due to be completed by 1976.

Religious groups

The people. The ethnic composition of Tehrān is similar to that of Iran in general. The majority of the inhabitants are Muslim, a Christian minority includes Armenians and Assyrians, and there are also small numbers of Jews and Zoroastrians. Persian is the language in general use, with about a quarter of the population using the Azari dialect. The Armenian and Assyrian minorities speak their own languages. Colleges and universities use many textbooks in English or French.

Housing. There are about 370,000 dwelling units in the city; about 40 percent of the population live in one-room units, about 30 percent in two rooms, and the remaining 30 percent in houses with three or more rooms. Almost 85 percent of the houses have piped water and electricity.

Architecture. Because it has grown rapidly since 1925, Tehrān, of all Iranian towns, has the least Oriental aspect. Since the 1950s a number of buildings with from ten to 18 stories have been constructed.

As it is a comparatively young city, Tehrān lacks the historical and architectural heritage of towns such as Isfahan. Among the significant buildings constructed since 1800 are the Sepāh-sālār Mosque, the Baharstān Palace (which now seats the *majles*, or parliamentary deputies), the Shams ol-Emāreh, the Golestān Palace (one of the world's most celebrated palaces; used as a museum, it contains the famous peacock throne as well as the jewel-studded Nāderī throne), the Niavaran Palace, and the Masjed-e Shāh (another beautiful mosque, located in the bazaar quarter). Since 1925 a number of other important buildings have been added, including various ministries, the police headquarters, and the Senate, in addition to the Sa'adābād Palace, the Reza Shāh Mausoleum, and—most significant of all—the Marmar, or Marble Palace.

Manufacturing

Economic life. There are about 2,000 industrial establishments of varying size in the city and its immediate environs. These are engaged in the manufacture of such items as textiles, cement, sugar, tobacco, footwear, chinaware and pottery, household utilities, glass and glass products, electrical equipment, pharmaceuticals, and furniture. There is also a car-assembly industry, and an oil refinery is in operation at Rey.

The nation's chief city, Tehrān produces 51 percent of all Iran's manufactured goods and accounts for 33 percent of its total investment and for 60 percent of all of its wages and salaries. About 30 percent of Iran's enterprises are located in the city, and there are numerous government and private banks and insurance companies, as well as a stock exchange.

Government. As the capital city, Tehrān is administered by the national government. There is also a municipal council, composed of 30 members, all of whom are elected every four years by the Iranian residents of the city who are over 18 years of age. The council elects a mayor (as distinct from the governor), who, together with his staff, is responsible for the provision of municipal services.

Public utilities. Public utilities, including the water supply, electricity supply, and telephone service, are government owned and operated. Water is obtained from the Amīr Kabīr Dam, at Karaj, and from the Latyan (or Farahnāz Pahlavī) Dam. Electrical power is obtained from various sources, including the Amīr Kabīr and Latyan dams and the Mohammad Reza Shāh Dam, about 500 miles to the southwest.

Health and safety. The city has about 100 hospitals, and there are about 40 hospital beds available for every 10,000 people. The health standards of Tehrān hospitals are among the highest in Asia. There are about 1,700 doctors and about 800 dentists in the city.

Fire protection is provided by one main fire station and five substations. In addition, well-equipped fire stations are maintained by the army, the state railway, and the National Iranian Oil Co. There is one main police headquarters, 18 major police stations, and five substations.

Education. Kindergartens—of which there are about 175, with an enrollment of 10,000 children—are privately operated. There are about 1,200 public and private primary schools, with more than 500,000 pupils, and 500 public and private high schools, with about 230,000 pupils. There are also a number of vocational schools, teacher-training centres, schools for nurses, and business schools.

The universities

Tehrān has three universities, all public—the University of Tehrān and the National University of Iran and Āryamehr Industrial University. Together they have more than 30 faculties and 25,000 students.

Cultural life. The National Academy of Literature is located in Tehrān, where there are also about 12 cultural societies and councils sponsored by foreign countries. The city has a modern opera house, opened in 1967, nine theatres, and more than 100 cinemas.

There are 11 museums, of which four are of international repute and are noted tourist attractions. One of these, the Archaeological Museum, has on display the most precious art objects discovered at the excavations of Susa, Persepolis, and other sites in Iran. The Treasury Building, where the crown jewels are kept, houses a dazzling and priceless collection of jewels.

Among the dozens of libraries, the more important are the Mellī (national), the Malek, the Majles (parliament), and the library of the University of Tehrān.

The media. At the beginning of the 1970s there were about a dozen daily and about 40 weekly publications, all in Persian, as well as a number of monthlies. There were also a number of foreign-language publications. Tehrān had three radio transmitters and four television stations. Tehrān broadcasts television programs to the west and south of the country and was planning to extend its television broadcasting to the whole of Iran later in the 1970s.

Recreational facilities. There are a number of attractive parks and squares in the city, as well as a zoo. There are about 30 sports centres, some of which have stadiums. In 1971 a stadium for 100,000 spectators was inaugurated in preparation for the 1974 Asiatic Olympics.

Tektite

Tektites (from the Greek *tektos*, "molten") are glassy objects found in limited areas on the earth, and most probably formed on the moon or the earth. In diameter tektites range from a few tens of microns to about ten centimetres. Those larger than a few millimetres are all rich in silica;

Location and characteristics

they are somewhat like terrestrial obsidians (black volcanic glasses), but are distinguished from them and from other terrestrial volcanic glasses by their lower water content. An obsidian heated by a blowtorch will foam; a tektite will melt with the formation of only a few bubbles. Chemically, tektites are further distinguished from acid igneous (granitic) rocks by their lower content of soda and potash, and their higher content of lime, magnesia, and iron (Table 2). Under the microscope, tektites are seen to lack the small crystals (microlites) characteristic of terrestrial volcanic glasses.

Some terrestrial glasses produced by meteorite impact have approximately the same composition as tektites, but these impact glasses always contain some unmelted or partially melted material from the parent rock. Thus far, these inclusions have not been found in tektites.

Microtektites, of millimetre and smaller size, first discovered in 1968, have a wider range in composition than the large tektites; their silica content, for example, can be as low as 50 percent, similar to that of terrestrial basalts. Microtektites have been found so far only in deep-sea sediments, probably because of the difficulty of distinguishing them in the more abundant and coarser land sediments. They are distinguished from volcanic ash by their rounded shapes and by their chemical constitution, which, for the more silicic microtektites, is identical with that of the large tektites.

Tektite types

Form and markings. Four principal tektite types can be distinguished: (1) Microtektites (see Figure 1). These have diameters less than two millimetres. Their form is most often nearly spherical, although a few are oblate spheroids, and some are shaped like rods, teardrops, and dumbbells. These forms can be collectively described as those typically taken up by rotating liquid drops. Some microtektites also appear to be corroded, having deep grooves or pits. (2) Muong-Nong type tektites (see Figure 2, left). Named for the site where the first of this type was found, these are centimetre- to decimetre-size objects, and the class includes the largest known tektites. They are chunky in form, often tablet-shaped, and often show layering, each of the layers being a millimetre or so in thickness. At least some of the Muong-Nong tektites seem to be welded together out of fine particles resembling microtektites (see Figure 2, right). (3) Splash-form tektites (see Figure 3). These have shapes like the microtektites but are about 1,000,000 times as massive. Spheres (the majority), oblate spheroids, and a few dumbbells, canoe-shaped bodies, teardrops, disks, batons, and cylinders are found.

Splash-form tektites are always marked by corrosion. The two commonest kinds of corrosion are: (1) a system of hemispherical pits of all sizes (Figure 3, top left); and (2) a system of straight grooves, several times longer than they are wide, and of uniform width on a given specimen (Figure 3, top right). On oblate spheroids, the grooves tend to be perpendicular to the equator of the specimen (Figure 3, bottom left).

Some tektites also show long furrows that meander over the surface like worm tracks (Figure 3, bottom right). Others show narrow cuts, or sawtooth notches at the edges.

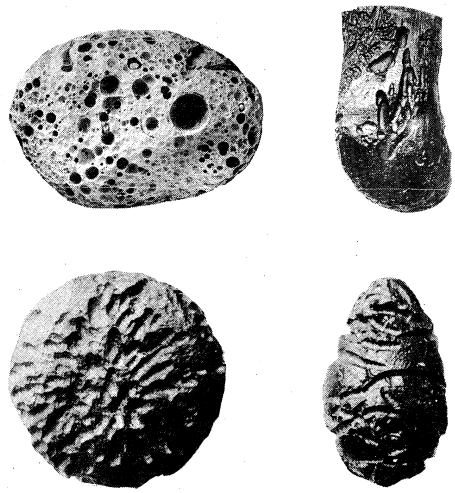

Figure 3: *Splash-form tektites.*
(Top left) Philippine tektite showing hemispherical pits. (Top right) Indochinite, after Alfred Lacroix, showing grooves. (Bottom left) Moldavite, after F.E. Suess, showing radial arrangement of grooves on a flattened ellipsoidal body (weight 56.4 g.). (Bottom right) Billitonite, after Suess, showing worm-track grooves (weight 40.3 g.).

Many specimens show a set of fine lines, somewhat like the grooves on a phonograph record, not usually parallel to the coarser grooves and furrows. These are the surface exposures of a system of contorted layers (schlieren) extending through the tektite and corresponding to variations in the silica content. They grade into the layering of the Muong-Nong tektites. (4) Australites and related forms. About 10 percent of the tektites found in Australia (australites) show a characteristic lenslike form, with an attached flange around the edge (Figure 4), the whole having the shape of a saucer of ice cream. The underside of the saucer is called the anterior side; the surface of the ice cream is the posterior side; and the edge of the saucer is the flange.

On the anterior side are found low circular or spiral ridges, concentric with the overall outline of the specimen. A set of fine ridges radiates from the centre. When a flanged australite is sectioned, the schlieren form reveals that molten glass has been drawn backward from the anterior side and coiled in the flanges.

Flanged australites have clearly been formed out of

bodies that are much like the splash-form tektites, by heating and melting at the anterior surface. Transition forms between the splash-form tektites and the australites have been found, some ("cores") in which part or all of the flange has dropped off, and others having only a clearly defined lens shape with a sharp keel.

Some tektites have interior voids with smooth, shining surfaces. These voids sometimes contain helium and neon at pressures of more than a few millionths of an atmosphere; others contain atmospheric gases at pressures of a little under one atmosphere.

Distribution. Tektites are found only within definite areas, called strewn-fields (see Figure 5 and Table 1). The

Location and dating of strewn-fields

North American strewn-field, dated at 33,000,000 years ago, has yielded a few tens of thousands of tektites, mostly splash-form, but with a few Muong-Nong type tektites and a few corelike specimens. The Czechoslovakian strewn-field, dated at 15,000,000 years ago, has yielded a few tens of thousands, mostly splash-form but with a few of the Muong-Nong type and at least one core-type specimen. These tektites are rich in silica and potash. The Ivory Coast strewn-field has yielded a few hundred specimens; it is dated about 1,000,000 years ago. Most of its specimens are of the splash-form type, but there are a few that suggest a trend toward the core type. In the Ivory Coast region, microtektites had been found up to 1970 only off the Liberian coast. Most of these match the larger Ivory Coast tektites in composition, but about 5 percent have a much more basic composition (the "bottle-green microtektites"). The Australasian strewn-field extends from South China over the Malay Archipelago to Australia and Tasmania.

Microtektite finds, including a few percent of the bottle-green type, indicate that the strewn-field also covers most

1. North American tektites (Texas, Georgia, Massachusetts)—33,000,000 years
2. Libyan Desert glass—26,000,000 years. Tektite?
3. Moldavites (Czechoslovakia)—15,000,000 years
4. Ivory Coast tektites (land and sea)—1,000,000 years
5. Australasian tektites (land and sea)—750,000 years
6. Aouelloul Crater (Mauritania) glass—300,000 years. Tektite?

of the Indian Ocean to points nearly as far away as Madagascar. Millions of specimens have been recovered; most are splash-form, but a considerable amount of Muong-Nong material has been found in Laos, Thailand, and South Vietnam.

Chemistry and petrography of tektites. If the microtektites are included, the compositional range in tektites extends from glasses that in some respects resemble terrestrial ultrabasic rocks all the way to rocks that are more acid than any terrestrial igneous rock. Typical compositions are shown in Table 2. These compositions should be thought of as points on continuous curves rather than as discrete classes.

Silica, SiO_2, is a convenient parameter against which to plot the other oxides. With silica content from 58–85 percent, almost all oxides show a steady upward trend with decreasing silica content. The exception is the potassium oxide, K_2O, content which is positively correlated with silica content. With a silica content of from 50–58 percent, new trends show themselves: the alumina, Al_2O_3, content levels off and the magnesium oxide, MgO, content climbs more rapidly (toward values of 25 percent) than for higher silica values.

Ordinary tektites (typically with about 70 percent SiO_2) are much like granites in composition, though deficient in sodium monoxide, Na_2O, and K_2O and enriched in MgO and ferrous oxide, FeO. These trends are similar to those found in rocks intermediate between the shales and sandstones. No parallel is found in a terrestrial igneous rock; it is, thus, generally considered that if tektites are terrestrial

in origin then they must have been derived from sedimentary rather than igneous rocks.

Reduced volatile constituents

Refined analyses have shown that water is present only to the extent of about 100 parts per million (ppm) in tektites, far below the value for terrestrial igneous or sedimentary rocks. Relative to the most nearly similar terrestrial rocks, tektites are depleted in other volatile (relatively low-melting) elements, particularly including copper, lead, tin, thallium, indium, and bismuth. Like terrestrial rocks, and to much the same extent, tektites are depleted in nickel, cobalt, and the precious metals, including gold, platinum, osmium and iridium, etc.

Isotopes in tektites. Considerable information about tektite history can be obtained by a study of the radioactive isotopes (see DATING, RELATIVE AND ABSOLUTE). The most important of these in the present context is potassium with atomic weight 40 (^{40}K), which decays into argon, ^{40}Ar, with a half-life of approximately 900,000,000 years. The ^{40}Ar is expelled when the material is strongly heated. Thus by comparing the amount of ^{40}K with the amount of ^{40}Ar found in a tektite, it is possible to determine how long ago the material was last thoroughly melted. The ages cited above for the tektite strewn-fields were found by potassium–argon dating.

Tektite ages

The isotope of uranium, ^{238}U, which is the parent of one of the principal radioactive-decay series of elements, may also decay by spontaneous fission. The tracks of the particles produced through fission are left in the glass and can be traced millions of years later by etching a polished surface. By comparing the number of tracks with the amount of uranium, it is possible to find the age of the glass since it was last melted.

Bodies that pass through space outside the earth's atmosphere are subjected to the action of primary cosmic rays that produce a number of radioactive isotopes including especially aluminum, ^{26}Al. This has been sought in tektites several times without success and its nonappearance, in all probability, means that tektites spent much less than 1,000,000 years as isolated objects in space. It is also possible to examine tektites for tracks due to fission fragments resulting from collisions of primary cosmic rays with atomic nuclei in tektites. Tracks produced this way can be distinguished from those due to ^{238}U. Their complete absence from tektites sets an upper limit of about 1,000 years to the sojourn of tektites in space.

The time elapsed since tektites received their present chemical constitution can be measured by isotope pairs appearing in radioactive-decay chains: rubidium, ^{87}Rb, and strontium, ^{87}Sr, into which it decays; ^{238}U and lead, ^{206}Pb; ^{235}U and ^{207}Pb; thorium, ^{232}Th, and ^{208}Pb. The point is that rubidium, uranium, and thorium are concentrated in volcanic rocks by the process that leads to the formation of lavas. Thus the rate of production of the radioactive end product, namely strontium or lead, is greatly enhanced. Because there is a spread in the ratio of rubidium to strontium in the tektites, it is possible to work out both the initial value of the ratio of the strontium isotopes $^{87}Sr/^{86}Sr$ (^{86}Sr is used because it is a nonradiogenic isotope that takes no part in the radioactivity) and the length of time since the lava was produced. A straightforward application of this method gives ages that tend to be lower than 100,000,000 years and, thus, too small to be measured accurately. When, however, the possible effects of volatilization are included, and when the assumption is made that the initial value of $^{87}Sr/^{86}Sr$ can be known in advance, then most tektites appear to be some 300,000,000 years old and those from the Ivory Coast are interpreted as having an age of 2,000,000,000 (2×10^9) years.

The problem of tektite origin. *Evidence on an origin beyond the moon.* Meteorites, which appear to arrive from beyond the moon, typically contain accumulations of isotopes and fission tracks corresponding to a sojourn in space of millions of years. For tektites the upper limit is around 1,000 years, so that it would appear that they cannot have come from beyond the moon.

The limited distribution of tektites on the earth also suggests a localized origin because there has clearly been little dispersion of the tektite showers. A cluster of objects travelling through space near the earth's orbit will be torn apart and dispersed by the differential gravitational attraction of the sun unless the average density is more than about a millionth of that of water. A cloud of tektites of this density and with a diameter equal to the size of the Australasian strewn-field would blanket the area to a depth of several metres and this is not observed; this again points to an origin within the earth-moon system.

Evidence for and against lunar origin. One of the specimens brought back from the Apollo 12 lunar flight bears a remarkable resemblance in major element composition to some tektites from Java. There are, however, serious discrepancies in the rare-earth elements, and in barium, uranium, and thorium; for these reasons it is disputed whether the specimen is really tektite material or not.

An important argument in favour of an extraterrestrial and probably lunar origin of tektites comes from aerodynamic studies of the australites. D.R. Chapman took lenses of tektite glass and subjected them to a heated air stream in an arc jet. The glass flowed backward and formed flanges similar to those observed in australites as shown in Figure 4. The similarity is not only external; thin sections show that a peculiar kind of folding is exhibited by both the natural and artificial glass of the flanges.

Aerodynamic studies

These studies leave little doubt that the flanged australites were shaped by aerodynamic ablation (erosion due to air-friction melting). Numerical analysis of the relevant conditions, which cannot be entirely duplicated in the wind tunnel, shows that velocities on the order of 11 kilometres per second are required to produce this ablation if the body enters at a steep angle to the horizontal. For very flat trajectories, the observed ablation can be produced by velocities in the neighbourhood of the earth satellite velocity of 8 kilometres per second.

Chapman and others have also drawn attention to the fact that the escape of tektites from the ground surface through the atmosphere is physically impossible unless the atmosphere is bodily removed in some manner or unless the air moves along with the tektite. Tektites cannot pass through more than about 1 percent of the normal atmosphere without having their velocity reduced to approximate equality with that of the air.

A second point that seems to favour a nonterrestrial origin is the fact that many tektites are composed of a homogeneous glass of low water content with less than 1 percent bubbles (vesicles). Typical terrestrial rocks or soils contain more than 5,000 parts per million of water. When heated, this amount of water is enough to form bubbles whose total volume at atmospheric pressure would be 30 or more times that of the glass. If tektites are terrestrial in origin, such bubbles must have formed and escaped. For typical bubbles, some 100 microns in radius, and for a viscosity of 10^2 poises, corresponding to about 1,800° C, approximately 15 minutes would be required to move the bubble one centimetre under a gravitational attraction like that at the earth's surface; but in flight the tektite would experience no gravitational force and would cool within a few seconds to temperatures below 1,800° C, so that bubbles, if they had been formed, would have remained.

Similarly the homogenization of glass demands complete diffusion of the components into one another. It has been shown that for diffusion distances of the order of 100 microns, minutes would be required for diffusion at a temperature of 1,800° C. Actual sandstones have grain sizes considerably larger than 100 microns; it would actually require the mixing of several hundred grains to reduce the sampling errors to the level of the observed inhomogeneities.

Comparison with other natural glasses

These arguments based on glass technology apply with particular force to three remarkable glasses whose silica content is higher than that generally accepted for tektites: Darwin glass, found in Tasmania; Aouelloul Crater glass, found around and to the east of a 250-metre crater near Atar in Mauritania; and Libyan Desert glass, found in western Egypt. These glasses range from 85 percent to 98 percent silicon dioxide, SiO_2. Darwin glass has the same date, according to fission track methods, as the Australasian strewn-field. Some workers associate these glasses, especially Aouelloul, with local sandy materials, but the above arguments from the field of glass technology seem to imply that they are extraterrestrial.

There are serious arguments against a lunar origin for tektites. Most importantly, up to the early 1970s, analysis of the lunar surface had not disclosed any regions of tektite composition. If they exist, such areas are restricted. Hence the suggestion that tektites are ejected from the moon by meteorite impact also requires a mechanism responsible for destroying a great part of the tektites produced and permitting only those of acid composition to survive. Another possibility is that (as Verbeek suggested in 1897) tektites are ejected not by impact but by volcanism; explosive volcanoes on the earth are always acid, but it has not been shown that acidic volcanism of a similar kind could have occurred on the moon.

The second important argument against the lunar origin is the localized distribution of tektites on the earth. Detailed mechanisms have been worked out by which a jet of material from some lunar crater might be distributed over a local area on the earth, such as a tektite strewn-field. But what of those tektites that have missed the earth on the first pass and have gone into orbit around the sun? Calculations show that these should eventually be captured by the earth but that their distribution over the earth's surface should be completely uniform, and this is certainly contrary to the facts. If tektites come from the moon, there must exist a mechanism in space that destroys them in a relatively short time so that they cannot come back from orbit around the sun. A suggested mechanism is the spin-up of the tektites, caused by asymmetrical radiation pressure and resulting in rotational bursting.

Evidence for and against terrestrial origin. The chemical constitution of tektites strongly resembles that of the earth's crust. Petrological analyses of lunar material show that the moon produces basaltic rocks with a broad resemblance to terrestrial basalts; but a lunar origin of tektites would imply the existence of rocks resembling terrestrial granites on the moon.

Presence of atmospheric gases in vesicles

Analyses of the gases in tektite vesicles show that some vesicles are nearly empty, but that others are filled with oxygen, nitrogen, and argon in the same proportions as in the earth's atmosphere. These vesicles do not appear to have leaks. If these gases had been trapped while the tektite was liquid, their presence would imply a terrestrial origin.

Correlations between tektite strewn-fields and terrestrial impact craters have been cited in support of a terrestrial origin for tektites. The moldavites in southern Bohemia, for example, occur some 200 to 300 kilometres from a large crater, the Ries Kessel, in southern Germany; tektites and crater are dated at 15,000,000 years ago. But, since there are differences in chemical composition, water content, oxygen-isotope ratios, and Rb/Sr ratios between the crater glass and the moldavites, there is probably no real relationship between them. Ivory Coast tektites occur 300–1,600 kilometres from the Bosumtwi Crater in Ghana; tektites and crater are dated at 1,000,000 years ago. Resemblances have been traced between the crater glass of Bosumtwi and the Ivory Coast tektites in chemical composition, Rb/Sr ratios, K-Ar dating, Pb/U ratios, and oxygen-isotope ratios. Though for any one criterion alone the relationship is weak, the cumulative effect is impressive and therefore a generic connection between crater and tektites is claimed by most authorities.

Since many tektites contain nickel-iron spherules, it is possible that if tektites were formed on the earth, the impact of a comet or a meteorite might have been associated with the event. Their chemical composition suggests that the impacts must have occurred in material with the composition of sandstone. In the cases of the Australasian and Ivory Coast groups the region also should contain a few percent of an unusual pyroxenite (to explain the bottle-green microtektites). The velocities to which the particles were accelerated must have been as much as six kilometres per second to cover the Australasian strewn-field, but higher velocities must have been very rare, in view of the lack of a worldwide distribution. The temperatures reached in the region where tektites were formed must have been 2,000° C or higher in order to explain the formation of relatively homogeneous glass and the loss of water in a very short time. The atmosphere must have been removed from the site by the impact or else must have moved outward with the tektites, having a velocity relative to them of a few tens of metres per second.

There are thus difficulties in assigning the origin of tektites unambiguously to either the earth or the moon, and even more to a site in space beyond the moon. Until enough of the negative evidence can be satisfactorily explained, the question of tektite origin must remain open.

(J.A.O'K).

Tel Aviv-Yafo

Combining the characteristics of an entirely new planned modern city with those of an ancient Mediterranean port,

a duality reflected in its hyphenated name, the Tel Aviv-Yafo of the 1970s is one of the more unique of the great Middle Eastern cities. Yafo (Arabic Yāfa, formerly called Jaffa), the ancient Joppa, had been an important city and port almost continuously since the beginning of the 2nd millennium BC. Tel Aviv, however, was named after Theodor Herzl's novel *Altneuland* (1902, translated into Hebrew as *Tel Aviv* [*tel*, "hill"; *aviv*, "spring"; hence "Hill of Spring"]), in which the founder of modern political Zionism laid down his ideas for a new Jewish state; the name also has a biblical association, being mentioned in Ezekiel as a settlement of exiled Jews in Babylon. Tel Aviv was founded by pioneer Zionist settlers in 1909 as a Jewish garden suburb of Arab Jaffa. Since the union of the two settlements in 1950 and the associated departure of the original Arab inhabitants, Tel Aviv-Yafo, a long, narrow city fronting the Mediterranean for about six miles along the southern portion of the Israeli coastline, has become the nation's largest urban centre and its main business, communications, and cultural centre. By 1970 the 20-square-mile municipality was the home of more than 380,000 people, all but 2 percent of whom were Jews; the metropolitan area, or conurbation, of which it was the centre, covered more than 115 square miles (300 square kilometres) and contained a little more than 1,000,000 people, or fully a third of the entire Israeli population. All local port operations ceased in 1965, with the opening of the port of Ashdod, 19 miles south of the city.

By courtesy of Israel Government Tourist Office

Tel Aviv from old Yafo, with a minaret in foreground and modern Shalom Tower in the background.

History. *Foundation and early growth.* Although Jaffa (Yafo) had been an ancient port and commercial centre, Tel Aviv is a new city, the foundations of which were laid in 1909, when the Jewish quarter of Jaffa had become overcrowded from the influx of immigrants. The Zionist founders of Tel Aviv set out to build a European-style suburb, with straight, wide streets, parks, and modern urban facilities and services. The suburb was to be run by an elected autonomous local council, although nominally it was part of Jaffa. Initially, an area of 27 acres of completely barren sand dunes, northeast of the Jewish quarter, was acquired. By the end of 1914 Tel Aviv had become a purely residential suburb of 245 acres, with 140 houses and 1,500 inhabitants. At its heart stood the Herzliyya Secondary School (now the site of Shalom Tower, the city's tallest skyscraper), on which the cultural and social life centred.

Zionist origins

During World War I the entire population of Tel Aviv, as well as the Jewish population of Jaffa, was expelled northward by the Turkish military authorities on suspicion of sympathy with the advancing British Army, and the settlements remained completely deserted for nearly a year. Only several months after Jaffa and Tel Aviv were taken by the British, on November 10, 1917, did many of the residents return to their homes.

The Balfour Declaration and the British mandate. Renewed growth began in 1920, with the wave of Jewish immigration that followed the Balfour Declaration and the establishment of the British mandate over Palestine (1923–48). Tel Aviv was separated from Jaffa and granted the status of a town in 1921, following anti-Jewish riots in Jaffa. By the end of 1926 the population had reached 38,000; central Tel Aviv, the area built up before World War I, became a thriving business centre, and a number of industries were established.

Urban growth and the incorporation of Jaffa

Urban growth gathered momentum in the early 1930s, after the Nazis rose to power in Germany. A substantial part of the flood of immigrants that subsequently sought refuge in what was to become Israel settled in and around Tel Aviv. By the end of 1933 the population of Tel Aviv had reached 72,000 and exceeded that of Jaffa, while by the end of 1936 it had risen to 130,000: Tel Aviv became Palestine's largest and most important city.

Nationhood and after. The birth of the State of Israel, in 1948, initiated a dynamic, if turbulent, stage in the development of Tel Aviv. The influx of immigrants caused the population to swell by no less than 60 percent within four years, reaching 350,000 toward the end of 1952. With the incorporation of Jaffa in 1950, the united city became known officially as Tel Aviv-Yafo. When Jaffa surrendered to Jewish military forces in 1948, almost the entire Arab population of 65,000 fled, and Jewish immigrants soon took over a virtually empty city. In the process of its expansion, Tel Aviv-Yafo also swallowed up six villages: five Arab and one (Sarona) German. The Arab villages were abandoned during the bitter 1948 war, while the German inhabitants of Sarona—founded in 1871 by members of a small Protestant sect known as the Tempelgesellschaft ("Temple Society")—had been deported by the British authorities during World War II.

During the 1950s and 1960s the steep rise in land prices in Tel Aviv-Yafo and the expansion of the central business, administration, communication, and entertainment centres brought about a sharp slowdown in the overall outward expansion of the city. A small but continuous decline in the population of the central city set in as inhabitants began an outward movement to homes in towns and suburbs outside the municipal area.

The environment. *The site.* The natural advantages of the site of Jaffa attracted settlement early in the ancient history of the region. The old part of Jaffa is situated on a 2,000-foot-long promontory on the otherwise straight coastline of southern and central Israel. A 100-foot-high hill is bounded by cliffs on the west and the north, while sand dunes and marshy areas made access difficult from the south and southeast. A row of reefs, running close inshore parallel to the coast, forms a natural breakwater for the small bight, or inlet, just north of the promontory. In addition to defensive advantages, the hill has easily accessible small springs and groundwater supplies, as well as an agricultural hinterland that extends almost to the eastern outskirts of the city.

Natural advantages

The climate. Tel Aviv has a typical Mediterranean climate. Winter and spring are mild and pleasant, the summer hot and humid. Rainfall is confined to winter months, mainly November–March. The mean daily temperature of the coldest month, January, is about 56° F (13° C) with an average minimum, for the same month, of 47° F (8° C). Temperatures seldom fall below 41° F (5° C), and frost is almost unknown. The mean daily temperature for the hottest month, August, is 80° F (26° C), with a mean daily maximum of almost 89° F (31° C). The hottest days of the year generally occur in

May or in September, when easterly desert winds bring heat waves; temperatures exceeding 95° F (35° C), however, are rare. The mean annual precipitation amounts to 22 inches (559 millimetres), but there is considerable variation from year to year.

Contemporary city layout. *The heart of the city.* Modern Tel Aviv-Yafo is built over three low ridges of soft sandstone hills that run almost parallel to the coastline. A narrow belt of small sand dunes covering the westernmost of these ridges expands inland where gaps in the relief occur. More sandstone ridges lie to the east, and the built-up area has now spread beyond them into the rich agricultural land of the undulating coastal plain. The ridges have influenced decisively the layout of the modern city and its street pattern. The long main arteries run north–south in the shallow troughs between ridges, with short east–west streets crossing gaps in the ridges.

There is a narrow, flat sand beach fronting the entire coast. The inhabitants of Tel Aviv and its suburbs are able to swim, or simply bask in the Mediterranean sunlight, along large sections of this beach. The first hilly ridge then rises steeply behind the beach in a series of cliffs, and the city's striking modern hotels line its crest. This impressive strip is cut in two places: the city's main east–west artery, Allenby Street, follows a gap one-half mile north of the Jaffa promontory, itself a spur of the coastal ridge; and the Yarqon River Valley cuts a wide gap across the entire belt of coastal hills and dunes.

Ridges and street patterns

The city's two main north–south streets, Ben-Yehuda and Dizengoff, follow the trough between the first and second ridge, as does Jaffa's main thoroughfare, Jerusalem Boulevard (previously King George V Boulevard). The main roads leading out of Tel Aviv to the north and northeast, Petaḥ Tiqwa and Haifa roads, run similarly between the second and third line of hills, while the city's most easterly quarters straddle the third ridge, though much of this ridge is outside the municipal area.

The suburbs. To the east and south, Tel Aviv-Yafo proper blends into a continuous built-up area including the substantial settlements of Ramat Gan, Giv'atayim, Bat Yam, and Ḥolon. The suburbs of Bene Beraq, Petaḥ Tiqwa, Qiryat Ono, and Or Yehuda lie farther east. To the north some open space and agricultural land, mainly given over to citrus groves and market gardening, lies between Tel Aviv and the towns of Herzliyya and Ramat ha-Sharon.

City regions. A rapidly growing central business district, the economic heart of Israel, occupies the older part of Tel Aviv and expands northward and eastward into the residential areas built during the 1920s and early 1930s. To the south and east lies the main manufacturing district, with numerous small industrial plants and workshops. Most big industries moved to outlying areas during the 1940s and 1950s, and the main industrial belt of the whole region centres on the major northeast highway running through Ramat Gan, Bene Beraq, and Petaḥ Tiqwa. Most government offices are concentrated in the district known as ha-Qirya (the former German village of Sarona), northeast of the business centre.

Transportation. Road transport is dominant in Israel, and Tel Aviv is the main national route focus and the headquarters of all major bus and truck companies. Cooperative societies operate the nearly 100 bus lines within the region and also the network of lines serving cities, towns, and rural areas throughout the country. There are two small railway stations, in the north for Haifa-bound trains and in the southeast for Jerusalem and Beersheba. Lod (Lydda) airport, nine miles to the southeast, serves the city's international air traffic.

The port of Jaffa was the country's second largest before it was shut down in 1965, on the inauguration of the modern port at Ashdod. Tel Aviv's small port also was closed in 1965, except for fishing boats.

The people. Tel Aviv's population has been declining from a 1963 peak of 394,000 and had fallen to 382,000 at the beginning of 1970, a drop due to a growing movement of residents, mainly young people, to outlying suburbs. The population of the whole region has continued to grow at an average rate of about 20,000 per year.

Composition. By 1970 the non-Jewish population of Tel Aviv-Yafo numbered about 7,100, nine-tenths of them Arabs, of whom nearly two-thirds were Muslims, and one-third Christians, mostly Greek Orthodox and Roman Catholic. The remaining tenth included Druzes, Armenians, and European Christians of various nationalities. Non-Jews in the whole metropolitan area barely numbered 1 percent of the total population.

Jewish and non-Jewish elements

Of the Jewish population of the city proper, 41 percent was born in Israel; 13 percent of the rest came from Asian countries, 5 percent from African—mostly North African—countries, and 41 percent from Europe and America. The region as a whole had an Israeli-born population of 42 percent, while 33 percent came from Europe and 25 percent from Asia and Africa.

Density. The mean density of population for the municipal area of Tel Aviv is 20,200 persons per square mile —reaching 64,500 per square mile in the northern part of the city—but less than one-half of this figure for the whole urban region. The average number of persons per room, however, indicates that the highest density is found in the slum areas in the southeastern part of Tel Aviv and in central Jaffa (see below *Housing*).

Housing. Most of Tel Aviv's buildings consist of three- and four-story concrete and cement brick homes, their height restricted by building laws. Only since the early 1960s have much taller buildings been allowed in some residential areas. Districts with small one- and two-story houses and villas take up only a small part of the municipality but occupy substantial parts of outlying regions.

The main slum areas of Tel Aviv-Yafo—still housing some 45,000 people by the early 1970s, in spite of an intensive slum-clearance program—have developed in the southeastern part of the city: ha-Tiqwa Quarter, 'Ezra Quarter, Shapira Quarter, Kefar Shalem (the former Arab village of Salamah), and parts of formerly Arab Jaffa. These slums are almost entirely inhabited by Jews who originate from Arab-speaking countries, mainly Yemen, Iraq, and Morocco, but also some from Iran and Turkey. They are mainly unskilled workers, peddlers, petty traders, and owners of small workshops.

There are no buildings of outstanding architectural beauty in the city proper or the surrounding region. The massive building of the Federation of Trade Unions (known popularly as the "Kremlin") was Tel Aviv's most conspicuous building until the early 1960s, when the urban skyline became studded with a growing number of tall buildings, mainly rather undistinguished office buildings. The Palace of Culture (Mann Auditorium; a concert hall), the Habima Theatre, the university library, the new municipal museum, and the law courts are, nevertheless, fine buildings.

Economic life. Tel Aviv's dominance in the economic life of Israel is clearly evinced by the fact that 25 percent of all the employed persons in the country work in the city, including almost 40 percent of Israel's employees in banking and commerce, 26 percent of those employed in manufacturing, and 30 percent of those engaged in transport work. Almost one-half of the workers resided outside of Tel Aviv municipality by the early 1970s.

More than one-half of Israel's industrial plants are found in the Tel Aviv metropolitan area. The main industries are: textile and clothing, food and tobacco, metal and engineering, vehicles and transport equipment, diamond polishing, furniture and wood products, printing and publishing, and electric and electronic instruments and equipment.

Main industries

Israel's only stock exchange is located in Tel Aviv, and virtually all the banks, insurance companies, and other enterprises operating in Israel locate their main offices in the city. Some 70 percent of Israel's wholesale trade is channelled through Tel Aviv firms, and its retail firms constitute one-quarter of the national total. The city is also the main centre of Israel's important tourist industry. The city has about 70 hotels, of which more than a dozen are in the luxury (five star) and first-class (four star) category. Herzliyya, a seaside resort just north of Tel Aviv, is the only other tourist centre of the region: it also boasts several large luxury and first-class hotels.

Governmental institutions and services. *Structure of government.* The city is governed by a 31-member council, elected for a four-year period by direct proportional elections. Every adult (above the age of 18) who has been residing in the city for at least one year has the right to vote. Administration is by the mayor and six deputy mayors elected by the city council.

Political parties and coalitions

The Labour Front (Hamaarakh) and the union of the Liberal and Freedom parties (the right-wing Gaḥal) are the largest political parties. The National Religious Party and several smaller parties also are active. A coalition headed by the Labour Front, in which the National Religious Party and two of the smaller parties are included, took control of the city in 1959, ending a period of right-wing rule that had been almost continuous since 1921.

Each of the peripheral towns has a similarly elected council (with fewer members) and mayor. All are governed by coalitions, mostly headed by the Labour Party.

Public utilities. Tel Aviv's water supply comes from two sources: wells sunk predominantly in the eastern municipal area and utilizing available groundwater supplies, and the national main, carrying water from the Jordan (via the Sea of Galilee) and the sources of the Yarqon (a dozen miles east of Tel Aviv) to the southern and drier parts of the country. The region's water supply, like that of the nation as a whole, is rationed as a result of the general water scarcity.

A modern sewage system with purification and disposal plants serves the entire municipal area, as well as about three-fourths of the metropolitan region. There is also a drainage system, connected with the sewage system, designed to prevent flooding of low areas during rainstorms. Parts of the sewage system that still empty into the sea cause some pollution.

Educational institutions. By far the greatest part of the educational institutions of Tel Aviv, ranging from kindergarten to university, are financed and run by the national Ministry of Education or by the city's department of education. Private institutions are comparatively few and are mostly kindergartens and institutions for professional training. Elementary education (ages six to 14) is almost entirely confined to state schools. About 30 of the 130 elementary schools are state religious schools. In addition to secondary schools, there are vocational schools and teacher-training colleges. Extramural studies are provided by the city authorities and the Federation of Trade Unions, and various voluntary organizations are active in the field of adult education.

Higher education

Tel Aviv University—incorporating the three leading regional hospitals for teaching purposes—was founded in 1953 and inaugurated in 1956.

The Bar-Ilan University, a religious university in Ramat Gan, was founded in 1955. Tel Aviv also has 12 rabbinical and theological institutes (yeshivas), but the main concentration of such schools is in Bene Beraq, to which students are drawn from Jewish communities in all parts of the world.

Cultural life. The Israel Philharmonic Orchestra, the only one of its kind in the Middle East, has its home in Tel Aviv, as do the Chamber Ensemble, Israel's two leading choirs (Rinat and Zadikov), the Israeli Opera, and nearly all of Israel's dozen or so theatres, including the Habima National Theatre and the Chamber Theatre, the country's most popular. Ten of Tel Aviv's 13 museums are municipal, and there are 40 private art galleries.

Tel Aviv has a municipal library with 15 branches, and each of the other local authorities has its own public library, generally with a number of branches.

The media. Most of Israel's newspapers and periodicals—including dailies in Hebrew, German, French, Polish, Hungarian, Romanian, Bulgarian, and Yiddish—are published in Tel Aviv, as well as more than 80 percent of the books and pamphlets that appear in the country.

The Israeli Broadcasting Authority has radio and television studios in Tel Aviv, although the central studios and offices are in Jerusalem. Armed forces broadcasting facilities are also housed in the city.

Recreation. Tel Aviv is poor in parks and public gardens, which cover only 5 percent of the municipal area. The main park areas are being developed along, and to the north of, the Yarqon River (including a 250-acre park) and in the northern part of the city's beach.

The smaller peripheral towns are much better provided with parks than the municipality itself. The region's largest park—the National Park— is situated within Ramat Gan, as is Israel's largest stadium (50,000 seats). Tel Aviv has two stadiums, one used for football matches and athletics and the other mainly for basketball, but most of the city's sporting activities are carried out on sport grounds and facilities outside the city.

Tel Aviv has a small zoo (which is, nevertheless, Israel's largest), extending over seven acres in the densely built-up area north of the central part of the city.

BIBLIOGRAPHY. There is much literature on all aspects of Tel Aviv in Hebrew but very little in European languages, most of it in English. Of the Hebrew publications, the most authoritative work is the detailed *Sefer Tel Aviv* (1936), prepared for the 25th anniversary of the city's founding, and containing chapters on the history, environment, and social life of the city. It contains seven coloured maps. A municipal bulletin (in Hebrew, some with English résumés), which appeared regularly several times per year between 1932 and 1956, contains much valuable data on the growth of the city. The *Tel Aviv-Yafo Municipal Yearbook* (annual) is the best source of information in English on the city. The detailed volumes from 1961 onward have a good summary in English of the annual report in Hebrew that forms the main part of the yearbook, and all statistical tables are given in both Hebrew and English. The 1969 volume of this yearbook has a good historical survey written on the occasion of the city's 60th anniversary. Each of the numerous books in many languages on the history and achievements of Zionist settlement in Israel deals with the founding, growth, and importance of Tel Aviv as an economic and cultural centre. DAVID BEN GURION, *The Jews in Their Land* (1966), is the best of recent books on this subject. A. BEIN, *The Return to the Soil: A History of Jewish Settlement in Israel* (1952; orig. pub. in Hebrew, 1945), is another good work of this kind. Tel Aviv's dominance among the urban centres of Israel is well portrayed in D.H.K. AMIRAN and A. SHAHAR, "The Towns of Israel," *Geogr. Rev.*, 51:348–369 (1961).

(M.Br.)

Telegraph

The telegraph was the first, for many years the most important, and even into the 1970s still a principal system of telecommunication, or communication at a distance. In common with other electrical communications media, such as the telephone, the purpose of the telegraph is the instantaneous transfer, by electrical means, of intelligence over distance. Telegraphy differs, however, from other electrical systems because, first, it transmits dispatches or messages as a sequence of codified alphabetic letters, numerals, punctuation, and symbols; and, second, it records them on paper as telegrams at a distant office for delivery to addressees not only as information but for subsequent reference.

The word telegraph was coined in France around 1792 to describe a pioneer optical-relay semaphore system invented by a French physician and inventor, Claude Chappe. Its literal derivation from the Greek *tele*, "far," *graphein*, "to write"—describes teleprinter telegraphy of the 1970s even more accurately than it did any of the systems from Chappe's through the electric telegraphs of the English inventor W.F. Cooke, the English scientist and inventor Sir Charles Wheatstone, and the United States inventor Samuel F.B. Morse. In a typical modern form, a business-office typist, with a few hours' adaptive practice, manipulates a typewriter-like keyboard literally "to write far" in a correspondent's distant office, upon a typewriter-like platen, as though the typing mechanism, platen, and paper were physically present and mechanically linked with the keyboard.

Prior to the general introduction of simple teleprinters in the 1930s, writing far, on the part of senders of messages, was accomplished chiefly through the intermediary of telegraph operators, who had laboriously mastered one of the dot-and-dash codes by which alphanumeric characters were translated into electrical signals that could be transmitted and at the reception point deciphered and written down.

Applications of telegraphy techniques

The techniques of telegraphy are now widely used in nonalphabetic, nonmessage systems including radar and telemetry, used to measure or transfer measurement data to a distance, either for record purposes or control of machines, weapons, or processes. Another example of increasing utility is the joining together, by means of the telegraph, of geographically separated computers either for storage of information or for processing; *e.g.*, in the control of space-flight vehicles by microwave radiotelegraph.

HISTORY

The history of telegraphy embraces four stages: nonliteral or nonalphabetic message transmission—*i.e.*, drums; visual telegraphy or semaphore; wire telegraphy; and wireless telegraphy, or radio. The term telegraph is reserved primarily for the third stage, wire telegraphy, which is emphasized in the following summation.

Pre-electric telegraphy. *Nonalphabetic signalling.* Prehistoric man learned to beat on resonant logs and tree trunks with a stick, then to make more effective drums of stretched membranes, and finally to use the knowledge to extend the range of his voice; rhythms and intonations applied to drum beats could be made to express emotions and ideas. The next step in communicating by means of the drum, the reed pipe, bone whistle, or ram's horn was to prearrange a set of meanings for certain sounds and sequences. The counting of beats led to the development of codes. Smoke signals by day and fires by night were also used by the ancient people of China, Egypt, Assyria, and Greece. Beacon fires, established on line-of-sight locations, brought to Queen Clytemnestra, at her palace at Argos, Greece, the news of the fall of Troy and her husband's imminent homecoming, in 1084 BC. As recounted by the poet Aeschylus nine relay points on natural prominences covered a total distance of some 500 miles (800 kilometres). Signal fires are also recorded as having been used by the Picts against the Roman invaders of Britain in the 1st century AD and by American Indians in Ohio in early colonial times.

Alphabetic signalling. According to the Greek historian Polybius a method of signalling the 24-letter Greek alphabet was devised by about 300 BC. The code was formed by placing the letters on a grid of five horizontal rows and five vertical columns, so that the first letter, alpha, fell on the first row of the first column and the last, omega, on the fifth row of the fourth column. To signal all 24 positions, ten vases were held in reserve behind two low walls, in a row, but separated by a few feet. In signalling omega, the sender would place five vases on the left wall and four on the right.

Essentially the same method was used by medieval prisoners to communicate through the wall of adjoining cells. Today's 26-letter Roman alphabet was contained within the five-by-five pattern because I and J were combined as one letter. The numbers were tapped out in series of pairs, 1-1 indicating A. This idea transferred the code from a purely spatial configuration to one involving time. In 1551 an Italian mathematician, Gerolamo Cardano, suggested that five torches on five towers could be used to spell out letters, with all five beacons figuring in the code as "light" or "dark." The invention of the telescope in the 17th century stimulated interest in visual signalling, and several fresh proposals were put forward by such men as the English physicist Robert Hooke, though none was immediately developed.

Optical telegraphs. Two optical telegraphs, built by and for government, were of particular importance: the semaphore of the First Republic, France, 1794; and the shutter telegraph of the Admiralty, England, 1795.

As to the first, Claude Chappe and his older brother invented in 1791 and applied the name telegraph to their system of two-arm semaphores (from the Greek: "bearing a sign"; see Figure 1A). In 1793 Claude Chappe was given the title "ingénieur-télégraphe." A relay station was a hilltop tower sheltering the operators and equipped with telescopes directed up-line and down-line. At the top of the tower a vertical timber supported a beam (the regulator). At each end of the beam an arm (indicator) could be made to assume seven angular positions 45 degrees apart. The 49 positions accommodated alphabetic letters and symbols.

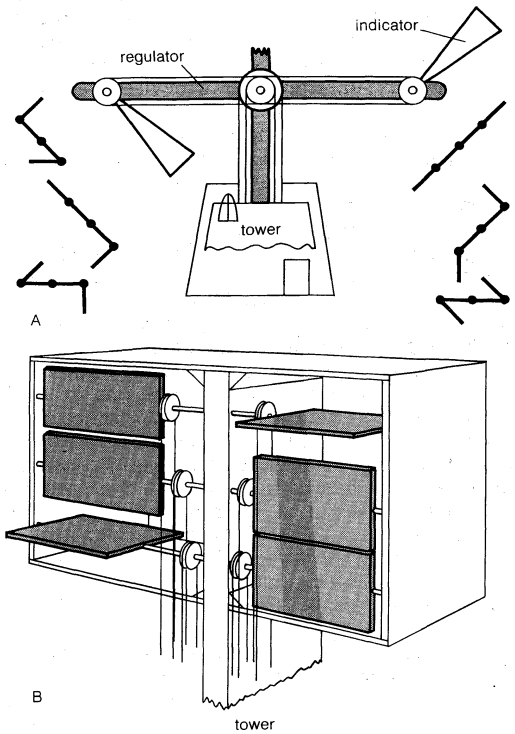

Figure 1: *Optical telegraphs.*
(A) Chappe semaphore. The heavy black lines indicate six of the many possible arm and indicator configurations, representing six hieroglyphs, or coded characters.
(B) Murray six-shutter semaphore.

The horizontal beam could be tilted 45 degrees clockwise or counterclockwise, or held in a vertical position. Signals associated with the positions of the beam provided communication in cipher or code. Towers were spaced three to six miles (five to ten kilometres) apart. At a rate of three signals a minute for each relay under conditions of good visibility, transit time from Toulon to Paris, through 120 towers, was 40 minutes, or, roughly, an hour for a message of 50 signals. This performance was more than 90 times as fast as mounted couriers.

The value of the semaphore telegraph was established when it was used to relay news of French victories over the Austrians at Quesnoy and Condé-sur-Escaut in August 1794. Within the decade, variations of Chappe's semaphore appeared in Russia, Sweden, and Denmark and eventually in Prussia, India, and Egypt.

The shutter telegraph

Only slightly later, in 1795, George Murray (1761–1803), an English bishop credited with many improvements in the telegraph, established for the British Admiralty another successful visual system called a shutter telegraph, consisting of six solid shutters (see Figure 1B), each independently rotatable 90 degrees on a centred horizontal axis, arranged in the three-by-two pattern shown. The code that governed how many and which shutters to open simultaneously was similar to that of Cardano's five light and dark torches except that a larger number of combinations was possible (64 as compared to 32).

Various forms of the Murray shutter rapidly appeared in England and spread to the United States, where a number of vantage points bearing the name Telegraph Hill and Signal Hill still dot maps. A Murray line, used principally by merchants, connected New York and Philadelphia until 1846.

It was while the United States Congress in 1837 was considering a petition to authorize a New York–New Orleans Chappe-semaphore line that Samuel F. B. Morse first argued for government support of his electric telegraph.

Telegraphs using electricity. Prior to the invention of the primary battery in 1800, attempts to communicate alphabetically by electricity had failed as operable systems, usually because conductors of useful lengths could not be insulated against leakage at their points of support. High voltages were impressed on the system at the sending end, but because of losses, the relatively high voltages required to energize the then-known devices for "reading" the signals sent (the attraction or repulsion of pith or cork balls, charged feathers, and bits of paper; or sparks jumping a small gap) were difficult to realize. Despite these obstacles, from 1727 onward investigators kept alive the hope of conveying electric charges away from their source and revealing them at a distance.

Early experiments

Many ingenious proposals were put forward. In 1727 an experimenter in London transmitted an electrical impulse over one-sixth of a mile of thread. Another sent an impulse over two miles of wire, the first wire to be strung through the air for communication. A remarkable letter, signed simply C.M., appearing in a magazine in Scotland in 1753, proposed using 26 separate wires, one for each letter of the alphabet, with a light ball suspended from each at the receiving end; the movement of a ball would signify a letter, which could be written down, creating a written message sent by electric current. A Swiss worker produced an experimental model following C.M.'s suggestion. An Italian physicist, Alessandro Volta, whose voltaic battery finally provided a dependable source of current, in 1777 proposed that an iron-wire signalling line, supported on posts, be strung from Como to Milan, Italy.

Other suggestions did away with the multiplicity of wires by substituting the use of time intervals, in the fashion of the wall tapping by medieval prisoners. Claude Chappe made the important suggestion that identical clockworks at either end of a communication wire could be made to indicate numbers which would be translated into words by a codebook. But Chappe abandoned his electrostatic experiments in favour of his optical semaphore; and in 1816 a synchronized-clock telegraph was produced in Hammersmith, England, with a dial rotated at one revolution per minute to permit reading of letters and numerals through an aperture in a fixed disk hiding the dial. The scheme, which was not pursued, was the precursor of stock tickers and printing telegraphs of a later era.

Electrolytic telegraphs. Other researchers explored another possibility. Noting that when certain liquids were decomposed by an electric current the current could be detected by the formation of bubbles, experimenters in Germany sent current impulses over wires by means of voltaic batteries; the impulses released bubbles in a trough at the receiving end. The scheme proved too slow to be useful.

Needle-telegraph pioneers. The observation of the deflection of a pivoted, magnetized needle by an electric current, reported by Hans Christian Ørsted of Denmark in 1819, pointed the way to the true future telegraph. André-Marie Ampère of France and others predicted the communications applicability of the idea, and as early as 1832 a Russian established a needle-telegraph circuit between the tsar's winter and summer palaces at St. Petersburg.

Carl Friedrich Gauss and Wilhelm Eduard Weber (Göttingen, Ger., 1833) constructed a two-wire telegraph line of copper, carried 1.4 miles (2.3 kilometres) over housetops. The receiver was a heavily constructed bar galvanoscope (a compass-like device for detecting the flow of current) on which was mounted a tiny mirror. A few feet away, a telescope-and-scale arrangement made it possible to observe and record slight movements of the bar. The galvanoscope-mirror device became the forerunner of the mirror galvanometer used on the first transatlantic cables. The code consisted of five successive deflections of the bar, right or left, for each character, again, after the manner of Cardano. It was the forerunner of the modern start–stop teleprinter code. Other researchers developed a two-wire, single-needle telegraph employing a uniform-length, five-unit code and erected a single-wire line nearly six miles (ten kilometres) long, on poles with crossarms, between Munich and Bogenhausen, with an earth (ground) return.

William Fothergill Cooke, an Englishman, devised (at Heidelberg, Ger., in 1836) a three-needle telegraph of six wires and, in 1837, formed a partnership with Charles Wheatstone in London to introduce electric telegraphy as an adjunct to visual signals on railways. Together they patented and, in July 1837, demonstrated for railway use a six-wire, five-needle apparatus that could be read visually (see Figure 2). At the receiver, five external pointers

Five-needle telegraph

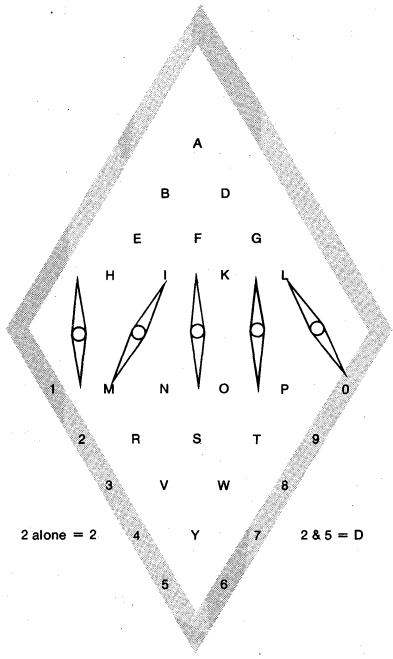

Figure 2: The Cooke and Wheatstone five-needle telegraph (see text).

were mounted on horizontal shafts that also held the needles of five galvanoscopes mounted behind the scribed panel. The needles moved clockwise or counterclockwise against stops as currents were fed through the respective wires by switches that applied voltage from a sending battery. The sixth wire served as the common return. To send a numeral, only one needle was moved at a time—the receiving operator's eye followed the line of axis of the deflected pointer diagonally toward a selected numeral on the lower edge of the display grid. To send a letter, two switches were moved at the same time; two pointers took diagonal positions and the proper letter was found at the intersection produced by their axes, whether in the upper half or the lower half of the grid. A codebook based on 20 letters and ten numerals handled the railway's requirements. The system was in use on the railway between Paddington (London) and West Drayton in July 1839 and was extended to Slough (18 miles [29 kilometres]) in 1843. Because six-wire construction was costly, Cooke and Wheatstone, in 1845, patented a successful single-needle instrument, but it required skilled operators. In 1846 several telegraph companies adopted it in England for public use; on the Continent it competed for favour with Morse's register (1844); it employed equal-duration, left and right deflections of a needle to denote characters, in a code resembling Morse.

Electromagnets applied to telegraphy. In 1825, it was learned that it is possible to increase the intensity of magnetic fields many times by introducing soft-iron cores into coils carrying current. The cores were shaped into horseshoe form to attract iron-bar armatures more effectively. Joseph Henry (Albany, N.Y., 1829) discovered laws governing the design of coils of electromagnets and of applied voltages to produce maximal effects. In 1831 he signalled over a one-mile (1.6-kilometre) circuit by causing a horseshoe electromagnet to swing a pivoted,

permanent-magnet armature and strike a bell; he predicted in the same year that his method would be used to communicate other intelligence electrically.

In the United States, Samuel F.B. Morse, in 1832, made sketchbook entries of ideas that involved the electromagnet in telegraphy. In general they called for rows of marks of different lengths on moving tape in response to signals of shorter or longer time duration applied by battery to denote the ten numerals. Use of a codebook was contemplated to include words, names, dates, and sentences. To gain transmitting speed, lead types for the numerals, individually cast, were to be assembled in a long composing stick called a port-rule; this was to be drawn rapidly under contacts that would apply battery to a two-wire circuit. Morse cast such types in brass molds in 1832. By 1835 he had abandoned his codebook idea and had drawn up the Morse Code of dots and dashes representing letters, numerals, and punctuation (see Figure 3, column A). His handmade model of 1835 contained type cast in Morse Code. Later he concluded that setting type was too slow and substituted a simple key to

Figure 3: (Column A) American Morse Code. (Column B) Continental, or International, Morse Code.

open and close the circuit by hand movement as on a piano key. After incorporating these improvements in the model, Morse demonstrated it to friends in his quarters in 1837, filed a patent caveat, and formed a partnership with Alfred Vail (as Cooke and Wheatstone were doing in England in the same year).

Vail and Morse quickly made drastic changes in the aspect of the receiver, or register, making the leverage compact and forming a message consisting of dots and dashes in a straight line, embossed on an unwinding band of paper. Public demonstrations of the new equipment were made in 1838 at Vail's shop in Morristown, N.J.; at New York University; before the Franklin Institute in Philadelphia; and United States government officials in Washington. A government appropriation became available to Morse early in 1843. He built his first line between Baltimore and Washington, 37 miles (60 kilometres), abandoning underground construction in favour of a pole line. Public use between cities was inaugurated on May 24, 1844, with the message: "What hath God wrought?" The registers were actuated by terminal relays.

Morse's first line

Early problems of growth. Open-wire pole lines, erected by separate private enterprises under Morse licenses, spread rapidly in the United States and Canada. Because messages had to be transferred between companies for forward handling, mergers were formed, beginning on a grand scale with the formation in 1851 of the Mississippi Valley Printing Telegraph Company, changed in 1856 to Western Union Telegraph Company. Though Morse was barred from obtaining British patents, he succeeded in introducing his register, as a competitor to Wheatstone's needle, to the various governments of Europe in rapid succession, beginning with France in 1845. Since it lacked letters with diacritical marks, the signalling code drawn up by Morse was not wholly satisfactory for use on the Continent. By agreement, a variant called Continental Morse (Figure 3, column B) was adopted by European countries in 1851. Morse's spaced letters (C, O, etc.) were replaced with unspaced letters. When demonstrated, Morse's 1844 line between Baltimore and Washington was operated as a complete metallic loop but before being extended to New York and Boston in 1845 the wire loop was replaced by a single wire with current return through the ground. The technical disadvantage of this more economical mode of operation was current leakage from wire to ground at every pole, especially in wet or foggy weather. Morse's register was modified from an embosser to an inker, using inked felt to moisten a tiny recording wheel affixed to the moving armature. The inker, in turn, was replaced by the exceedingly simple sounder (*c.* 1856) after operators (beginning with Vail) had developed the skill to write down what they heard the register "say" as accurately and even more quickly than they could transcribe on a blank what the register "wrote." Operating speed, acquired through practice, was limited by the sender. Normal operating speeds were 20 to 25 words a minute; only exceptional operators maintained speeds of 30 to 35. Railroad operators were often required to transcribe manifold copies by stylus rather than pen. The typewriter was adapted to telegraph office use soon after the introduction in 1878 of key-shift, typebar models.

Operating speeds

Lines and wires. Ezra Cornell, who erected Morse's first line, used glass doorknobs as insulators. Improved insulators of glass and porcelain were soon designed. Initially, wires were of iron; not until about 1900 was strong copper wire available. Lightning arresters and fuses were concomitant developments of the telegraph, anticipating use in power distribution.

Wheatstone and Morse experienced difficulty with insulation in underground installations, but the need was great for such installations. While pole lines were used on railroad rights-of-way in both the United States and Great Britain, practice differed as to city terminations, partly because cities in England were too congested to admit railways above ground. Consequently, underground wires laid in pipe, following gas- and water-mains practice, joined central telegraph offices with pole lines on the outskirts. Electrical failure due to moisture was common; tarred cotton, silk insulation, and gutta-percha proved ineffective. In 1860 aerial cables, consisting of 30 to 100 ground-return copper wires insulated with India rubber and overlaid with narrow tape to prevent abrasion, were being used successfully in construction over housetops in London. When introduced to underground practice, India rubber satisfied requirements.

District telegraphs. Though present-day readers may think of the telegraph in terms of distant-city or global interconnections, for the 35 years from 1845 until telephones became generally available in 1880, the telegraph was the standard metropolitan means of communication. The telegraph ended the isolation of police precincts and fire brigades. District telegraph systems with branch offices and wire networks were established in London (1859), Paris (1864), and in Germany and the United States at about the same time. They consisted of: (1) telegraph offices (in London there were 84), with wires converging at manual-relaying central offices that catered to businesses and the public; (2) a system of instruments and intracity wires offered for lease to business houses that employed their own operators; (3) general messenger services; and (4) burglar-alarm services. Among the messenger services was the pickup and delivery of domestic and foreign intercity messages. The district telegraphs maintained call boxes to summon messengers and for the filing of messages.

A need for a private wire system that required no knowledge of code was met by Wheatstone's direct-reading system, the so-called *A-B-C* system. Similar versions in France were known as Breguet and in Germany as Siemens-Halske. In these systems a step-by-step, ratchet-driven receiving indicator progressed around a clock face displaying all the letters and numerals. A character was

A-B-C system

read and recorded by the operator each time the pointer stopped. The sending communicator was another dial similarly arranged. When buttons around a circle were depressed they arrested all motion of the communicator and distant indicator. The rotating member inside the communicator was driven by a tiny crank that was turned by the operator. On its shaft was a magnetogenerator that made one-half of a turn per letter traversed, sending to the line one-half cycle of alternating current per letter. Cranking with one hand, the operator could push buttons with the other and continue to crank until inhibited by the depressed character. A speed of eight to 15 words a minute was possible. Wheatstone's magnetogenerator, which was the precursor of both the dynamo and alternator, had avoided the need for a battery.

The advantages of private wires, otherwise called leased or dedicated circuits, spread from the districts to intercity use in the United States in 1869. Among earliest users were newspaper publishers, quickly followed by stockbrokers.

Telegraphs and the press. In the United States the telegraph and the railroad mail (1834) became catalysts for an evolving journalism. The "penny press," with the aid of the telegraph, was able to feature domestic "spot news" in place of journalism's traditional editorial comments in support of political parties and commentary on intelligence received by mail. After 1866 this transformation carried over into news received by cable.

The concept of a press wire service originated in England with the telegraphic activity of Paul Julius Reuter, who supplemented incomplete line construction on the Continent by using pigeons to bridge gaps (1849). In the 1860s he was operating submarine cables wholly or partly owned by Reuters Limited as a news agency. In the United States the first intercity, leased wire service was the Associated Press' New York–Philadelphia–Baltimore–Washington service of 1875. The Associated Press had previously been established (1848) to pool telegraphic expenses.

Increasing the efficiency of wires. Much ingenuity was expended in devising direct-current repeaters so contrived that an operator receiving on line B could interrupt the operator sending on A, and in turn send to him. Also important to the efficient utilization of lines was the so-called duplex, perfected in Germany, which made it possible for one wire to provide separate eastbound and westbound paths for simultaneous transmissions. The schematic wiring of the (later) bridge polar duplex (Figure 4) shows the variable resistances and capacitances

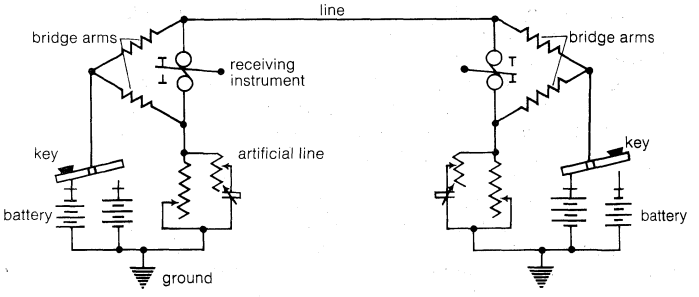

Figure 4: Bridge polar duplex circuit.

used in both artificial lines. These are carefully adjusted to balance (*i.e.*, to match) those of the main line and distant terminal. Balance is achieved when the key at the west terminal, for example, is moved up and down and the west receiving instrument is completely unresponsive to it. The east terminal is balanced similarly. On this facility four operators can handle two telegrams at the same time.

The quadruplex

Thomas A. Edison, in 1874, designed a double duplex, called the quadruplex, requiring the services of eight operators who handled four messages at one time, two in each direction. It filled a need for about 35 years and was confined to hand Morse sending.

A high-speed automatic Morse system (1858), the achievement for which Wheatstone was knighted, was used throughout the world until around 1910 on landlines, and in the early 1970s it was still being used in radiotelegraphy. An inker—a greatly improved Morse register which could run at 70 to 300 words a minute—was the receiver.

The transmitter, first driven by clockwork then by motor, was the first to use holes punched in tape as the control for keying. While sitting in front of a mallet punch, the operator struck anvils with two mallets, one for dots and the other for dashes, with middle feed holes. A third anvil punched feed holes only to separate letters and words. When the tape was passed through the transmitter, sensing pins, called pecker rods, came up through the holes to establish keying contacts. The mechanism was so designed that the contact would lock up on the top hole for the duration of a dash, then be unlatched by the bottom hole following. In time, the slow preparation of tape by mallets was superseded by faster, typewriter-like keyboards.

Using the telephone. During the early days of the telephone, it was found that ground-return circuits on intercity open-wire lines caused intolerable levels of cross talk among telephones. Consequently, two-wire metallic operation was adopted. In the 1880s the simplex circuit was devised (see Figure 5A) in which a ground-return tele-

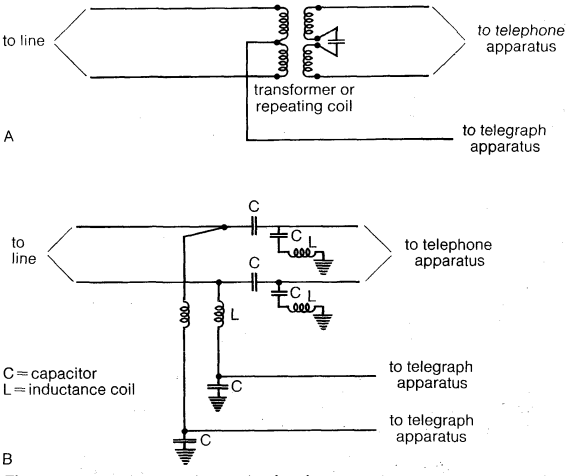

Figure 5: *Telephone-telegraph circuits.* (A) Simplex circuit; (B) composite circuit.

graph could be derived from a working metallic telephone pair without interference. Later, a composite set (see Figure 5B) permitted the derivation of two grounded telegraphs. Composite sets were still to be found occasionally in 1970 in use on intercity trunk circuits.

Submarine cables. The first underwater conductors were laid by Morse in New York Harbor (1842) and by Cornell across the Hudson River (1845). Both were constructed of copper, insulated in part with India rubber, and both were short-lived. Three Mississippi River cables (1853) were successful. Machines to apply gutta-percha as insulation were devised by Werner (Sir William) Siemens (London, 1847); submarine cables so insulated were laid from Dover to Calais, 1850–51. The next cables were laid across the Irish and North seas. A cable crossed the Mediterranean in 1855. Two were laid in 1856 from Newfoundland to Canada to meet anticipated transatlantic cables. Before 1866, the year that the first two successful Ireland–Newfoundland cables were completed, there were 51 cables elsewhere. Transatlantic attempts in 1857, 1858, and 1865 were unsuccessful. The 1858 cable worked 27 days before it failed, and the 1865 cable was pieced out and completed in 1866. Cyrus West Field, a United States financier, and William Thomson, Lord Kelvin, British physicist and inventor, are famed for their skill and persistence in seeing the transatlantic projects through.

The first transatlantic cable

In 1865 a New York–Paris landline telegraph route was surveyed through British Columbia, Alaska, Bering Strait, and Siberia. Actual construction began northwestward

from British Columbia and eastward from St. Petersburg. Completion of the first two entirely successful transatlantic cables in 1866 ended the project, but public and governmental interest in it was a factor in the purchase of Alaska from Russia by the United States in 1867.

After 1866 nearly a score of transatlantic cables were laid by the British, French, and Americans. Cables laid by Americans in 1924, 1926, and 1928 were inductively loaded with helical tapes of a magnetic alloy (Permalloy or mu-metal) wound around the conductor and under the insulation. By equalizing the arrival time of the high- and low-frequency components of the transmitted signal, the transmitting speed—hence, traffic capacity—of these newer cables was raised. Coupled with the use of vacuum-tube amplifiers that were made available in the early 1920s, the fastest of these cables worked in printer-multiplex of eight channels instead of one. By the 1940s, there were 20 transatlantic cables. In the 1950s, some of the cables failed and could not be repaired economically. Telephone cables were laid, beginning in 1956; cable and radio companies alike leased telegraph bands of frequencies in the new cables with the result that the last of the exclusively telegraph transatlantic cables was abandoned in 1966, after a century of cable-system service. In oceans other than the North Atlantic, telegraph cables still operated because alternative facilities obtainable from some telephone cables or satellite-relay services were economically unfeasible.

The original mirror galvanometer (Kelvin, 1858) required two receiving operators, one to watch and call out the signals, the second to transcribe. The method was replaced by Kelvin's delicate ink-siphon recorder (1867), which marked a wavy line on a strip of paper drawn in front of one operator. The dots and dashes of Continental Morse were of equal length, but the dots were transmitted as one polarity and the dashes as the opposite polarity (about 24 volts). The cable was grounded between letters. This was the shortest of all codes used in telegraphy. In the mid-1920s, rotary repeaters and code converters precisely controlled by tuning forks or pendulums made it possible to repeat cable signals on landline or radiotelegraph circuits and vice versa. A submerged vacuum-tube amplifier, powered from shore, was first inserted in an Anglesey–Isle of Man cable in 1943, and in a transatlantic cable for the first time in 1950.

Military uses of the telegraph. The telegraph was first employed militarily by the Allied Army in the Crimean War, at Varna, Bulgaria (1854), where lines were erected to connect command headquarters with troop units. In the same war a submarine cable was laid (1855) across the Black Sea. In the United States a transcontinental telegraph was built in the 1850s. From the Mississippi westward a solitary wire at first ran through a string of forts along the route of the pony express and of ox-drawn Conestoga wagons. The wire reached the Pacific in 1861, just as the Civil War began.

Use in the U.S. Civil War

The American Civil War made enormous use of the telegraph. Telegraph operators enlisted in large numbers; the president of the merged telegraph companies was made a general and put in charge of all the telegraphs in the North. Lines already installed were placed at the disposal of the army; others were constructed to follow the armies. New techniques suitable for army field use were developed to unreel and reuse wire strung between command posts. Batteries, keys, relays, and sounders became essential war materiel.

In the Spanish–American War (1898), landline and cable telegraphs were geared for the first time to meet the needs of newspaper war correspondents. The war also marked the first time in which cables were cut at sea as an act of belligerency (at Cienfuegos, Cuba, and at Manila), resulting in new provisions in international law to protect such installations. In the Russo-Japanese War (1904–05) radiotelegraphy was used for the first time, both in tactical deployment and in news coverage by civilians.

World War I brought the first use of teleprinter encryption, in which two identically prepared, but meaningless, key tapes are used. One is passed through the transmitter to garble the intelligence tape, while the other, passed through the receiving teleprinter, restores the original message.

The outstanding electric-signalling innovation of World War II was radar, a form of radiotelegraphic direction finder. Radar techniques have been integrated with those of telegraphy to produce some modern forms of the latter.

Early printing telegraphs. In 1846, only two years after Morse, Royal E. House of the United States invented a printing telegraph. The transmitter had a keyboard of 28 keys, each assigned a character. Behind the keyboard was a cylinder on the surface of which projected short pegs aligned on a one-turn helix. The cylinder was turned with a crank; its motion was arrested when a peg was blocked by a depressed key. Contacts that closed and opened the line, once for each letter, were positioned at the end of the cylinder. The impulses through an electromagnet stepped a ratchet and printing wheel to corresponding positions at the receiver. When rotation stopped, a miniature press forced a blackened silk ribbon against an endless paper strip, backed by the embossed letter on a wheel, to make a printing impression. Motive power was treadle-compressed air. The system was crude and required two men to send and two men to receive. Its speed was described as "twice as fast as Morse." It lasted only a few years, but is remarkable for its anticipation of the typewriter ribbon, the simplex tape printer of the 1930s, the so-called Hughes printer, and the stock ticker.

House's printing telegraph

David Edward Hughes (Kentucky, 1855) patented a system which became standard in Europe. His chief point of departure from House was to regulate the transmitting cylinder and the receiving typewheel by tuning forks and to keep both rotating without stopping; the only signals sent over the line were one dash per revolution for synchronization and one dot for each letter pressed against paper tape. The tape was gummed and was attached to a blank sheet of paper for delivery. The equipment, antedating electric motors, was driven by weights raised by a treadle and was handled by one operator at each station.

Stock tickers, step-by-step tape printers, operating at 40 words a minute, mounted on pedestals and under bell jars, had a long life (1867–1932). Generically, the piano-keyboard, pegged-cylinder transmitter of House and Hughes was combined with the one-alternation-per-character scheme of Wheatstone's *A-B-C*. In the receiver an electrically polarized relay actuated a weight-driven escapement (a ratchet device that permits motion in one direction only and in equal steps) on the printing wheel to move the various letters into position at high speed. Printing was accomplished by impact from an arm actuated by an electromagnet too sluggish to be moved by the rapid reversals of letter-selecting currents but responsive to the steady application of either pole of the battery, applied when the transmitting cylinder's rotation was arrested by a peg-striking key. Two printing wheels, rotating as a unit, were used, one to print letters, the other numbers and fractions. A unison signal brought all tickers on the line into initial register and made the tickers self-winding. By 1933 the market had outgrown step-by-step tickers. They were replaced by 500-characters-per-minute teleprinters. In 1964 these, in turn, were replaced by 900-characters-per-minute, six-level code teleprinters (see below). The use of transparent tape and narrow screens for the projection of quotations for general viewing dates from 1924; the automatic quotation boards for brokerage office data display, from about 1927.

Time-division multiplex. Jean-Maurice-Émile Baudot (France, 1845–1903), in 1872, invented a time-division multiplex-printing telegraph system containing elements from which modern equipment has evolved. The idea of synchronized rotary motion at both circuit ends (which Chappe had proposed in 1790) led, in 1853, to a proposal that in sweeping a full circle, the first half of the synchronized rotating arms' revolution could put the line at the disposal of one pair of operators, while the second half could be used by a second pair. A further proposal, that a uniform five-unit code be utilized, was made in 1860. Nothing came of either idea at the time. Baudot thought in terms of multiplexing the line, time-dividing its capaci-

Baudot's system

ty among not two but several pairs of operators. By 1877 the French Administration of Posts and Telegraphs had officially adopted Baudot's working system, the heart of which was a distributor consisting of a stationary faceplate of concentric copper rings swept by brushes mounted on a rotating assembly (see Figure 6). Depending

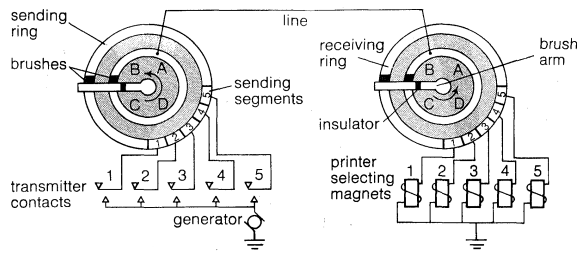

Figure 6: *Baudot time-division multiplex system.* (Left) Sending ring of one distributor and (right) companion receiving ring (see text).

upon traffic-load capacity and requirements of the line, the faceplate was divided first into sectors: if they were 90° quadrants, as shown, the multiplex became known as a quad; if 120°, a triple; if 180°, a double. A quad would keep four operators busy at each end, interweaving the characters, one at a time, from four telegrams. Each faceplate sector, whatever its arc, was further subdivided into segments representing code pulses of equal length, corresponding to the five levels of the Baudot code. For simplicity Figure 6 shows only the sending ring of one distributor and its companion receiving ring at the far end of the line. There were auxiliary rings, not shown, and brush mounts on the rotating brush arm which paced the transmitting operation and the printing. On the receiving side, each of Baudot's quad printers had the time of three-quarters of a revolution to print and clear out the character that had been set up in its five selecting bars during the initial one-quarter turn. There was therefore no line time lost in separating a character from its follower—a clear gain over Morse Code in any of its forms.

Baudot went further in loading his time-division multiplexed line by duplexing it in the manner described earlier. Baudot adopted the corrected-synchronism method of Hughes but added necessary adaptations to avoid mixing up the channels.

Baudot's inventions of the 1870s were contemporary with the typewriter and although his machines printed on tape some of his patents were used in page-writing typewriters. He was sole originator of the idea of using five sliding, notched, selecting code bars, or disks, as a means of permuting 32 printer controls, as called for by his code. Generically, his method, which was still being used in the early 1970s, was to block the downward movement of the keys of a typewriter-like mechanism by placing a bundle of thin code bars (numbered one to five) on edge, transversely under the keybars. These bars were then slotted in such a manner that the proper key would be actuated upon receipt of the proper code signal.

The paging function. In the late 1890s attention was directed to transmitting telegrams in page form, dispensing with gumming wheels and similar expedients to affix narrow tape to paper blanks at the receiver.

Donald Murray (England, 1903), taking much from Baudot, devised a time-division multiplex system used by the British Post Office. For receiving, his page printers used cut blanks; for transmitting, he used a typewriter-like keyboard after Rowland (U.S., 1899); but, in five-level configuration, he punched tape with it, like Wheatstone. Murray designed a transmitter to accept such tape and also permuted Baudot's 32 code combinations, assigning those with fewest punched holes scientifically to letters and functions most frequently encountered in telegrams: what is today loosely and not undeservedly called Baudot is in fact Murray's code, revised in minor respects by later American practice and European agreements.

Murray sold his American rights to Western Union and Western Electric in 1912. To American variants of Murray apparatus was added the auto control—a device like a telephone dial, which was probably the first to interpolate extraneous control signals into language transmission without harm. The auto control dialed control-bell signals, one to five, in the printer's uppercase *J*, printing nothing. Single open wires with ground-return were assigned two, three, or four duplexed channels, each handling 40 to 66 words a minute eastward and westward.

Regeneration of signals. Signals in transit through a succession of repeaters suffer cumulative deterioration from their original timing of transitions between the instant the electrical circuit is closed and when the circuit is opened, due partly to extraneous interference the signals pick up enroute and partly to variations in the value of circuit constants. On wires of transcontinental length and on ocean cables, rejuvenation is required. The principles of a rotary repeater, which completely regenerated signals to their pristine timing, was comprehended among the inventions Murray sold overseas. The principles were not put to work until some returning World War I veterans, who saw telegraph service in Europe, installed a rotary repeater in the United States in 1919. Signal regeneration is of great modern importance in feeding error-free input to computers.

Start–stop printer systems. Though well suited to intercity trunk lines, the multiplex was not adapted to the need for a simple, one-channel, back-and-forth or two-way printer system. To fill the need the simplex printer (later called teleprinter generically, and often, in the United States, by its tradename, Teletype) was developed and applied widely between 1924 and 1928. The simplex at first reverted to the tape-printing method of Baudot and his predecessors for reasons of cost, ruggedness, efficiency, and ease of making paste-over corrections. The tape was manufactured with adhesive on the back and passed through a hand-held wick-moistener before being affixed to the blank and severed, line by line, with a cutting thimble worn on a finger. Since this process was not popular among untrained operators, page-printing machines were furnished for private-wire use.

Simplex printer

The electricity source by that time was being kept so close to 60 hertz (cycles a second) that small synchronous motors in printers could sweep brushes of small distributors over five commutator segments in perfect step. The brushes stopped by being declutched after sweeping the fifth-level pulse in each revolution and then restarted on the next character by a clutching signal received over the line. The start pulse was of the same duration as each of the five signalling pulses; the stop, or rest, pulse was about 1.5 times as long. In modern parlance, the five-level code was transmitted as 7.5 units, pulses, or bits. Start–stop transmission lent itself readily to being repeatered by simple forms of start–stop regenerators. Today there is nothing so ubiquitous in telegraphy as the self-synchronizing, start–stop teleprinter, or teletypewriter—in five- to eight-level codes and seven to 11 units.

A 1930 model Teletype was basic to a manually-switched teletypewriter exchange service (TWX), started by American Telephone & Telegraph Company in the United States in 1931. Within 15 years, 65,000 Teletypes had been manufactured, and the name had entered the language through the press in connection with police networks. TWX service in the United States was converted to automatic switching in 1962 and extended to Canada in 1963; at the same time a speed option of 100 words per minute was offered to supplement and possibly to eventually replace the 75 word-per-minute machines. Telex, an automatic-switching service in Europe and elsewhere, originated in Germany and rapidly expanded to other countries after World War II.

Frequency-division multiplex. Though carrier telegraphy (superposition of several telegraph signals on a single carrier) had been anticipated by Bell in his quest for a harmonic telegraph in 1875, practical systems had awaited the development of components such as band-separation filters and vacuum-tube circuitry. Techniques for carrier telephony and telegraphy were perfected at the same time in 1918.

The centres of voice-frequency bands are spaced 4,000

hertz apart for telephony (3,000 hertz on submarine cable). In 1940 frequency-modulated (FM) carrier in preference to amplitude modulation (AM) was adopted in the United States and later became the international standard in Europe.

"Copying telegraph"

Facsimile telegraph systems. In 1850 F.C. Bakewell, in London, invented a "copying telegraph," consisting of tinfoil wrapped around a rotating cylinder, upon which writing, added by a pen dipped in varnish, could be scanned by a contact carried by an endless screw. The receiver was similar, except for the substitution of paper wet with a chemical. Successful manipulation of the scanning process in telegraph offices had to wait for the discovery of substances and methods (1934) leading to a dry-process recording paper not affected by long exposures to light. By 1964 over 40,000 simple drum scanner-recorders, known as Desk-Fax, were handling over 50,000,000 messages annually. Operation required no skill, yet insured error-free copy.

The TelAutograph is a short-line telegraph invented by Elisha Gray of the United States and A.C. Cowper of England about 1895. The transmitter has two rheostats (variable resistors) varied through mechanical linkages by the motion of a stylus held in the hand and moved as in ordinary writing. It leaves a sending record, if desired, by pen on a wide band of paper beneath. Each rheostat is connected to a separate line transmitting a varying current to a coil at the receiving end. The armatures of these coils are correspondingly linked to a recording pen resting on paper. The pen thus reproduces roughly the original stylus writing in facsimile. Refinements were made possible by servomechanisms developed during World War II.

Telegraphic radio-beam circuits. Expansion and improvements have made microwaves a mainstay of telegraphy in many countries in the early 1970s. By combining wideband telephone and telegraph dependably on a single telecommunication facility, radio consigned the open-wire plant of the late 1940s to early obsolescence. Telegraph contracts with the railroads were not renewed in the 1950s, and pole lines, except on some multiconductor-cable routes, were abandoned.

Reperforators. A useful means of transmission is to duplicate at the receiver of station B a counterpart of a tape used to transmit at station A. This was done by Murray with five-level code and by F.G. Creed (England, 1902) with three-level cable code. Reperforators and transmitters in the early 1940s were placed in juxtaposition and operated as a unit. For the benefit of switching operators and as an aid in reading the holes in tape, a combined printer reperforator printed a translation either on the edge of a slightly wider tape or directly on the perforations. In the latter the tape was cut chadless; *i.e.*, the holes were not punched all the way through, producing small bits of paper (chads) to be discarded, but were punched as hinged lids. They did not impede penetration by the sensing pins but did permit overtyping.

Beginning in 1934 reperforator offices were installed in the United States, based on the switching from circuit to circuit of start–stop printer-reperforator transmitters. In the early 1940s the telephone and telegraph companies started to apply similar equipment on a wide scale to large leased teletypewriter networks. This system is described as store and forward. In both applications mentioned there is a momentary storage at the receiving reperforator from line A, cross-office transmission at high speed, and an orderly accumulation of tape at the sending reperforator on line B to queue up with other messages awaiting transmission in turn.

Automatic switching

Two-letter indicators, otherwise called director signals, punched ahead of all other elements of message transmissions automatically to switch messages through reperforators, were in private-wire networks in 1943 and in public-message switching in 1947. Automatic switching may be said to mark the beginning of modern telegraphy.

MODERN TELEGRAPHY

Large business and governmental users of telegraph services began to demand facilities compatible with the computer and its associated machinery, coupled with the need for language and nonlanguage systems on a worldwide basis. As a result wire and radio-telegraph companies broadened their bandwidth offerings, redesigned terminal equipment for greater speed and versatility, and designed switched communication paths through a maze of facilities. New developments include coaxial cables; microwave radio; waveguides; satellite links; and, experimentally, beams of coherent light (laser).

High-speed data transmission. Analogue (continuous) signals can be converted to digital (discrete) signals by pulse-code modulation techniques in which information is transmitted as a series of pulses (see TELEPHONE AND TELECOMMUNICATIONS SYSTEMS). Digital signals are desirable because they degenerate far less than analogue signals when passed through repeaters enroute to their destination, and because they can be electronically regenerated and freed from noise picked up along the way. Pulse-code modulated signals are equally amenable to complete electronic regeneration at every repeater; so are teleprinter and data signals traversing a pulse-code modulated circuit.

Telegraph and telephone companies in Canada and the U.S., and government telecommunication administrations elsewhere, offer combination telephone-data services under trade names like Datel, Data-Phone, and Broadband Exchange, whereby patrons dial voice-frequency connections as they would long distance. By mutual agreement buttons are then operated, activating apparatus for sending data telegraphically at high speeds. Digital facilities for handling the entire call were being installed on a wide scale in the early 1970s.

Like most telegraphic make-and-break contact signals, the wave form of the electrical pulse generated by a dot is square topped, and each transition from the 0-to-1 and the 1-to-0 conditions is abrupt. A curve having such an abrupt rise time becomes sloped and rounded off as it travels along a transmission line. The more sloped the curve, the more it is susceptible to further degradation by the addition of impulse noise picked up enroute from various sources. Devices are installed at various points along the transmission line to counteract some of the adverse effects of the line. These are called equalizers, and they serve to prevent excessive sloping or rounding off of the curve.

Envelope-delay distortion

The same type of transformation in the arrival curve occurs when a square-top pulse modulates a carrier frequency. In carrier practice the phenomenon is called envelope-delay distortion. It has a minor effect on voice reproduction in a voice-frequency band assigned to telephony but has to be carefully equalized in telegraph channels assigned to high-speed data handling. The time required for a pulse to reach its full amplitude (rise time) determines the capability of a circuit to handle traffic. A circuit is pushed to its traffic capacity when a succession of bits like 01010101 is speeded up to the point that it can no longer be properly detected and reshaped at the first repeater. One expedient for increasing operating speed is to move repeaters closer together. Some representative repeater spacings are: open-wire line, 250 miles (400 kilometres); open-wire carrier, 100–150 miles (160–240 kilometres); loaded multipair cable, 50 miles (80 kilometres); repeatered submarine cable, 45 miles (72 kilometres); broadband-microwave carrier, 15–30 miles (24–48 kilometres), determined by line-of-sight, not transmission; underground telephone carrier, 6–17 miles (10–27 kilometres); coaxial cable, 4–8 miles (6–13 kilometres); pulse-code modulated cable pair, 1.2 miles (1.9 kilometres).

Signals and noise. Pulses are also deformed by extraneous electrical disturbances collectively called noise. Lightning may induce into wire and radio facilities alike enough energy to obliterate signals. Interference in telegraph lines from paralleling power lines may occur when circuit breakers trip or insulators fail. Sparking motors, commutators, and contacts near line wires or in telegraph switching centres cause a buildup of noise. Crosstalk (interference to adjacent circuits) among telecommunication circuits, caused by proximity of conductors, can be a

major source of noise. This effect can be minimized by transposing open-wire pairs at intervals so that one wire lies first on the left and then on the right side or by interweaving twisted pairs in multipair cable. In both cases the objective is to prevent two pairs from being contiguous for more than a fraction of their length. Wherever possible, opposite-bound transmissions are assigned to different multipair or coaxial cables.

Signal-to-noise ratio

The general level of noise may be measured and compared with the strength of signal to give a factor known as the signal-to-noise ratio. Additive bursts of noise in a circuit cannot be entirely avoided; in practice they are continuously counted during prescribed units of time, and when the count is excessive an alarm is sounded for attention.

Telegraph lines, by type. Telegraph lines are basically similar to telephone lines, and almost invariably the same facilities are used for both. The construction of new open-wire lines is being avoided because of mechanical and electrical vulnerability, but continued operation of many older lines is economically justified. Buried multipair cable is widely used on long and short hauls and is pulled through underground ducts for local runs in municipalities. River and swamp subfluvial crossings are ordinarily protected by burying. Manholes not only facilitate repairs and provide points on the lines a mile or so apart for inserting devices to improve transmission but often contain repeaters that are fed electrical power over the signal conductors. The number of pairs in a cable may run from 25 to 900 or more. Insulation is paper pulp or, more recently, the plastic polyethylene. Lead sheaths have been replaced by polyvinyl chloride plastic with an underlay of steel and aluminum sheathing. Aerial cable is made similarly; in place of manholes, junction boxes and other equipment are installed on or near poles. A typical pair in cable will accommodate 24 voice-frequency channels in one direction. Coaxial cables transmitting video signals and wideband carriers up to the 12-megahertz (12,000,000 cycles per second) range are in common use. Eight such cables may surround a bundle of standard pairs and be laid underground as a unit. A coaxial cable is made up of a central conductor separated from a flexible, cylindrical, outer conductor by low-loss insulation, often consisting of ceramic wafers and air. When used as a transoceanic submarine cable, sea-bottom hydrostatic pressures encountered make it necessary to replace the ceramic with polyethylene, which is less efficient and lowers the traffic capacity to 720 voice channels or less.

Line-of-sight microwave radio is a backbone element in the present-day, high-speed, telegraphic data transmission plant. Traffic capacity of a single microwave circuit may be 1,800 voice-frequency channels. In one application in the late 1960s a 1,200-voice-channel telegraph microwave carried teleprinter pulses, signals for facsimile transmission, broadband (high-speed) data, and special time-division-multiplexed video at rates up to 40,000,000 bits a second. Frequency modulation was used throughout to reduce susceptibility to circuit and extraneous noise. In the early 1970s satellite circuits were in daily international broadband telegraph use. Synchronous satellites, maintaining fixed positions 22,300 miles (35,880 kilometres) above the Atlantic, Pacific, and Indian oceans and earth stations dotting the globe constituted the system (see SATELLITE COMMUNICATION). Consideration was being given to eventual substitution of digital for analogue transmission, and for expansion of satellite repeaters to provide intracontinental and domestic telegraph and data links.

Satellite transmission

High-frequency bands in the radio spectrum carry major international telegraph loads overseas. Frequency-shift keying shares acceptance with time-division multiplexing of single-sideband systems with subcarriers for high-speed Morse, teleprinter (the prevailing mode), and radiophoto transmissions. Tropospheric (over-the-horizon) circuits are used in special situations. The telegraph frequency-modulated carrier is used extensively for remote control of switching, telemetering, and teleprinter communication over high-voltage power lines. Modern submarine cables, developed primarily for transoceanic telephony, share the overseas-telegraph data-traffic loads with satellites.

Direct-current keyed facilities. The rate at which direct currents are interrupted, or keyed, for signalling purposes is measured in bauds. Steady reversals could be described, for example, as taking place at 50 bauds, 50 bits per second, 25 cycles per second, or at 25 hertz. All mean the same; bauds and hertz are speed terms.

A pair of wires connecting a customer with a telegraph office or a subscriber with a telephone exchange is called a loop; often the loop is divided into sending and receiving legs. Such legs have to operate at the baud or bit rate called for by the service. On–off keying is usually accomplished by closing and opening the circuit, whether the circuit is powered by dc or ac. Circuit loops from the central office to the subscriber and return are usually supplied with a battery voltage or an alternating current (audio frequency) from the central office. If these loops are unusually long and are operated on direct current, the telegraph code may be transmitted by reversing the polarity of the dc power, instead of closing and opening the circuit. Teleprinters and data sets are designed to be versatile in initiating suitable signals on loops. An important condition to be signalled is whether the circuit is idle and, hence, available or busy and not available.

Pulse-code modulation. Pulse-code modulation has been briefly mentioned earlier in the contexts of its digital generation and its adaptability to regeneration and repeater spacing; it is discussed at greater length in the article TELEPHONE AND TELECOMMUNICATIONS SYSTEMS. Pulse-code modulation techniques in the early 1970s were rapidly being adapted to the interweaving of multiple streams of data going directly into data-processing inputs at rates up to 50 kilobits (50,000 bits) a second and bypassing the digital-to-analogue conversion necessary to transmit digits over frequency-division telephone carriers. The growth of pulse-code modulation networks has been rapid in Japan, the United Kingdom, France, and the United States.

Equipment refinements. Most of the elaborate relays and mechanical switches formerly used in direct-current telegraphy were made obsolete by the substitution of ferrite magnetic cores, arranged in arrays, or grids. Magnetization of a core will temporarily store pulses until called upon by a computer control to transfer them to an ongoing circuit or logic operation. Such cores or magnetized areas on memory tapes, drums, or disks, with no contacts mounted on parts having mechanical inertia, overcome the drawbacks of the fastest of relays. The techniques and hardware of digital-logic circuit design which evolved in the computer field in the 1960s were being applied widely in the telegraph field in the early 1970s.

Ferrite magnetic cores

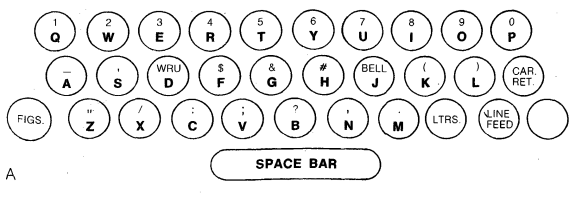
Multichannel carrier facilities. By means of frequency-division multiplex, 4,000-hertz voice-frequency bands can be utilized for teleprinter and data facilities. Guard bands between channels prevent overlap and reduce the usable band to about 3,000 hertz. For 75-words-per-minute printers, where the operating rate is 57 bauds, as many as 26 channels may be spaced 120 cycles apart in a voice band. For 100-words-per-minute eight-level printers operating at 110 bauds, 18 channels may be spaced 170 cycles apart.

Some digital transmissions (for example, high-speed data) need bands in excess of voice-band widths. Broadband facilities are available for such applications in steps from 48 kilohertz to eight megahertz wide. The latter figure has been used for digital signals in missile tracking; the former for frequently-used systems of alternate voice and data.

The terminal–facility interface. Simple relays, contact rectifiers, or modulators and demodulators (often built as a unit called a modem) are inserted between customers' or branch-office loops and the multiplexed carrier channels. Modems convert binary bits at the telegraph office into a suitable form to modulate the telegraph carrier. The digital-analogue modems designed to couple business machines located on business premises with intercity

voice-carrier or broadband facilities are usually called data sets.

Baudot-Code teleprinters. Teleprinter codes have been standardized for circuits that cross international borders. They are adopted by government telegraph administrations or representatives in the International Telecommunications Union headquarters in Geneva, usually upon recommendation of the International Consultative Committee on Telegraphs and Telephones. Its International Alphabet No. 2, as amended, usually called the Baudot Code, permits countries to assign certain code combinations to nationally-used symbols and letters (such as $, £); it merely prohibits their use in international telegrams.



The Baudot Code

Domestic manufacturers produce conforming teleprinters for use domestically, others internationally for sale abroad.

All makers have produced several types. The one selected for brief description here is the 75-words-per-minute Teletype model 28 of 1953, still in wide use in the early 1970s. Its keyboard is shown in Figure 7A and the layout of its printing typebox, viewed from the front of the printer, in Figure 7B. The typebox is a lightweight member moved in steps by a carriage along the line being typed and carrying horizontal, spring-mounted type pallets, in holes arranged as shown. Any one of these, bearing raised type on its end next to the paper platen, may be tapped on the near end by a carriage-borne hammer and driven against the ribbon and paper. In its function of aligning pallets under the hammer, the typebox has two "home" column positions, shown as vertical blank spaces; the typebox is positioned at one or the other by receipt of the figures (FIGS) or letters (LTRS) signals, controlled by keyboard keys so marked. Assuming the LTRS-mode to have been selected, the mechanism that moves the typebox up and down (four positions, from the top) and left and right (four positions left, four right) will take its direction, in order, from the five pulses which arrive in succession to represent any letter transmitted.

The shaded squares represent nonprint code characters. The pallets bear no type; the hammer does no work. In the back of the printer is a function box containing coded levers and contacts, responsive to incoming characters at the same time the typebox is responsive. These levers and contacts do such things as space the typebox carriage between words; bring the carriage back to the beginning of a line (carriage return—C.R.); feed the paper up one line on the platen (line feed—L.F.); and ring a supervisory bell. The function-box mechanism can be arranged at will to carry out the valuable attribute of reading signals—*i.e.*, watching for sequences of two, three, or even more characters and acting upon them. For instance, a FIGS-shift followed by ?/ might constitute a sequence which, upon receipt of the stroke, would throw a switch, starting up tape reperforators to interweave information

into the traffic stream. FIGS H is often used to shut down connected teleprinters by switching off their motors. Alternatively, a two-character combination might be selected to disable the machine as a printer but enable it to exercise control and switching functions, thus giving it great versatility in programming the interpolation of constant information stored in tape or devices awaiting release. Examples are telegram serial numbers, place of origin of message, time of day, date. The function box is also a means for controlling printer operations such as tabulating, backspacing for underlining, and automatically measuring paper feedout.

An advantage of typeboxes over the typebars of older teleprinters is that special applications of any code, such as Baudot, can be made simply by changing the typeboxes and key-caps.

ASCII-*type printer systems.* The inadequacy of Baudot five-level code in meeting all practical communicating and switching needs first became apparent when computers achieved a high degree of acceptance in the early 1960s, at which time a competitive effort was made by communication carriers, supported by teleprinter manufacturers, to transmit data economically in the high volumes generated by business machines. Independent system designs found a common denominator in 1966, at least temporarily, in the seven-level American Standard Code for Information Interchange (ASCII). As embodied in the Teletype model 37 of 1968, to which reference will be made, the seven-level code is signalled at 150 words a minute (15 characters a second) from an eight-level tape shown in Figure 8. Circles represent holes punched in the tape by depressing control keys (top line), such as carriage return (CR) and line feed (LF), no

holes being punched in levels 6 and 7. For alphanumeric symbols (three lines at bottom), depressing a key, with shifts, will punch levels 1 to 5 as shown above it; levels 6 and 7 as indicated at right; and level 8 (parity check for errors) only if needed to make the hole count even. Seven levels accommodate 2^7, or 128, different alphanumeric and control signals. The typist has a four-row keyboard and typebox which print normally lowercase alphabetic letters (new in general telegraphy and shown on the bottom line of the code). A shift to uppercase (capital letters) is made by depressing a shift key and holding it there so long as uppercase is being used, then releasing it to revert to lowercase, the same as on an office typewriter. The number of units, or bits, per eight-level character is ten: seven for intelligence, one for parity check, one for start, and one for stop.

Other modern teleprinters. Several other proprietary codes and systems are in common use over leased telegraph facilities. Computer manufacturers offer telegraphic peripheral units and transceivers that produce readouts at prodigious speeds. Some that print a whole line at a time consist of 80 to 120 wafer-like typewheels—essentially 80 to 120 separate, ganged printers—lined up across the paper band. Each one is independently controlled, not bit after bit, as on a wire, but all bits in each character thrown in at the same instant. In some models the wheels do not stop—a throwback to the Hughes printer of 1855. Outputs are of the order of 1,000 lines a minute, or at the rate of 333 words a second if the lines were filled. Other systems produce copies from cathode-ray tubes, electrostatic, photographic, and electrother-

mally produced chemical papers, with speeds in the range of 5,000 to 11,000 words a second.

Classes of protection

Error detection and correction. There are two classes of protection: one in which errors in transmission are detected and flagged in some way at the receiver for correction, the other in which errors are detected and automatically corrected before being printed or entering a computer. Complete redundancy in transmission; *i.e.*, sending everything twice and making an automatic check for identity, is simple but would be wasteful of long-distance facilities. Expedients are used to avoid it yet retain the advantages of moderate redundancy. For extreme accuracy (probability being one in 100,000,000 for undetected errors in words of 23 bits each), a code is used that involves a set of several nonprinted characters following each computer word. For many years automatic error-correction has been applied to transoceanic radiotelegraphy in the form of the independently invented J.B. Moore (U.S.) and H.C.A. van Duuren (The Netherlands) uniform codes. The Moore time-division-multiplex printer code consists of seven-level characters, each of which contains three 1s and four 0s. Upon receipt, each character is measured instantaneously for that three to four ratio and rejected by nonprinting if any other ratio is measured. On a fully operative duplex circuit, the receiver at B automatically interpolates an unprinted signal in B's transmission back to A, signifying that a mutilation has occurred; takes over control of A's transmitter; backs A's transmitter a measured number of characters to compensate for the interruption; and triggers resumption of movement of A's tape, beginning with the errored character.

Digital computers and peripheral units. What telegraph customers do with data processors is a concern of the telegraph carriers that tailor-make adaptable facilities. Inventories of a branch office may issue punched cards that it is desired to duplicate for record and processing at the concern's head office or warehouse. The telegraph company must be able to cause the stack of cards to be reproduced at a distance quickly and accurately. Plant payrolls, based on names of employees and their time clocked in and out, may be presented to the carrier in bookkeeping-machine form to transmit to an accounting office to be processed, for checks to be written, and for performance to be analyzed. For patrons offering multichannel magnetic tape to be reproduced in a distant office at high speed, data sets that operate on a voice bandwidth are furnished by telegraph carriers. There is a growing field of shared computers and contract processing, both kinds involving occasional interrogation by wire of specialized data banks and obtaining teleprinter responses. An example is stored library-book listings and current-literature abstracts, retrieved by computers upon presentation of descriptors or names of authors.

In addition to these tasks performed for customers, telegraph companies use computers and associated equipment to conduct their own technical functions. In these operations the logic and memory units of computers are employed far more often than the arithmetic unit. To telegraphy, the whole assemblage is less a computer than a complex switch. The control unit, in accordance with stored programs, moves about among the interoffice lines connected with the input, conducting a rollcall to uncover messages bidding for connections; probing the message headers for entitlement to priority service; determining traffic destinations; calling the roll of facility outlets and alternative routes toward destination; assigning, from apparatus held in stock reserve, the necessary interface units; and accomplishing memory storage, access, and transfer. All this complementary equipment may be, as required, independently programmed.

The timing control

A most important component of the control unit of computers, particularly those operating in tandem as in telegraph practice, is the timing control; the techniques for maintaining synchronism between transmitter and receiver are an integral part of this control.

One purpose of installing computers in place of store-and-forward relay systems has been to eliminate that component of total origin-to-destination delay caused by message handling within the office. Computers, by reviewing the status of all messages in storage as frequently as once a second, have cut to one or two seconds cross-office transmissions which formerly took a minute or more.

Carriers and administrations that offer public message service through computers are obligated to provide memory units—random-access magnetic drums, disks, tapes, and matrices—of adequate size to accept all traffic and to guard its integrity. The computer has no control of destination equipment, which may be busy; nor of lines from computer to destination, which may be inadequate at a given moment to handle all loads offered, even though many alternate routes have been engineered into the switching plan. Communication computers are different from others in the comparatively huge amounts of material offered memories for brief retention, from a few seconds to several minutes. For safety, communication computers are often installed as dual-input pairs—one on line, the other for standby protection against catastrophic failure.

Computers used by the several international carriers at the United States gateway connecting points with the landline telegraph companies have the versatility of computers described later under large private-wire systems. In addition they transform Canadian and United States message formats into others conforming to requirements for delivery in various parts of the world, and vice versa. They act as a buffer against slight speed differences between American and European teleprinters, and they supply serial numbers to messages so that messages may be billed to customers and connecting carriers and taken into account for international settlements in foreign currencies.

Telegraph networks. A description of the public system for the handling of telegrams is best approached through consideration of the simpler private-wire systems, both small and large.

Small private-wire systems. A simple two-way duplexed circuit joining two teleprinters can be extended in usefulness by providing for extra drops or stations en route; each drop can remain silent until activated by local initiative or from a distance. In the case of some press associations more than 200 newspapers are so connected to a duplexed round robin 4,300 miles (6,920 kilometres) long; dispatched from a head office, each newspaper can send in response to query and command and continuously copy all transmissions in both directions around the loop.

Load traffic studies

Within an industrial organization a traffic study is commonly made of loads among all offices; the busy hours and busy half hours during representative days are determined; and costs of alternative patterns of lines and operations are estimated. Out of these studies come least-cost figures for a hierarchy of branch, group, area, and zone offices; their location; an estimation of speed of service to be expected; a circuit layout; and the specification and cost estimates for the rental of lines and equipment. Depending upon all the factors, the types of operation fall into three classes: (1) fully automatic, in which dialed numbers or director letter combinations in message headers set up the paths from points of origin to points of destination; (2) semi-automatic, in which operators at zone offices read destinations by examination of printer-reperforator tape and push buttons to establish connections across the office and onto outgoing circuits; (3) or torn-tape operation, used in compact offices, in which reperforated tape can be torn in message lengths and the lengths inserted in transmitters.

Large private-wire systems. The largest known private network in the world in 1968 was operated by and for the military arm of the United States government on hired facilities. It had nine major computer-controlled centres and 2,700 outstations in the country and ten more zone centres to serve 1,600 transatlantic and transpacific stations. Its compatible and cross-connected civilian counterpart is a fully automatic hybrid network of three zone centres; an average of eight district offices subsidiary to and connected with the zone centres; finally, more than

1,600 subscribers' teleprinters and data sets in 600 cities —a hierarchy of three echelons. It is called hybrid because the zones and districts each carry on simultaneously both alternative functions of private and public networks: (1) a circuit-switching function to join facilities together end to end, point to point, to extend from a dialing subscriber all the way through to his called party, to use ad lib after the connection has been completed; (2) a message-switching function for accepting messages, one at a time, into temporary storage, dismissing the subscriber, then discharging a responsibility to establish a route (thus, store and forward) which the message is to follow to reach its destination.

Capabilities of the processing computer

In sending single, off-network messages, the subscriber dials his zone centre by number. There his equipment is put through to a store-and-forward processing computer, which has many capabilities besides switching calls through. In its memory are stored all alternate routes that messages can take. It makes interconnections with "outside" networks. It can convert one keyboard code, like Baudot or ASCII, to another. It can render compatible the unmatched speeds of teleprinters. It makes message-format conversions. It can provide teleprinter or wideband data channels. It recognizes and appropriately schedules several classes of transmission priorities, and it distinguishes between full-rate and overnight messages. It has a store-and-forward memory. It can accept and switch multiple-address messages; *i.e.*, messages having one text but deliverable to any number of addresses. In its memory it can retrieve lists of such multiple addresses, identified as frequently used groups. It performs message accounting and makes statistical analyses.

The user of this store-and-forward private service must present messages to the computer in a fixed format, subject to the computer's rejection if incorrect. For this reason, off-line preparation of correct tape is preferred over on-line keyboard manipulation.

In a store-and-forward system it is inevitable that queues of messages should be formed in the computer's memory, each awaiting its turn for transmission to addressees whose teletypewriters are in use. The computer supervises this queue and constantly makes attempts to find the terminal available, following a mathematically determined pattern of intervals between attempts and maintaining an orderly, first-come-first-serve lineup in queue.

Teleprinter-subscribers' exchanges. Intermediate between private-wire leased systems and the public telegram service are the public teletypewriter exchanges, interconnected throughout the world. These systems are much larger than any private-wire system, but basically their operation differs only in detail from circuit switching in the large private-wire systems just described. The exchanges do not incorporate store-and-forward features. In 1969 the largest such system had 43,000 subscribers, using 75-word Baudot and 100-word ASCII-keyboard printers.

In 1970 the Western Union Telegraph Company acquired TWX from the American Telephone & Telegraph Company and amalgamated it with Telex in the continental U.S. The resulting four-echelon hierarchy of switching points consisted of nine zonal junction points, an average of ten districts per zone and eight subdistricts per district.

Directories supplied to customers differ from the usual telephone directories by embracing continental U.S. and Canada. Busy conditions en route and at the called terminal are fully exposed to the calling subscriber; hence, the number of facilities and pieces of switchable equipment placed for prompt completion of on-demand calls have reached a high mark in telegraphy through Telex and TWX. On the receiving side a Telex will operate unattended. The calling subscriber may ring a bell in the printer to attract attention of anyone present.

Telex and TWX

Characteristic of Telex calls in Europe and America has been the employment of a time-and-zone meter and clock-driven counter that is associated with the subscriber's loop and registers cumulative bulk-charge usage by the month; the clock rate in beats a minute is greater or less in proportion to the mileage zone determined by the number called. Most Telex and TWX connections are half duplex; *i.e.*, they will work alternately, back and forth. Ordinarily the printer associated with a keyboard records faithfully what is sent, but if for some reason the receiving operator wishes to interrupt, he may do so by striking keys at random. This will break up the copy at both ends of the wire to signify an interruption.

Three landline-system telegraph computers went on line in New York, Chicago, and San Francisco in 1969; their versatility was initially applied to Telex calls in the same way that computers had hitherto been applied to large private-wire installations described earlier. A subscriber dials the computer by number for Telex computer communications service beyond that afforded by his ordinary directory calls. If he encounters a busy condition in making a regular call, for instance, and does not wish to wait to redial, the computer, on signal, will store his message immediately and will transmit it to destination as soon as the called party's machine is free. Or the subscriber may offer a collect message; not only will the computer handle it but will bill the addressee also. The computer will relay Telex messages to TWX subscribers. The Telex subscriber may file public telegrams with the computer, addressed to nonnetwork addressees—also multiple-address messages with identical texts, whether for Telex or off-network addressees. It is estimated that in 1969 there were 200,000 Telex subscribers in 154 countries.

Public telegram service. The acceptance and delivery of regular and overnight telegrams requires the functioning of telegraph offices and agencies connected electromechanically, in one way or another, with reperforator centres—area-relaying offices—so located that each acts as the focal point for traffic originating in or destined to most localities in the area. Each reperforator office is tied in with every other by direct teleprinter channels. With a few exceptions, full duplex operation of 75-words-a-minute Baudot tape printers was characteristic of operation.

In addition to the network of facilities interconnecting area-switching centres, there was a separate network of multiple-trunk duplexed printer channels between pairs of the dozen largest terminal cities and even between a few pairs of city branch offices, like commodity exchanges. The area and terminal networks were mutually supporting as alternate, automatically switchable routes in the event of interruptions to portions of either network.

Gentex and Telex. In telegraphically compact countries like Belgium and The Netherlands, Telex lines and equipment are furnished to each post office so that separate connections may be established from post office of origin to post office of destination for each telegram as it is filed. The service is called Gentex. The economics justifying this is favourable where lines are short and cheap and the facility-utilization factor of no moment.

Operations in large cities. In the early 1970s within a large city there was often a complex of branch offices, and in such cases the hierarchy of facilities appeared on a third level, tributary to the main, or central, office. The central office had pneumatic tubes radiating underground through ducts to the branches for transporting telegrams physically in both directions. Its other ties with a branch were mainly by teleprinters and facsimile-telegram Desk-Fax machines; the telephone was used to a lesser extent. Major business customers of the public message service frequently bypassed the branch offices in one direction or both; some of them manned teleprinter or Desk-Fax tie lines with the main office; some preferred the telephone for sending, others for receiving telegrams. Uniformed messenger boys and call boxes in business offices, once mainstays of message pickup and delivery from main and branch offices, had virtually disappeared.

Desk-Fax

Special arrangements in routing reperforated traffic between main and branch offices were found necessary in large terminal cities. Not only were there complications due to house numbers on one street being assigned to different branches, but many telegrams bore no addresses other than a firm's name. Also the delivery preferences of patrons had to be consulted—whether service was to be by messenger, telephone, Desk-Fax, or teleprinter tie line.

The use of facsimile enjoyed popularity among customers until Telex offered advantages as a substitute. The Desk-Fax telegram had merely to be wrapped around a cylinder and in two minutes it could be transmitted or received by a scanning process. In large cities all inbound city tape telegrams were converted to page form: it was done (without computers) by a translator which could count text characters. On the first word space after the 58th character it would automatically insert carriage return and line feed; and so on, from line to line. Additionally, it would count lines from prefix to signature. If there were fewer than 16, it would insert the remainder up to 16 to feed the page blank as a standard-size telegram out of the burster printer. The burster was a device that tore the blank loose from its roll and deposited the completed telegram on a conveyor belt, to be assembled with others for delivery by facsimile or pneumatic tube and messenger. At the same time, punched tape in page mode would be created for semi-automatic switching. An operator, with an explicit route chart to memorize or consult, would push one button in a raster of buttons to transmit the telegram to a branch office by wire, or to a tie-line operator, or telephone delivery department. Complexities of this kind are within the scope of a programmed switching and translating computer; in the early 1970s plans were being formulated to incorporate them into a redesigned public telegram system.

Telegraph offices and agencies. Between 1945 and 1970, the physical character of telegraph service changed considerably. Individual customers were less frequent users, except for the purpose of sending money. For other services the customer usually used the telephone rather than going to the telegraph office to place his message. A number of conveniences, such as special holiday-greeting messages and congratulatory telegrams, were offered.

Successful experiments were carried out with equipment by means of which telegram-recording operators could send dictated messages directly into the public-message system. The message, as it was built up, was displayed on a TV-like screen under electronic control of associated apparatus. If the patron wished to change a phrase or strike a sentence or insert a word, what had appeared on the screen could be obliterated at once and the new material substituted. When dictation was finished, the operator would add (using the proper keyboard controls) the route to be followed and billing information. Meanwhile the equipment had been converting the message format to one required for switching through the network. No other work remained to be done in the office or elsewhere except automatic switching.

Other pilot tests in the 1970s were being made to link this type of operation with centralized, single-number telephone bureaus, at the disposal, toll free, of anybody, anywhere, to dial for filing telegrams by telephone as input into the rapidly evolving nationwide computer network.

Imminent developments. Modernization of the present reperforator system for handling public telegrams will involve replacing it with a complex of computer centres in all the large cities of the world. To these computers, all telegraph offices and agencies, area telephone-recording centres, and the rapidly growing, specialized, industry-oriented series of teleprinter-data networks will be tributary, ultimately creating a worldwide electronic-communication system with universal automated connections.

Telemann, Georg Philipp

In the eyes of his 18th-century contemporaries, Georg Philipp Telemann was the greatest living composer. The dreaded critic Johann Mattheson wrote of him that "Corelli and Lully may be justly honoured but Telemann is above all praise." Through his public concerts Telemann introduced to the general public music previously reserved for the court, the aristocracy, or a limited number of burghers. His enormous output of publications provided instrumental and vocal material for Protestant churches throughout Germany, for orchestras, and for a great variety of amateur and professional musicians.

The son of a Protestant minister, Telemann was born at Magdeburg, Germany, on March 14, 1681. He was given

By courtesy of the Kunsthalle, Hamburg

Telemann, engraving by Georg Lichtensteger (1700–81).

a good general education but never actually received music lessons. Though he showed great musical gifts at an early age, he was discouraged by his family from becoming a professional musician, at that time neither an attractive nor a remunerative occupation. By self-teaching, however, he acquired great facility in composing and in playing such diverse musical instruments as the violin, recorder, oboe, viola da gamba, chalumeau, and clavier. In 1701 he enrolled at the University of Leipzig as a law student, but musical activities soon prevailed and were to engross him for the rest of his life.

Early career at Leipzig

Leipzig became the stepping-stone for Telemann's musical career. The municipal authorities there realized that, apart from his musical gifts, the young firebrand possessed extraordinary energy, diligence, and a talent for organization. They commissioned him to assist the organist of the Thomaskirche, Johann Kuhnau, by composing church cantatas for alternate Sundays, and also gave him a position as organist at the university chapel, Neuenkirche. Telemann reorganized the collegium musicum, the student musical society, into an efficient amateur orchestra that gave public concerts (then a novelty) and became director of the Leipzig Opera, for which he also composed. Telemann's next positions were at two princely courts: first as *kapellmeister* (conductor of the court orchestra) in Sorau (now Żary, Poland: 1704–08), then as *konzertmeister* (first violinist) and later *kapellmeister* in Eisenach (1708–12). By playing, conducting, studying, and composing he gained the musical knowledge, practical experience, and facility in composing that were to be vital when he assumed the musical directorship of Frankfurt am Main (1712–21) and Hamburg (1721–67). In Frankfurt he was musical director of two churches and in charge of the town's official music. As in Leipzig, he reorganized the students' collegium musicum and gave public concerts with the group. In Frankfurt Telemann started publishing music that made him famous not only in Germany but also abroad. As musical director of Hamburg,

Musical director of Hamburg

one of the outstanding musical positions of the time, he supplied the five main churches with music, was in charge of the Hamburg Opera, and served as cantor at Hamburg's renowned humanistic school, the Johanneum, where he also was an instructor in music. In Hamburg, too, he directed a collegium musicum and presented public concerts. In 1729 he refused a call to organize a German orchestra at the Russian court. He had also declined an offer in 1722 from municipal authorities in Leipzig to succeed Kuhnau as organist of the Thomaskirche. This proffered position, which had been promised him 17 years earlier by authorities in the event of Kuhnau's death, manifested the high esteem in which even the young Telemann was held. (Following Telemann's refusal, the position fell to Johann Sebastian Bach.) In addition to all his activities in Hamburg, he also supplied (by contract) the courts of Eisenach and Bayreuth, as well as the town of Frankfurt, with music and continued to publish his compositions.

Qualities and style of Telemann's music

A master of the principal styles of his time—German, Italian, and French—he could write with ease and fluency in any of them and often absorbed influences of Polish and English music. He composed equally well for the church as for opera and concerts. His music was natural in melody, bold in harmonies, buoyant in rhythm, and beautifully instrumentated. Profound or witty, serious or light, it never lacked quality or variety. Telemann's printed compositions number more than 50 opuses, among them (counting each as one item) the famous collection *Musique de table* (published in 1733; containing 3 orchestral suites, 3 concerti, 3 quartets, 3 trios, and 3 sonatas); the first music periodical, *Der getreue Music-Meister* (1728–29; containing 70 compositions); *Der harmonische Gottesdienst* (1725–26; 72 church cantatas); and 36 fantasias for harpsichord.

Except for a brief journey to France (1737–38), where he was enthusiastically received, Telemann never left Germany. He married twice and had eight sons and three daughters. His first wife died young in childbirth; his second wife absconded with a Swedish officer, leaving Telemann with a debt of 3,000 taler. Apart from being a prolific composer, he was also a keen writer; his two autobiographies of 1718 and 1739 are comparatively well documented. He published a long poem after his first wife's death, and many words in his vocal compositions came from his own pen. Especially noteworthy are Telemann's many prefaces to collections of his music, which contain a great amount of practical advice on how his compositions (as well as those of his contemporaries) should be performed. A friend of Bach and Handel, he was godfather to Bach's son Carl Philipp Emanuel, who succeeded as musical director of Hamburg after Telemann's death on June 25, 1767, at the age of 86.

The multiplicity of Telemann's activities and the great number of his compositions are remarkable, indeed. In his lifetime he was most admired for his church compositions. These vary from small cantatas, suitable for domestic use or for use in churches with limited means, to large-scale works for soloists, chorus, and orchestra. His secular vocal music also has a wide range, from simple strophic songs to the dramatic cantata *Ino*, written at the age of 84. Of his operas the comic ones were the most successful, particularly *Pimpinone*. His orchestral works consist of suites (called *ouvertures*), concerti grossi, and concerti. His chamber works are remarkable for their quantity, the great variety of instrumental combinations, and the expert writing for each instrument.

After Telemann's death, the new music styles of Haydn and Mozart obliterated the older ones. And in the 19th century, when the works of Bach and Handel were reappraised, Telemann's reputation was reduced to that of prolific but superficial scribbler. In the 20th century, however, a historically and aesthetically more correct opinion has been formed, largely through studies by Max Schneider and Romain Rolland. New editions of his work have appeared, especially since the 1930s, and the interest of players, conductors, and publishers has increased.

MAJOR WORKS

OPERAS: More than 50, including *Der gedultige Socrates* (first performed 1721); *Der neu-modische Liebhaber Damon* (1724); *Pimpinone* (1725).

ORATORIOS AND CANTATAS: *Der Tag des Gerichts* (1762); *Ino* (1766); *Die Tageszeiten; Der Tod Jesu; Die Auferstehung Christi; Seliges Erwägen*, 46 Passions.

INSTRUMENTAL: *Musique de table*, productions 1–3 (published 1733); innumerable concerti, suites, quartets, and sonatas, for varying instrumental combinations.

Telemetry

Telemetry, as a name, designates a highly automated communications process by which measurements are made and other data connected at remote or inaccessible points and transmitted to receiving equipment for monitoring, display, and recording. Originally the information was sent over wires; modern telemetry more commonly uses radio transmission. Basically, the process is the same in either case. Among the major applications are monitoring electric-power plants, gathering meteorological data, and monitoring manned and unmanned space flights.

History. The original telemetry systems were termed supervisory because they were used to monitor electric-power distribution. In the first such system, installed in Chicago in 1912, telephone lines were used for transmitting data on the operation of a number of electric-power plants to a central office. Such systems spread to other fields besides power networks and underwent extensive improvements, culminating in the introduction in 1960 of the so-called interrogation–reply principle, a highly automated arrangement in which the transmitter–receiver facility at the measuring point automatically transmits needed data only on being signalled to do so. The technique is applied extensively throughout the world in such fields as oil-pipeline monitor-control systems and oceanography, in which a network of buoys transmits information on demand to a master station (see illustration).

Aerospace telemetry

Aerospace telemetry dates from the 1930s, with the development of the balloon-borne radiosonde, a device that automatically measures such meteorological data as temperature, barometric pressure, and humidity and that sends the information to an earth station by radio.

Aerospace telemetry for rockets and satellites was inaugurated with the Soviet satellite Sputnik, launched in 1957, and systems have grown in size and complexity since then. Observatory satellites have performed as many as 50 different experiments and observations, with all data telemetered back to a ground station. The techniques developed in aerospace have been successfully applied to many industrial operations, including the transmission of data from inside internal-combustion engines during tests, from steam turbines in operation, and from conveyor belts inside mass-production ovens.

Telemetering systems and components. A telemetering system consists of an input device called a transducer, a medium of transmission (usually radio waves), equipment for receiving and processing the signal, and recording or display equipment.

The transducer. The transducer converts the physical stimulus to be measured, such as temperature, vibration, or pressure, into an electrical signal and, thus, operates as the actual measuring instrument. A fuller discussion of transducers is included in the article ELECTRONICS.

Transducers can take many forms. They can be either self-generating or externally energized. An example of the self-generating type is a vibration sensor based on the use of a piezoelectric material—that is, one that produces an electrical signal when it is mechanically deformed (see also PIEZOELECTRIC DEVICES).

One class of transducer, which includes radiation detectors, produces a pulsed or numerical type of digital output, as distinct from an encoded digital output. This is also provided by rotary flowmeters, the output of which is generated when a magnet on a turbine rotor moves close to a stationary coil.

Many externally energized transducers operate by producing an electrical signal in response to mechanical deformation. Typical physical inputs producing such deformations are pressure, mechanical stress, and acceleration. A simple mechanical transducer-sensing device is a strain gauge based on the change in electrical resistance of a wire or a semiconductor material under strain.

Another externally energized transducer, called the variable-reluctance type, is one in which the magnetic circuit is broken by an air gap. The mechanical movement to be measured is used to change this air gap, thus changing the reluctance, or opposition, to the production of a magnetic field in the circuit. The change in reluctance is then translated into an electrical signal. A somewhat similar device is the variable-capacitance transducer, in which mechanical motion is converted to a change in capacitance in an electronic circuit.

Temperature sensors

Temperature sensors can be divided into two classifications: temperature-dependent resistance elements and self-generating thermocouples. Thermistors are of the first type; they have a high negative temperature coefficient—that is, their resistance drops very rapidly as the temperature increases. The thermistor is small and provides rapid response to changes in temperature. Thermocouples are wire junctions of dissimilar metals that produce an electrical current when heated; they have a very low output, and each must be used with a second thermocouple held at a constant cold temperature for a reference point.

There are many types of specialized sensors and transducer systems. One is the previously mentioned radiosonde system, designed specifically to radio weather information from a balloon to a ground station. Weather-sensing and transmitting elements usually measure temperature, pressure, and humidity. In manned space probes, sensors for measuring such factors as the astronaut's blood pressure, heartbeat, and breathing rate are employed. Sensors have also been developed to indicate the rate of flow of a fluid through a pipe.

Communications links. In the early 1970s, communications facilities for telemetry still consisted of either radio or wire links. Alternatives such as light beams or sonic signals were under investigation, but environmental factors such as atmospheric obstructions and local masking noises made them impractical except for specialized applications.

Radio communication is used for aerospace work and for supervisory systems in which it is impractical to provide wire line links. For public utility installations in built-up areas, radio communication is usually ruled out by the difficulty of finding antenna sites and unobstructed line-of-sight radio paths. In such cases, cables and line links are used.

An important consideration in radio links is the choice of operating frequency, a choice limited to bands allocated by international agreement. Propagation varies enormously over the range of frequencies involved. For aerospace applications in which transmissions must penetrate the atmosphere, the frequency range is 100 megahertz (100,000,000 cycles per second) to 10,000 megahertz, or a wavelength of from three metres to three centimetres.

Line links for supervisory applications usually employ a comparatively narrow band. They may utilize the whole or only a section of a conventional voice channel with a bandwidth of 3,000 hertz (cycles per second). The link may be either a direct wire circuit or one of the channels in a carrier communications system.

The performance of radio and line links for telemetry depends on two basic system characteristics: the amount of power lost over the radio propagation path or on the transmission line, and system noise, which may either be inherent or a function of engineering design.

Multiplexing and sampling. A telemetry system ordinarily must handle more than one channel of information (*e.g.*, routine measurements from an orbiting satellite, or flow rate and reservoir levels in a water-distribution network). These data-measurement channels are brought together by a process known as multiplexing, which combines the channels into one composite signal for transmission over the communication link. (An explanation of multiplexing is contained in the article TELEPHONE AND TELECOMMUNICATIONS SYSTEMS.)

Multiplexing may be based on either a time division or a

frequency division. In time division, channels are combined one after another in time sequence; in frequency division, each channel is assigned on an individually allocated, discrete frequency band, and these bands are then combined for simultaneous transmission. Finally, data may be handled within the telemetry system in a continuous (analogue) or discrete (digital) way. The latter systems are relatively more complex because it is necessary to convert analogue signals to digital form, a process known as encoding, for a purely digital arrangement.

Time-division multiplexing involves a sequential action in which samples are selected in turn from a number of different measurement channels for transmission to the receiving point. In fixed cycle selection, a switching device connects a particular channel to the outgoing communication link in accordance with a pre-arranged sequence.

With a so-called address–reply system, data are sent only as a result of a command signal: sampling is in accordance with a predetermined scanning program. The program is flexible because it can be arranged to meet priority requirements for information, as, for instance, when an alarm condition develops.

Transmission. A process called modulation is used to impress the information on the carrier frequency. Of the many design choices that must be made, that of the modulation method is among the most important. Not only does it have a direct influence on system performance but it also tends to define areas of design in both the sender and receiver (see also RADIO).

Modulation methods fall into two divisions. The first includes amplitude and frequency modulation (as in commercial amplitude-modulation and frequency-modulation broadcasting) and related types. These related types include two pulse-based methods in which several pulses are spaced out in time, each pulse representing one information channel. The two types are pulse-width (or pulse-duration) modulation and pulse-position modulation. In the first, the information produces variations in the width (or duration) of the pulse; in the second, the variation is in the position of the pulse with respect to time. In the second main class, pulse-code modulation, the information is coded digitally into groups of pulses and then transmitted.

Pulse-based methods

In most telemetering systems, modulation is carried out in two stages. First, the signal modulates a subcarrier (a radio-frequency wave the frequency of which is below that of the final carrier), and then the modulated subcarrier in turn modulates the output carrier. Frequency modulation is used in many of these systems to impress the telemetry information on the subcarrier. If frequency-division multiplexing is used to combine a group of these frequency-modulated (FM) subcarrier channels, the system is known as an FM/FM system.

Processing the received signal. At the receiving end of the telemetry chain, two tasks must be performed: the original measurement data must be extracted from the received signal, and it must be presented or displayed in intelligible form.

The extraction of the data takes place in two stages and is the reverse of the steps taken in producing the modulated composite transmitting signal. Initial demodulation produces the modulated subcarrier; this subcarrier is then split up into its original measurement channels by demultiplexing (the reverse of multiplexing). The separated signals are fed individually to their respective points in the presentation system.

Data is presented in "real time"—that is, at the instant the variable is being measured—and in one or more recorded forms. Magnetic tape is the most widely used recording medium.

The presentation of aerospace data differs from that of supervisory data. For the routine requirements of the latter, formal diagram displays normally are provided, together with printout of the data by electric typewriter. Aerospace systems, on the other hand, being experimental in nature, generally display a wide range of measurements. Almost without exception, data are recorded in a form suitable for processing by computers.

Special applications and techniques. New applications of telemetry are constantly appearing, particularly in the fields of research and scientific investigation. An important area is biomedical research, in which biological information is telemetered from inside patients by means of microminiature transmitters that are either swallowed or surgically implanted. External monitoring of body conditions can be carried out with surface transducers, as is done with astronauts.

Biomedical telemetry

Another scientific area in which telemetry is applied is oceanography. In this case, unmanned instrumented buoys are interrogated by a central master station at appropriate intervals. Both oceanographic data (*e.g.*, water temperature and salinity) and surface meteorological information are recorded, ready to be transmitted to the master station in response to interrogation.

In mechanical engineering, information is transmitted from inside prime movers (electric, gas, steam, and diesel engines) over various types of radio links to an external receiver. Information normally includes temperature and pressure.

Telemetry is frequently provided by television-like facilities usually employing a low bandwidth communication link. Such a facility is advantageous when a visual indication is desired of a process inaccessible to humans. Applications include rocket-motor testing and remote observation of operations with highly radioactive material.

YOUNG, *Telemetry Engineering* (1968), a general text covering both aerospace telemetry in which measurement data is transmitted from an aerospace vehicle, such as a manned capsule, over a one-way radio path, and supervisory telemetry, which is characterized by address–reply–interrogation of outstations by a central master station over a two-way communication system; *International Telemetering Conference Proceedings* (1963), a unique conference that was the first of its kind to review the whole of the formative period in the field of telemetry, with its *Proceedings* covering both aerospace and supervisory telemetry; H.L. STILTZ (ed.), *Aerospace Telemetry* (1961), a text giving detailed information on aerospace telemetry; G.E. MUELLER and E.R. SPANGLER, *Communication Satellites* (1964), a work covering the use of artificial space satellites in communication.

(R.E.Y.)

Teleostei

The name teleost is applied to members of the Teleostei, a diverse group (infraclass) that includes virtually all of the world's important sport and commercial fishes, as well as a much larger number of lesser known species. The infraclass is distinguished primarily by the presence of a homocercal tail; *i.e.*, one in which the upper and lower halves are about equal. The teleosts, sometimes called "advanced bony fishes," comprise some 20,000 species (about equal to all other vertebrate groups combined), with new species being discovered each year.

General characteristics of teleosts

The great abundance of some large species, such as the tunas and halibuts, and of smaller species, such as the various herrings, have made teleost fishes extremely important to mankind as a food supply. In almost every part of the world local fishes are used as food by men at all stages of economic development. In addition to being a commercial food resource, teleost fishes provide enjoyment to millions of people and in many countries of the world support a large sport fishing industry. As aquarium subjects both marine and, especially, small freshwater teleosts provide esthetic beauty for millions of aquarists, supporting a multimillion dollar industry. Part of the interest in teleosts as aquarium subjects is derived from the great diversity of their anatomical structures, functions, and colour. Indeed, these fishes vary more in structure and behaviour than do all the mammals, birds, reptiles, and amphibians combined. Teleosts range in size from tiny gobies less than an inch long when fully adult to large marlins exceeding 11 feet in length and 1,200 pounds in weight. Another large fish, the ocean sunfish (*Mola*), reaches at least 10 feet and may weigh more than a ton.

Natural history. Different species and groups have widely varying life cycles and behaviours. Teleost fishes are adapted to widely varied habitats from cold Arctic and Antarctic oceans that remain colder than the freezing

point of fresh water to desert hot springs that reach temperatures over 100° F. Usually a particular species will have a restricted temperature tolerance, often between 10° to 20° F above and below the mean temperature of its environment. In terms of physical habitat, the advanced bony fishes are adapted to a wide and interesting variety of conditions, from fast, rock-laden torrential streams in the Himalaya Mountains to the lightless depths of ocean trenches 35,000 feet below the surface, where many species manufacture their own light.

A species of teleost fish is usually restricted to one kind of habitat at any given stage of its life cycle. It may occupy this habitat throughout its life, or it may change habitats as it grows older. The various species living in rocky marine shores, mud flats, sandy shores, and coral reefs are usually all different, a diversity of habitat adaptation reflected in the life cycle, behaviour, locomotion, anatomy, and reproduction. Some cyprinodonts or killifishes, for example, confined to annual ponds in Africa and South America, live only the few months during the rainy season that their ponds retain water. They hatch from eggs buried in the mud, grow up, lay their own eggs in the mud in the short space of four to eight months. Such fishes are known as annuals. Others, such as the Pacific salmon, hatch from eggs laid in the gravel of cool, temperate zone streams, spend their first year growing in the streams, then enter the sea to grow and migrate for two, three, or four years, finally returning to the streams where they first grew up. There they lay their eggs and die. Such fishes, spawning in fresh water and living most of their lives in the ocean, are called anadromous.

Reproductive behaviour

Many freshwater and marine teleosts lay eggs on rocks or aquatic plants, the male and sometimes the female defending the eggs and even the young against predators. Many of these fishes will live two, three, or four years or more, usually spawning in the spring in temperate regions and in the rainy season in the tropics. There are large numbers of teleosts, especially those in the ocean, whose breeding habits are unknown. Most fishes lay numerous eggs, often simply scattering them over plants or in the open ocean, where they provide food for many organisms, only a few young surviving to adulthood. Most offshore marine teleosts lay planktonic (free-floating) eggs, whereas most freshwater fishes lay demersal eggs; *i.e.*, eggs that sink to the bottom. Some teleosts, such as certain of the perchlike African cichlids, some catfishes, and some marine fishes (*e.g.*, cardinal fishes) are oral brooders, the male or female incubating the eggs in its mouth.

Some fishes, for example, some of the sea perches (Serranidae), are functional hermaphrodites, one individual producing both sperm and eggs. Self-fertilization is evidently possible in some cases, but more often the fish plays the male and female roles alternately. In some species an individual is a male during the early part of its adult life and a female later.

About a dozen families of teleosts produce living young. In some the eggs are abundantly supplied with yolk and merely hatch in the ovary (ovoviviparous), in others the eggs have little yolk, the young hatch at a relatively undeveloped state and are nourished by a placenta-like structure of the ovary (viviparous).

The behaviour of teleosts is as varied as their other attributes. Some oceanic fishes travel in close-ordered schools, seemingly responding to predation from larger fishes almost as a single organism. Larger, predatory fishes are usually solitary and hunt or wait for prey alone. Many marine shore and freshwater fishes establish territories during the breeding season, and some may travel in relatively loose schools or shoals when not breeding. Many kinds of teleosts enter into symbiotic relationships with other species of fishes and organisms, for example, a small, blind goby along the California coast lives together with a shrimp in the shrimp's cavelike tubular dwelling. The shrimp carries food to the goby while the goby keeps the shrimp's burrow clean. Many species of wrasse pick parasites from larger fishes, even entering the mouths of these fishes to clean the gill chambers. On the other hand, in South America some small catfishes, one to four inches long, appear to be parasitic on certain other species of catfishes that reach lengths of over eight feet. The smaller fishes enter the mouths of the larger catfishes and feed on gill tissue. Unfortunately, little is known about the behaviour of most teleosts, but study of the details of their behaviour has been greatly increased in the last several decades.

Form and function. Defining teleost fishes by functional morphology is hard, for they have evolved into many diverse shapes; but if a relatively simple teleost, a trout, is examined, its basic swimming motion can be determined. Forward motion is provided by bending of the body and caudal fin; waves of muscular action pass from the head to the tail, pushing the sides of the body and tail against the water and forcing the fish forward. The structure of the tail and the efficiency of the swimming mechanism is the prime character that distinguishes teleosts from other, "lower," fishes. The dorsal fin and the anal fin (a ventral median fin) are used partly to aid in stability and in turning, and partly in forward locomotion. The paired pelvic or ventral fins and the paired pectoral fins behind the head are used to help stabilize the body and to turn the fish. The fusiform shape of the trout reduces the turbulence and drag of water flowing over the fish's body, offering least resistance to the water.

Locomotion

The head of the fish must be adapted for feeding, breathing, and detecting prey and enemies. At the same time it must be relatively streamlined, offering as little resistance to the water as possible. The head of a trout is well formed for these functions by being fusiform but expandable, where necessary, to take in food and water. The fish forces the water in one direction, into the mouth, over the gills, and out the gill slits. Back flow is prevented by valves at the mouth and by the gill covers. The fish, however, can eject undesirable particles and water out the mouth by special action. The teleost head is efficient in having eyes and organs for the sense of smell located in optimum spots for seeing and smelling food. At the same time these organs offer little resistance to water flowing over the head.

For a classification of teleosts see the article FISH.

BIBLIOGRAPHY. For references to the literature on teleostei, see the bibliographies for the article FISH and for the articles on the individual teleost orders.

Telephone and Telecommunications Systems

The term telephone (from the Greek roots *tēle*, "far," and *phonē*, "sound") was first used to describe any apparatus for conveying sound to a distant point. Specifically, the word was applied as early as 1796 to a megaphone, and not long afterward to a speaking tube. The name string telephone was given some years after its invention (1667) to a device in which vibrations in a diaphragm caused by voice or sound waves are transmitted mechanically along a string or wire to a similar diaphragm that reproduces the sound. Still later, devices employing electric currents to reproduce at a distance the mere pitch of musical sounds were called telephones. Nowadays, the name is assigned almost exclusively to apparatus for reproducing articulate speech and other sounds at a distance through the medium of electric waves. The term telephony covers the entire art and practice of electrical speech transmission, including the many systems, accessories, and operating methods used for this purpose. Telecommunications broadens the concept still further to cover all types of communication, including television data, teletypewriter, and facsimile.

This article is divided into the following sections:

I. History
- Development of the telephone
- Long-distance telephony
- Other uses for telephone circuits

II. Principles and problems of telecommunications
- The digital communications system
- Analogue-to-digital conversion
- Modulation techniques
- Examples of communications systems

III. Telecommunications networks
Telephone networks
Data-message networks
IV. Future trends in communications

I. History

The essential elements necessary for the telephone were available at least a third of a century before Alexander Graham Bell's patent was granted in March 1876. The concept of sound as a vibration was understood at the beginning of the 19th century, as was the fact that the vibration could be transferred to solid bodies. Michael Faraday in 1831 showed how the vibrations of a piece of iron or steel could be converted into electrical pulses. Though science and technology by that time had reached the point that all that needed to be known for the invention of the telephone was known, more than 40 years were to pass before the telephone was actually to appear.

What was needed was an entrepreneur who could foresee the applications for such a device. Why it took so long for such a person to appear is a question that can be only partially answered by suggesting that it may have been because the social need was not great enough. Though it could be expected that a few persons were experimenting with the idea in the intervening period, in fact there were very few. In the 1820s an English scientist, Charles Wheatstone, demonstrated that musical sounds could be transmitted through metallic and glass rods. By the time he had become involved with the telegraph in the late 1830s, however, he had abandoned the earlier line of investigation and apparently never attempted to connect the two fields. Charles Bourseul of France seems to have been the first to suggest a means for transmitting sounds electrically by means of a diaphragm making and breaking contact with an electrode. There is, however, no evidence that he ever did more than contemplate its possibilities. Other inventors similarly failed to appreciate the potential of instruments they had designed, and Bell, in 1875, appears to have been the first to understand not only that the electrical transmission of voice was possible but that it was commercially practical as well.

DEVELOPMENT OF THE TELEPHONE

Operating principles. The principles of the telephone are the same today as they were in the 19th century. The voice vibrates the air, which in turn vibrates a diaphragm. The motion of the diaphragm produces a corresponding vibration in an electric current. In the ordinary modern telephone, the diaphragm presses against an assembly of carbon particles and causes their electrical resistance to vary, so that an electric current flowing through the particles is altered and fluctuates in accord with the pressure on the particles. At the receiver, the current flows through an electromagnet. As the power of this magnet fluctuates, so does its attraction for an adjacent steel diaphragm. The diaphragm vibrates, moving the air and producing sound.

Other methods of telephone construction are possible, and several were actually considered in the 19th century.

Work of Philipp Reis

In 1861 Philipp Reis, a German schoolteacher, designed several instruments for the transmission of sound. In them, a contact in an electrical circuit was established between a metal point and a metal strip resting on a membrane in the transmitter (Figure 1). It was Reis's theory that as the membrane vibrated the metal point would bounce up and down, producing intermittent contact and intermittent current, synchronous with the vibrations, and that, furthermore, the height of the bounce, the force of its return, and the size of the current pulse would vary with the intensity of the sound. Thus, he expected that something of the quality as well as the intensity of the sound would be conveyed. Reis's receiver consisted of an iron needle surrounded by a coil and resting on a sounding box. It was designed to operate on the principle of magnetostriction (a phenomenon in which the length of a metal rod varies as the magnetic field through it varies). It had been known since 1837 that an interrupted current would produce corresponding "ticks" in such a device. Reis believed that simple musical tones could be transmitted by the apparatus—which he called a telephone—and such demonstrations with his instruments were common. In addition, however, there were several reports of successful speech transmission. These reports were subsequently discounted in court cases upholding the Bell patent, largely because it was recognized that speech transmission would be impossible if the instruments operated as Reis believed they did. It is a fact, however, that if the sound entering a Reis transmitter is not too strong, contact between the metal point and the metal strip will not be broken. Instead, the pressure of the former on the latter will fluctuate with the sound, causing fluctuations in the electrical resistance and therefore in the current. Similarly, the receiver will respond to continuously fluctuating as well as to intermittent currents (but not by magnetostriction). The sensitivity, however, is extremely low, so low that it is not unreasonable to question the validity of the limited testimony regarding successful voice transmission in the 1860s.

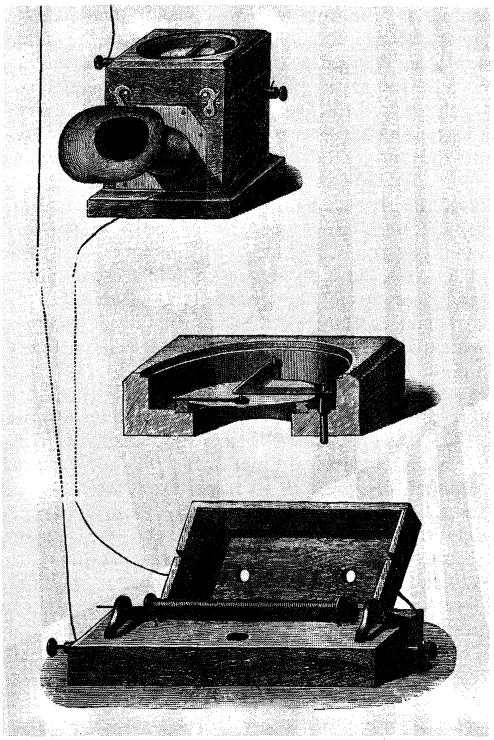

Figure 1: Contemporary sketch of early Philipp Reis telephone transmitter (top) and magnetostriction receiver (bottom). Cut-away view of transmitter in centre shows electrical contact points (see text).

There is no evidence that Reis himself thought of his devices as more than "philosophical toys," good for lecture demonstrations to illustrate the nature of sound. He authorized their reproduction, and numerous copies were sold for this purpose. No one apparently tried to coax any more out of them.

Early instruments of Gray and Bell

In the period 1872–75 inventors Elisha Gray and Alexander Graham Bell, both working in the United States, developed a number of ideas and instruments that were strikingly similar. Gray, who had been placed at an early age on his own resources, worked his way through three years at Oberlin College and by 1870 was fairly well-known and moderately successful as an electrical inventor, primarily in the field of telegraphy. Bell's education stopped after one year at the University of Edinburgh. Although he was well-read in many subjects, his knowledge of electricity was virtually nonexistent at the time his family emigrated to Canada, in 1870, for his health.

Interested in telegraphy, Bell attempted to solve a problem that had attracted many inventors: that of sending several telegraph messages over the same wire at the same time. He approached the problem through acoustics, and Gray approached the same problem through electricity. Each arrived at the concept of a harmonic telegraph, the transmitter of which consisted of a series of metallic

reeds, vibrating at different frequencies, each near its own electromagnet, with the coils all attached to the same transmission line. A similar arrangement at the receiving end placed a series of tuned reeds near a set of electromagnets, each hooked to the line. When transmitting reed A vibrated, it induced a current of a corresponding frequency into the wire. This current went to all the receiving coils, but only reed A, tuned to the same frequency, responded. Similarly, transmitting reed B was tuned to receiver B. Though it seemed theoretically reasonable that several independent signals could be sent out at the same time, in fact the system very quickly broke down and the idea proved to have no commercial value.

Both men began to consider the fact that if a few tones could be sent over a wire at the same time, a great many tones could be transmitted, enough indeed to represent the human voice. Gray understood how he might build a receiver and immediately constructed such a device in the spring of 1874. It consisted of a steel diaphragm in front of an electromagnet, virtually identical with the common modern receiver. But he had no transmitter. Meanwhile, Bell had been considering the possibility of multiple-reed transmitters and receivers (many tuned reeds near a single coil), though he had constructed nothing. In the summer of 1874 he conceived a membrane receiver (similar to Gray's but using a skin membrane with a piece of iron attached to the centre). Having no transmitter, he did not construct the device. In the spring of 1875, however, Bell was led by his telegraph experiments to believe that the inductive force from a piece of iron on a vibrating membrane near a coil might be powerful enough to act as a transmitter, and that his receiver might be sensitive enough to produce the desired effect. In June his assistant, Thomas Watson, constructed two identical instruments, one to be used as a transmitter, one as a receiver. The experiment was performed but failed (it probably would have worked if Bell's surroundings had been quieter). Bell temporarily abandoned the telephone to attend to his financial needs, but he remained convinced he was on the right track. By the end of the year he was writing patent specifications.

That same autumn Gray developed a transmitter in which a moving membrane caused one rod to move near another in water to which a small amount of acid had been added to make it electrically conducting (Figure 2).

By courtesy of the Smithsonian Institution

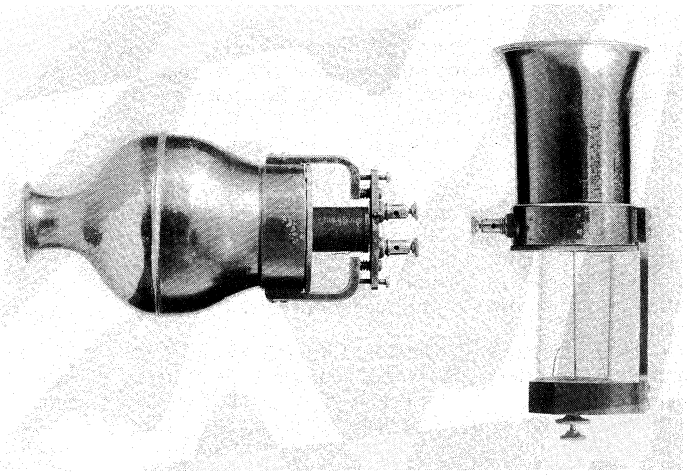

Figure 2: Photograph of Elisha Gray's telephone receiver (left) and transmitter (right). The container for acidulated water and the vertical rod connected to the diaphragm are visible in the transmitter photograph (see text).

As the distance between the rods changed, so did the electrical resistance, and thus the current in the circuit. Apparently Gray did not attempt to test his device. He did prepare a description to be filed at the Patent Office as a caveat, or "notice of invention." The caveat was filed on February 14, 1876. Bell, meanwhile, had completed his specifications and had them notarized in Boston on January 20. They were filed, as a patent application, on February 14.

At this point, neither man had successfully transmitted speech. In some ways Gray was closer to a solution: he used a metal diaphragm that was considerably more efficient than Bell's skin membrane, and he had designed a variable-resistance transmitter. Seemingly as an afterthought Bell had inserted a variable-resistance clause in his patent application; his main emphasis, however, was on the induction device. Gray apparently lost confidence. Perhaps he was convinced that Bell had beaten him; or perhaps he was still unable to see the potential of the idea. In any case, he did virtually nothing to develop his work further in the next critical years.

Bell, on the other hand, clearly felt the goal was at hand. On March 10, 1876 (three days after the patent was issued), he successfully transmitted words using a variable-resistance transmitter formed by a metal rod attached to a membrane, the top of the rod dipped into acidified water. The receiver was a damped reed (damped by holding it against the ear) of one of his telegraphic tuned membranes. Experiments using other variable-resistance transmitters followed, without success. By April he had reverted to his old induction transmitter and found that with some modifications it worked well enough to be demonstrated, most noticeably at the Centennial celebration in Philadelphia in June (Figure 3).

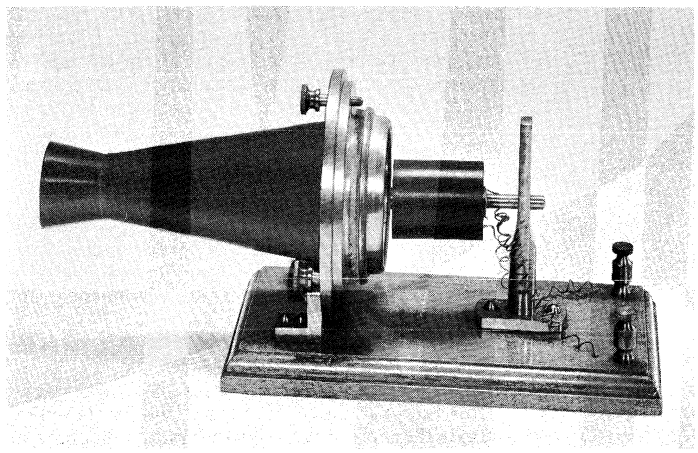

Figure 3: An early Bell induction instrument, successfully demonstrated in June 1876. The instrument could be used either as a transmitter or as a receiver. Voice currents flow through the cylindrical coil (centre).

The device was still not efficient enough for public use, and it took Bell and Watson the remainder of the year to make it so. The major improvement during that time was substitution of a steel diaphragm for the skin membrane. Commercialization began early in 1877.

Bell's patent claims

Bell's patent claims were granted by the U.S. courts in the broadest possible manner to cover the principle of speech transmission by electricity. Elsewhere they were restricted to the special devices.

There were, of course, other claimants, such as Elisha Gray. But regardless of the merits of particular claims, it is clear that as an innovator and entrepreneur Bell was virtually alone in recognizing the commercial potential of the telephone.

Immediately after the introduction of the commercial telephone, two things became obvious: that the transmitter was its weakest link and that it would be profitable to develop a better one. Apparently it was also obvious that a variable-resistance device, preferably using some form of carbon, represented the best direction in which to go. Carbon-resistance transmitters were soon developed by several inventors, with Thomas Edison eventually winning the basic patent rights. By 1878, Edison transmitters, essentially the same as modern devices, were being used commercially.

Other methods. A new type of receiver was invented by Edison in 1878 to avoid interference with the Bell patent in England. In his device a metal stylus rested lightly on a chalk drum, and the transmitted current flowed from stylus to drum as the drum was rotated by

hand. Fluctuation in the current caused variations in the frictional resistance between the two components, resulting in corresponding variations in sound that could be heard distinctly. This receiver, in combination with Edison's carbon transmitter, was called his "loud speaking" telephone. Its use was short-lived, however, since the Edison and Bell interests in England soon joined forces, henceforth relying on the Bell induction receiver and the Edison carbon transmitter.

Still another method of transmitting sound electrically was developed in 1878 when A.E. Dolbear, a professor of physics, devised a transmitter in which the diaphragm was one plate of a small battery. When it vibrated, so did the voltage of the battery and the current in the circuit. In a separate arrangement Dolbear designed a receiver with metal plates in the form of a capacitor. The fluctuating current caused one plate to vibrate, producing sound. Dolbear's devices were not competitive as telephone instruments, though the capacitor principle proved valuable in some microphone designs in the 20th century.

Patents. Since the Bell patent, No. 174,465, is often called the most valuable ever issued in the U.S., a brief look at its history is appropriate. In 1877 Bell offered to sell it to Western Union for $100,000; Western Union instead bought the Gray, Edison, and other patents and moved to develop its own telephone network. Suit for infringement was brought by the Bell Company in 1878. In due course Western Union decided to capitulate, obtaining 20 percent of the profit made by the Bell Company on the rental of telephone instruments and relinquishing their own patents. Subsequent court cases in the United States pitted Bell against claims made for several other inventors. A number of these cases were joined together in an appeal to the Supreme Court. In a 4–3 decision in 1893, the Court upheld Bell's claims in the very broad scope mentioned earlier.

Networks. Although to some extent the commercial development of the telegraph could serve as a guide, there were many special problems in the path of the telephone. One of the most formidable arose from the fact that instead of a single terminal in each town, there were many, and each had to be connected to any of the others at a moment's notice. Obviously, the lines had to be brought together at one or more common points where connections could be made. The first commercial telephone switchboard was placed in service in New Haven, Connecticut, in January 1878. It served 21 telephones and consisted of a series of switches so mounted that the various lines could be interconnected. There now existed microphone and receiver, and the wires and switching mechanism necessary to hook them together. There also existed a large number of people who were ready to accept the idea that these new devices were useful to them.

First commercial switchboard

19th-century telephony. Within a very short time after its introduction, telephony was a sophisticated system, capable of connecting moderately large numbers of users over relatively short distances. As a result it is perhaps not surprising that expansion of its uses should have been so rapid, though this is as much a testimony to the energy of the system's promoters as it is to its mechanical and electrical completeness. By March 1880, there were 138 exchanges in operation in the United States, with 30,000 subscribers. By 1887, only a decade after the commercial introduction of the telephone, there were 743 main and 444 branch exchanges connecting over 150,000 subscribers with about 146,000 miles (235,000 kilometres) of wire. Developments in other countries were also rapid, and by 1887 the number of subscribers in Canada was over 12,000, in the United Kingdom 26,000, in Germany 22,000, Sweden 12,000, France 9,000, Italy 9,000, and Russia 7,000.

Some attempts were made to expand the telephone to other uses. Most notable were systems of wired broadcasting, introduced experimentally as early as 1881 and commercially in the 1890s. In the experimental arrangement, microphones were placed on a concert stage in Paris, while in a nearby room receivers (the transmission was stereophonic, consisting of two channels) were provided for listening. Commercially wired broadcasting was most highly developed in Budapest, starting in 1893. By the turn of the century there were 6,500 subscribers in that city. Music, news, stock market reports, and even dramatic presentations were transmitted over the wires on a schedule of up to 14 hours a day. This system continued until supplanted by radio in the 20th century. Similar systems were developed in London and Paris.

LONG-DISTANCE TELEPHONY

As soon as distances of more than local extension were attempted, problems arose and produced a variety of ingenious products and procedures.

Hard-drawn copper wire, the first of these innovations, was stronger than ordinary copper wire and was a better conductor of electricity than the steel wire commonly in use. After a long-distance test between Boston and New York in 1883 proved its worth, hard-drawn copper became the standard material for overhead wire lines.

Development of strong copper wire

Underground cables, important in the cities where mazes of telephone poles and wires were becoming a hazard, were also essential in crossing rivers, lakes, and oceans. Experiments performed in the 1880s led to the widespread use of dry-core cable in the 1890s. The value of the dry core (in which each wire conductor was surrounded by paper and air and the bundle of wires enclosed in a watertight cover) was that it improved the transmission properties of the cable.

It was soon found that reliance on a ground return (having a circuit formed by a wire in one direction and a conducting path through the earth in the other) produced severe problems when two or more wires were routed close to each other. The signals in one wire would get mixed up with the signals in the others in a phenomenon called cross talk. The first public demonstration of an all-metal (two-wire) circuit was made between Boston and Providence in 1881, but general commercial adoption did not take place until the 1890s.

The loading coil. Over the years the length of transmission had increased as various improvements were made. But about 1,200 miles (1,900 kilometres), the distance achieved when Boston and Chicago were connected successfully in 1893, seemed to be a practical maximum. The basic problem was one of distortion introduced into the signal by the electrical characteristics of the circuit. A British theorist, Oliver Heaviside, in 1887 showed the conditions under which distortion could be minimized and suggested that this be done by increasing the inductance of the circuit or line. In 1893 Heaviside suggested further that this might be done by introducing coils along the cable at periodic intervals, but he went no further in calculating precise values or in performing tests. American engineers attempted to apply the theory by using a bimetallic wire of copper and iron to increase the inductance. Work was later shifted to the use of discrete coils located at regular intervals along a line, a technique called loading. The first loaded circuits were opened to public use in May 1900. These applications were completely successful, and the principle was rapidly applied elsewhere. Line lengths doubled; in addition the coil made possible a reduction in the size of wire used on short lines, with consequent valuable savings.

The repeater. Once the distortion problem was mastered, another need became apparent: that of a means for boosting, or amplifying, the signal. Early efforts attempted to combine the telephone receiver and microphone into something analogous to the telegraph repeater. Though a successful instrument, called a mechanical repeater, was designed in 1904, it was insensitive to low input energy, and the amplification varied somewhat with the frequency of the input signal. It served, however, for a number of years, until replaced by the superior vacuum tube.

Signal boosters

Although the three-element vacuum tube was invented by Lee De Forest in 1906, its usefulness as an amplifier in a telephone repeater was not immediately realized; the first commercial demonstrations were made in 1915, when it was shown that three repeaters, or relays, were sufficient to carry voice signals across the United States.

De Forest's vacuum tube consisted of a filament (source of electrons), a plate (collector of electrons), and a wire mesh in between for controlling the flow of electrons. A small signal impressed on the grid could result in a greatly amplified signal at the plate.

Getting a signal across the ocean proved more difficult. Repeaters were short-lived, and there was no way to replace them in a submarine cable. Furthermore, many would be needed because of the distortion imposed on the signal. A submarine telegraph cable involves two conductors—one the wire, the other the water—and the effect is to blur the input signal. Commercial transatlantic telephony, therefore, had to rely upon shortwave radio at first; this service was available starting in 1926.

Radio techniques were useful on land also. High-frequency microwave radio links have been commonplace since 1946, when they were first used experimentally. The bandwidth of such a facility is broad enough to handle large numbers of telephone conversations. Even before this, however, the principle of superimposing a number of voice signals on a carrier wave was employed on a coaxial cable, a tubular conductor with another conductor concentric with it. The first commercial messages using the carrier technique were sent in 1937 between New York and Philadelphia.

Transatlantic cable telephony was made possible by the development of a vacuum-tube amplifier with a life expectancy of 20 years, long enough to make the cable laying economical. The development of the plastic polyethylene, which has exceptionally good insulating properties, also contributed to making the project practical.

A coaxial cable with submerged repeaters was laid as a test between Miami and Havana in 1950. When it proved successful, two transatlantic cables were laid in 1956; there were 51 one-way repeaters in each line between Scotland and Newfoundland. Sixteen larger two-way repeaters were used in a single line from Newfoundland to Nova Scotia. The system was capable of handling 60 telephone conversations at a time. Other cables have subsequently been laid in the Atlantic and elsewhere.

Satellite repeaters

Another means of spanning long distances became possible with the advent of satellites. The possibilities were first demonstrated in 1962 by the satellite Telstar, a low-orbit nonsynchronous relay station. Regular commercial service was made possible when the synchronous satellite Syncom II was positioned over the Atlantic in 1963. A synchronous satellite is one whose period of rotation is the same as that of the Earth; if positioned above the equator, it thus appears to be stationary, whereas a nonsynchronous satellite moves with respect to the Earth's surface. Radio signals are sent up to the satellite from one point on Earth, are amplified, and are retransmitted back to another point on Earth (see also SATELLITE COMMUNICATION).

Multiplexing. In view of the fact that the telephone was created out of attempts to develop a multiplex telegraphy system—that is, a system for sending several telegraph messages over the same wire at the same time—it is not surprising that efforts should have been made at an early date to multiplex telephone signals. In 1883 an arrangement was patented that produced what is known as a "phantom" circuit. If one pair of wires carried one conversation and a second pair of wires another, then by proper electrical balancing the two pairs could be used to constitute a third, or "phantom," circuit. Maintaining a balance, however, proved difficult, and it was not until 1910 that a successful practical method was found.

More recently, attention has been paid to utilizing the waste time that occurs in any telephone conversation. One method, called time assignment speech interpolation, was especially well suited to the first two Atlantic cables since they had been laid in pairs, with each cable carrying channels in only one direction. Each cable was only being used, on the average, less than 50 percent of the time. Circuitry installed in 1960 was able to detect the instant that each new speech element commenced and assign it to a vacant channel. The effect was to double the capacity of these cables. Recent improvements in the technique have led to an even larger capacity.

Another method of increasing the capacity of existing channels is by taking only periodic samples of the wave to be transmitted. This technique, which has long been used for multiplex telegraphy, involves a brush rotating rapidly around a segmented disk so as to make successive contact with each of the several segments. In order to convey the more subtle complexities of voice communication, however, the frequency of sampling must be much more rapid and therefore must be done electronically. Experiments in recent years have shown that high quality reproduction can be achieved, with the result that as many as 12 conversations can be carried over a channel formerly reserved for one. The technique, known as pulse code modulation, is discussed in more detail later in this article.

Switching. As the volume of telephone usage has increased, the problems of joining transmitter and receiver have become more complex. By the mid-1880s the switchboard had evolved to a point where hundreds and even thousands of subscribers could be handled. Special switches and flexible cords were devised. Switchboards were produced in multiple units with identical parts so that more than one operator could service the same telephones, and methods were devised whereby each operator could determine which lines were "busy" without listening in.

Originally, individual telephones had been equipped with their own batteries. The first central office with a common battery for talking and signalling was installed in Lexington, Massachusetts, in 1893. Among other things, the development meant that the subscriber could signal the operator merely by lifting the receiver from its hook. Beginning in 1894 this signalling could be done by miniature light bulbs on the switchboard.

Automatic switching systems were contemplated as early as 1881, when an automatic system was shown at the Paris Electrical Exposition. That system proved impractical, but a workable arrangement was patented in 1889. Important modifications were made over the next few years. The essentials of the system consisted of a mechanism that could send out a series of pulses that would first raise, then rotate a shaft through a corresponding number of steps to make the appropriate contact. Thus for the number 295, the shaft would be raised two steps, then revolved through nine large steps, then through five intermediate contact points.

The original patent specifications required the caller to press a different button the required number of times for each number, and separate lines to the central station were necessary for each button. Improvements eliminated the need for extra lines, and in 1898 a dial mechanism was patented, eliminating the buttons.

First dial mechanism

The first large test installation of automatic equipment was made in Newark, New Jersey, in 1914; actually the system should be termed semi-automatic, since an operator was still used to accept the incoming calls. The first fully automatic system was installed in Omaha in 1921.

OTHER USES FOR TELEPHONE CIRCUITS

Networks of telephone wires were necessary to provide connections among individual telephone instruments. But once created they were then available for a variety of other purposes, all of them concerned with the transfer of information over distance. Thus lines that may have been developed primarily for telephone service now carry telegraph, telephoto, and television signals and data in a form that can be fed directly into processing devices (that is, computers can "talk" to each other over these lines). As a consequence it has become impossible to discuss modern telephone systems apart from telecommunications systems in general. (B.S.F.)

II. Principles and problems of telecommunications

Telecommunications in the 1970s centres on the problems involved in transmitting large volumes of messages over long distances without damaging loss due to noise and interference. Such problems with short-distance messages are not as severe; the signal travels over two-wire lines as described earlier without additional processing.

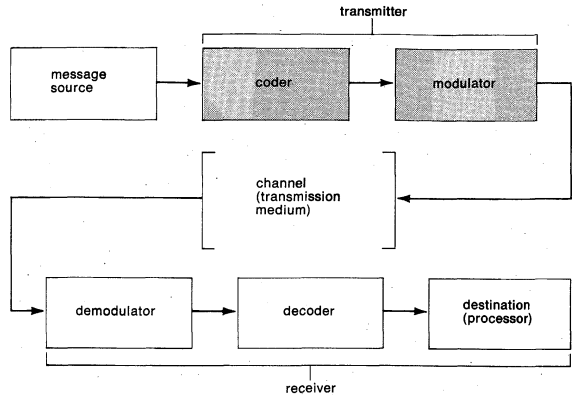

Figure 4: Simplified block diagram of a typical long-distance telecommunications system.

Figure 4 shows the basic components of a typical long-distance telecommunications system capable of transmitting voice, teletypewriter, facsimile, data, or television signals. If digital transmission is employed, signals are first processed in a coder that completely transforms their character. Typically the coder includes filtering and coding circuits that convert the signal into digital form; in data transmission this step is bypassed because the signals are already in digital form.

For analogue transmission, that is, transmission of voice and other signals without converting them to digital form, the coding stage may be omitted. Most modern TV and voice communication use the analogue system; data, teletypewriter, and many other forms of telecommunications use digital techniques.

Function of the modulator

After coding, the signal is further processed in a so-called modulator, a device for impressing the intelligence signal onto a radio-frequency signal of the proper frequency for the form of transmission to be used. High-frequency signals are usually used for radio transmission; low-frequency signals are used in coaxial cables and other wire lines (described later). The combination of coder and modulator is called the transmitter.

A receiver picks up the transmitted signal at the destination. A demodulator eliminates the carrier wave, and a decoder transforms the message signal into usable form. In many systems the decoder and demodulator are not physically distinguishable but are simply parts of a subsystem that combines both. In two-way communications systems, with a transmitter and receiver at either end, a modulator–demodulator combination, called modem for short, is employed.

In transmission of speech, music, or picture information, the object is high fidelity—that is, the best possible reproduction of the original message. In some cases, however, other pertinent information may have to be extracted from the received signal. Examples include processing of seismic signals (natural or man-made Earth vibrations) to obtain information about the medium through which they are transmitted and the processing of sonar and radar signals. Signal processing that involves the interpretation of data includes such medical data as electrocardiograms and X-rays and environmental data such as air-pollution measurements.

THE DIGITAL COMMUNICATIONS SYSTEM

Binary system. The basis of relatively noise-free and interference-free telecommunication is the so-called binary signal. The simplest possible signal of any kind that can be employed to transmit messages, the binary signal consists of two states only: the dot–dash of Morse code, an on–off signal in teletype, a 0 or 1 in binary arithmetic, and a punch or no-punch command of computer cards. Practically all voice, picture, instrumentation, and other data can be coded in binary form. Figure 5 illustrates two kinds of binary signal. Both signal sequences carry the same information; *i.e.*, the binary sequence 101,100, or on–off–on–on–off–off. Once a particular pair of signals has been selected, the presence of one or the other is determined by the binary symbol, 1 or 0, to be transmitted. These signals are called binary digits, or bits. The transmission rate is described as one bit per time unit. In practice, on–off (Figure 5A) or bipolar (Figure 5B) signals or variations thereof are used.

The simplest form of modulator transmits bursts of a radio-frequency signal when a 1 appears and nothing when the 0 appears. This is the binary version of amplitude modulation, or AM (described later). This binary AM system contains a radio-frequency oscillator, designed to transmit a particular frequency only when a 1 appears and to stop transmitting when the 0 appears.

Other forms of modulation used for binary signalling include frequency-shift keying, in which a binary 1 or 0 causes the frequency to shift to either one of two predetermined frequencies (representing either 1 or 0); and phase-shift keying, in which the sign, or polarity, of a high-frequency carrier shifts between positive and negative when the binary input shifts from 0 to 1. The first method is the binary version of FM, or frequency modulation (explained later); the second is an example of phase modulation (PM).

Frequency-shift keying

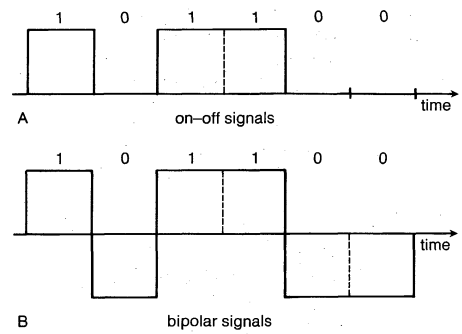

Figure 5: Representation of the binary number (101100) as (A) on–off signals and (B) as bipolar signals.

Distortion and noise. As a high-frequency radio signal travels through the transmitting path, noise and interference are encountered. Some of this comes from switching circuits and antennas; most is encountered in the atmosphere, or the space between the transmitting and receiving antennas. In addition, the message may be distorted during transmission.

One common type of distortion is called alternate path propagation, in which a signal traverses two or more different paths, usually because of reflections, and the split signals arrive at the receiver at slightly different times, causing echoes, or in the case of television transmission, ghosts. This is called multipath effect. If the separate paths are of identical length, the individual signals are in effect added together; if the path lengths differ so that they are exactly out of step, they are said to be out of phase with each other, and the result will be to subtract one from the other and reduce the strength of the total received signal. If they are in phase, they add, strengthening the signal, but the overall result of several signal paths, leading to signals that are in phase and out of phase by varying amounts, is fluctuation. Shortwave broadcasts, in which signals are directed into space and reflected back by the Earth's ionosphere, typically show fading characteristics, characterized by fluctuating amplitude.

There are many other sources of signal distortion and attentuation:

Noise added during transmission can include interfering signals in the same frequency range, interference from nearby electrical sources, the effects of electrical storms in the atmosphere, and spurious effects introduced by malfunctioning circuits. The effect of these noise sources often can be minimized or eliminated by appropriate equipment design. In addition to these noise disturbances, there is a type due to "spontaneous fluctuations" that can never be eliminated. The Sun and the Earth's atmosphere continually generate electrical energy at all frequencies. All sources of heat emit so-called thermal noise. Such

Thermal noise

noise can also arise within the communications system itself.

Systems design involves predicting the average effect of distortion and noise and providing maximum protection against them. Various modulation and coding schemes have been devised for this purpose, and one of the reasons for using binary signal transmission is in fact to benefit from the improved noise immunity that such transmission offers.

Although signal distortion and noise introduced by the transmission medium are common to all forms of communication, the relative effects differ in various systems. In telephony, signal distortion is a much more serious problem than noise. In space communications, however, in which signals are transmitted over extremely long distances, the desired signal energy received may be only as strong as, or even considerably less than, the noise and it then becomes a major task to sort out the signal from the noise.

Receiving the digital signal. The binary amplitude-modulated signal (explained later) arriving at the receiver (Figure 4) contains whatever noise and distortion was added during transmission. The demodulator portion of the receiver strips away the high-frequency carrier, leaving only a distorted version of the original binary signal sequence and the noise. A typical distorted, noisy signal is shown in Figure 6. Both the distortion and the added

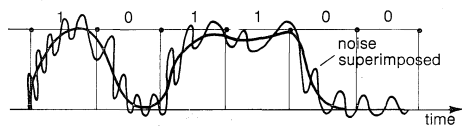

Figure 6: The binary signal of Figure 5A after it has been distorted and noise introduced during transmission.

noise tend to mask the original signal sequence and thus introduce errors in deciphering. One of the major tasks in communications technology is to develop techniques for reducing errors in decoding the message signal. Because of the presence of spontaneously occurring noise whose effects are random and unpredictable, some errors will always be made. A typical design criterion is to limit the average number of errors to no more than one for every 100,000 bits transmitted.

Methods for minimizing errors include appropriate processing of the signals at the transmitter, coding at the transmitter to make the signals and noise as distinguishable as possible, insertion of filters at the receiver to decrease the noise energy without destroying too much of the signal characteristics, and appropriate signal processing at the receiver. For systems in which fading and multipath predominate, diversity techniques have been developed: several replicas of the signal are transmitted, either in time (time diversity) or using different antennas, receivers, and transmitters (space diversity). By appropriate combination of the separate versions of the received signals, the fading effects may be overcome to some extent.

ANALOGUE-TO-DIGITAL CONVERSION

Thus far the transmission of binary signals has been stressed. If the signal to be transmitted is already binary in form (teletypewriter, computer output), there is no problem. But ordinary voice communications via telephone are not in binary form; neither is the temperature, pressure, solar-flare data, or other data that might be gathered for transmission back to Earth as a part of a space-probe mission. Such forms of data are said to be analogue, or continuously time varying, in contrast to digital (discrete number) data transmission, of which binary transmission is the most important case. In digital communications systems, analogue signals must first be converted to digital form. The process of making this signal conversion is called analogue-to-digital (A/D) conversion.

The sampling process. The basis of the process is sampling, or measuring the analogue wave shape to be transmitted at equally spaced discrete instants of time. The sampled values are further approximated by a specified set of discrete numbers; these numbers are converted to their equivalent binary form and the binary numbers transmitted.

The fact that samples of a continuously varying wave in time (Figure 7A) may be used to represent a wave relies on the assumption that the original wave is constrained in its rate of variation with time. In Figure 7A, for example, the most rapid variation of the analogue signal occurs roughly in the centre. The time between the minimum and maximum excursion is labelled $1/B$ seconds. B is called the bandwidth of this signal and is usually given in hertz (Hz), or cycles per second.

The term bandwidth then indicates the maximum frequency range of the transmitted signal. In the case of an audio signal having a maximum frequency of 4,000 hertz, the bandwidth is 4,000 hertz. If the signal contains components at a frequency higher than the bandwidth, distortion may occur or the high-frequency components may be filtered out. In general, the higher the bandwidth, the less the distortion. The concept of bandwidth is central to all telecommunications.

In terms of this concept of bandwidth, there is a fundamental theorem that states that the signal may be uniquely represented by discrete samples spaced no more than one over twice the bandwidth ($1/2B$) apart. This theorem is commonly referred to as the sampling theorem, and the sampling interval ($1/2B$ seconds) is referred to as the Nyquist interval (after the American scientist Harry Nyquist).

As an example, in telephone practice the bandwidth is commonly fixed at 3,300 hertz. Filters are actually inserted to prevent higher frequencies from coming through. Samples therefore should be taken every $\frac{1}{6,600}$ second. In practice somewhat more samples are used, 8,000 per second, with a spacing or interval of $\frac{1}{8,000}$ second (125 microseconds).

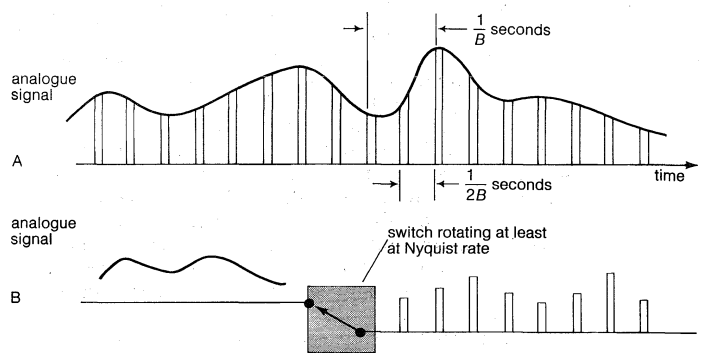

Figure 7: (A) Continuously varying sound wave sampled at intervals of $1/2B$ seconds (B is the bandwidth). (B) Conceptual form of the sampling process (see text).

Figure 7B shows the sampling process carried out conceptually. The analogue signal is shown being sampled periodically by a switch rotating at least at the Nyquist rate, $2B$ times a second. A mechanical switch is shown for clarity, but in practice high-speed electronic switches are used. The switch essentially allows a small portion of the analogue wave to go through, repeating this process at least $2B$ times each second.

Conversion to binary form. Not only voice signals but other analogue signals require conversion into binary form for pulse transmission; in each case an arbitrary scale of numbers is chosen to represent varying amplitude. For ease in conversion to binary form, the scale is usually a multiple of 2; that is, 8, 16, 32, 64, 128, and so on, depending on the degree of precision required. For example, if the problem is transmitting the temperature inside a space vehicle back to an Earth station, the potential variation is only between 9° and 25° C, and the precision required is not high, a scale of 16 might be used. This would permit using one scale number to represent each degree C between 9° and 25°, and readings would omit fractions. If, on the other hand, in the same circumstances a higher degree of precision were required,

a scale of 256 might be employed, permitting the division of the 16 degrees into decimal fractions to record such readings as 15.2° or 21.6°.

Amplitude level requirements

In digital transmission of voice, 128 levels are commonly used because tests have shown that this provides adequate fidelity for the average telephone listener. An unnecessarily large scale is not desirable, because larger scales require more transmitted bits per number. That this is so may be seen from an examination of the encoding process. A portion of an encoding table is shown below:

binary equivalent	decimal number (or signal level)
000	0
001	1
010	2
011	3
100	4
101	5
110	6
111	7

It is apparent that eight levels require three binary digits, or bits; 16 levels require four bits; and 128 levels require seven bits. In general 2^n levels require n bits. A binary encoder performs this conversion.

If 128-level transmission is used, each quantized signal sample must be represented by a sequence of seven bits. All of these bits must be transmitted before the next sample appears. To use more levels, more binary samples would have to be squeezed into the allotted time slot between successive signal samples. The circuitry becomes more costly, and the bandwidth of the system following the binary encoder becomes correspondingly greater, requiring an increased bandwidth for the transmission medium, or channel. Some channels (telephone wires are one example) may not have the bandwidth capability required for the increased number of binary samples and would distort the binary signals. Others are limited by law to a specific bandwidth. Although the accuracy required determines the number of quantization levels used, the resultant binary sequence must still be within the bandwidth tolerance allowed.

An example of a sequence of quantized samples and its

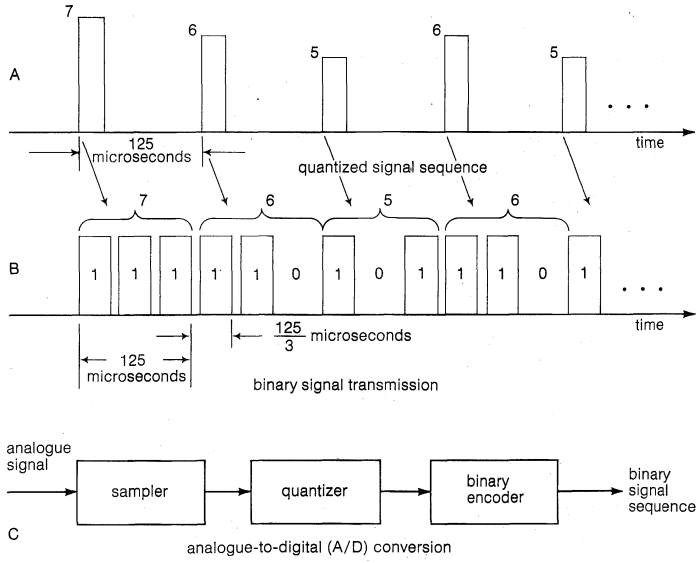

Figure 8: (A) Quantized samples of an analogue signal and (B) the conversion of these samples to equivalent binary pulses. (C) Simplified block diagram of the analogue-to-digital conversion process.

binary equivalent is shown in Figure 8A and 8B, respectively. The numbers 7, 6, 5, 6, 5 have been selected arbitrarily. Eight-level (three-bit) samples are shown for simplicity. The entire analogue–digital processing—sampling, quantizing, binary encoding—is shown in block-diagram form in Figure 8C.

The binary signals of Figure 8B provide superior noise immunity to the equivalent quantized sequence of Figure 8A. The receiver has merely to recognize either one of two states in the binary case—the presence or absence of a signal in the on–off sequence shown or a positive or negative signal in a bipolar sequence—an easier task than recognizing one of many possible amplitude levels. More importantly, the maximum signal amplitude that may be used is determined by the transmitter power. In Figure 8A the number 7 uses the maximum power available, while lower numbers use less power. For a given average noise added during transmission, the lower amplitude signals are more readily affected by the noise. In binary signal transmission the signal level is always the same, and all signals are transmitted at the maximum amplitude. The coding into binary form thus provides considerably enhanced noise immunity.

One of the major aims of communications system design has been to find other forms of coded communications signals that provide still better noise immunity. Some of these techniques will be considered later in this article.

MODULATION TECHNIQUES

Pulse code modulation. Communications systems that use digitized and coded signals are commonly called pulse-code-modulation (PCM) systems. Binary digital systems constitute the most frequently encountered form of PCM systems.

Minimization of noise and interference

The basic characteristic of the PCM system is that it transmits signals in a form that largely overcomes the problems of noise, interference, and other distortion. In addition, the system has other advantages: (1) The signals may be reshaped and strengthened en route, since the information is no longer carried by continuously varying pulse amplitudes but by discrete symbols. The reshaping is carried out by specially designed circuits called repeaters that perform two functions: amplification and reshaping. The signals, having been attenuated (lost power) during transmission, are amplified and reshaped to their original power level and form to combat noise. (2) All-digital circuitry can be used throughout the system. With the advent of integrated circuits this has become economically desirable, and pulse-code-modulation communication of all forms—telephony, telemetering, pure data transmission—is under rapid development throughout the world. (3) Digital signals are in the appropriate form for computer processing. Sophisticated computer techniques may thus be used to carry out signal processing if needed.

A typical pulse-code-modulation system consists of an analogue–digital converter, an appropriate form of modulator at the transmitter to raise the binary signals to the desired frequency range for transmission, and a receiver.

Multiplexing. *Time multiplexing.* An additional process carried out at the transmitter is of utmost importance in the value of pulse code modulation. A multitude of independent signal messages may be sequentially combined for transmission over a common channel. In telephony, for example, a telephone signal (group of pulses) must be sent every $\frac{1}{8,000}$ of a second; yet the transmission of the signal takes so little time that a large part of the $\frac{1}{8,000}$ of a second is not used. By a process called time multiplexing, a number of signals, representing sequential parts of different telephone messages, can all be sent one after the other and sorted out again at the receiver. The process is diagrammed in Figure 9. Each of the four signal lines shown is successively (sequentially) sampled, the successive samples appearing on the common line following the sampler. In this example each signal line is assumed to be of the same bandwidth, so that the minimum sampling rate required is the same for each.

Versatility of PCM system

A single pulse-code-modulation system may carry several other kinds of signals besides voice. These other signals may not require a sampling frequency of $\frac{1}{8,000}$ of a second; some data transmissions may have very slow fluctuations, requiring sampling only once an hour; a great number of such signals can be accommodated along with one or more voice transmissions. In such mixed transmissions, signals with the same bandwidth are first multiplexed into a single stream of samples; different band-

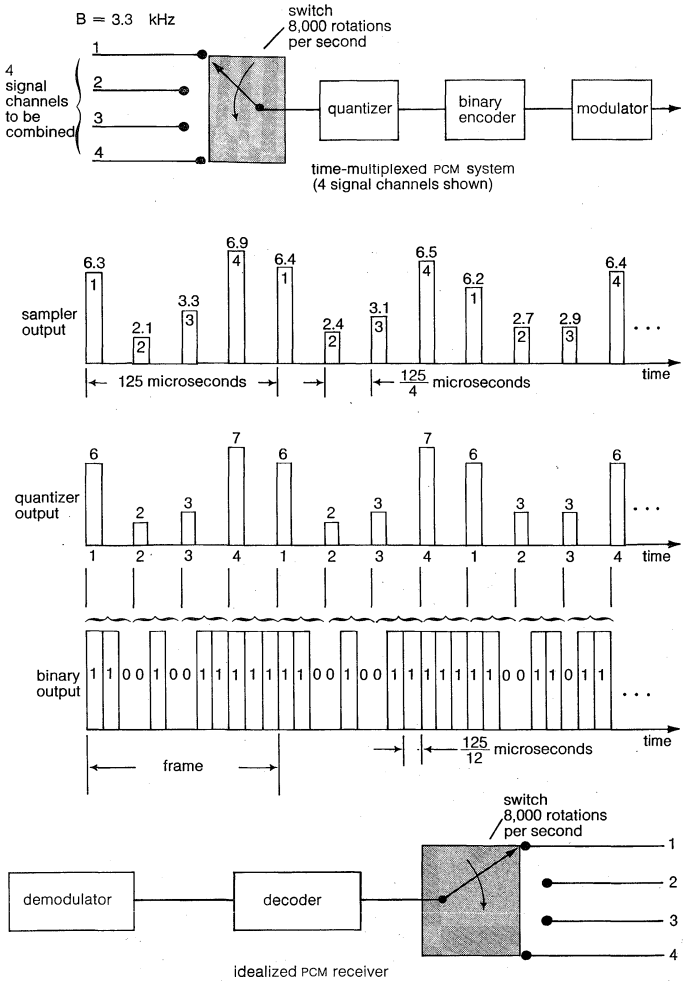

Figure 9: *Elements of a time-multiplexed pulse-code-modulation (PCM) system.*
At the top is a simplified block diagram of the sampler, quantizer, encoder, and modulator for a four-channel system. The analogue signal for each channel is successively sampled, quantized, and then converted to a binary output. At the bottom is a simplified block diagram of an idealized PCM receiver, consisting of a demodulator, decoder, and channel-switching arrangement synchronized with the transmitter sampling switch.

width samples are then interleaved. The sequence of binary signals that represents one sample of each of the signals multiplexed is said to constitute a frame.

The number of signals time multiplexed into one stream varies from application to application. In one telemetering system used aboard a meteorological spacecraft, 544 inputs are multiplexed, of which 32 are sampled once every second, and 512 are sampled once every 16 seconds. Two levels of multiplexing are thus used. In a pulse-code-modulation system used for short-range telephone communication, 24 speech signals are time multiplexed for transmission over the same line. In PCM telegraph systems 660 telegraph channels are multiplexed. In many of these applications seven-bit analogue-to-digital conversion is used; that is, a group of seven bits represents a single sample of the transmitted information.

As more signal channels are multiplexed, the number of bits per second required to represent the composite data stream increases. The bandwidth required of the transmission medium goes up correspondingly, and the high-speed circuitry required to handle the flow ultimately limits the number of channels that may be multiplexed. The circuitry limitation has been changing rapidly, however, due to advances in digital technology. Integrated circuits and smaller electronic components and spacings have been bringing about a revolution in the speed or bandwidth of operation of these circuits.

In one type of telephone system 24 subscribers are time multiplexed into a single circuit. With an eight-kilohertz (thousands of cycles per second) sampling rate and seven-bit binary transmission, 24 × 8,000 × 7 bits of information are transmitted every second. In practice an additional bit time interval is inserted after each seven-bit sequence, so that 1,536,000 (24 × 8,000 × 8) bits per second are actually transmitted. Laboratory demonstrations of systems carrying over 500,000,000 bits per second have been successfully carried out, and such systems may become commercially practicable in the near future. A system of this type could carry hundreds of simultaneous telephone conversations or six simultaneous television broadcasts. Television bandwidths are typically six megahertz (6,000,000 hertz). To sample six signals at twice this rate, using seven-bit analogue-to-digital conversion, would require over 500,000,000 bits per second. The bandwidth required is also of the order of 500 megahertz or more, thus bandwidth considerations play a key role in engineering a system. Coaxial cables, millimetre wave guides, and optical tubes are being considered as transmission media for such high-bandwidth systems.

The reception of time-multiplexed signals requires precise synchronization with the transmitter (Figure 9). After demodulation (removing the carrier frequency), the binary signals are decoded back into quantized signal form. Each signal is then sent to its appropriate destination (in the case of telephony the appropriate telephone line). Electronic switches precisely synchronized with those at the transmitter are used.

Insertion of synchronization processes

The synchronization problem is commonly handled by inserting in every frame a particular symbol or sequence of symbols that is readily recognized at the receiver. The receiver timing information necessary for synchronized switching is then derived from these synchronization pulses.

For telephone communication over short distances of ten to 50 miles (16 to 80 kilometres), a system has been tested in which a network of 24 telephone subscriber lines are time multiplexed, sampled, and coded into pulse code modulation for carrier transmission. Each voice channel is first filtered to a bandwidth of 4,000 hertz, which determines the signal bandwidth, sampled and multiplexed at the 8,000-per-second rate. Seven-bit quantization and binary encoding are used. The binary pulses occupy half of the 0.65 microsecond's time allocated to them. Each seven-bit signal sequence is followed by an additional eighth time slot, which carries the exchange-area signalling information necessary to connect subscribers. In addition, a framing pulse is added at the end of each frame for synchronization.

Frequency multiplexing. As has been noted, the shift to a specified frequency is accomplished by varying, or modulating, a radio-frequency signal. This signal is called the carrier, and the resultant modulated carrier may be shown to possess frequency components or side bands (described later) in the vicinity of each carrier. If each group of signals modulates a different carrier, the resultant composite group consists of frequencies in the vicinity of each carrier. By spacing the carrier frequencies far enough apart, the signals can be kept distinct. When the group of signals is sent simultaneously from one point to another, the process of combining signals shifted in frequency is called frequency multiplexing. It is sometimes used in place of time multiplexing. More commonly a group of pulse-code-modulation signals, each consisting of a time-multiplexed sequence of signals, is in turn frequency multiplexed. The combination of time and frequency multiplexing thus results in the simultaneous transmission of many individual signals.

The use of frequency multiplexing is particularly common in telephone transmission. Each of the base band signals in a given set, whether time-multiplexed pulse code modulation or the original analogue telephone message, is first raised in frequency to an appropriate carrier, with the carriers spaced apart by at least twice the bandwidth so that the amplitude-modulated signal may be separately recovered. The frequency-multiplexed set, consisting of the sum of all of these signals, may then in turn modulate another, much higher frequency carrier

for final transmission over the appropriate transmission medium.

Amplitude modulation. The simplest form of modulation is amplitude modulation (AM), in which the modulating signal slowly varies the amplitude of a carrier. The on–off binary signal sequence switches the carrier on and off.

Carrier and side bands

Physically, an amplitude-modulated signal consists of the carrier frequency plus two side bands separated from the carrier frequency by an amount equal to the frequency of the modulating (voice) signal. Each of these side bands, one above and one below the carrier frequency, carries all of the modulating information. The signal as a whole, therefore, carries with it superfluous information. It is possible to transmit one side band only, eliminating the carrier and the other side band, and still retrieve the modulating information intact.

Systems are in use in which the carrier is taken out before transmission; in systems of this type (suppressed carrier) the carrier is restored at the receiver. Special circuitry and techniques are required at the receiver in such systems. Since the economics involved make it impractical to build such receivers for widespread use, suppressed-carrier transmission is not used for normal radio broadcasting but is reserved for point-to-point communications and other shortwave radio applications, in which it achieves a substantial saving in transmitted power.

Suppressed-carrier systems with both side bands transmitted are commonly called double-side-band AM systems. Systems with one of the two side bands removed (filtered out) are called single-side-band systems and are in common use for all forms of point-to-point communications (radio and wire transmission, data, telephony, telegraphy). Since they too require insertion of a carrier at the receiver, they are not used in conjunction with home receivers. These systems provide still further power reduction and a reduction by one-half in bandwidth.

Frequency-multiplexed single-side-band systems are common in commercial practice. These systems range from those multiplexing simultaneously a few telegraph circuits to those combining many hundreds of telephone circuits.

Frequency modulation. In amplitude modulation, the amplitude of the carrier varies in accordance with the information-bearing, or modulating, signal. In frequency modulation (FM), on the other hand, the frequency of the carrier varies in accordance with the modulating signal. The resultant modulated carrier has a frequency spectrum centred about the unmodulated carrier frequency, again with upper and lower side bands, but the spectrum bears no simple resemblance to the spectrum of the modulating signal.

A simple form of frequency modulation occurs when the modulating signal is a pulse-code-modulation output. In this case the frequency of the carrier shifts between two values, one when a binary pulse is present in the modulating signal and the other when no pulse is present. As an example, in a typical telephone data set using frequency modulation, the two frequencies are 1,200 hertz and 2,200 hertz. At much higher radio frequencies, they could be any pair of frequencies in the desired band. Such a binary FM system is called a frequency-shift-keying (FSK) system. As the spacing between the two frequencies (or frequency deviation) is increased, the FM bandwidth increases accordingly. For small frequency deviations, however, the FM bandwidth corresponds to the AM bandwidth.

Frequency-shift keying

If a continuously varying (analogue) signal rather than the binary data signal is used as the modulating signal, the overall bandwidth of the modulated signal is approximately twice the frequency deviation plus twice the modulating signal frequency. The bandwidth is thus greater than for an AM system. An FM system in which the frequency shift is much greater than the modulating signal frequency is called a wide-band FM system. If the frequency shift is less, it is called a narrow-band FM system.

Even though frequency modulation requires wider bandwidths than the corresponding AM systems, it is employed as a modulation technique because wide-band FM signals are more effective than the equivalent AM signals in combatting noise and interference. The larger the modulation index (and hence the wider the bandwidth required for transmission), the more effectively FM performs.

EXAMPLES OF COMMUNICATIONS SYSTEMS

All telecommunications systems in use throughout the world follow some or all of the basic principles outlined above. They differ principally in the specific types of messages handled and the channels or media over which they are transmitted. When digital techniques are employed, once the various types of signals have been encoded into digital form and combined, they cannot be identified as to original source until they are decoded at their destination. The modulation technique (AM, FM) is selected after cost, power, bandwidth requirements, the availability of the proper transmitters and receivers, and the way the particular modulation technique is matched to the channel to introduce a minimum of distortion have been carefully considered. All possible combinations of the various techniques discussed are in fact in use in actual systems.

The two major communications media—wire and radio—are discussed below, with examples of systems drawn from each. Wire transmission commonly refers to the transmission of electrical signals over various types of wire lines including open wire, multipair cable (twisted pairs), and coaxial cable. These lines are used to transmit voice frequencies, telegraph, low-speed data, signalling for carrier systems (combining many voice or data signals by multiplex techniques), and television. Radio transmission commonly refers to the transmission, through the air or space, of electrical signals in relatively narrow frequency bands.

Radio communications. Because radio space is potentially available to any user, international and national regulations have evolved to limit usage, frequency bands available, and geographical limits of transmission. International radio regulations have been developed by the International Telecommunication Union in Geneva.

International Telecommunication Union

Two committees of the International Telecommunication Union are charged with studying technical and operating questions relating to telecommunications and issuing recommendations. These are the International Radio Consultative Committee (CCIR), dealing with radio communications, and the International Telegraph and Telephone Consultative Committee (CCITT), dealing with problems in telegraphy and telephony.

Among the regulations developed by the International Telecommunication Union are those pertaining to radio spectrum utilization, or allocations within particular frequency bands of the radio spectrum. The allocations are generally made on the basis of service type, or usage. The types of services include fixed service, involving radio communication between specified fixed points (point-to-point high-frequency communication and shortwave and microwave links are examples); mobile radio (aeronautical mobile, maritime, land mobile); radio navigation (aeronautical and maritime); broadcasting (AM, FM, and TV broadcasting intended for general public usage); amateur radio; space communications (telemetry, tracking, Earth–space communications as in satellite communications, and communications between space stations); radio astronomy; and standard frequency (radio transmission of specified frequencies of high precision for scientific and technical purposes).

These services are in general distributed in specific bands throughout the radio spectrum, from a few kilohertz to 40 gigahertz (40,000 megahertz). Each service in turn uses several of the modulation techniques mentioned.

In the U.S., for example, AM broadcasting is allocated the 535–1,605 kilohertz band, FM is allocated the 88–108 megahertz band, and television broadcasting is allotted four bands, 54–72 megahertz, 76–88 megahertz, 174–216 megahertz, and 470–890 megahertz (the ultrahigh frequency [UHF] band).

International point-to-point communications

Fixed, point-to-point communication, commonly used for international radiotelegraphy and radiotelephony, is allotted about 60 percent of the spectrum in the so-called HF (high-frequency) band from three to 30 megahertz. Transmission in this range depends on reflection from the ionosphere, a series of ionized layers of the atmosphere ranging in height from 50 to 300 kilometres (30 to 200 miles) above the Earth. Ionization is caused primarily by radiation from the Sun and so varies with height and in time. Transmission conditions thus change with time, resulting in received signals that fluctuate in amplitude. Special procedures are required for shifting frequencies within the high-frequency band as certain frequencies become unusable due to the changing conditions of the ionosphere. Diversity techniques (multiple frequencies, multiple transmitters and receivers, and multiple antennas) are used to combat fading.

High-frequency radiotelegraph systems commonly use either frequency-shift keying or single-side-band transmission with subcarriers. The data transmitted includes Morse, teletypewriter, and other signals. The international standard of signal transmission is 50 signal intervals per second (or 50 baud). With binary data transmission one baud is one bit per second. If one of four possible signals is transmitted every interval, as would be the case with four-frequency FSK, one baud would correspond to two bits in that interval. Automatic error-correction equipment keeps the number of errors in data transmission to less than one in 10,000 bits. Time-division multiplexing is extensively used, with either two or four 50-baud signals being multiplexed to form 100- or 200-baud channels respectively.

Single-side-band systems are employed for high-frequency radiotelephony. These systems use from three- to 12-kilohertz bandwidths, accommodating one to four voice channels respectively. In the four-voice-channel system, two channels are transmitted above and two below the carrier frequency. These voice channels can be used alternately to accommodate a group of frequency-division-multiplexed telegraph channels. In one technique, three single-side-band telegraph subcarriers (channels), each carrying 200 baud and requiring 340 hertz bandwidths, are spaced 340 hertz apart to cover a portion of the voice 2,465 hertz band. Each telegraph channel is in turn capable of accommodating four 50-baud teleprinter channels in time-multiplexed form. Facsimile and radiophoto transmission is also carried out with high-frequency communications channels (see also RADIO; TELEGRAPH).

Wire transmission. Wire lines transmit communications signals ranging from relatively narrow bandwidth telegraph and telephone (voice and data) to wide bandwidth, multiplexed signals and television. The major wire lines employed are open wire (bare-line conductors mounted on poles), multipair cables (aerial cables on poles, cables buried in the ground, underground cables in conduits, and submarine cables for water crossings), and coaxial cables. Each type provides progressively greater bandwidth and hence allows more signal channels to be transmitted (multiplexed).

Major wire lines

Typical multiplexing arrangement

A single open-wire pair may be used for carrier telephony up to a frequency of 150 kilohertz. In one typical carrier system, 12 voice channels, each requiring nominally four kilohertz, are frequency multiplexed using single-side-band techniques. Transmission in one direction is by means of the 40–88 kilohertz range, while transmission in the other direction uses the 100–148 kilohertz range.

Cable systems provide wider bandwidths than the open-wire systems (up to 500 kilohertz) and hence can accommodate more voice or telegraph channels. In one typical case, 24 voice channels are combined to form a composite single-side-band signal covering the range 40–140 kilohertz. Transmission in the reverse direction in this case is handled by using another pair of wires in the 164–264 kilohertz range.

Coaxial cables allow considerably more bandwidth, ranging into the megahertz range. As many as 600 voice channels may be combined by successive multiplexing to attain a final composite single-side-band signal with the 600 channels stacked side by side in frequency.

Any voice channel or group of channels could be used to accommodate a group of narrower bandwidth telegraph channels. Up to 24 telegraph channels may be multiplexed into one voice channel. Generally this is accomplished by frequency-shift-keying techniques. The spacing between signals in the final multiplexed group is 120 hertz for 60-word-per-minute telegraphy systems and 170 hertz for 100-word-per-minute systems.

III. Telecommunications networks

Where communication between a large number of information sources is desired, the sources must be organized into some form of network, as direct connections between any two among a large number would obviously be uneconomical and technically difficult. Generally there are two aspects to the problem of network organization in a geographically distributed communications system. Since most sources (such as an individual telephone subscriber) are idle a good portion of the time, it is possible first to combine or concentrate communications traffic in a localized area. Interconnections are then provided between the various concentration points to effect the appropriate distribution of the signals. Network organization involves the design of systems to carry out the concentration and distribution of traffic in an economical manner, with a minimum of time delay.

The time-multiplexing and frequency-multiplexing techniques discussed earlier are schemes for combining signals from various sources. There is no concentration involved, however, since a channel (whether in time or in frequency) is always allotted to each source.

Telephone and telegraph networks are prime examples of well-established communications networks. They consist of both public and private systems. There exist as well many other types of data-gathering and distribution networks—telemetry networks used in the remote control and operation of geographically distributed industrial processes, communications networks for railroads, and automobile traffic control in large cities. Airline reservation systems, bank and stock transaction systems, time-shared computer systems, community antenna, or cable television (CATV): these are all examples of modern data-gathering and distribution networks.

A multitude of data-concentration techniques and various types of network distribution systems are in existence or in the process of being developed. Two major classes, the telephone network and message (digital-data) networks, will be described.

TELEPHONE NETWORKS

A telephone subscriber is usually connected by way of a loop (two- or four-wire line) to a local telephone exchange or end (central) office. End offices are in turn interconnected via a hierarchy of switching centres. The connection medium between centres is called a trunk, which consists physically of cable, coaxial cable, or microwave-radio links.

A typical incoming telephone call is routed at its end office into an appropriate outgoing trunk. With the message destination known, various alternative routes are available. Under the modern direct-distance-dialing system, five classes of switching centres (see Figure 10) come into play. The class 5, or end, offices are the lowest in the hierarchy. They interconnect customers' lines directly and are connected to other end offices and, by trunk, to a higher office in the hierarchy. Class 4 switching centres, called toll centres, lead to the higher centres.

A typical set of possibilities for routing a call between an end office in one city and the destination end office in another city is shown in Figure 10. The order of choice in leaving a particular centre is indicated by number. Thus, primary centre 1 is connected directly, via a high-usage trunk, to toll centre 2, which in turn connects to the destination end office. This would be the first choice in routing to end office 2. If this trunk is fully occupied, the route via regional centre 2 is used. If this in turn is unavailable, the route via sectional centre 1 is used. In prac-

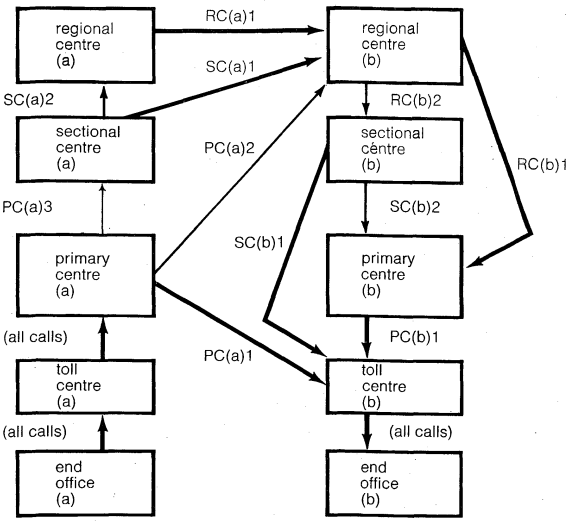

Figure 10: Simplified block diagram of a typical telephone circuit with five classes of switching centres, showing possible alternate routings of a call from end office (a) to end office (b). The order of preference for routing from a given office is indicated by number (see text).
From *Transmission Systems for Communications;* Bell Telephone Labs

tice, a maximum of seven different links may be allowed.

Automatic switching

Automatic switching using alternate routes provides large economies in connection. High-usage groups are provided between any two offices that carry a sufficiently high mutual traffic.

Figure 11 is an example of a simplified telephone system connecting a group of cities. Various types of channels

From *Transmission Systems for Communications;* Bell Telephone Labs

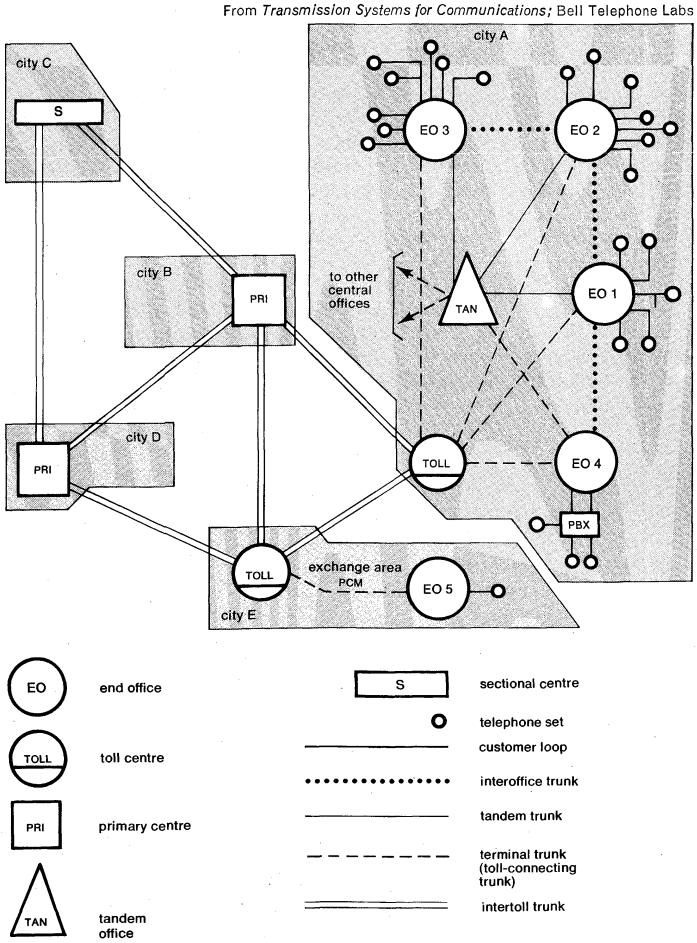

Figure 11: Simplified telephone system for interconnecting a block of cities. The intertoll trunks may be microwave radio, coaxial cable, multipair cable, or open-wire lines and may utilize various types of multiplexing. The exchange area trunk may utilize a pulse-code-modulation (PCM)system.

are used for the interconnecting trunks: coaxial cable, microwave radio, multipair cable, and open-wire line. Each of these carrier systems in turn uses various types of frequency-division-multiplexed schemes to combine many message channels. In the figure, PCM indicates pulse code modulation and PBX a private branch exchange.

Various hierarchies of frequency-division multiplexing, combining individual message channels into groups, then further into mastergroups and supergroups, have been developed following recommendations of the International Telegraph and Telephone Consultative Committee and other organizations.

Microwave-radio communications account for about one-half the trunk mileage in the U.S. In these systems the groups of frequency-multiplexed messages treated earlier are most commonly used to frequency modulate carriers in the microwave range. The most common carrier frequencies used are 6,000 and 11,000 megahertz for short-haul transmission (up to 250 miles) and 4,000 and 6,000 megahertz for long-haul transmission (up to 4,000 miles). Overall bandwidths available in these bands are 500 megahertz for the four- and six-gigahertz bands (one gigahertz equals 1,000 megahertz) and 1,000 megahertz for the 11-gigahertz band. Only a fraction of this bandwidth is actually used. For a microwave system, three mastergroups and one supergroup, with a total of 1,860 message channels, are combined to form the modulating signals. The bandwidth of this overall group is on the order of eight megahertz.

Common carrier frequencies

The extremely high frequencies used in microwave transmission enable relatively small antennas to be employed for focussing the energy. Signals are transmitted line of sight between relay stations located 20–30 miles (30–50 kilometres) apart. These repeaters serve to repower the signal periodically. In long-distance transmission the receiver at a relay station converts the microwave FM signal to 70 megahertz. It is then amplified, as much as possible of the noise and interference are removed, and the signal is converted back to the desired microwave frequency for retransmission. Four antennas are commonly used at any one station: two for reception (one for each direction) and two for retransmission.

Switching and dialing. The procedure that enables telephone messages to be placed into a system and switched into a trunk is called switching. As noted earlier, a loop commonly connects the subscriber to a telephone exchange (end office). This loop (using two-wire transmission) provides a path for the two-way speech signals as well as the signals used for ringing, switching, and supervisory functions. The telephone set on the customer's premises consists of a transmitter for converting voice energy into electrical energy, a receiver for performing the reverse process, and appropriate circuitry for carrying out the necessary additional functions.

The conversion from acoustic to electrical energy is accomplished by varying the resistance of carbon granules held between a cup and a diaphragm. Lifting the telephone headset off its hook connects a battery current from the central office to the subscriber's set. This current, flowing through the granules, is varied, or modulated, in accordance with varying pressure on the diaphragm. The telephone receiver is similar in function to a loudspeaker: the varying portion of the loop current passes through a winding on a permanent magnet, causing the magnetic field to vary accordingly, and this in turn changes the force on a diaphragm, causing it to vibrate in accordance with the current fluctuations. The diaphragm moves the air in front and the vibrations are picked up by the ear as a sound wave.

The local exchange office to which a telephone is connected must make the connection between the telephone and an appropriate outgoing trunk. The connection is made by a switching system located at the exchange office. Switching systems have been classified according to the type of switches used (stepping switches, rotary, panel, crossbar); or whether they are electromechanical, electronic, or combinations. A connection must be made at the intersection of an incoming wire and an appropriate outgoing wire.

Since the number of trunks is typically much smaller than the number of subscriber lines, there is a great deal of line concentration, which in turn is possible because an individual customer uses his phone only a small portion of the time.

The appropriate connection is obtained from the number dialed in by the subscriber. A typical seven-digit code allocates four digits (for a maximum of 10,000 possibilities) to a subscriber loop in any one exchange. The exchange itself is identified by the first three digits. The seven numbers are transmitted to the exchange via the subscriber loop by appropriate dialing. In the common dial system each digit dialed sends a different number of pulses to the office. These address digits either control the settings of switches or, in more modern systems, are stored and then used to set up a circuit. In push-button dialing now being introduced, as each button is pushed a two-frequency tone is generated and sent to the central office. The resultant train of tones is interpreted as equivalent dial pulses at the central office and used to set the appropriate switches.

Push-button dialing

The seven digits allow 9,000,000 telephone numbers to be assigned. Where needed, additional "area code" digits can be assigned; at present three such additional digits are in use in the United States and Canada and two in the U.K.; for international dialing, two international code digits precede the country number and an additional digit to show the language of the party calling.

Typical automatic switching systems in operation include the step-by-step system, used throughout the world for local exchanges and private branch exchanges, accommodating up to 10,000 lines; various crossbar systems for local offices, with up to 30,000 lines; and a computer-controlled electronic switching system capable of handling up to 60,000 lines, employed for both local and toll service exchanges.

Video-telephone service. Early in the 1970s the Bell System introduced video-telephone service. The equipment consists of a 12-button push-button telephone; a display unit with picture (viewing) tube, camera tube, and loudspeaker; a control unit with a microphone; and associated circuitry. The picture signal consists of 250 lines, displayed 30 times per second on a 5½-inch by five-inch screen. The bandwidth required to transmit the signal is one megahertz. The voice-only portion of the telephone call and the voice portion of the video service use normal two-wire subscriber loops. Two more pairs of wires are needed in a telephone cable, however, for the picture signals, one pair for each direction of transmission. Picture (video) signals are switched separately at the central office to which they are connected. Because of this additional switching requirement, not all switching systems can accommodate the system.

For transmission beyond six miles, the picture, voice, and interoffice information are all encoded at a local office into a 6.3-megabit-per-second digital pulse-code-modulation signal. To accomplish this the signal is sampled some 2,000,000 times per second. Three binary digits per sample are then used to produce a six-megabit rate. Voice and data signals of much lower bandwidth are also digitized and then intermixed with the video bits.

Three bits per sample provide representation of the signal by eight amplitude levels, resulting in a coarse and grainy picture. A modified form of pulse code modulation called differential PCM is used to improve picture quality. In this system, the difference between successive amplitude samples is encoded and sent. If the signal is changing slowly, as is normally the case in a picture signal, the encoder signal is often close to zero. More of the eight quantization levels can thus be allocated to this region and fewer to the higher amplitude region, which occurs less often and only when rapid motion is taking place on the screen.

Most 6.3-megabit-per-second encoded video-phone signals are transmitted over microwave radio or coaxial cable trunks. With microwave, up to three such digital signals plus necessary synchronizing signals are sent over one channel. For this purpose, the three signals plus synchronizing signals are sequentially time multiplexed (interleaved), providing a multiplexed bit rate of 20.2 megabits per second. This binary digital stream is then further encoded into a four-level digital stream of 10.1 megabits per second. Each successive pair of binary digits is combined to form one of four possible levels. The encoding results in one-half the bandwidth requirement but reduces signal immunity to noise and distortion. The four-level pulse train is then used to frequency modulate a carrier for transmission over a microwave system.

Encoding for coaxial transmission

Encoding for coaxial transmission is somewhat different. The noise level is less than for microwaves, and there is no signal fading as there is in radio transmission. Eight-level digital transmission can be used to reduce the required bandwidth.

DATA-MESSAGE NETWORKS

Telegraph networks have traditionally provided the capability for data transmission in the form of written messages. The 1960s, however, saw an explosive growth in data generation and transmission, brought on by the widespread use of high-speed computers. Stock market and bank transactions are rapidly consummated via data-transmission facilities, airline reservations are routinely processed via geographically widespread data networks, and large companies carry out business and bookkeeping transactions via high-speed data networks.

Techniques for efficiently processing, transmitting, and routing these data messages are still undergoing development. Much of the data is currently transmitted over the public telephone networks or private, leased voice-quality lines. More engineering effort, however, is going into the development of high-speed data-transmission and switching facilities.

In the early 1970s, data-transmission facilities are conveniently classified into categories of public switched networks or private (leased) lines or networks.

Regular public telephone systems may be used for the transmission and routing of data. Teletypewriters and other low-data-rate (so-called sub-voice-grade) equipment transmitting at up to 150 bits per second can be connected to a teletypewriter exchange service (TWX). Each subscriber has his own dial-up number and is listed in a national directory. Several TWX channels plus telephone circuits can be sent over one voice channel on the telephone network after combining at the local telephone exchange to which they are connected. The Telex service of Western Union and TWX were combined into a single national service in 1970.

Higher data rate signals, at 1,200 bits per second and 2,400 bits per second (voice-grade signals), representing computer or other data-source outputs, may be transmitted by converting the signals into a form suitable for transmission over the telephone network. One device for this purpose uses both frequency-shift-keying (FSK) and phase-shift-keying (PSK) techniques.

Voice-grade signals

The use of voice-grade telephone lines limits the rate of transmission of digital data. Distortion introduced by these lines may be readily corrected in voice signals since the ear is relatively insensitive to distortion of voice signals over a wide range. This distortion is harmful to rapidly varying digital signals, however, introducing many errors at the receiver if not corrected. The problem arises because a connection between two distant points may be routed differently at various times. The transmission characteristics and hence distortion introduced vary with different routing and require different amounts of equalization (correction).

With a voice signal, random variation in distortion is tolerable as long as some average equalization is introduced, but this is not the case with digital signals. Adaptive equalizers—*i.e.*, correction networks introduced at the destination to compensate automatically for deleterious transmission characteristics—are employed to correct the problem. With these equalizers, transmission rates as high as 9,600 bits per second may be possible over the telephone network. The higher transmission rates are accomplished by combining several successive binary digits in a binary data stream and transmitting one of a multiple set of amplitudes or phases of a pulsed carrier. This

reduces the required bandwidth, enabling the signal to be transmitted over a three-kilohertz bandwidth line.

Worldwide public teletypewriter service is available through an automatic teletypewriter exchange service called Telex. This was first set up in Europe after World War II by the various European telecommunications utilities. It was introduced in Canada in 1956 and in the U.S. in 1957 and is now combined with the Bell System TWX. The system operates at 66 words per minute (50 baud, or 50 bits per second). Each subscriber has his own number and may dial any other number in his own country, just as with the telephone system.

Private-line data communications

Private-line systems for data communications have come into widespread use in the past decade. These may provide point-to-point communications or, in the case of large systems, network switching as well. They provide an advantage over public systems in that they are assigned (dedicated) to a specific purpose or customer and hence may be specially conditioned to provide superior performance. Voice-grade private lines transmit 2,400 and 4,800 bits per second with conditioning, and adaptive equalization features allowing up to 9,600 bits per second are available.

Private wide-band data channels allowing up to 500,000-bits-per-second transmission are also currently available.

When many message sources are to be interconnected in one common private network, switching and routing techniques must be incorporated. Standardized procedures had not been adopted by the early 1970s. Unlike telephone (voice) data, different message sources to be interconnected may have vastly different data rates, data statistics, and data-transmission requirements. The data sources to be switched into the same network may include a telemetry signal that is transmitted continuously at a few bits per second, a teletypewriter producing 50 bits per second intermittently, and a satellite computer communicating at a high data rate with a master computer. Unlike the telephone network, in which direct transmission is required and a busy signal is given when the destination or trunks are all occupied, many data messages may be stored until transmission becomes possible. Priority classifications may be set up, with certain messages allowed to go through and others temporarily held up. Some sources may be regularly queried as to whether immediate transmission is required or can come through as facilities become available.

The strategies of combining or concentrating sources with different data rates, of temporarily storing certain messages, and of determining how to connect the sources and how to route them can all be accomplished by computer, and the trend is in the direction of completely automatic computer-message switching.

Roll-call polling

Several methods are available for connecting many data terminals to one central point or computer. The methods include connection of the terminals to a computer in a time-shared mode or to a local exchange before retransmission elsewhere. In the so-called roll-call polling technique, a computer successively asks, or polls, each terminal in prearranged order whether a message is to be transmitted. If the answer is yes, polling stops and the message is transmitted. Polling then continues with the next terminal. If the answer is no, the computer goes on to the next terminal. Some terminals may be interrogated more than once in a particular sequence, and priorities are often introduced. In the hub polling technique, the terminals are all connected in a line. The first terminal is polled by the computer. If it has nothing to send, the polling message is forwarded down the line to the next terminal. The computer resumes control only when a particular terminal down the line has something to transmit. At the end of the transmission, the computer resumes the polling at the next terminal, which in turn forwards the message down the line. In the contention, or asynchronous, technique, an individual terminal requests transmission when needed. If a transmission channel is available, transmission proceeds. If not, the channel waits its turn in line.

In these techniques, as in the method of concentrating low-speed data for retransmission at a higher rate, data storage becomes significant. Devices, called buffers, used to provide this function include magnetic tape, disc, and other kinds of memory devices. Paper tape has long played the same role in teletypewriter systems.

Error control. It has been noted that errors occur in data transmission. More specifically, in binary transmission a 1 may be received as a 0 or vice versa or two adjacent levels may be confused in multilevel phase or amplitude pulse transmission, because of noise added during transmission or on reception of a pulse signal, signal distortion during transmission, signal fading during transmission, and other effects. Much of modern communications research involves the search for new communications systems and techniques that will provide improved error performance. Appropriate signal design and encoding at the transmitter and unique modulation techniques all play a role. Different receiver configurations and processing techniques are also compared on the basis of their error performance.

If noise is the predominant perturbing effect of the transmission medium, frequency modulation provides improvement over amplitude modulation. If fading plays a significant role, single-side-band transmission is usually preferred. Errors may occur in fading when the signal level drops to a level comparable to that of the noise. At this point an FM system deteriorates rapidly compared to an AM system. The FM improvement is possible only when the signal level is high compared to the noise. If noise is the limiting factor in systems performance, the receiver incorporates a matched filter, whose frequency response is just that of the binary signal pulses received.

Noise appearing at the receiver antenna is the predominant deteriorating effect in space communications. In telephone data transmission, however, it is the signal distortion introduced during transmission that plays the major role. Particular types of pulse shapes at the transmitter are used to minimize the distortion. Repeaters spaced at relatively short distances along the transmission path prevent distortion from building up. Equalizers, both of the fixed type and the adaptive type mentioned earlier, reduce the distortion as well.

Signal distortion

With all of these improved techniques, errors still occur, and error-detection and correction techniques are necessary. By appropriately coding a binary pulse-code-modulation sequence, for example, it is possible to detect errors and even to correct them. In such a scheme additional binary digits (redundant bits) are added at the transmitter to the binary message stream in a controlled manner. There are many techniques for adding the redundant bits and determining the optimum number to use, and significant improvements in performance can be realized by their use.

It is possible, by inserting a large number of redundant bits, actually to locate the error in question and correct it. With still more redundant bits two or more errors may be corrected. The disadvantage is that as more redundant bits are added the transmission rate is reduced accordingly. Thus if five redundant bits are added to ten message bits, there is a one-third reduction in the data rate.

Coded binary transmission has been used in recent space probes. At the large distances involved, the signal power returned is so small compared to the noise received at the Earth receiving-station antennas that the binary pulses must be stretched out over a relatively long time to provide enough signal energy to overcome the noise. The use of coded transmission reduces the errors or allows a faster rate of transmission for the same error rate.

As an example, the signal received from a space vehicle 1,000,000 miles out in space may be on the order of 10^{-16} watt. If the distance is increased by 10,000,000 miles, the received power is about 10^{-18} watt. To keep the average number of errors to less than one in 100,000 binary digits—a common design figure—the maximum data rate is 1,000 bits per second. At 1,000,000 miles each bit must last at least 0.001 second to ensure enough signal energy. If the distance is increased to 10,000,000 miles, the maximum data rate is only ten bits per second. Thus, normal voice communication with existing techniques is not possible at these distances.

Increasing data rate. A theorem from information theory, developed in 1948 by U.S. scientist Claude Shannon, is invoked to increase the data rate. Dr. Shannon proved that for a communications channel with white noise added (random noise the intensity of which is constant at all frequencies), there exists an upper limit to the information rate in bits per second that may be transmitted over the channel. This he called the capacity of the channel. Packing more bits per second into the channel than this theorem allows increases the probability of an error being introduced. By using a data rate less than the allowed upper limit of capacity, however, the error rate can be made to approach zero with appropriate encoding. The theorem does not tell how this encoding may be carried out, and much of the error-correction encoding effort has gone into this question of finding good codes.

The capacity of the channel depends on three parameters: the bandwidth of the channel (the maximum frequency component it can transmit), the signal power received, and the noise power measured at the same point as the signal. In particular, as the bandwidth gets larger, the capacity increases to a maximum value directly proportional to the ratio of signal power to noise intensity. For instance, in the specific space communications example, maximum capacity is 14,500 bits per second at the 1,000,000-mile range (compared to 1,000 bits per second without coding) and 145 bits per second at the 10,000,000-mile range (compared to ten bits per second). The figures indicate the possible advantage in coding for space communications and indicates why coded systems are used.

Similar considerations may be applied to the three-kilohertz voice channel used with the public telephone network. Although distortion plays a greater role than noise in this case, a channel capacity may be found for it as well. Typically, it is on the order of 20,000 bits per second. Since 9,600 bits per second may be possible with multilevel transmission and adaptive equalizers, the theoretical limit of channel capacity has been much more closely approached than in the space communications example. In data networks of the future, with the individual links especially devised for data rather than voice, these numbers may be expected to increase considerably. Coding techniques have been investigated for a different type of noise than that which appears in space channels. In the telephone channel, noise bursts tend to occur because of faulty switches in exchanges and lightning bursts. These bursts may last for many bits, wiping out all signal pulses while they last. Various error-control techniques and codes have been developed to handle the problem.

IV. Future trends in communications

Some examples of future systems have already been noted in passing: public switched networks especially designed for high-speed data transmission, extremely wide band data transmission (systems allowing 500 megabits per second transmission), and the widespread use of computers in all these systems.

With the increased concentration of population in large metropolitan regions, more efficient means are being sought to provide the data requirements envisioned in the future. One result could be a computer terminal in each home, with shopping, banking, and other services carried out routinely. Widespread use of cable television would provide an alternate, wide-band communications system in each home, parallel with the telephone system. All kinds of data and picture services could be provided via such a system. Professional, social, shopping, business, and educational activities could all be conducted inside the home.

Cable television

Public-service communications of various types—fire, police, education, health, transportation—are commonly carried out separately in urban areas. These communications could perhaps be more effectively conducted via one flexible computer-controlled system, adjusting the capacity to each service as required. To this must be added the communications requirements within cities of business data sources, computer networks of the future, radio operated taxicabs, traffic-control systems, information-retrieval systems, and others, complicating the task of allocating communications resources effectively.

Synchronous communications satellites, already extensively used for international voice and TV communications, can be readily adapted to provide worldwide data coverage. They are also being considered as an alternate means of communications coverage within a nation or continent. Trunk connections between distant switching centres might be made via satellite. Educational TV broadcasts, covering an entire region, might also be transmitted this way (see SATELLITE COMMUNICATION).

The current communications capabilities could be increased in a dramatic way by broadening the radio spectrum into the millimetre (100,000 megahertz and higher) and optical-frequency (1,000,000 gigahertz and above) ranges. These extremely high frequencies allow proportionately wider bandwidth signals to be transmitted. It has been suggested, for example, that a single millimetre channel could provide the capacity of a quarter of a million voice channels. Still higher frequency optical communications could provide the possibility of at least 1,500 colour TV channels on one optical-frequency carrier. There are major technical problems in the transmission of these extremely high frequency signals, however. The development of the optical laser has provided a coherent carrier source needed for optical-frequency communications (see also LASER AND MASER). Millimetre wave-guide transmission systems, millimetre pipes, are under intensive developement in that range of frequencies (see also ANTENNAS AND WAVE GUIDES). Manufacturing tolerances are strict; discontinuities, bends, and imperfections must be kept to within a fraction of a millimetre for long sections of pipes. The problems are even more difficult in the optical range; the atmosphere tends to scatter the coherent light rays, while fog and rain absorb them. Point-to-point communications over long distances might be possible in space. But there the narrow beams involved mean highly sophisticated tracking systems in which the highly directional transmitting and receiving antennas must be kept constantly lined up with one another. In the case of terrestrial communications over long distances, scattering and absorption probably preclude transmission through the air. Optical pipes, lens systems, and fibre optics have been suggested as alternate transmission approaches and are under intensive investigation. These may materialize as economic and reliable competitors or adjuncts to existing communications facilities. (M.Sch.)

Use of extremely high frequencies

Telescope

A telescope is an instrument used to view distant objects. The word is derived from the Greek *tēle*, "far," and *skopein*, "to see." Modern telescopes are of two types, optical and radio. In optical telescopes light is collected and focussed so that it can be magnified and either examined through an eyepiece or photographed. The light may also be directed into an auxiliary device, such as a spectrograph (see also OPTICS, PRINCIPLES OF; OPTICAL ENGINEERING). A radio telescope may consist of a single wire, a pattern of wires, a spherical or parabolic dish, or a number of dishes arranged in a pattern. Very sensitive electronic detectors and amplifiers have been developed for radio telescopes, which are usually much larger and more complex than optical telescopes. In one such telescope, the long-baseline radio interferometer, the two elements may be separated by hundreds or even thousands of miles.

EARLY HISTORY

The effects achieved by looking through a magnifying lens, and especially by looking through two lenses in alignment, are so startling that it is likely that the telescope was "invented" independently and accidentally many times before Galileo turned it on the heavens in 1609. Glass was made in Egypt as early as 3500 BC, and crude lenses have been unearthed in Crete and Asia Minor believed to date from 2000 BC. Euclid wrote about the reflection and refraction of light in the 3rd century BC, and in the 1st century AD the Roman writer Seneca noted that the glass globe filled with water referred to by the Greek dramatist Aristophanes could be used as a magnifying glass. The 11th-century Arab scientist Alhazen (al-Ḥansan ibn al-Haythan) published the results of his experiments with parabolic mirrors and the magnifying power of lenses. Alhazen's works were translated into Latin in 1572, but much earlier Roger Bacon (*c.* 1220–*c.* 1292) had recognized the usefulness of lenses, writing:

Alhazen's experiments

> . . . thus from an incredible distance we may read the smallest letters . . . the Sun, Moon, and stars may be made to descend hither in appearance . . . which persons unacquainted with such things would refuse to believe.

The invention of the printing press in the 15th century, followed by the ever-increasing need for spectacle lenses by scholars, probably made inevitable the final invention of the telescope and its widespread use. It is clear that the oft-repeated statement that the telescope was first invented in 1608 by Hans Lippershey in Middelburg, the United Netherlands, is incorrect. Lippershey made a number of telescopes in 1608 and sold them to the government of the United Netherlands, which was particularly interested in their military applications. His request for a 30-year privilege or patent was denied on the grounds that "many other persons had a knowledge of the invention." Telescopes were on sale in Paris early in 1609 and in that same year appeared in Germany, in various cities in Italy, and in London.

Galileo heard of Lippershey's invention, and reinvented the telescope, using basic optical principles. His first telescope, constructed in a day, magnified three diameters and consisted of a convex lens (curving outward) and a concave lens (curving inward) fitted into opposite ends of a tiny lead tube. The results were so gratifying that Galileo made several larger telescopes, grinding his own lenses. His largest telescope was 1¾ inches (about 4.4 centimetres) in diameter and had a magnifying power of 33 diameters. With these simple instruments he discovered the mountains and craters of the Moon's surface, the satellites of Jupiter, the starry nature of the Milky Way, and the fact that Venus undergoes phases like those of the Moon. His observations showed that Venus shines by reflected sunlight, is spherical, and goes around the Sun, contrary to Ptolemaic theory. These discoveries of Galileo's resulted from two distinct characteristics of a telescope, its magnifying power and its light-gathering power. The magnifying power made it possible for him to see the changes of phase in Venus, while the light-gathering power permitted him to detect Jupiter's faint satellites and the countless dim stars of the Milky Way. The light-gathering power is proportional to the square of the diameter (or aperture) of the lens, while the magnifying power depends on the relative focal lengths of the object glass and eyepiece, which in turn depends on the curvature and composition of these lenses.

Rarely has a new scientific instrument had a more dramatic impact than that of Galileo's telescope, which not only advanced scientific knowledge by enormous strides but stirred vast waves in philosophy and religion by upsetting the traditional picture of a universe centred on a stationary Earth.

From the 17th century on, telescopes grew steadily in size and power. The cost of construction naturally increased as well, often in a way difficult to justify at the time of construction because no one can predict what a new, more powerful telescope will discover. For example, the 200-inch Hale reflector on Mt. Palomar has been used to make a series of important discoveries that lay entirely beyond the conceptions of professional astronomers in 1928, the year of the telescope's funding.

OPTICAL TELESCOPES

Optical telescopes are of two basic types, refracting and reflecting. In recent times a combination of the two has been devised.

Refracting telescopes. The term refracting refers to the bending of light by a lens. The large lens, called the object glass, of a Galilean telescope is convex; the eyepiece, placed in front of the focus of the object glass, is concave. The image formed by this combination of lenses is enlarged and erect (Figure 1). The instrument is short and light, and its principle is used in present-day opera glasses. Both the magnification and field of view are limited. The modern visual refracting telescope is based on the Galilean telescope as modified in accordance with the suggestion of Galileo's contemporary, Johannes Kepler, who pointed out the advantages of using a convex eyepiece placed in back of the focus (see Figure 1), greatly enlarging the field of view. The image produced by this eyepiece is inverted, because it is a magnification of the small, inverted image formed by the objective at the point P. It is possible to reinvert the image by adding additional lenses, as is done in telescopic gun sights and in the telescopes used in engineer's transits. The loss of light through absorption by these additional lenses is sufficiently severe, however, so that an erecting eyepiece is not used by astronomers, who publish photographs "upside down" in order to correspond to the orientation seen at the telescope.

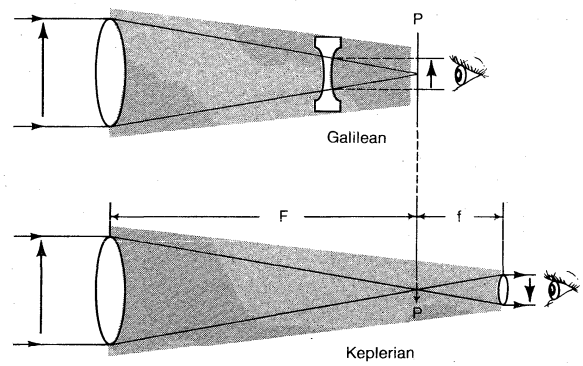

Figure 1: Galilean and Keplerian telescopes (see text).

Other advantages of the Keplerian telescope, generally adopted by astronomers about the middle of the 17th century, are its increased possibilities for magnification (up to 1,000 times or more) and the fact that a small object—such as a thin wire or wires—can be placed at the common focus, P, of the two lenses. By bringing the image of a star as seen in the eyepiece exactly into coincidence with the intersection of two crosswires, which are also seen in focus, the astronomer can determine the position of the telescope—and the star—with great accuracy. This advantage was first pointed out by the English astronomer William Gascoigne, who developed the microm-

eter, based on this principle, and who used this device before 1640 for measuring planetary diameters. The micrometer revolutionized astronomical measurement and made it possible to measure positions much more accurately than was possible with the open sights used earlier. The micrometer is still used effectively today in the precise measurement of the positions of the stars, planets, Moon, and Sun; in the measurement of differential positions of comets, asteroids, and close double stars; and in measuring the diameters of planets and satellites. Telescopic sights eventually led, in the 1890s, to a revolution in naval gunnery.

Use of the micrometer for astronomical measurement

The magnifying power, M, of an astronomical telescope is defined as the ratio of the focal length, F, of the objective to the focal length, f, of the eyepiece: $M=F/f$ (Figure 1). The focal length of a lens is approximately the distance from the principal focus to the midpoint of the lens. Increasing the magnification can be accomplished by using an eyepiece of shorter focal length. The astronomer usually has a collection of eyepieces of different focal lengths to meet his varying needs; higher magnification corresponds to a reduced field of view. A practical limit to the magnifying power that can be usefully used with a large telescope is normally set by the quality of the astronomical viewing. It is of little value to magnify an image that is greatly diffused and distorted by the atmospheric irregularities in the light path. Other optical effects also play a role, especially for the smaller telescopes, and magnifications of 50 or 60 for each inch of aperture (diameter of the objective lens) is about the useful limit.

The early astronomers, using refractors, soon discovered that the stellar images were defective in a degree not accounted for by poor optical glass or imperfect shaping of the lens surfaces. It was the result of an image defect known as chromatic aberration. In passing through a prism, light is changed in direction (refracted) and this change in angle varies with the wavelength, blue light (of shorter wavelength) being refracted somewhat more than red light. A lens may be thought of, very approximately, as two prisms base to base, hence blue light comes to a focus closer to the lens than does the red light (see Figure 2). Similar differences in the position of the focal

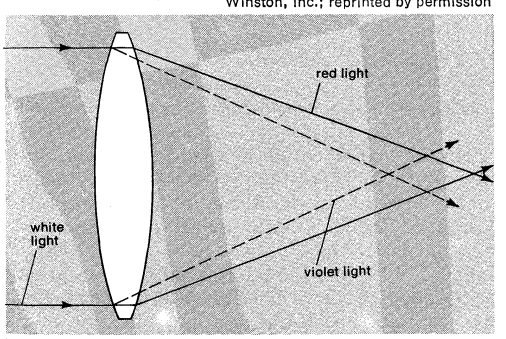

Figure 2: Chromatic aberration (see text).

point exist for other colours. A stellar image inspected at the red focus would show an out-of-focus blue halo, and vice versa. A compromise focus in the green-yellow would show a smaller purple halo—a combination of the out-of-focus blue and red light. Chromatic aberration can be minimized by using very thin lenses, which are necessarily of very long focal length. Incredibly long and unwieldy telescopes were thus constructed that had focal lengths of over 200 feet (60 metres); for example, the English astronomer James Bradley used a telescope of 212-foot (65-metre) focal length in measuring the diameter of Venus in 1722.

Following his discovery in 1666 that light of different colours is refracted in different amounts, Isaac Newton erroneously concluded from some hasty optical experiments that all refracting substances disperse the colours in constant proportion to their average refraction; and this being true, no combination of lenses could eliminate these colour effects and hence no further improvement in the refracting telescope could be expected. About 70 years later, Chester Moor Hall of Essex, England, concluded otherwise, arguing correctly that the human eye is a complex lens showing no chromatic aberration, and, therefore, it should be possible to combine lenses of different kinds of glass to eliminate this aberration. He successfully constructed the first achromatic telescope in 1733 by combining lenses composed of different kinds of glass. Unfortunately he did not publicize his accomplishment. John Dollond of London independently invented the achromatic telescope in 1758, and modern refractors are based on his use of a combination of a convex lens or lenses of a type of glass known as crown glass, combined with a concave lens of a type of glass known as flint glass. This correction of chromatic aberration is possible because the refractive characteristics of flint glass lens are such as to counteract the refractive characteristics of the crown glass lens, thus correcting the aberration. The correction is complete at only two widely separated wavelengths, however, and other wavelengths show a residual chromatic aberration. The variation of focus setting with wavelength is usually evaluated for a large refractor so that the astronomer can make the best compromise setting for the particular colour region within which he is working.

First achromatic telescope

Dollond's telescopes were immediately successful but were limited in size to three or four inches in diameter because at that time it was not known how to cast larger flint glass disks. This limitation was overcome in time, and a century later, spurred on by the desire for greater and greater light-gathering power, ever-larger refractors were constructed, culminating near the end of the 19th century in the 36-inch telescope at the Lick Observatory and the 40-inch telescope at the Yerkes Observatory. The lenses for these giant telescopes, still the largest refractors in the world, were made by the U.S. firm of Alvan Clark and Sons. Their optical work was superb, the secret of their success being their remarkable patience in the use of local correction (figuring) to obtain the sharpest possible focus. This technique was better than striving for mathematically true curves, because of the inhomogeneities in the glass. These opticians stimulated the expansion of astronomy in the U.S. in the period 1850–1900.

Reflecting telescopes. A reflecting telescope is a device in which the light is gathered and focussed by a mirror. In his *Optica Promota*, James Gregory, a Scottish mathematician, suggested the reflecting telescope in 1663 but the opticians of the day were not able to grind good mirrors for him. In Gregory's design the light reflected from the primary concave mirror was reflected again by a smaller concave mirror, reaching the observer's eye by passing through a circular hole in the primary. Isaac Newton turned his attention to the problem and successfully devised methods of grinding and polishing an alloy of tin and copper known as speculum metal. His mirror was spherical, rather than paraboloidal, and the image was viewed horizontally at the side of the tube by means of a flat mirror inclined at an angle of 45° at the upper end of the tube. His second telescope, presented to the Royal Society on January 11, 1672, had a magnifying power of 38 diameters. The speculum metal mirror had a focal length of 6⅓ inches (16 centimetres) and a diameter of about two inches (five centimetres). Because the light rays in such a telescope are only reflected and not refracted, chromatic aberration is nonexistent and this is an inherent advantage of all reflectors. Nevertheless, the invention was not of practical value until about 1740, when James Short of Edinburgh succeeded in routinely grinding concave mirrors; he sold reflecting telescopes as an ordinary workshop product. These reflectors became favourites with astronomers and amateurs, who found them preferable to the longer, thinner refractors with their pale and blurred images. It was not easy, however, to attach these mirrors to measuring instruments, so refractors were still used in this most important type of professional work.

The reflecting telescope was greatly advanced by William Herschel of England, often called the father of stellar astronomy, who made his own mirrors because they

were too expensive to buy. Herschel's sensational discovery of the planet Uranus in 1781 was made with a seven-inch (18-centimetre) reflector, which was large enough to show the disk. His two most famous telescopes (1789) were of 19-inch (48-centimetre) and 48-inch (122-centimetre) aperture. Herschel developed the art of making and figuring his mirrors of speculum. This alloy reflects only about 60 percent of the light that falls on it, even when freshly polished. It tarnishes rather quickly to a much lower reflectivity, and the removal of this tarnish requires a long and tedious job of refiguring. The largest speculum mirror ever made was a 72-inch (183-centimetre) reflector (first used in 1845), constructed by Lord Rosse, an Irish amateur astronomer, who discovered the spiral structure of nebulae with it.

Herschel's improvements

The development of the silver-on-glass mirror in the 1850s and '60s overcame the difficulties inherent in the use of speculum mirrors. A fresh coating of silver has a reflectivity greater than 90 percent throughout the visible spectrum, and a tarnished mirror can be easily resilvered without refiguring. The reflectivity starts falling at a wavelength of 4500 angstroms (one angstrom is 10^{-10} metre) and is so low at 3300 angstroms as to be essentially useless in this important region of the ultraviolet. A method of depositing aluminum on an astronomical mirror in a vacuum was developed by John Strong in California in 1931. Aluminum has a high reflectivity in the ultraviolet, scatters relatively little light, and a coating, when properly protected, is extraordinarily tough and will last many years.

Relative advantages of refractors and reflectors. Both types of telescope have been brought to a high state of perfection, but each type has its own special advantages, disadvantages, and purposes. Since light must pass through a lens, the glass from which it is made must be optically homogeneous and free of bubbles. The glass of a mirror need only be mechanically homogeneous, a less severe requirement. There are four surfaces to figure on the two lenses of a refractor and only one surface for a reflector. Reflectors are therefore less expensive to build than refractors of the same aperture, and their complete lack of chromatic aberration is an advantage in spectrographic and photographic work. Small differences in temperature between different parts of a large mirror can often seriously distort the shape of the mirror, but this disadvantage has been largely overcome by the use of low-expansion glasses. Because of chromatic aberration, refractors are normally built with longer focal lengths than reflectors of the same aperture. A large refractor is somewhat more unwieldy in use and requires a much larger and more expensive dome than a reflector of the same light-gathering power. The flint lens of a refractor becomes increasingly opaque to wavelengths shorter than 4000 angstroms and the refractor is relatively useless in this spectral region. If refractors larger than 40 inches (100 centimetres) in diameter were built they would require larger and hence thicker lenses, which would absorb more light, thus tending to offset the increased light-gathering power. For this reason alone, the largest optical telescopes must be reflectors. The largest optical telescope, with a 236-inch (six-metre) diameter reflector, was under construction in the early 1970s near Zelenchukskaya, in the Caucasus, 1.3 miles above sea level. The 850-ton telescope, built and test assembled in Leningrad, has an 82-foot (25-metre) tube and a mirror almost 20 feet (6½ metres) in diameter. A special furnace was needed to melt the glass, which took two years to cool. The heavy mirror is kept from deflecting under its own weight by a support system attached to the rear surface by means of drilled cavities. Because of mechanical problems involved in mounting the large machine, the Soviet instrument has an altazimuth mount, with horizontal and vertical axes, instead of an equatorial mount as do other large optical telescopes. The 700-ton movable section of the telescope may easily be turned, because of hydraulic oil-pressure bearings on both axes. Reflectors possess great advantages in spectroscopic work and excel especially in the observation of faint objects such as nebulae and galaxies.

Largest optical telescope

Refractors usually have much wider fields of good definition than reflectors. In current practice, refractors are used almost exclusively in visual observations and astrometric measurements of stellar parallax and binary stars and in the overall visual and photographic determination of stellar positions. Observations of annual stellar parallax (the apparent shifting of the image of a nearby star with respect to the images of more distant background stars caused by the orbital motion of the Earth about the Sun) are particularly important. Such observations of parallax are fundamental to the knowledge not only of stellar distances but also to the knowledge of stellar luminosities and velocities.

A large reflector is more flexible than a refractor in that a choice of usually three focal lengths (and three f-numbers) are available. These are known as the prime, Cassegrain and coudé focuses. For example, the 200-inch Hale telescope has a focal length of 660 inches (1,680 centimetres), giving it an f-number (focal length divided by diameter) of 3.3 at the prime focus. To make use of this focal length and f-number the observer sits in a cage directly in the beam of starlight. The consequent percentage loss of starlight is small, and with only one reflection loss—from the main mirror—loss of light is kept to a minimum. In the Cassegrain arrangement, the light is reflected by a hyperbolic mirror inserted in front of the prime focus, passes through a hole in the large mirror, and comes to a new focus in back of the mirror. The Cassegrain focal length is 3,000 inches, giving an f-number of 15. In the coudé arrangement the light is reflected by other auxiliary mirrors (by two alternate paths, depending on the declination setting) down the polar axis of the telescope. The coudé focal length is 6,000 inches, giving an f-number of 30. The great advantage of the coudé focus is that it does not move as the telescope follows the star in its diurnal motion. At this point a fixed, large, and efficient coudé spectrograph has been built that would be difficult to attach to any moving part of the telescope.

The Schmidt telescope. A continuing and highly important observational problem is to determine the contents of the universe. For this purpose it is necessary to photograph the entire sky, including as faint objects as possible, with as large a scale as possible, and to photograph in many wavelength (colour) regions. The requirement in the normal optical regions (wavelengths of 3000–10,000 angstroms) is a very large achromatic telescope with a wide field of good definition (of the order of five degrees square), which is also fast enough (with a small enough f-number) that the limit imposed by the light of the night sky background can be reached in reasonably short exposure times. Parenthetically it should be stated that two such telescopes would be necessary, one in each hemisphere. The large parabolic reflector is not the answer—its field of good definition is much too small. The refracting telescope is too small, too slow, and not sufficiently achromatic but does have the necessary wide-angle characteristics. A telescope combining the best features of both refractor and reflector has been found to be the solution, and such an instrument is the Schmidt telescope.

The coma defect

The primary image defect in a parabolic reflector is coma—star images off axis are not round but look like tiny comets with their tails pointed away from the plate centre. This effect increases linearly with distance from the optical axis, and for different objectives and for a given angle off axis, coma worsens rapidly as the diameter of the objective is increased, varying as the square of the aperture.

A spherical mirror has no unique axis of symmetry and therefore should exhibit no coma. But on axis (off axis also) the rays reflected from the outer region of the mirror converge to a focus that is closer to the mirror than the focus of the rays coming from the inner regions of the mirror. This image defect, also present in refractors, is called spherical aberration, and a spherical mirror generates poor images for light coming in from all angles. All rays of light that pass through an aperture located at the centre of curvature of the mirror strike the mirror surface perpendicularly, hence there is no off-axis aberra-

tion. If a thin, weak lens (called a correcting plate) is placed at this point, it can be shaped so as to correct completely for spherical aberration, at the expense of introducing a small but tolerable amount of chromatic aberration. This ingenious optical system was invented in 1930 by Bernhard Schmidt, an optician at the Bergedorf Observatory, Hamburg, who also made the first such telescope. The main disadvantages of such a telescope are (1) the difficulty in making the correcting plate, which has a complex curvature; (2) the curvature of the focal plane, which requires curved photographic plates or films; and (3) the increased (doubled) length of the telescope tube. The telescope is achromatic over a wide colour range, can be made in large size with a very wide useful field, and is fast (has a small f-number). The mirror is normally made substantially larger than the correcting plate so that off-axis rays will not miss the mirror (see Figure 3).

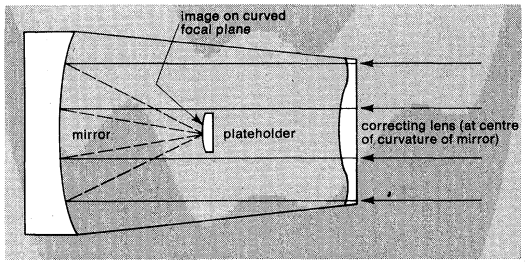

Figure 3: The Schmidt telescope.

The largest Schmidt telescope is the 52.8-inch-aperture instrument at the Karl Schwarzschild Observatory in Jena, East Germany. Its primary mirror has a diameter of 79 inches. Even larger Schmidt telescopes should be possible, but other things being equal, the focal length of a Schmidt must be increased more rapidly than the aperture in order to keep critical chromatic aberrations to tolerable levels. Schmidt telescopes have been used effectively in relatively poor climates because so much information can be acquired in a short time. They are also used extensively as cameras in astronomical spectrographs, in the photography of meteors, and in tracking artificial satellites. Schmidt cameras, with their wide-angle properties and their bright images, are widely used in science and industry.

Special types. *Solar telescopes and instruments.* The Sun is an object of special interest to astronomers and many unusual and different telescopes and instruments have evolved specifically for solar astronomy. A few will be described.

McMath solar telescope

The size of the Sun's image in a telescope is $\frac{1}{108}$ of the focal length. In the popular 35-millimetre camera of 50-millimetre focal length, the solar image is only one-half millimetre across (one-fiftieth inch), while the McMath solar telescope at Kitt Peak National Observatory near Tucson, Arizona, with a focal length of 300 feet (90 metres) yields an image three feet (0.9 metre) in diameter. Like most large solar telescopes it is fixed in direction. Sunlight is reflected, from an 80-inch (200-centimetre) fused silica flat mirror, 500 feet (150 metres) obliquely down the south polar axis at an angle of 32° —the latitude of Kitt Peak. This beam, focussed by a 60-inch (150-centimetre) concave mirror, is returned up the axis slightly below the incoming beam to a 48-inch (122-centimetre) flat mirror that directs the image vertically downward to spectrographs and other instrumentation.

Because solar radiation is intense and hot, special precautions must be taken in regard to the effect of the heat in solar telescopes. The entire McMath telescope, which is two-thirds underground, is cooled to the temperature of its surroundings. The 80-inch mirror is located 100 feet above the terrain to minimize ground effects. The bold step of evacuating the air from the entire telescope was taken in the 30-inch-diameter, 180-foot-focal-length, pyramidal tower telescope dedicated in 1969 at Sacramento Peak Observatory, Sunspot, New Mexico. A lengthy solar site survey made in Southern California by the Hale Observatories showed that the best solar seeing occurred at sizable lakes, mountain lakes combining good seeing with good transparency of the atmosphere. As a result, the Big Bear Solar Observatory is located on an artificial island in Big Bear Lake at a 6,735-foot altitude in the San Bernardino Mountains.

The solar corona has a brightness only one-millionth that of the Sun and prior to 1931 could only be observed at the time of a total solar eclipse. It was only by going to a high mountain peak and by building a "perfect" telescope, free of all scattered light, that the French astronomer, Bernard Lyot, first succeeded in photographing the corona on a daily basis. The largest coronagraph, at Sacramento Peak (a duplicate is at the High Altitude Observatory in Boulder, Colorado), uses a 16-inch-diameter single lens completely free of bubbles, scratches, dust, and other defects. Elaborate precautions, involving sophisticated instrumentation, are taken to prevent the light of the solar disk from reaching the photographic plate. Because of the chromatic aberration introduced by the single lens, this is possible only over a narrow range of wavelengths, which can be varied. For this reason, a narrow-band filter is used that transmits the light in just the desired band. A green emission line of iron is strong in the corona, and direct photographs and motion pictures of the corona can be made in the light of this and other strong coronal emission lines. The chief application of the coronagraph, however, is in the spectroscopy of the corona.

Spectroheliograph

The spectroheliograph is an instrument used to photograph the Sun in the light of a "single" wavelength—typically a narrow band of wavelengths centred on either 6563 angstroms or 3933 angstroms, emission lines of hydrogen and ionized calcium. An exit slit is placed in the focal plane of a solar spectrograph to isolate this narrow band of wavelengths. That slice of the solar image that falls on the entrance slit of the spectrograph appears as a monochromatic image at the exit slit. If the two slits are synchronously moved perpendicular to their length, the entire solar image may be scanned and recorded on a photographic plate or film. If this is done repeatedly, time-lapse motion pictures can be made. Daily photographs are taken with the spectroheliograph at many solar observatories throughout the world.

It is also possible to construct narrow-band filters that essentially do the same thing. Such filters with a pass band at 6563 angstroms of from one-eighth to 20 angstroms have been constructed; those used in coronal work have bandwidths of about two angstroms. By these techniques, activity on the solar disk, and in the chromosphere (prominences) and corona, can be repeatedly and routinely photographed.

The solar magnetograph, a device for measuring the magnetic field at a point on the solar disk, was developed (1952) at Mt. Wilson Observatory (now part of Hale Observatories) near Pasadena, California, by Horace W. and Harold D. Babcock. It is used daily at the 150-foot tower on Mt. Wilson to map the changing magnetic field over the solar disk precisely and in detail.

Meteor cameras. Bright meteor fireballs are rare at any one spot and astronomers have great difficulty in analyzing their paths through the atmosphere and their point of impact (if any), especially when the sources of information are the scattered and unreliable observations of laymen. The paths and solar system orbits of many faint meteors have been routinely derived from photographs obtained by using two widely separated wide-angle meteor cameras to photograph an overlapping region of the sky. By using a rotating shutter, the simultaneously photographed meteor trails appear as a series of dashes. The derived distances, velocities, and decelerations also give information about physical conditions in the upper atmosphere. A Super-Schmidt camera, developed for meteor photography, has a 12-inch (30-centimetre) aperture and a focal length of only eight inches (20 centimetres). A field of 55° is covered and exposure times, with fast films, are limited to only ten minutes by the sky

background. The focal surface in such a camera is highly curved, with a radius of curvature of only eight inches, and the film must be heated and molded to conform to this surface.

Radar detection

Meteors have been detected by radio and radar as well. A meteoroid leaves a trail of ionized air that reflects radar signals, thus making it possible to measure both range (distance) and direction out to the trail. Velocities can be derived from the rate at which these factors change. Simultaneous observations from two radar stations give the altitude, velocity, and direction of fall of the meteoroid. This technique is especially useful in that it permits daylight meteors and meteor showers to be observed.

Transit circle (meridian circle). The observational problem that dominated the thoughts of the majority of the astronomers during the 18th and 19th centuries was to establish a network of positions and proper motions of many thousands of stars with the highest possible precision and as free as possible from systematic errors, and to observe the changing positions of the Sun, Moon, and planets with respect to this fundamental network.

The basic instrument that was developed to accomplish this was the transit (or meridian) circle. This instrument consists of a refractor that may be moved only in the plane of the meridian by rotation about a horizontal axis fixed in the east–west direction. The meridian is that imaginary great circle on the celestial sphere that passes through the celestial poles, zenith, nadir (direction vertically downward), and the north and south points on the horizon. Stars are accurately timed as they cross the meridian and differences in time are differences in right ascension. A large vertical circle, precisely graduated and fixed to the telescope tube, can be read through microscopes. The position of the nadir can be fixed on this circle by observations of reflections of the cross wires from a mercury surface directly under the telescope. The location of the celestial pole, and thus the latitude of the observer, is determined from observations of stars above and below the pole from which the declination of any other observed star may be derived. Modern transit circles use sophisticated instrumentation often involving photographic and photoelectric recording, with positional errors of the order of 0.25 second of arc. Observations are normally limited to relatively bright stars that are visible in a low-power telescope.

Double telescopes. As will be noted below, radio telescopes have been usefully operated in pairs as an interferometer. An optical interferometer, serving as an intensity interferometer, was built in Australia by R.H. Brown and R.Q. Twiss. It is used to measure the angular diameters of a few of the brightest stars. Two optically crude 264-inch reflectors, each a mosaic of many small mirrors, are mounted on rails and can be separated up to an eighth of a mile. Starlight is focussed on the sensitive surface of a phototube in each telescope, and by correlating the outputs of the two phototubes it is possible to derive angular diameters as small as 0.0007 second of arc.

Examples of more conventional double telescopes are the 18-inch photovisual and 24-inch photographic refractors fixed side by side on the same mounting at the Royal Cape Observatory, near Cape Town, South Africa, and the double 16-inch Edinburgh reflectors in which one telescope is continuously monitoring a bright star in a cluster and the other is offset differentially by known amounts to observe photoelectrically the other cluster members.

Future of the optical telescope. In spite of the many advantages of radio telescopes (see below), the future of optical telescopes seems assured, since there will be a continuing need for new and highly specialized small instruments. Both visual and photographic astrometry (positional measurements) of the brightest half-million stars can be carried out most effectively with 6- to 8-inch refractors. The radial velocities, spectral types, colours, magnitudes, and polarizations of these brighter stars are incompletely known, even though they could be observed with high precision, using reflectors or Schmidt telescopes, or both, in the 24- to 36-inch range. The big, important problems in astronomy and cosmology seem to be the province of the larger reflectors and it is here that the greatest progress in optical astronomy may be expected. The useful life of a large reflector—unlike that of many radio telescopes—is certainly more than half a century, since this instrument can be continually modernized and improved by new auxiliary instrumentation, such as spectrographs and photoelectric photometers. As a result of improvements of this kind, the 20-inch telescope of today can make a variety of observations that would have been impossible with a 200-inch telescope as recently as the 1940s.

RADIO TELESCOPES

The Earth's atmosphere (including the ionosphere, the region of ionized air high above the Earth) is transparent to incoming electromagnetic radiation in two great wavelength windows. One, the optical window, which includes visible light, is from 3000 to about 140,000 angstroms; the other, the radio window, extends from a few millimetres to about 30-metres wavelength. Up until the 1930s only the optical window was used, with special emphasis on the photographic region from 3500 to 5000 angstroms and the partially overlapping visual region from about 4500 to 7000 angstroms.

In 1931 Karl Jansky, a U.S. engineer, was studying radio noise in the 15-metre range with a directional antenna. He received the first known extraterrestrial radio noise signals, which he correctly concluded came from the general direction of the galactic centre in the constellation Sagittarius. In 1937, also in the U.S., Grote Reber constructed a parabolic reflector antenna (dish) in his backyard in Wheaton, Illinois, and used it to scan the sky for radio noise. In 1940 he published the first radio map of the Milky Way; it was made at a wavelength of 1.9 metres. The directional properties of Reber's dish were such that he could receive signals in a conical beam about 12° wide. A lack of resolving power or the ability to distinguish between two closely spaced sources, inherent in the use of radio wavelengths, and the consequent inability to determine positions accurately, has plagued radio astronomy since its inception, especially in the crucially important matter of trying to identify radio sources with optical telescopes. Radio sources are extraordinarily weak and, with few exceptions, are very much weaker at centimetre wavelengths than at metre wavelengths. As with optical telescopes, the resolving power of a radio telescope increases linearly with its aperture, with the result that very large steerable dishes have been built, up to 20 times larger than their optical counterparts. The first of these was the Mark I 250-foot (76-metre) dish (paraboloid) at Jodrell Bank, Cheshire, near Manchester. Building this experimental telescope was a remarkable engineering achievement.

Jodrell Bank radio telescope

Another result has been that very large directional antennas called arrays have been constructed that look entirely different from any optical telescope (see ANTENNAS AND WAVE GUIDES). These antennas may be fixed or partially fixed (mounted on rails) to the Earth's surface and have large collecting areas measured in acres. Finally, a wide variety of very large unfilled aperture radio telescopes (telescopes in which portions of the aperture do not have signal-collecting equipment) have been built, which in an extreme form become very long base-line interferometers with the two elements (radio telescopes) observing the same object simultaneously, separated by an ocean at a distance of a few hundred million wavelengths. The resolving power of such a device is measured in thousandths of a second of arc, which is very much better than is possible with any optical telescope.

Dish antennas. Radio telescopes vary so greatly in design that none can be called truly typical, but one widely used type consists of a large metal parabolic dish reflector mounted on a support tower (see Figure 4). This dish can be rotated in azimuth (horizontal direction) about a vertical axis and (independently) in altitude (vertical direction) about a horizontal axis; this is called an altazimuth mounting. The drive system is controlled by a high-speed computer so that the telescope can be pointed

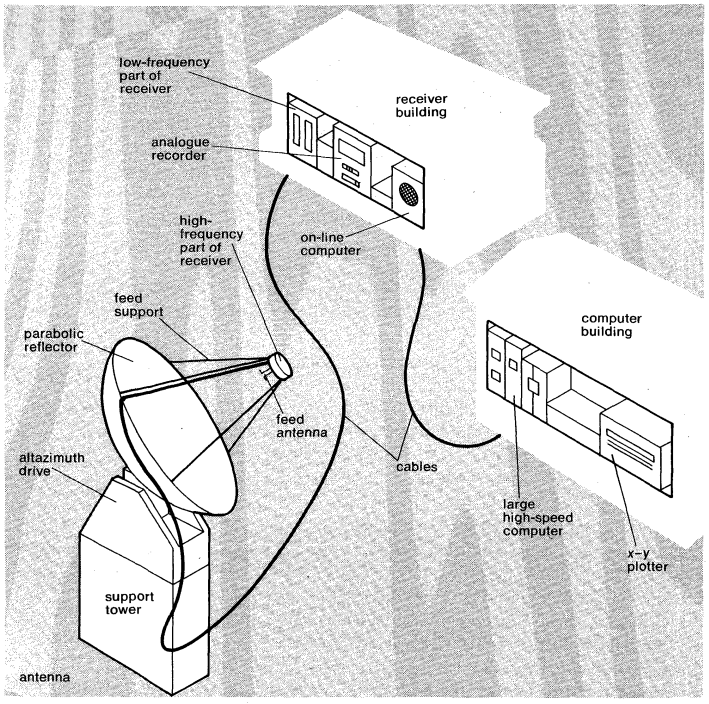

Figure 4: Radio telescope system.
From J.D. Kraus, *Radio Astronomy* (1966); McGraw-Hill Book Co.

accurately to any designated celestial position (right ascension and declination) and kept on that point as the Earth rotates. The drive may also be so controlled as to permit scanning in either right ascension or declination, or in other coordinates. The dish's surface reflects and focusses the incoming radiation to a small pickup device called a feed antenna. After preamplification at this point the amplified radio power is conveyed by cable to an adjacent building where it is further amplified, detected, and perhaps integrated over long periods of time. This may be done over a single band of frequencies, or simultaneously and independently over dozens of adjoining narrow bands of frequencies. The signals may be displayed on a moving chart or recorded in digital form on tapes for further processing by a high-speed computer. This entire system, not just the antenna, is called a radio telescope.

The largest fully steerable dish in the world is the Bonn 328-foot (100-metre) radio telescope located at Max Planck Institute for Radio Astronomy near Bonn, West Germany, and dedicated in 1970. The largest one in the Southern Hemisphere is the 210-foot (64-metre) dish located at Parkes, Australia. It is difficult to build such dishes rigidly enough so that they preserve their parabolic figure sufficiently well at all orientations, and the larger the dish the more it will deform under its own weight. If a surface deviates more than about a tenth of a wavelength from the ideal parabolic curve it will begin to lose efficiency; this deformation problem is therefore 100 times more severe at centimetre wavelengths than at metre wavelengths. The surface of the Jodrell Bank Mark I dish was renovated (1970–71) so that full operating efficiency could be achieved in the 21-centimetre region, a region that is important for observations of interstellar hydrogen. Recent theoretical studies have shown how a 100-metre dish may be constructed so that when shifted from one orientation to another gravitational forces will cause the surface to deform continuously from one paraboloid to another; this can be done down to wavelengths as short as one centimetre. Such dishes are called homologous reflectors; the Bonn dish is the first such and can be used effectively at one-centimetre wavelengths.

An important modification of the fully steerable dish is the large meridian-transit dish, a design first used by Reber. Such a device is first pointed in the desired direction along the meridian and then locked in place. It thus scans a specific strip in the sky as the Earth rotates. Observations on any given source with devices of this kind are limited to a few seconds or minutes as the source crosses or transits the meridian, but they are much less expensive to build, are much less complex, and can be designed and built quickly. The largest unit of this type in the world is the 300-foot- (90-metre-) diameter dish at Green Bank, West Virginia; it can be used at wavelengths as short as 20 centimetres. Another basic modification is the fixed spherical dish, the largest of which is the 1,000-foot (300-metre) spherical reflector at Arecibo, Puerto Rico, operated by Cornell University. The surface of this antenna is constructed of wire mesh anchored in a large natural depression in the ground. The radio waves are reflected from this surface to the focal point of the sphere, where a pickup arrangement or feed is located that is specially constructed to correct for spherical aberration. This feed swings from a truss that can be controlled to steer the beam anywhere within 20° of the zenith.

A modification of the fixed spherical dish is the fixed parabolic cylinder. An example is the 400-foot by 600-foot cylindrical reflector at the University of Illinois. The focal "point," or feed, of this survey-type telescope is the focal line of the parabolic cylinder and is some 600 feet (180 metres) long. Beam steering (adjusting the direction for maximum signal pickup) is in declination only and is controlled by adjustments of the pickup or feed arrangement.

Arrays. The work of English astronomers shortly after World War II clearly pointed to the need to survey the entire sky for radio sources with the highest possible positional accuracy, and shortly thereafter a wide variety of most ingenious antenna arrays were constructed, notably in Cambridge, England, and Sydney, Australia. In the metre-wavelength region receiver sensitivities and radio-source intensities are such that, with quite small antennas, more objects can be detected than can be resolved (separated) by the instrument. As the area of the antenna is increased the situation becomes worse, since the number of sources increases faster than the number that can be resolved. The emphasis then and into the 1970s has been on the construction of antenna arrangements that have a higher resolving power than their physical area would suggest. One such arrangement is the Mills Cross, developed in Australia by B.Y. Mills; at Cambridge University, a phase-switching interferometer has been used.

The Mills Cross

The original Mills Cross consists of two 1,500-foot- (460-metre-) long arms crossing at 90°, and containing 500 suitably designed antenna elements located above a wire mesh reflector (see Figure 5). The beam width is

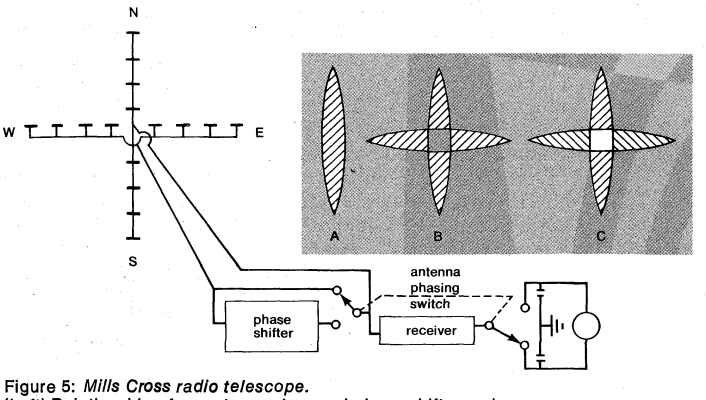

Figure 5: *Mills Cross radio telescope.*
(Left) Relationship of arms to receiver and phase shifter and (right) receiving pattern of (A) one arm, (B) two arms connected out of phase.

0.08° at a wavelength of about 3.5 metres. The north–south arm has a fan-shaped beam pattern 0.6° wide in the east–west direction, and the east–west arm has a similar pattern in the north–south direction (along the meridian). If the two arms are connected in phase (Figure 5b) a source at the intersection of the two beams will be strongly received. If the two arms are connected out of phase (Figure 5c) the signals from this same source will

completely cancel one another. A source located in a region of only one of the lobes will be picked up regardless of the phase relationships, but if the connections to the recorder are switched synchronously and rapidly with an antenna phasing switch, the signals from such a source will cancel out. A source at the intersection of the two lobe patterns will not. The result is a narrow pencil-like beam with the resolving power equivalent to a dish having a diameter equal to the extent of the arms. In practice, the beam can be shifted in declination by proper phasing of the dipoles in the north–south arm. The cross has the disadvantages that it operates satisfactorily only at the wavelength for which it was designed, it does not have the energy-collecting ability of a dish of the same size, and it cannot track a source. But these disadvantages do not impair its primary function as a high-resolution survey instrument.

A newer University of Sydney cross at Molonglo, Australia, has arms nearly one mile (1,600 metres) in length. Both arms consist of cylindrical parabolic reflectors about 40 feet (12 metres) wide. The beam is steered in declination along the meridian by tilting the east–west arm about its long axis and phase shifting the feeds of the stationary north–south element. The feed is arranged to provide simultaneous beams at a number of adjacent declinations. This makes it possible to survey the sky strip by strip in a reasonable length of time. The beam width is 3′ of arc at 408 megahertz (0.74 metre), a considerable improvement over the original Mills Cross. The new cross has distinguished itself in the discovery of more than half of the known pulsars, rotating neutron stars whose pulses provide extraterrestrial clocks accurate to one part in 100,000,000. Such objects were unknown and undreamed of at the time of its construction.

Phase-switching radio interferometer

The phase-switching radio interferometer is the basis for a wide variety of radio telescopes, including arrays used for surveys. To understand its operating principles, consider two antennas located on an east–west line and connected to the same receiver. Radiation from a point source will reach one antenna before the other, unless the source is on the meridian. If the path difference is an integral number of wavelengths (or zero), the signals will be in phase and the receiver output will be a maximum; if 180° out of phase the signals will cancel and there will be no output. As the source moves across the sky in its diurnal motion, the path difference will change continuously, causing variations in the receiver output. The result will then be variations of signal intensity on the recording chart, called interference fringes. The spacing of these fringes will depend on the declination of the source, the spacing being least for a source on the celestial equator (east–west plane perpendicular to a line between the celestial north and south poles). The fringes will be superimposed on the signals caused by background radiation. If, however, the phase of one of the antennas with respect to the other is periodically and rapidly reversed, and the output of the receiver is reversed in synchronism, a phase-switched interferometer results. Only the fringes are seen; the background radiation and the receiver noise are cancelled out. The right ascension of the source may be obtained by identifying and timing the central fringe maximum; the declination may be obtained from the spacing of the fringes. The amplitude of the fringe pattern is proportional to the intensity of the source.

If the source is not a true point source but is somewhat extended, part of it may be producing a maximum at the same time that another part is producing a minimum, and there will be a partial cancellation with consequent reduced amplitude of the fringe patterns. The larger the source with respect to the fringe pattern, the more complete this cancellation will be. The spacing of the fringes, however, is inversely proportional to the separation of the antennas; as the separation is increased, a point will eventually be reached—for an extended source—where the fringes will disappear. This principle is used to measure angular diameters of radio sources. The spacing of the fringes can also be changed by varying the wavelength at which observations are made.

The two antennas do not have to be on an east–west line nor do they have to be of the same size or type. One antenna may be large dish or array, while its much smaller companion is movable, perhaps on rails. For antenna separations of a few miles or more the transmission line to the common receiver may become too long and a radio link may be used. For a very long base-line interferometer the path length of radio waves through the Earth's changing ionosphere varies so much as to make it impractical to use a radio link. In such cases the signals are recorded separately on magnetic tapes at each station, timed with extreme precision by atomic clocks and brought together later for correlation and analysis.

More than two antennas may be used as an interferometer. If a number of equally spaced antennas are used the system is called a grating interferometer. If a sky survey is repeatedly made in which one (or both) of the arrays or dishes is shifted on rails day by day to a new location so as to eventually "fill in" a very large area, the resulting magnetic tape recordings may all be synthesized in a computer so as to simulate what would have been observed by a radio telescope with this very large area. This is called aperture synthesis. There is a second way in which a large aperture may be synthesized. If a line aperture is rotated, a two-dimensional aperture may be generated. It is possible to use the Earth's rotation to perform this type of synthesis. A single area of the sky may be observed continuously for many hours with a number of in-line dishes, and from the synthesis, made possible by high-speed computers, may be derived a detailed, high-resolution contour pattern of a relatively small area of the sky.

Radio-heliograph

The Culgoora (Australia) radioheliograph is a remarkable solar telescope that provides nearly instantaneous moving pictures of the activity in the Sun's atmosphere as exhibited at a frequency of 80 megahertz (3.75 metres). Ninety-six 45-foot (14-metre) dishes are equally spaced in a circle of 1.86-miles (3 kilometres) diameter. The signals received by each dish are brought to a central receiving station and processed electronically to form the final image; this image is displayed on a cathode-ray tube and photographed on motion picture film. This telescope has a total receiving area equivalent to a 400-foot (120-metre) dish but has the resolving power of a 9,800-foot (3,000-metre) dish. The field of view is about 2°—four solar diameters. Observations are made daily, even through clouds, and active regions on the Sun can be easily detected, kept under watch, and compared with photographic observations made with conventional optical telescopes.

AUXILIARY INSTRUMENTS

Almost all astronomical research is done photographically or photoelectrically, rather than visually. If a photographic plate is placed in the focal plane, a telescope becomes a large camera. A photograph provides a permanent record that can be measured and studied in detail at any convenient later date under optimum conditions. Astronomical exposure times are often measured in hours rather than in fractions of a second. Special guiding techniques must be used to keep the telescope centred on the object being photographed. A star image outside the field being photographed may be kept accurately centred on illuminated cross hairs; sometimes an auxiliary guiding telescope is used, firmly attached to the main telescope tube. Objects can be photographed that are many times fainter than can be seen by looking through the eyepiece. One photographic plate may contain a vast amount of information. For example, a plate from a large Schmidt telescope could easily have 1,000,000 star images and 100,000 galaxian images on it. In principle it is possible to derive not only the relative positions of all these objects but also their magnitudes. A more rewarding activity is to make a second plate at a later date—sometimes years later—and compare it with the first. This comparison will disclose those few very interesting stars that have moved, or have varied in brightness.

Exposure times

Spectroscopic instruments. The most commonly used photographic emulsion is insensitive to wavelengths long-

er than 5000 angstroms and is useful in ground-based research down to 3000 angstroms, the limit imposed by the atmosphere. There are a wide variety of other emulsions that can be used, usually with colour filters, in the visual, red, and infrared regions out to a limit of about 12,500 angstroms. These different emulsions also find their uses in spectroscopy, which occupies at least half of the available observing time of large reflectors (see also ASTRONOMICAL SPECTROSCOPY, PRINCIPLES OF; SPECTROSCOPY, PRINCIPLES OF).

In a prism spectrograph, the light of a star first passes through a slit located in the focal plane. The diverging beam is then collimated (made parallel) by a collimating lens. It then passes through a prism, or series of prisms, which disperses the light into a spectrum. Finally, the spectrum is brought to a focus on the photographic plate by a camera lens, the violet rays being bent more by the prism than the red rays. A grating spectrograph uses a reflection grating as the dispersing device. The grating is a glass plate coated with aluminum on which many parallel lines have been closely ruled. All of the parts of the astronomical spectrograph—slit, the two lenses, the prism or grating, and the photographic plate—must be attached to a rigid framework so that they do not shift during a long exposure. The interior of a spectrograph is often kept at a constant temperature. A comparison spectrum provides standards of known wavelength against which the stellar spectrum may be compared and measured. To preserve spectral purity, the width of the slit must be such that its monochromatic image on the plate is 0.015 to 0.020 millimetre—of the order of the resolving power of the emulsion. When high dispersion is desired it is necessary to use a long focal length camera lens, necessitating in turn a very narrow slit and loss of starlight. This can be overcome in part by using a very large collimated beam, hence a very large spectrograph. Such an instrument must, of necessity, remain stationary. It is placed at the coudé focus, since in this arrangement the focus does not move with the telescope.

Grating spectrograph

Spectroscopy is the observational basis of much of the astrophysics and stellar astronomy of today. The spectrograph can be used to determine the masses and radii of stars, as well as their distances and velocities. It can also be used to determine stellar rotations, temperatures, magnetic fields, chemical compositions, and other properties. The spectrograph has been used to establish the expanding nature of the universe and its approximate age; the radial velocities of galaxies have been measured spectroscopically at distances of several billion (thousand million) light-years.

Instruments for photoelectric photometry. The photoelectric cell is now of basic importance in another fundamental field in observational astronomy, photometry. Light striking certain alkali surfaces causes electrons to be emitted from that surface, the number of electrons emitted being strictly proportional to the intensity of the light. Light, in itself, is difficult to measure with high precision, especially in all of the various colours; an electric current can be precisely measured and the colour regions standardized by the use of appropriate filters. Photoelectric photometry came of age in 1946 with the introduction of the 1P21 photomultiplier tube, developed during World War II. This tube not only converts a beam of light into a beam of electrons but, through a process of secondary emission, it multiplies the original phototelectrons by factors of the order of a million within the small vacuum tube (see also ELECTRON TUBE). Photomultiplier tubes have been especially effective in the observations of tens of thousands of stars for their ultraviolet, blue, and "visual" magnitudes. Observations of the magnitudes and colours of the faintest photographable stars and galaxies are also possible. Red and infrared photocells have also found their uses, and very sensitive photoconductive (lead sulfide) cells have been successfully employed, especially at the University of Arizona, in connection with wavelengths up to and beyond 36,000 angstroms. A number of large observatories have developed photoelectric scanners that combine the spectroscope and the phototube. With such a device, the energy distribution of very faint objects, as well as the bright stars, can be obtained. A multichannel spectrometer that has been in operation at Mt. Palomar Observatory (now part of Hale Observatories) since 1969 allows simultaneous observations with 32 photomultipliers in 32 wavelength bands. A technique of this sort permits collection of data far more rapidly than if the channels were observed one at a time. Furthermore, simultaneous observations may be substantially more accurate, because of changing sky conditions.

Photomultiplier tube

OTHER DEVELOPMENTS

Telescopes above the Earth. The atmosphere influences astronomical observations in many undesirable ways. It enlarges the stellar images. It causes the intensity of the image, especially in a smaller telescope, to fluctuate rapidly (scintillate) and causes the image to change rapidly in its apparent position. The atmosphere completely absorbs the incoming radiation, hence the information it contains, in the wavelengths outside the optical and radio regions; within these regions the absorption may be so great, as in the case of overcast skies, or may vary so rapidly as to make useful observations impractical or impossible.

The optical region is chopped up in the infrared by strong absorbing bands of water vapour that mask, partially or completely, spectroscopic features of the planets and the Sun in this region. Sensitive infrared spectrographs have been operated successfully in aircraft at altitudes of 40,000 feet or higher, where this water-vapour absorption becomes negligible. Using airborne spectrographs, astronomers have scanned the solar spectrum out to 51,000 angstroms with high resolving power. Balloons have carried instruments and telescopes to altitudes up to 120,000 feet where the seeing is so good that the theoretical resolving power of the telescope has been reached. An unmanned balloon, Stratoscope II, launched in March 1970 by Princeton University astronomers, reached 80,000 feet. Direct photographs with a 36-inch reflecting telescope of the planet Uranus at a resolving power of 0".1 of arc showed for the first time the conspicuous limb (outer edge) darkening and a slight oblateness (flattening) of the disk. Earlier stratoscope flights had resulted in excellent photographs of the Sun.

Infrared spectrographs

Rocket observations made from just above the Earth's atmosphere, notably by astronomers at the U.S. Naval Research Laboratory, have extended the solar spectrum in detail to the one-angstrom X-ray region. Over a hundred X-ray sources have been discovered. Of the few that have been optically identified, the most exciting is the pulsating radio star, called a pulsar, in the Crab Nebula. This X-ray source pulsates 30 times a second, as in the optical and radio regions, but with much greater energy (see also X-RAY SOURCES, ASTRONOMICAL; PULSARS).

Although it is still in its infancy, space astronomy has already had spectacular successes. Instruments have been landed on the Moon and Venus. There have been a number of flights close to Venus and Mars. A Mars flyby provided the first direct photography and knowledge of the Martian craters. The side of the Moon facing away from the Earth has been thoroughly photographed and mapped. By the early 1970s there were a number of orbiting solar and astronomical observatories in operation and more were to come. Planning the instrumentation for these expensive "sites" must be based almost entirely on knowledge garnered by ground-based astronomy. Each new space observatory requires years of thoughtful preparation in order to make the most useful types of observations, particularly since observations involve new types of telescopes and instrumentation for previously little-used wavelengths. The instruments must be remote-controlled from distances of a few hundred miles to 100,000,000 miles. Amazingly detailed information—such as that obtained by a direct photograph—must be sent back to Earth over these same enormous distances. Telescopes and cameras must be protected from the intense unfiltered radiation of the Sun and from erosion by micrometeorites. A very high level of reliability must be built into their operation. Observations of the stars in the far ultraviolet have just begun, and if the

Remote-controlled instrumentation

history of radio astronomy is a guide, important discoveries can be expected with the opening up of this previously inaccessible wavelength region.

International cooperation. A number of telescopes and observatories have been built and operated on an international basis. Harvard University, Ireland, and North Ireland jointly financed the 32-inch Schmidt telescope located near Bloemfontein, South Africa; this observatory is operated by this group and other European countries. An Anglo-Australian 150-inch reflector will be erected in the early 1970s at Siding Springs, Australia. The Carnegie Institution of Washington, D.C., and radio astronomers of the Argentine jointly built twin 100-foot dishes near Buenos Aires. Six European countries are jointly building and operating the very large European Southern Observatory north of La Serena, Chile, and the nearby Cerro Tololo Inter-American Observatory is used by visiting U.S. astronomers, as well as by Chilean and other South American astronomers. There is still a great need for more radio telescopes in South America and South Africa, particularly to carry out very long base-line interferometry of southern sources jointly with Australia.

BIBLIOGRAPHY. The early history of the telescope is discussed in H.C. KING, *The History of the Telescope* (1955); and A. PANNEKOEK, *De Groei van ons Wereldbeeld* (1951; Eng. trans., *A History of Astronomy*, 1961). Modern instruments are treated in G.P. KUIPER and B.M. MIDDLEHURST (eds.), *Telescopes* (1960); G.R. MICZAIKA and W.M. SINTON, *Tools of the Astronomer* (1961); G.O. ABELL, *Exploration of the Universe* (1969); and J.D. KRAUS, *Radio Astronomy* (1966). Specific telescopes are described in the publications of the observatories operating them. See also current issues of the monthly periodical *Sky and Telescope*.

(J.B.I.)

Television

Television is the electrical transmission of pictures in motion and the simultaneous electrical transmission of the accompanying sounds. Additional discussion of the principles upon which such transmission is based will be found in the articles RADIO and ELECTRONICS; programming aspects are covered in the article BROADCASTING.

This article is outlined as follows:

I. History
- Mechanical systems
- Electronic systems
- The development of colour

II. Principles of picture transmission and reception
- Basic considerations
- The television picture signal
- Television camera tubes
  - Iconoscope
  - Orthicon
  - Image orthicon
  - Vidicon
  - Flying spot scanner
- Video amplification
- The television channel
- The television transmitter
- The television receiver
- Television picture tubes

III. Compatible colour television
- Basic principles—United States system
- European colour systems
- Colour camera and picture tube
- Colour transmitter and receiver

IV. Applications of television
- Television recording
  - Commercial systems
  - Home recording and playback systems
- Television broadcasting
  - Transoceanic broadcasts
  - Community antenna television (CATV) systems
- Closed-circuit television

The purpose of a television system is to extend the senses of vision and hearing beyond their natural limits. Television systems are designed, therefore, to embrace the essential capabilities of these senses, with appropriate compromises between the quality of the reproduction and the costs involved. The aspects of natural vision that must be considered in a television system include the ability of the human eye to distinguish the brightness, colours, details, sizes, shapes, and positions of the objects in the scene before it. The aspects of hearing include the ability of the ear to distinguish the pitch, loudness, and distribution of sounds. The television system must also be designed to override, within reasonable limits, the effects of interference and to minimize visual and aural distortions in the transmission and reproduction processes. The particular compromises adopted for public television service (*i.e.*, by broadcast means) are embodied in the television standards adopted and enforced by the responsible government agency in each country.

Television technology deals with the fact that human vision employs many hundreds of thousands of separate electrical circuits, in the optic nerve from the retina to the brain, to convey simultaneously in two dimensions the whole content of the scene on which the eye is focussed, whereas in electrical communications it is feasible to employ only one such circuit (*i.e.*, the broadcast channel) to connect the transmitter and the receiver. This fundamental disparity is overcome in television by a process of image analysis and synthesis, whereby the scene to be televised is first translated into an electrical image, and the latter is then broken up into an orderly sequence of electrical impulses that are sent over the channel one after the other. At the receiver the impulses are translated back into a corresponding sequence of lights and shadows, and these are reassembled in their correct positions on the viewing screen.

How television differs from the human eye

This sequential reproduction of visual images is feasible only because the visual sense displays persistence; that is, the brain retains the impression of illumination for about 0.1 second after the source of light is removed from the eye. If, therefore, the process of image synthesis occurs within less than 0.1 second, the eye is unaware that the picture is being reassembled piecemeal, and it appears as if the whole surface of the viewing screen were continuously illuminated. By the same token, it is then possible to re-create more than ten complete pictures per second and to simulate thereby the motion of the scene so that it appears to be continuous.

In practice, to depict rapid motion smoothly, it is customary to transmit from 25 to 30 complete pictures per second. To provide detail sufficient to accommodate a wide range of subject matter, each picture is analyzed into 300,000 or more elementary details. This analysis implies that the rate at which these details are transmitted over the television system exceeds 4,000,000 per second. To provide a system suitable for public use and also capable of such speed has required the full resources of modern electronic technology.

I. History

MECHANICAL SYSTEMS

Early ideas for the realization of television assumed the transmission of every picture element simultaneously, each over a separate circuit (as, for example, a system suggested by George Carey of Boston in 1875); but in about 1880 the important principle—subsequently adopted in all forms of television—of rapidly scanning each element in the picture in succession, line by line and frame by frame, with reliance on persistence of human vision, was proposed, notably by W.E. Sawyer in the United States and Maurice Leblanc in France. This established the possibility of using only a single wire or channel for transmission.

In 1873 the photoconductive properties of selenium were discovered; that is, the fact that its electrical conduction varied with the amount of illumination. This appeared to provide an important clue to the secret of practical television and led in 1884 to a patent by Paul Nipkow in Germany of a complete television system. The distinctive feature of Nipkow's system was the spirally apertured rotating disk that provided, at both sending and receiving ends, a simple and effective method of image scanning. Until the advent of electronic scanning, all workable television systems depended on some form or variation (*e.g.*, mirror drums, lensed disks, etc.) of the mechanical sequential scanning method exemplified by the Nipkow disk.

Nipkow system

As illustrated in Figure 1, the image to be televised is focussed on a rotating disk having square apertures arranged in a spiral. As the disk rotates, the outermost aperture traces out a line across the top of the image, and the light passing through the aperture varies in direct proportion to the light and shade (*i.e.*, brightness values) of that line of the image as it is traversed by the aperture. When the outermost aperture has passed over the image, the next inner aperture traces out another line, parallel to and immediately below the line just traced. The changes in the light passing through the second aperture represent, in sequence, the brightness values present in the image along this second line. As the disk continues to rotate, successive lines are traced out, one beneath the other, until the whole area of the image has been explored, one line at a time. The process is repeated with each rotation of the disk; the more apertures, and hence lines, the greater the detail that can be analyzed.

In this way the detail of the whole image is sequentially explored in an orderly manner. The light passing through the apertures enters a photoelectric cell that translates the sequence of light values into a corresponding sequence of electric values. These are transmitted over a single circuit to the receiver, where the electrical impulses cause light to be produced by a lamp (such as a gas-discharge lamp) capable of reproducing the sequence of light values. The light from the lamp is projected onto the surface of a disk similar to that at the transmitter. This disk must rotate in precise synchronism, and, by a scanning process the reverse of that already described, the brightness values are reassembled in their proper positions and the original image is reproduced. Provided the rotation is at sufficient speed, persistence of vision enables the eye to see the image as a whole rather than as a series of moving points. The need for exact synchronism between camera and receiver scanning speeds is fundamental not only to the mechanical system that has been described above but to every television system.

Selenium, when used as the photosensitive material for the photoelectric cell, had a serious handicap; its response to changes of light was very slow. Researches in Germany resulted (1913) in a potassium hydride-coated cell with both an improved sensitivity and the ability to follow rapid changes of light. This made possible for the first time a practical working system.

In 1897 K.F. Braun of Germany had introduced a cathode-ray tube with a fluorescent screen; that is, a screen that produced visible light when struck by a beam of electrons. The Russian scientist Boris Rosing in 1907 suggested its use in the receiver of a television system that, at the camera end, made use of mirror-drum scanning. Rosing succeeded in transmitting and reproducing some crude geometrical patterns and so ranks as an important pioneer.

In 1904 the English physicist J.A. Fleming invented the two-electrode valve; the American inventor Lee De Forest added the grid in 1906 and made amplification possible, another essential step toward practical television.

In 1908 came a most remarkable contribution by the Scottish electrical engineer A.A. Campbell Swinton, who outlined a method that, in all essentials, is the basis of modern television. Lack of amplifiers and other difficulties confined this to what Swinton called "an idea only," but he clarified and elaborated it in an address to the Röntgen Society of London in 1911. He proposed, in essence, the use of cathode-ray tubes, magnetically deflected, at both camera and receiver. In the former was a mosaic screen of photoelectric elements; the image of the scene to be transmitted was focussed onto this screen, the back of which was then discharged by a cathode-ray beam tracing out a line-by-line scanning sequence. Swinton's brilliant ideas were too advanced for early application, and it was left to others to put them into practice many years later.

Swinton's proposals

Meanwhile, experimenters in Europe and the United States were trying to make a less ambitious beginning. The neon gas-discharge lamp, produced by D.M. Moore of the U.S. in 1917, made it possible to vary the light intensity at the receiver by varying the electrical input to the neon lamp, thus in effect producing modulated light. It was adopted by J.L. Baird in England and C.F. Jenkins in the United States, both of whom in 1923 began experimenting with mechanical methods using the Nipkow principle. In 1926 Baird gave the first demonstration of true television by electrically transmitting moving pictures in halftones. These pictures were formed of only 30 lines, repeating approximately ten times per second. The results, though inevitably crude—flickering badly and with a dim receiver screen a few inches high—nevertheless became the start of television as a practical technology and did much to stimulate further research, while also forming the basis of some experimental broadcasting in England between 1929 and 1935.

ELECTRONIC SYSTEMS

Mechanical systems lacked sensitivity, as became progressively manifest with attempts to increase the number of lines and thus the degree of definition of the pictures. Swinton and others had pointed out that television pictures, for good quality and definition on a screen of reasonable size, would need to be analyzed into at least 100,000 and preferably 200,000 elements. Since the number of elements is approximately equal to the square of the number of lines, it can be seen that any system using 30 or even 100 lines would be inadequate—300 being more nearly the minimum. Although mechanical systems were with difficulty made to operate on 200 and more lines, thought increasingly turned toward the greater potential of electronic methods. A most important landmark was V.K. Zworykin's patent, first filed in 1923, for the iconoscope camera tube. Later, he constructed such a tube; and by 1932 the Radio Corporation of America (RCA), with an improved cathode-ray tube for the receiver, demonstrated all-electronic television (initially on 120 lines), so proving the soundness of Swinton's theoretical ideas. The compactness and convenience of the electronic camera were remarkable, and its sensitivity, greatly aided by the unique "storage" feature of the iconoscope, was comparable with motion-picture cameras of the time.

Continuing work on electronic systems was greatly stimulated. In the United States the development was mainly carried out in the RCA laboratories; very soon the number of scanning lines was increased to 343, and other improvements followed rapidly. German investigators also were active, especially in the development of high-vacuum cathode-ray tubes. By 1935 a regular broadcasting service had begun in Germany, though with medium definition only—180 lines. In The Netherlands, too, the Philips Laboratories took up television research.

In Great Britain, Electric and Musical Industries (EMI) set up in 1931 a television research group under Isaac (later Sir Isaac) Shoenberg, a dynamic and farsighted man of long experience in the field of radio transmission in both the Soviet Union and England. He fostered the evolution of a complete and practical system based on: (1) a camera tube known as the Emitron—an advanced version of the iconoscope—and (2) an improved high-vacuum cathode-ray tube for the receiver. The team produced by 1935 a complete and practical system, including all of the complex electronics surrounding the camera and receiver tubes, as well as the intervening control and amplifying circuits. Shoenberg saw the need to establish a system that would endure for many years, since any subsequent changes in basic standards—particularly the number of scanning lines and their repetition rate—could give rise to severe technical or economic problems. He therefore proposed the use of 405 lines with 50 frames per second, and interlaced scanning (see below) to give 25 pictures per second without flicker—ambitious for those days, but fully justified by events. The government authorized the British Broadcasting Corporation to adopt these standards, as well as the complete EMI system, from the outset of the world's first public high-definition service, which was launched in London in 1936. Until 1964 they formed the sole basis of the British service, later being gradually superseded by the international 625-line standard. Initially, and for a short time only, the system was under comparison with alternate

broadcasts from a 240-line, 25-picture system developed by the Baird company. The latter employed mechanical scanning methods in the camera and suffered from lack of sensitivity as well as other limitations.

By the mid-1930s electronic television was fast advancing in all its aspects. Important questions were the settling of basic standards (number of lines and frames per second) before the introduction of public broadcasting services in the United States and elsewhere, though these questions were not everywhere fully resolved until about 1951. The United States soon adopted a picture repetition rate of 30 per second, while in Europe it became 25. These two standards have been perpetuated, and all the countries of the world use one or the other, though technical advances have now obviated the original need for disparity. The arguments in relation to the number of lines were based on the need for an effective compromise between, on the one hand, adequate picture definition, and, on the other, a frequency bandwidth that could be technically and economically acceptable. World standardization has never been achieved, though for new television services all countries are adopting one of only two standards, namely, 525 lines per picture at 30 pictures per second—the United States standard—and 625 lines at 25 pictures per second, usually known as the European standard. Complications arise when programs are transmitted between countries using different standards.

United States and European standards

Regular television broadcasting began in the United States in 1941, but most other countries, apart from Great Britain, were not ready to begin services until the 1950s, when television was widely introduced throughout the world. When wartime restrictions governing the manufacture of receivers were removed in 1946, the stage was set in the United States for a rapid growth of the television broadcasting industry. By 1949 there were 1,000,000 receivers in use; the 10,000,000 mark was passed in 1951 and the 50,000,000 mark eight years later. About half of that number were in use in the 50 other nations that by then had established regular program services.

By the early 1970s, receivers in use throughout the world totalled about 275,000,000; about 93,000,000 were in the United States, 18,000,000 in the United Kingdom, 8,000,000 in Canada, 25,000,000 in Japan, 28,000,000 in the Soviet Union, 12,000,000 in France, 17,000,000 in West Germany, and 10,000,000 in Italy.

Technical advances have been continuous, particularly the great improvements in camera tubes (*e.g.*, the image orthicon and the Vidicon, the latter of which was at last able effectively to exploit the photoconductivity principle) that were made from 1945 onward (see below *Television camera tubes*). By the early 1950s technology had progressed so far, and television had become so widely established, that the time was ripe to tackle in earnest the problem of creating television images in natural colours.

THE DEVELOPMENT OF COLOUR

Colour television was by no means a new idea, since its attraction and possibility early engaged the imaginations of inventors. A German patent in 1904 contained the earliest proposal, while in 1925 Zworykin filed a patent disclosure for an all-electronic colour television system. The first practical demonstration of television in colour was given by Baird in 1928; he used mechanical scanning with a Nipkow disk having three spirals of 30 apertures, one spiral for each primary colour in sequence. The light source at the receiver comprised two gas-discharge tubes, one of mercury vapour and helium for the green and blue colours, and a neon tube for red. In 1929 H.E. Ives and colleagues at Bell Telephone Laboratories transmitted 50-line colour television images between New York City and Washington, D.C.; this also was a mechanical method, but one that sent simultaneously the three primary colour signals over three separate circuits. In the same year Frank Gray, also of Bell Laboratories, applied for a patent that described a method of transmitting two or more signals over a single channel; this introduced important new principles that were to be the foundation of modern (compatible) colour television as it was developed about 20 years later.

It soon became apparent that two basic approaches to colour television were possible. One was the frame-by-frame sequential transmission of signals corresponding to each of the three primary colours. This method was in most respects relatively simple to achieve but involved an increased rate of scanning in order to avoid colour flicker, with resulting transmission difficulties from both the higher bandwidth and the inability to use existing black-and-white receivers to reproduce any pictures originated in colour. This kind of system is therefore usually described as noncompatible. The alternative approach—practically much more difficult, even daunting at first—recognized the advantage to be derived from a colour transmission system in which signals representing the three primary colours were transmitted simultaneously and which could also be compatible with existing black-and-white transmissions. Such a system would mean that any pictures originated in colour could still be receivable (in black and white) on a black-and-white receiver.

Compatible and noncompatible colour television

In 1938 Georg Valensi of France pioneered the path to compatible colour television when he patented a method that enabled

> the output from a single transmitter to be received not only by television receivers provided with the necessary equipment but also by the ordinary type of receiver which is more numerous and less expensive and which reproduces the pictures in black and white.

Although Valensi's proposals have not been precisely adopted in practice, they were influential in later approaches to the problem of compatibility.

Experimental work on colour (on high-definition standards) was taken up in both Great Britain and the United States during the late 1930s. Similar methods were explored by Baird in Great Britain and Peter Goldmark of the Columbia Broadcasting System (CBS) in the United States, both of whom demonstrated sequential systems using rotating colour filters on the cameras and the receivers. The CBS method was used for some experimental broadcasts before World War II, and these were resumed in 1951 as a service authorized by the Federal Communications Commission (FCC). Public interest was small, however, and after only a few months the broadcasts were abandoned.

Serious attention was then given by the National Television Systems Committee (NTSC) in the United States to the development of a fully compatible simultaneous system. The committee's work led in 1953 to a system capable of operating within the current black-and-white standards and was accepted by the FCC. The essentials of this system, known as the NTSC system, have formed the basis of colour systems throughout the world. The basic principle is the combination of two image transmissions: one carrying information about the brightness, including the finest details of the televised scene, to which black-and-white receivers respond; the other, of coarser structure, carrying the colour information. This second component has no appreciable effect on black-and-white sets, while colour receivers use a combination of the two image transmissions. Since the ability of the human eye to perceive detail is most acute when viewing white light, the brightness component of the colour images carries the impression of fine detail, and the superimposed coarse colour information does not substantially alter the sharpness of the resulting colour picture.

In the United States, public broadcasting using the NTSC system began in 1954. The same system was adopted by Japan, where it came into service in 1960. Other countries favoured modifications of the NTSC system. One such was devised by W. Bruch of the German Telefunken Company; known as PAL (phase alternation line), this comprised a small but subtle variant of the NTSC method. The other, SECAM (*système électronique couleur avec mémoire*), differing rather more radically, had been put forward earlier by Henri de France in Paris. Both alternatives aimed at reducing the sensitivity of the colour system to certain forms of distortion encountered in transmission and broadcasting, and had special application to European conditions. Countries were divided in their preferences: in 1967 Great Britain and the Federal Republic of

The SECAM system

Germany began colour broadcasting using the PAL system, while in the same year France and the Soviet Union also introduced colour, adopting the SECAM system. One or the other of these three systems was being adopted by all countries in the 1970's.

Colour television is technically much more complex than black and white. In the early 1970s most cameras embodied either three or four pickup tubes, while in the receiver a shadow-mask, three-gun, cathode-ray tube, first demonstrated in 1950, formed a successful and widely adopted type of display device for domestic purposes. Widespread purchase of colour receivers began in the United States in 1964. By the early 1970s, more than 40,000,000 colour sets were in use throughout the world; about 31,000,000 were in the United States, 5,000,000 in Japan, 1,300,000 in West Germany, 1,000,000 in Canada, and 750,000 in the United Kingdom. Beginning in 1971, purchases of colour receivers in the United States exceeded sales of domestically manufactured black-and-white sets. (T.H.B.)

II. Principles of picture transmission and reception

BASIC CONSIDERATIONS

The quality and quantity of television service are limited fundamentally by the rate at which it is feasible to transmit the picture information over the television channel. As noted above, in modern practice the televised image must be capable of being dissected, within a few hundredths of a second, into more than 100,000 picture elements. This implies that the electrical impulses corresponding to the picture elements must pass through the channel at a rate as high as several million per second. Moreover, since the picture content may vary from simple close-up shots having little fine detail to comprehensive distant scenes in which the limiting detail of the system comes into play, the actual rate of transmitting the picture information varies from time to time, from a few impulses per second to several million per second. The television channel must be capable, therefore, of handling information over a continuous band of frequencies several million cycles wide. This is testimony to the extraordinary comprehension of the sense of sight. Hearing is comparatively crude. The ear is satisfied by impulses that can be carried over a channel only 10,000 cycles wide.

In the United States, the television channel occupies a width of six megacycles (6,000,000 hertz, or cycles per second) in the radio spectrum. This is 600 times as wide as the channel used by each standard sound broadcasting station. In fact, each television station uses nearly six times as much spectrum space as all the commercial amplitude-modulation (AM) sound broadcasting channels combined. Since each television station must occupy so much spectrum space, few channels are available in a given locality. Moreover, the quantity of service is in conflict with the quality of reproduction. If the detail of the television image is to be increased, other parameters of the transmission being unchanged, the channel width must be increased proportionately, and this decreases the number of channels that can be accommodated in the spectrum. This fundamental conflict between quality of transmission and number of available channels dictates that the quality of reproduction shall just satisfy the typical viewer under normal viewing conditions. Any excess of performance beyond this ultimately would result in a restriction of program choice.

Flicker. The first requirement to be met in image analysis is that the reproduced picture shall not flicker, since flicker induces severe visual fatigue. Flicker becomes more evident as the brightness of the picture increases. If flicker is to be unobjectionable at brightness suitable for home viewing during daylight as well as evening hours (25 to 100 footlamberts), the successive illuminations of the picture screen should occur no fewer than 50 times per second. This is approximately twice the rate of picture repetition needed for smooth reproduction of motion. To avoid flicker, therefore, twice as much channel space is needed as would suffice to depict motion. The same disparity occurs in motion-picture practice, in which satisfactory performance with respect to flicker requires twice as much film as is necessary for smooth simulation of motion.

Projecting each picture twice

A way around this difficulty has been found, in motion pictures as well as in television, by projecting each picture twice. In motion pictures, the projector interposes a shutter briefly between film and lens while a single frame of the film is being projected. In television, each image is analyzed and synthesized in two sets of spaced lines, one of which fits successively within the spaces of the other (Figure 2). Thus the picture area is illuminated twice during each complete picture transmission, although each line in the image is present only once during that time. This technique is feasible because the eye is comparatively insensitive to flicker when the variation of light is confined to a small part of the field of view. Hence flicker of the individual lines is not evident. If the eye did not have this fortunate property, a television channel would have to occupy about twice as much spectrum space as it now does.

It is thus possible to avoid flicker and simulate rapid motion by a picture rate of about 25 per second, with two screen illuminations per picture. The precise value of the picture-repetition rate used in a given region has been chosen by reference to the electric power frequency that predominates in that region. In Europe, where 50-hertz power is the rule, the television picture rate is 25 per second (50 screen illuminations per second). In North America the picture rate is 30 per second (60 screen illuminations per second) to match the 60-hertz power that predominates there.

The higher picture-transmission rate of North America allows the pictures there to be about five times as bright as those in Europe for the same susceptibility to flicker, but this advantage is offset by a 20 percent reduction in picture detail for equal utilization of the channel.

Image structure. The second aspect of performance to be met in a television system is the detailed structure of the image. A printed halftone engraving may possess several million halftone dots per square foot of area. Such reproductions are intended for minute inspection, and the dot structure must not be apparent to the unaided eye even at close range. Such fine detail would be a costly waste in television, since the television picture is viewed at comparatively long range (five to 15 feet, or 1.5 to 4.5 metres, in the typical home setting) and the picture area is not greater than about two square feet (1,800 square centimetres). Under these conditions, a picture structure of about 200,000 halftone elements is a suitable compromise. This detail is about equal to that provided by 16-millimetre home motion pictures and substantially exceeds that of the eight-millimetre film widely used for amateur cinematography.

Picture shape. The third item to be selected in image analysis is the shape of the picture. This has been standardized universally as a rectangle the width of which is one-third longer than its height. This 4:3 ratio (aspect ratio) was originally chosen to match the dimensions of standard 35-millimetre motion-picture film (prior to the advent of the wide-screen cinema) in the interest of televising film without waste of frame area. The width of the screen rectangle is greater than its height, as in the proscenium of a theatre, to accommodate the horizontal motion that predominates in virtually all televised events.

Scanning. The fourth determination in image analysis is the path over which the image structure is explored at the camera and reconstituted on the receiver screen. In the original Nipkow disk, this path was a series of arcs of circles (Figure 1). In modern television, the pattern is a series of parallel straight lines, each progressing from left to right, the lines following in sequence from top to bottom of the picture frame. The exploration of the image structure proceeds at a constant speed along each line, since this provides uniform loading of the transmission channel under the demands of a given structural detail, no matter where in the frame the detail lies. The line-by-line, left-to-right, top-to-bottom dissection and reconstitution of television images is known as scanning, from its similarity to the progression of the line of vision in reading a page of printed matter. The agent that disassembles

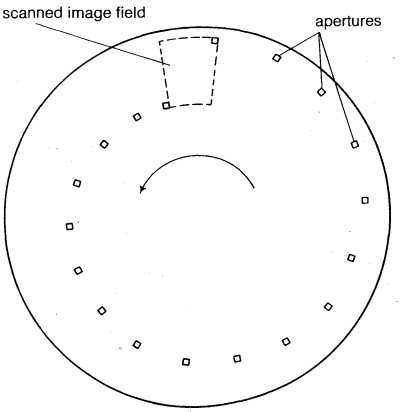

Figure 1: Nipkow disk for an 18-line picture (see text).

the light values along each line is called the scanning spot, and the path it follows is the scanning pattern, or raster.

The geometry of the modern scanning pattern is shown in Figure 2. It consists of two sets of lines. One set, marked A, is scanned first, and the lines are so laid down

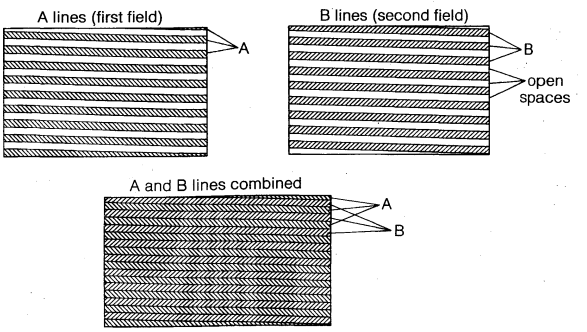

Figure 2: Interlaced scanning, combining two separate scanning cycles (fields) to form a complete picture (see text).

that an equal empty space is maintained between lines. The second set, marked B, is laid down after the first and is so positioned that its lines fall precisely in the empty spaces of set A. The area of the image is thus scanned twice, but each point in the area is passed over once. This is known as interlaced scanning, and it is used in all the television broadcast services of the world. Each set of alternate lines is known as a scanning field; the two sets together, comprising the whole scanning pattern, are known as a scanning frame. The repetition rate of field scanning is standardized in accordance with the frequency of electric power, as noted above, at either 50 or 60 fields per second. Corresponding rates of frame scanning are 25 and 30 frames per second. The localities for various scanning standards are listed in the Table.

Interlaced scanning

The total number of lines in the scanning pattern has been set to provide a maximum pictorial detail of the order of 200,000 picture elements. Since the frame area is four units wide by three units high, this figure implies a pattern of about 520 picture elements in its width (along each line) and 390 elements in its height (across the lines). This latter figure would imply a scanning pattern of about 400 lines, were it not for the fact that many of the picture details, falling in random positions on the scanning pattern, lie partly on two lines and hence require two lines for accurate reproduction. Scanning patterns are designed, therefore, to possess about 40 percent more lines than the number of picture elements to be reproduced on the vertical direction. Actual values in use in television broadcasting in various regions are 405 lines, 525 lines, 625 lines, and 819 lines per frame, as listed in the Table. These values have been chosen to suit the frequency band of the channel actually assigned in the respective geographical regions.

The scanning spot is made to follow the paths shown in Figure 2 by imparting two repetitive motions to the spot simultaneously (Figure 3). One is a horizontally directed back-and-forth motion. The spot is moved at constant speed from left to right and then returned as rapidly as possible, while extinguished and inactive, from right to left.

Television Systems of the World

region or country	number of lines per frame	number of pictures per second	maximum detail (picture elements per frame)	available picture bandwidth (MHz)	channel bandwidth (MHz)
United Kingdom	405–625	25	130,000–210,000	3–6	5–8
North America, South America, Japan	525	30	130,000	4	6
Europe, Australia, Africa, Eurasia	625	25	210,000	6	8
France and French dependencies	625–819	25	210,000–440,000	6–10.4	8–14

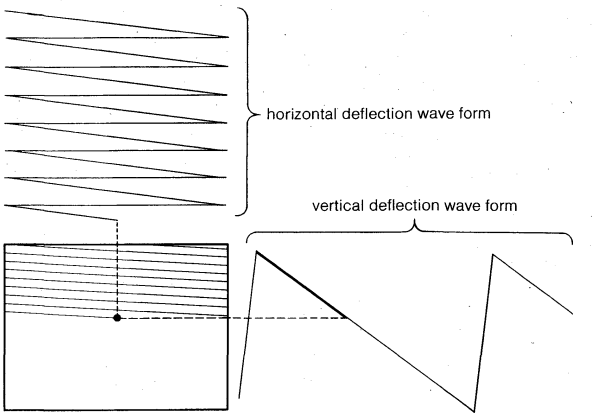

Figure 3: Scanning pattern and wave forms for horizontal and vertical deflection in sequential parallel-line scanning.

Simultaneously, a vertical motion is imparted to the spot, moving it comparatively slowly from the top to the bottom of the frame. This motion spreads out the more rapid left-to-right scans, forming the first field scan of alternate lines and empty spaces. When the bottom of the frame is reached, the spot moves vertically upward as rapidly as possible, while extinguished and inactive. The next top-to-bottom motion then spreads out the horizontal line scans so that they fall in the empty spaces of the previously scanned field. Precise interlacing of the successive field scans is facilitated if the total number of lines in the frame is an odd number. All the numbers of lines used in ordinary transmissions (see the Table) were so chosen.

The return of the scanning spot from right to left and from bottom to top of the frame, during which it is inactive, consumes time that cannot be devoted to transmitting picture information. This time is used to transmit synchronizing control signals that keep the scanning process at the receiver in step with that at the transmitter. The time lost during retracing of the spot proportionately reduces the actual number of picture elements that can be reproduced. In the 525-line scanning pattern used in the United States, about 15 percent of each line is lost in the return motion, and about 35 out of the 525 lines are blanked out while the spot returns from bottom to top of two successive fields. The scanning area actually in use for reproduction of the picture contains a maximum of about 435 picture elements along each line and has 490 active lines, capable of reproducing 350 picture elements in the vertical direction. The frame can accommodate at maximum, therefore, about 350×435 or 152,000 picture elements. The detail-transmission capacity of the scanning patterns of other systems is listed in the Table.

Time needed for scanning

The time taken by the scanning spot to move over the active portion of each scanning line is of the order of 0.00005 second (50 microseconds). In the United States system, 525 lines are transmitted in one-thirtieth of a second, which is equivalent to about 64 microseconds per line. Up to 15 percent of this time is consumed in the

horizontal retrace motion of the spot, leaving 54 microseconds (54×10^{-6} seconds) for active reproduction of as many as 435 picture elements in each line. This represents a maximum rate of $435 \div 54 \times 10^{-6} \cong 8{,}000{,}000$ picture elements per second.

Two picture elements can be approximately represented by one cycle of the transmission signal wave. The signal must therefore be capable of carrying components as high as 4,000,000 hertz (four megahertz, MHz). The United States six-megahertz television channel provides a sufficient band of frequencies for this (plus an additional two megahertz for transmission of the sound program, to protect against interference, and to meet the requirements of vestigial side-band transmission [see below *The television channel*]).

The relationship between the ideal and actual scanning patterns is shown in Figure 4. The part shown as darker is lost as the spot retraces. The remaining area of the pattern is actively employed in analyzing and synthesizing the picture information and is adjusted to have the four by three dimensions of the standard aspect ratio. In practice, some of the active area may also be hidden behind the decorative mask that surrounds the picture tube of the receiver, as shown by the dashed line.

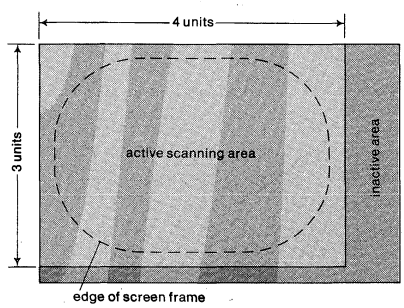

Figure 4: Active and inactive portions of scanning pattern.

THE TELEVISION PICTURE SIGNAL

The signal wave form (the sequence of electrical impulses that makes up a television picture signal) embodies all the picture information to be transmitted from camera to receiver screen as well as the synchronizing information required to keep the receiver and transmitter scanning operations in exact step with each other. The television system, therefore, must deliver the wave form to each receiver as accurately and as free from blemishes as possible. Unfortunately, almost every item of equipment in the system (amplifiers, cables, transmitter, the transmitting antenna, the radio wave in space, the receiving antenna, and the receiver circuits) conspires to distort the wave form or permits it to be contaminated by "noise" or interference.

Distortion and interference

Among the possible distortions in the signal producing the picture are: (1) failure to maintain the rapidity with which the wave form rises or falls as the scanning spot crosses a sharp boundary between light and dark areas of the image, producing a loss of detail or smear in the reproduced image; (2) the introduction of overshoots, which cause excessively harsh outlines; and (3) failure to maintain the average value of the wave form over extended periods, which causes the image as a whole to be too bright or too dark.

Throughout the system, amplifiers must be used to keep the television signal strong relative to the random electrical currents (noise) that are everywhere present. These random currents, caused by thermally induced motions of electrons in the circuits, cause interference having a speckled appearance, known as "snow." Pictures received from distant stations are subject to this form of interference, since the radio wave is then so weak that it cannot override the random currents in the receiving antenna. Interference of a striated type may be caused by the signals of stations other than that to which the receiver is tuned. Care in the design of the receiver tuner and amplifier circuits is necessary to minimize such interference,

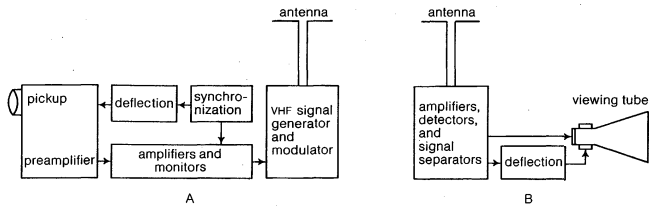

Figure 5: Essential elements of (A) transmitter, and (B) receiver.

and channels must be allocated to neighbouring communities at sufficient geographical separations and frequency intervals to protect the local service.

The television signal wave form can be conveyed within transmitting and receiving apparatus, and over short distances, by wires and cables. For transmission over greater distances, however, as in network connections and over the air, the signal wave form must be imposed on a high-frequency carrier wave. The broadcast transmitter, for example, is actually a generator of very-high-frequency or ultrahigh-frequency radio waves. When such a current (known as the carrier current) is passed through the transmitting antenna, it produces a radio wave of the same frequency that travels through space and induces a weaker, but otherwise identical, current in the receiving antenna.

At the transmitter the picture signal wave form changes the strength, or amplitude, of the high-frequency carrier current by a process known as amplitude modulation. The alternations of the carrier current are thus constrained to take on a succession of amplitudes that match the shape of the signal wave form (see also RADIO). The functions of the television system that generate, transmit, and utilize the television signal wave form are shown in Figure 5. The scene to be televised is focussed by a lens on a camera tube, within the camera. A scanning spot within the camera tube is passed over the image in the scanning pattern of Figure 3, its motion being controlled by the synchronization generator. The latter equipment also renders the scanning spot inactive during its retrace motions and generates the necessary synchronization signals. The camera produces the signal wave form; the synchronizing signals are then added, and the complete signal wave form is established. The signal is then amplified as required, by amplifiers capable of operating over the wide band of frequencies (from a few hertz to 4,000,000 or 5,000,000 hertz) necessary to preserve the precise shape of the wave form. In a transcontinental network, the signal may pass through more than 100 such amplifiers in tandem before it finally reaches the transmitter. There the wave form is amplified to a high power level. Concurrently, the carrier current is generated by other circuits of the transmitter. The signal wave form and carrier current are then combined in the modulator, which imposes the wave form on the carrier. The modulated carrier current may then be further amplified (typically to 10,000 watts or more) and finally passed through the transmitter antenna, which radiates the television radio wave. A similar but enormously weaker current is induced in any receiving antenna within the service area. Reception of excellent quality is possible when the power picked up by the receiving antenna is as low as 0.00000001 (10^{-8}) watt. The power picked up from a distant station may be as low as 10^{-11} watt; but even this low power is capable of producing reception of acceptable quality.

Amplifying the wave form

The transmitter antenna must be as high and in as exposed a location as possible, since the radio waves tend to be intercepted by solid objects, including the Earth's surface at the horizon. Reception beyond the horizon is possible, but the signal at such distances becomes rapidly weaker as it passes to the limit of the service area.

In the receiver, the current from the antenna is passed through a tuner that separates it from other currents of different carrier frequencies that may be present from other stations. The desired current is then amplified in several successive amplifier stages, while still in the amplitude-modulated form. Passage through a detector fol-

lows. The picture signal wave form is thereby recovered and is passed through still another amplifier before passing to the picture tube. The picture screen displays a scanning spot the brightness of which is controlled by the picture signal. Simultaneously, the signal is applied to synchronizing circuits, which abstract from it the synchronizing signals. These are used to control the motion of the scanning spot so that it traces out the scanning pattern in precise synchronism with the motion of the scanning spot in the camera.

Transmission and reception of the accompanying sound program are accomplished by apparatus similar to that used for frequency-modulated (FM) radio broadcasting. The carrier frequency for this sound channel is usually spaced 4.5 megahertz from the picture carrier and is separated from the picture carrier in the receiver by appropriate circuitry.

The amount of amplification conferred on the picture and sound currents by a typical television receiver is extremely large. When tuned to a station at a distance of 50 miles (about 80 kilometres), the power picked up by the antenna is typically 10^{-11} watt, as noted above, whereas the signals fed to picture tube and loudspeaker, after amplification, are of the order of one watt; that is, the receiver produces a faithful amplification of the order of 100,000,000,000 times.

TELEVISION CAMERA TUBES

Common elements of television camera tubes

The television camera tube is an electronic device that converts an optical image into a sequence of electrical impulses; *i.e.*, it produces the television picture signal. Three types of television camera tube are in wide use: the image orthicon, the orthicon, and the Vidicon. These devices differ in detail but have in common the following elements: (1) a photosensitive surface (on which the scene is focussed) that converts each light value into a corresponding value of electric charge and forms thereby an electrical image; (2) a means of storing the electrical image—that is, a way of causing the charge to accumulate during the interval of several hundredths of a second between successive scannings of each line in the image; (3) an electron beam, formed in an electron gun and deflected over the electrical image, following the scanning pattern of Figure 2; and (4) a mechanism for producing an electrical current or voltage that is proportional at every instant to the electric charge accumulated at the point passed over by the electron beam at that instant.

Means are also provided for extinguishing the scanning beam during its retrace motions, so that no television signal is then generated. A television pickup device that does not store the electrical image is the flying spot scanner.

Iconoscope. The iconoscope is no longer used, since it is not as sensitive as the image orthicon and its images are subject to uneven shading and flare. But it is well suited to introduce the concepts of electron image storage and scanning in simple form. The iconoscope is housed in a dipper-shaped, vacuum-tight glass envelope, as shown in Figure 6. Within the wide end is a flat sheet of mica. A uniform metallic coating (the signal plate) is placed on the rear surface of this sheet, away from the image. The front surface of the mica is covered with a mosaic comprised of many hundreds of thousands of tiny globules of silver.

During the manufacture of the tube the mosaic is treated with cesium vapour and oxygen, so that each globule has a surface of the oxides of silver and cesium. This combination of elements provides a surface from which electrons are readily liberated, by the photoelectric effect, when light falls on it. Since the globules are insulated from each other and from the signal plate by the mica, the loss of electrons under illumination causes the globules to assume and hold a positive charge, the charge on each globule being proportional to the strength of the illumination falling on it and to the time it has been illuminated.

When an optical image is focussed on the mosaic, the whole surface assumes a distribution of positive charge that matches the distribution of light in the image, and

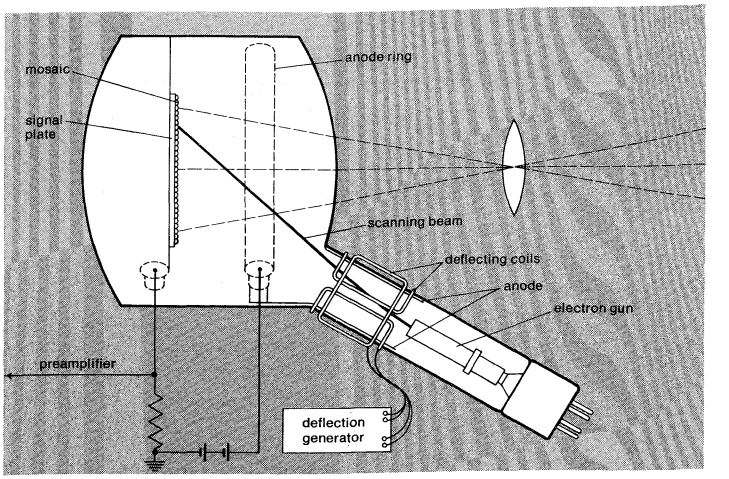

Figure 6: Iconoscope camera tube.

the amount of charge at each point steadily increases, if the optical image is maintained, until the scanning spot passes over the globule at that point.

Iconoscope scanning spot

The scanning spot of the iconoscope is formed by a narrow beam of electrons, shot out of an electron gun in the side arm of the tube. On its way to the mosaic, this beam passes within two sets of electromagnet coils. Currents like those of Figure 3 are passed through these coils, causing the beam to be deflected horizontally at a rapid rate and vertically at a slower rate. The extent of the horizontal motion is adjusted from top to bottom of the mosaic, so that the pattern traced out by the electron beam on the mosaic is a rectangular pattern like that in Figure 2.

As each globule is passed over by the beam, it undergoes a sudden change in electrical potential, the amount of the change being proportional to the light falling on it. The change in potential of the globule is transferred through the mica support to the signal plate behind it, the globule and plate forming in effect the plates of an electrical capacitor. Thus, as the beam passes in succession over the globules lying along a given scanning line, the signal plate assumes a succession of voltages (the picture signal) that match the corresponding succession of light values along that line. The signal plate is connected to an amplifier, external to the iconoscope, that increases the strength of the picture signal.

The phenomenon of charge storage, by which the magnitude of the electrical image is continually increased between successive scannings of each line, is of the utmost significance in television technology. The Nipkow disk (and other non-storage television pickup devices) employs only the light that is present at a given point in the image at the instant the scanning spot passes over that point. Since in modern television the area of the scanning spot is only about one two-hundred-thousandth of the area of the scanning pattern, only this small fraction of the light of the image can be used. But when the image charge is stored in increasing amount for the full interval between successive scannings of a given point, the accumulated charge is then theoretically about 200,000 times the single charge that can be accumulated during the time the beam moves through its own width.

Orthicon. The orthicon camera tube was the first successor to the iconoscope. This tube (Figure 7) is housed in a cylindrical glass structure, on one end of which the optical image is focussed on a mosaic. This mosaic is similar to that of the iconoscope but is made up of a precise array of squares of photosensitive material, formed by evaporation of the material onto a transparent support. A transparent metal coating on the reverse side serves as the signal plate.

The optical image is focussed on the signal plate, passing through it and the support to the mosaic, where it creates and stores a positive electrical charge image, in the manner of the iconoscope. The electron beam is directed toward the mosaic and deflected by electromagnet coils

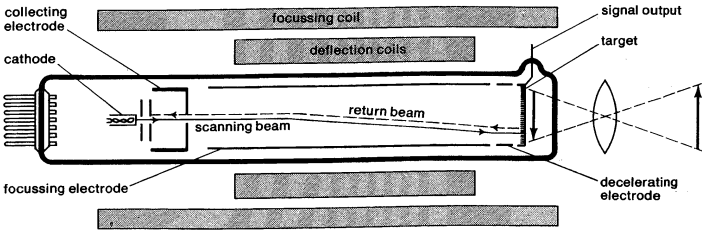

Figure 7: Orthicon camera tube.
By courtesy of RCA

surrounding the tube, so that it passes over the mosaic in the standard interlaced scanning pattern. The electrons are accelerated by a low voltage, so that they strike the mosaic with a low velocity and do not liberate any substantial number of secondary electrons. Instead, the negative electrons in the beam land on the mosaic squares, neutralizing the stored positive charge and ultimately building up a negative charge. The electrons in the beam are then repelled and return to the opposite end of the tube, where they are removed by a positive collecting electrode that surrounds the electron gun. The change in electrical potential, undergone by each mosaic element as its charge is neutralized, is transferred by capacitive action, as in the iconoscope, to the signal plate. The latter thereby undergoes a succession of voltage changes that constitute the picture signal and that are passed to amplifier stages external to the tube.

Image orthicon. The image orthicon is the most highly developed of the television camera tubes and is perhaps the most remarkable electronic device in existence. In its most refined form, its sensitivity to light is phenomenally great. It can respond to light levels far below those capable of exposing motion-picture film or affecting the eye itself. Less sensitive image orthicon tubes are used in broadcasting practice; they serve to produce satisfactory image quality under any light levels likely to be encountered in studio and outdoor scenes.

Sensitivity of the image orthicon

The image orthicon (Figure 8) is similar to the orthicon but includes an additional electrical-imaging process and contains a high-gain amplifier based on the phenomenon of electron multiplication. It is housed in a cylindrical glass envelope having an enlarged section on one end, which is closed by an optically flat glass plate on the inside of which is deposited a continuous photosensitive coating (photocathode). The optical image is focussed through the glass support onto the coating, where it liberates electrons by photoelectric emission, the emission at each point matching the amount of light in the image at that point.

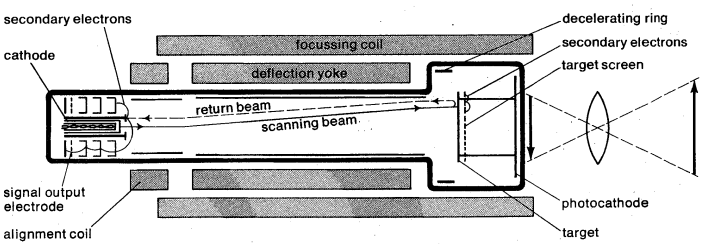

Figure 8: Image orthicon camera tube.

The liberated electrons stream away from the photosensitive surface, through the enlarged cylindrical portion of the tube, until they encounter the target electrode, a piece of very thin glass of uniform thickness. The streams of electrons induce secondary emission of electrons from the surface of the glass, and the latter are collected by a fine-mesh screen that lies parallel and close to the glass target; the streams of image electrons pass through it on their way to the target.

The changes in electrical potential induced by secondary emission are transferred to the opposite face of the target, where they are scanned by the electron beam. Because of the characteristics of the glass target, the fine structure of the electrical image is preserved throughout the scanning interval. Moreover, as the streams of electrons from the photocathode continue to fall on the target glass, the intensity of the electrical image continually increases; that is, storage of charge occurs.

Both the photocathode and the target are continuous surfaces and in themselves contribute no structural limit to the detail of the image. The fine-mesh screen that collects the secondary electrons from the target could, however, impose a limit on detail, and consequently the holes in the screen must be substantially smaller than the scanning spot. Actually, the screen possesses nearly 1,000,000 holes in an area of 1.5 square inches (about ten square centimetres), compared with the roughly 200,000 picture elements into which the image is dissected.

The stored charge image on the reverse side of the target is scanned by an electron beam that, like that of the orthicon, is accelerated at lower voltage and is actually slowed down before hitting the target, so that the scanning electrons have a very low velocity when they strike the target. Consequently, the secondary emission caused by scanning is negligible.

In the standard interlaced scanning pattern the electron beam is magnetically deflected over the electrical image by coils external to the tube. When the beam electrons hit the target, they neutralize the stored positive charge, as in the orthicon, and when equilibrium is reached, further electrons may not land on that spot. Thereafter, the electrons in the beam are turned around at the target and return to the vicinity of the electron gun at the other end of the tube. At this juncture the action differs from that of the orthicon. Instead of taking the picture signal from a signal plate at the target, the return beam of electrons is used. The number of electrons returning from each point in the scanning pattern is conditioned by the prior positive charge neutralization occurring at that point. Consequently, the return beam constitutes a picture signal current.

The return beam

When the return beam reaches the opposite end of the tube, it is passed through an amplifier structure that contributes greatly to the sensitivity of the tube. This structure, known as an electron multiplier, comprises several metal pinwheels. The surfaces of the pinwheel vanes are treated to emit secondary electrons copiously when the return-beam electrons hit them; more electrons are emitted than strike the surface. The pinwheel shape causes the secondary electrons liberated at the first vane to be deflected to the next vane in the same structure, where still further emission of secondary electrons occurs. The magnified stream then passes to the next pinwheel structure to the rear, where the process repeats and the electron stream is cumulatively multiplied. The amplified current at the final stage of the electron multiplier is passed out of the tube to a conventional vacuum-tube or transistor amplifier.

Vidicon. The Vidicon camera tube, first used in the early 1950s, was the first camera device to employ the phenomenon of photoconductivity. In its early form it was sluggish (objects in motion were reproduced with noticeable smear), and hence it was limited to industrial applications. Later versions were free of this defect, and the Vidicon now enjoys wide use in broadcasting, in monochrome and colour service. The tube elements (Figure 9) are contained in a cylindrical glass envelope, substantially smaller than the image orthicon and hence more adaptable to portable cameras. At one end, a transparent

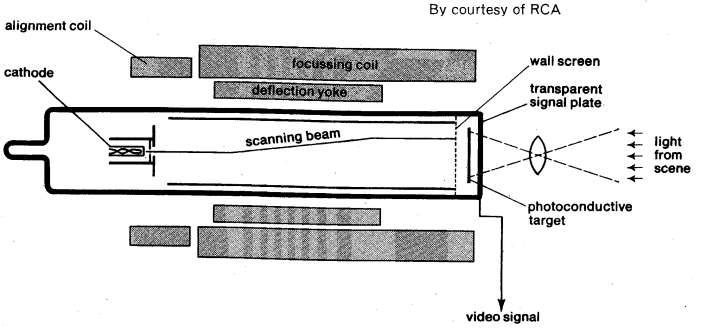

Figure 9: Vidicon camera tube.

metallic coating serves as a signal plate. Deposited directly on the signal plate is a photoconductive material (*e.g.*, a compound of selenium or lead) the electrical resistance of which is high in the dark but becomes progressively less as the amount of light increases.

The optical image of the Vidicon

The optical image is focussed on the end of the tube and passes through the signal plate to the photoconductive layer, where the light induces a pattern of varying conductivity that matches the distribution of brightness in the optical image. The conduction paths through the layer allow positive charge from the signal plate (which is maintained at a positive voltage) to pass through the layer, and this current continues to flow during the interval between scans. Charge storage thus occurs, and an electrical charge image is built up on the rear surface of the photoconductor.

An electron beam, deflected in the standard interlaced scanning pattern, scans the rear surface of the photoconducting layer. The beam electrons neutralize the positive charge on each point in the electrical image, and the resulting change in potential is transferred by capacitive action to the signal plate, from which the television signal is derived.

The electron beam scanning spot size imposes the only limit on the image detail. It is possible, therefore, to derive an image of broadcast quality (200,000 or more picture elements) from a photosensitive area no larger than 0.2 square inch (1.3 square centimetres). This permits the use of small and comparatively inexpensive lenses, with correspondingly large depth of focus for a given lens opening. The internal structure of the tube is very simple, and this, with its small size, makes it adaptable to a wide range of camera arrangements in broadcasting, industrial, and military applications.

Flying spot scanner. Another form of television pickup device, used to transmit images from film transparencies, either still or motion pictures, is the flying spot scanner (Figure 10). The light source is a cathode-ray tube in which a beam of electrons, deflected in the standard scanning pattern, impinges on a fluorescent phosphor surface. The beam produces thereby a spot of light that moves in the scanning pattern on the face of the tube. The light from this spot is focussed optically on the surface of the photographic film transparency to be televised. As the image of the spot moves, it traces out a scanning line across the film, and the amount of light emerging from the other side of the film at each point is determined by the transparency of the film at that point. The emerging light is collected and caused to enter a photoelectric cell, which produces a current proportional to the light entering it.

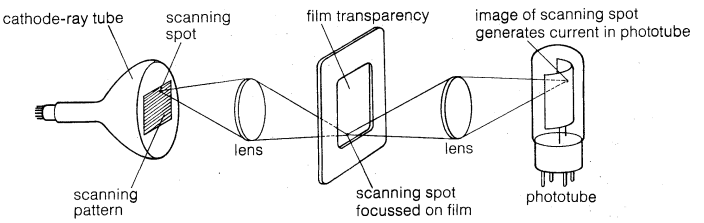

Figure 10: Flying spot camera system.

This current thus takes on a succession of values proportional to the successive values of film density along each line in the scanning pattern; that is, it is the picture signal current. No storage action occurs, so the light from the cathode-ray tube must be very intense and the optical design very efficient to secure noise-free reproduction. The flying spot system may be used with motion-picture film if an optical immobilizer is used (see below *Television recording*).

VIDEO AMPLIFICATION

The picture signal wave form produced by the television camera is initially very weak, of the order of a few hundredths of a volt, and is therefore vulnerable to the random currents (noise) present in the succeeding transmission circuits. Immediately upon leaving the camera, therefore, the signal must be strengthened, and this process must be repeated at intervals throughout the transmission to the picture tube at the receiver. The strengthening process, known as video amplification, occurs in electron tubes or transistors (see ELECTRONICS).

Video amplifiers, of both the tube and transistor varieties, can be designed to cover a remarkably comprehensive range, amplifying a picture signal comprising any combination of frequency components lying from ten hertz to as high as 10,000,000 hertz. This implies not merely that the amplitudes of all such components are uniformly increased but that their relative times of occurrence are strictly preserved. Only if these requirements are met can the fine structure, as well as the gross outline, of the picture signal wave form be preserved from the camera to the receiver picture tube.

THE TELEVISION CHANNEL

When the band of frequencies in the picture signal is imposed on the high-frequency broadcast carrier current in the modulator of the transmitter, two bands of frequencies are produced, above and below the carrier frequency (as described in the article RADIO). The side bands are identical in frequency content; that is, both carry the complete picture signal information. One of the side bands is superfluous and, if transmitted, would wastefully consume space in the broadcast spectrum. Therefore, the major portion of one of the side bands is removed, and the other is transmitted in full. Complete removal of the superfluous side band is possible, but this would complicate receiver design. Hence, a vestige of the unwanted side band is retained to serve the overall economy of the system. This technique is known as vestigial side-band transmission. It is now universally employed in all of the television broadcasting systems of the world.

Side bands

The television channel for a black-and-white picture (monochrome) contains the picture carrier frequency, one complete picture side band, and a vestigial portion of the other picture side band. In addition, the carrier for the sound transmission and its side bands is included within the channel. Since the band of frequencies needed to convey the sound is very much narrower than that needed for the picture, it is feasible to include both sound-carrier side bands. Frequency modulation (see RADIO) is employed to transmit the sound information. To avoid mutual interference between sound and picture, the picture and sound side bands must not overlap. Moreover, some space must be allowed at the edge of the channel to avoid interference with the transmissions of stations occupying the adjacent channels.

These requirements are met in the television channel shown in Figure 11. Each contains the following bands: 4.5 megahertz for the fully transmitted picture side band, 1.25 megahertz for the vestige of the other picture side band, 0.15 megahertz for the sound carrier and its two side bands, and the remaining 0.1 megahertz to guard against overlap between picture and sound and between channels. In compatible colour transmissions an additional colour-information signal, shown as the chrominance subcarrier, is included within the fully transmitted picture side band (see below).

The television channels of the United States are assigned 6 megahertz each in the following segments of the spectrum: VHF (very-high-frequency) channels 2, 3, and 4,

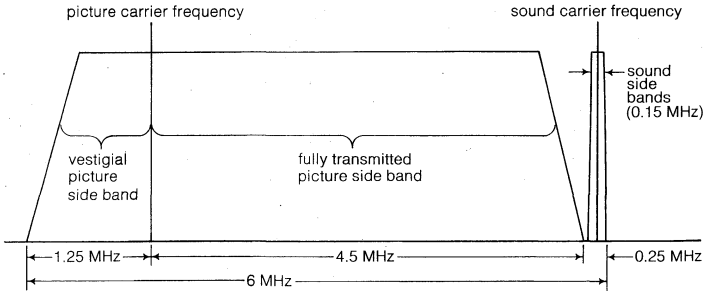

Figure 11: Allocation of television channel for monochrome broadcasting in the United States.

54–72 megahertz; 5 and 6, 76–88 megahertz; 7 through 13, 174–216 megahertz; and the UHF (ultrahigh-frequency) channels, 14 through 83, 470–890 megahertz. These channels are allocated to communities according to a master plan established and administered by the Federal Communications Commission. No more than seven VHF channels are provided in any one area (this number is allocated only to New York and Los Angeles). Many smaller cities must be content with one or two channels.

In the major cities of Europe, fewer channels (typically two to four per city) are provided, because the higher population density and closer spacing of cities precludes more assignments within the available spectrum and because fewer program services are offered. In most countries the programs are produced solely by government agencies, in contrast to the commercial sources of the United States. Program services competitive to the government outlets exist in Great Britain, Canada, Japan, and in parts of South America. Tokyo, for example, has seven channels.

THE TELEVISION TRANSMITTER

The task of the television transmitter is to produce the picture and sound carriers, and their side bands, in conformity with the arrangement of the channel assigned to it. The electronic equipment that performs these functions is shown in Figure 12. The central element is the synchronizing generator, which controls the timing of the scanning of the camera and produces the synchronizing impulses. It applies three control functions to the camera: timing for horizontal (line-by-line) deflection of the scanning beam; timing for vertical deflection (field-by-field); and the blanking impulses that extinguish the scanning spot during its retrace motions. The camera, under the control of the synchronizing generator, produces the picture signal without the synchronizing impulses. The picture signal is passed first through a preamplifier within the camera housing and then through additional amplifiers in the control room of the studio, where it is combined with the synchronizing impulses. At this point, it is customary to inspect the quality of the reproduced image by feeding the signal to a monitor that displays the image on a picture tube. The monitor screen is viewed by the program director and operating personnel so that shortcomings can be corrected.

The synchronizing generator

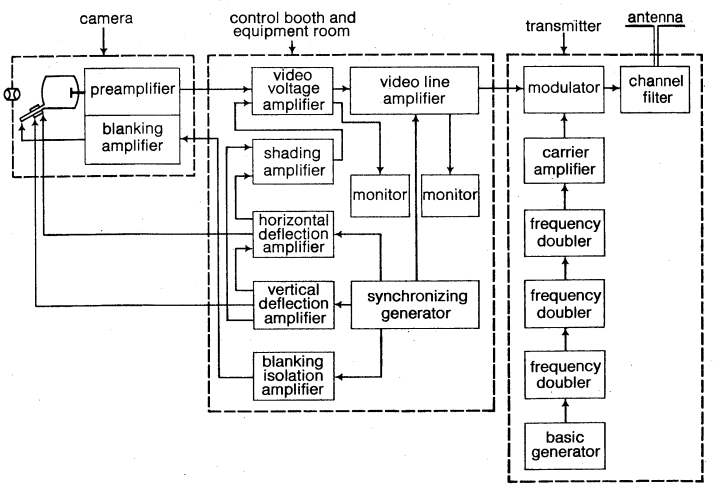

Figure 12: Block diagram of monochrome television transmitter.

The adjusted picture and sound signals are fed to the network that interconnects stations or, in local broadcasts, to cables leading directly to the transmitter. The latter is usually located at some distance from the studio to permit placing the transmitting antenna in as favourable a location as possible with respect to the intended service area.

The transmitter performs two functions: generation of the carrier currents for picture and sound, and imposition of the sound and picture signals on the respective carrier currents. Precautions are taken to assure that the frequencies of the carrier waves have precisely the values assigned to the channel in use. The carrier currents have frequencies accurate to roughly one part in 200,000.

The carrier current and the picture signal are combined in the modulator. The modulated carrier contains two identical side bands; the major portion of one of these (that occupying frequencies below the carrier) is removed by a wave filter, and the remaining part, plus the picture carrier current and the fully transmitted side-band currents, is passed to the transmitting antenna. A similar arrangement produces the sound carrier current and its side bands. These are also fed to the transmitting antenna, which is designed to direct the radiated waves along the surface of the Earth and to minimize radiation toward the sky.

THE TELEVISION RECEIVER

At the receiver the sound and picture carrier waves are picked up by the receiving antenna, producing currents that are identical in form to those flowing in the transmitter antenna, but much weaker. These currents are conducted from the antenna to the receiver by a lead-in transmission line, typically a one-half-inch (12-millimetre) ribbon of polyethylene plastic in which are embedded two parallel copper wires. This form of transmission line is capable of passing the carrier currents to the receiver, without relative discrimination between frequencies, on all the channels to which the receiver may be tuned.

At the antenna terminals of the receiver, the picture and sound signals are at their weakest, so particular care must be taken to control noise at this point. The first circuit in the receiver is a radio-frequency amplifier, particularly designed for low-noise amplification. The channel-switching mechanism (tuner) of the receiver connects one of several individual circuits to this amplifier, each tuned to its respective channel. This amplifier magnifies the voltages of the incoming picture and sound carriers and side bands in the desired channel by about ten times, and it discriminates by a like amount against the transmissions of stations on other channels.

From the radio-frequency amplifier, the signals are passed to a mixer that transposes the frequencies of the sound and picture carriers to values better suited to the subsequent amplification processes. The transposed frequencies (intermediate frequencies) remain the same, no matter what channel the receiver is tuned to. In typical receivers they are located in the band from 41 to 47 megahertz.

Since the tuning of the subsequent amplifiers (intermediate-frequency amplifiers) need not be changed as the channel is switched, they can be adjusted for maximum performance in the 41–47-megahertz range. Two to four stages of such amplification are used in tandem, increasing the voltage of the picture and sound carriers by a maximum of 25 to 35 times per stage, representing an overall maximum amplification of the order of 10,000 times. The amplification of these intermediate-frequency stages is automatically adjusted, by a process known as automatic gain control, in accordance with the strength of the signal, full amplification being accorded to a weak signal, less to a strong signal. After passage through the intermediate amplifiers, the sound and picture carriers and their side bands reach a relatively fixed level of about one volt, whereas the signal levels applied to the antenna terminals may vary, depending on the distance of the station and other factors, from a few millionths to a few tenths of a volt.

Automatic gain control

From the last intermediate amplifier stage, the carriers and side bands are passed to another circuit, known as the video detector. An averaging circuit or filter then forms, from the detector output, (1) a picture signal, which is a close replica of the picture signal produced by the camera and synchronizing generator in the transmitter, and (2) a frequency-modulated sound signal. Thus far, the picture and sound signals are handled simultaneously in each amplifier and detector circuit. Both may be passed through a video amplifier, if necessary, which increases their voltage by about ten times.

At this point the picture and sound signals are separated. Another video amplifier passes the picture signal to the picture tube, where it controls the brightness of the scanning spot. Simultaneously, the picture signal wave form is passed to a circuit (the synchronizing signal separator) that selects the blank periods in the wave form containing the superimposed synchronizing signals.

Finally, the sound signal is passed through a sound intermediate amplifier and frequency detector (discriminator, or ratio detector) that converts the frequency modulation back to an audio signal current. This current is passed through one or two additional audio-frequency amplifier stages to the loudspeaker.

Meanwhile, at the synchronizing signal separator the synchronizing signals are passed through circuits that separate the horizontal and vertical synchronizing impulses. They are then passed, respectively, to the horizontal and vertical deflection generators, which produce the currents that flow through the electromagnet deflection coils, causing the scanning spot of the picture tube to be deflected across the viewing screen in the standard scanning pattern.

The synchronizing signals control the timing of these currents, causing the scanning spot of the receiver to move synchronously with that of the camera. Pains are taken in the synchronizing action of the receiver to prevent the scanning motion from being disturbed by interference, since such disturbances would displace the picture elements from their correct positions in the pattern. It is one of the achievements of the modern television system that the scanning pattern is stably reproduced even when the picture signal is so weak and infested with noise that the picture elements themselves are barely recognizable. This fact is of particular significance in colour transmissions.

In addition to the amplifiers, detectors, and deflection generators described above, the receiver contains two power-converting circuits. One of these (the low-voltage power supply) converts the alternating current from the power line into the direct current needed for the tube or transistor circuits; the other (high-voltage power supply) produces the high voltage, typically 15,000 to 20,000 volts, needed to create the scanning spot in the picture tube.

Viewer's receiver controls

The receiver controls commonly provided for adjustment by the viewer are: (1) the channel switch, which connects the required circuits to the radio-frequency amplifier and superheterodyne mixer to amplify and convert the sound and picture carriers of the desired channel; (2) a fine-tuning control, which precisely adjusts the superheterodyne mixer so that the response of the tuner is exactly centred on the channel in use; (3) a contrast control, which adjusts the voltage level reached by the picture signal in the video amplifiers, producing a picture having more or less contrast (greater or less range between the blacks and whites of the image); (4) a brightness control, which adjusts the average amount of current taken by the picture tube from the high-voltage power supply, thus varying the overall brightness of the picture; (5) a horizontal-hold control, which adjusts the horizontal deflection generator so that it conforms exactly to the control of the horizontal synchronizing impulses; and (6) a vertical-hold control, which performs the same function for the vertical deflection generator. Additional adjustments provided for the serviceman include adjustments for the height and width of the picture (magnitudes of the deflection currents) and adjustments (linearity controls) to secure precisely uniform rates of horizontal and vertical scanning to avoid distortion of the shapes of the objects in the picture. Colour receivers have additional controls for hue (tint) and intensity (vivid versus pastel), as described below.

TELEVISION PICTURE TUBES

A typical television picture tube is illustrated in Figure 13. The tube is a highly evacuated, funnel-shaped structure. The viewing screen is located inside the tube face, a slightly curved glass plate that closes the wide end of the funnel. The screen itself, in monochrome receivers, is typically composed of two fluorescent materials, such as silver-activated zinc sulfide and silver-activated zinc cadmium sulfide. These materials, known as phosphors, glow with blue and yellow light, respectively, under the impact of high-speed electrons. The phosphors are mixed, in a fine dispersion, in such proportion that the combination of yellow and blue light produces white light of slightly bluish cast. A water suspension of these materials is settled on the inside of the face plate of the tube during manufacture, and this coating is overlaid with a film of aluminum sufficiently thin to permit the bombarding electrons to pass without hindrance. The aluminum provides a mirror surface that prevents the backward-emitted light from being lost in the interior of the tube and reflects it forward to the viewer.

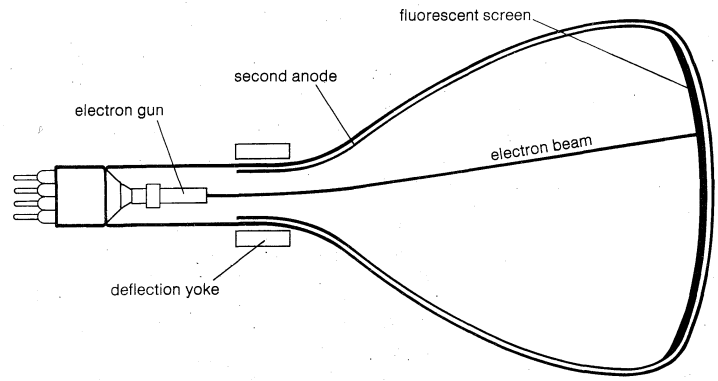

Figure 13: Basic elements of monochrome picture tube.

The electron gun

At the opposite end of the tube is the electron gun, a cylindrical metal structure that generates and directs a stream of free electrons, the electron beam.

A part of this gun is a cylindrical sleeve made electrically positive with respect to the cathode (the element that emits the electrons). The positively charged sleeve (first anode) draws the negative electrons away from the cathode, and they move down the sleeve toward the viewing screen at the opposite end of the tube. They are intercepted, however, by a flat disk (the control electrode) having a small circular aperture at its centre. Some of the moving electrons pass through the aperture; others are held back.

The television picture signal is applied between the control electrode and the cathode. During those portions of the picture signal wave form that make the potential of the control electrode less negative, more electrons are permitted to pass through the control aperture, whereas during the more negative portions of the wave, fewer electrons pass. The brightness control applies a steady (but adjustable) voltage between control electrode and cathode. This voltage determines the average number of electrons passing through the aperture, whereas the picture signal causes the number of electrons passing through the aperture to vary from the average and thus controls the brightness of the spot produced on the fluorescent screen.

As the electrons emerge from the sleeve, each electron experiences a force that directs it toward the centre of the viewing screen. The electron beam is thus brought to focus on the screen, and the light there produced is the scanning spot. Additional focussing may be provided by an adjustable permanent magnet surrounding the neck of the tube. The scanning spot must be intrinsically very brilliant, since (by virtue of the integrating property of the eye) the light in the spot is effectively spread out over the whole area of the screen during scanning.

Scanning is accomplished, as outlined above, by two sets of electromagnet coils. These coils must be precisely designed to preserve the focus of the scanning spot no matter where it falls on the screen, and the magnetic fields they produce must be so distributed that deflections occur at uniform velocities.

The current in the horizontal deflection coil must change very rapidly in order to provide a rapid retrace of the scanning spot on the face of the picture tube. This

rapid rate of change of current causes pulses of high voltage to appear across the circuit feeding current to the coil, and the succession of these pulses, smoothed into direct current by a rectifier tube, serves as the high-voltage power supply.

The two sets of deflection coils are combined in a structure known as the deflection yoke, which surrounds the neck of the picture tube at the junction of the neck with the funnel section.

Variation in picture tubes

Picture tubes vary widely in screen size and are usually characterized by measurements made diagonally across the tube face. Tubes having diagonals from as small as three inches (7.5 centimetres) to 18 inches (46 centimetres) are used in typical transistor portable receivers, whereas tubes measuring from 23 to 27 inches (58 to 69 centimetres) are used in table- and console-model receivers. The design trend has called for greater angles of deflection, with correspondingly wider funnel sections and shallower overall depth from electron gun to viewing screen. The increase in deflection angle from 55° in the first (1946) models to 114° in models produced in the 1970s required corresponding refinement of the deflection system because of the higher deflection currents required and the greater tendency of the scanning spot to go out of focus at the edges of the screen.

III. Compatible colour television

BASIC PRINCIPLES—UNITED STATES SYSTEM

The technique of compatible colour television comprises two transmissions. One of these, the luminance (brightness) transmission, employs methods essentially identical to those of the monochrome television system. The second, the chrominance (colour) transmission, has virtually no effect on monochrome receivers. When used with the luminance transmission in a colour receiver, however, it produces an image in full colour.

The luminance–chrominance method of representing colour values is one of several alternative ways in which coloured light may be analyzed and synthesized. This method is particularly appropriate in a television system since it produces a compatible signal that can serve both black-and-white and colour receivers by the same broadcast.

Historically, compatibility was of great importance because it allowed colour transmissions to be introduced without obsolescence of the many millions of monochrome receivers in use. In a larger sense, the luminance–chrominance method of colour transmission is advantageous because it utilizes the limited channels of the radio spectrum more efficiently than other colour transmission methods.

To create the luminance-chrominance values, it is necessary (in the present state of technology) first to analyze each colour in the scene into primary colours. Coloured light may thus be analyzed by passing the light through three coloured filters, typically red, green, and blue. The amounts of light passing through each filter, plus a description of the colour transmission properties of the filters, serve uniquely to characterize the coloured light.

The fact that virtually the whole range of colours may be synthesized from only three primary colours is essentially a description of the process by which the eye and mind of the observer recognize and distinguish colours. Like visual persistence, this is a fortunate property of vision, since it permits a simple three-part specification to represent any of the 10,000 or more colours and brightnesses that may be distinguished by human vision. If vision were dependent on the energy versus wavelength relationship (the physical method of specification), it is doubtful if colour reproduction could be incorporated in any mass-communication system.

By transforming the primary-colour values, it is possible to specify any coloured light by three other numbers: (1) its luminance (brightness or "brilliance"); (2) its hue (the redness, orangeness, blueness, or greenness, etc., of the light); and (3) its saturation (its vivid versus pastel quality). If the intended luminance value of each point in the scanning pattern is transmitted by the methods of the monochrome television system, it is only necessary to transmit, via an additional two-valued signal, supplementary information giving the hue and saturation of the intended colour at the respective points in the scanning pattern.

Chrominance, defined as that part of the colour specification remaining when the luminance is removed, represents two independent quantities, hue and saturation.

The chrominance signal

In the colour television system of the United States, the chrominance signal is an alternating current of precisely specified frequency (3.579545 ± 0.000010 megahertz), the precision permitting its accurate recovery at the receiver even in the presence of severe noise or interference. Any change in the amplitude of its alternations at any instant corresponds to a change in the saturation of the colours being passed over by the scanning spot at that instant, whereas a shift in time of its alternations (a change in the "phase angle" of the alternations) similarly corresponds to a shift in the hue. The colour information in the European (PAL and SECAM) systems described below is carried on a chrominance signal frequency of 4.43+ megahertz. In the United States system, as the different saturations and hues along each scanning line are successively uncovered by scanning in the camera, the amplitude and phase, respectively, of the chrominance signal change accordingly. The chrominance signal is thereby simultaneously modulated in amplitude and in phase. This doubly modulated signal is imposed on the picture signal carrier current, along with the luminance signal.

The television channel, when occupied by such a compatible colour transmission, appears as shown in Figure 14 (compare this with the channel when occupied by a black-and-white transmission, Figure 11). The chrominance signal takes the form of a subcarrier located precisely 3.579545 megahertz from the picture carrier frequency.

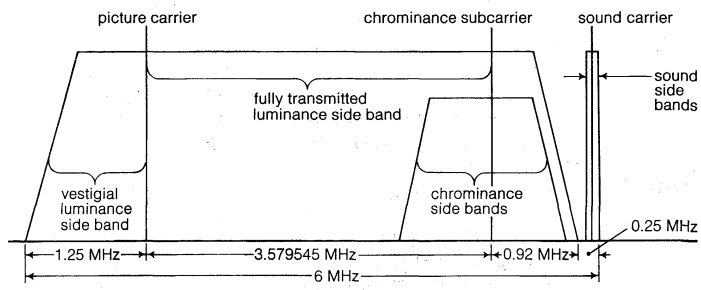

Figure 14: Allocation channel for compatible colour transmission in the United States.

The picture carrier is thus simultaneously amplitude-modulated by the luminance signal to represent changes in the intended luminance, and by the chrominance subcarrier that, in turn, is amplitude-modulated to represent changes in the intended saturation and phase-modulated to represent changes in the intended hue.

When compatible colour transmissions are received on a monochrome receiver, the receiver treats the chrominance subcarrier as though it were a part of the intended monochrome transmission. If steps were not taken to prevent it, the subcarrier would produce interference in the form of a fine dot pattern. The dot pattern, fortunately, can be rendered almost invisible in monochrome reception by deriving the timing of the scanning motions directly from the source that establishes the chrominance subcarrier itself. The dot pattern of interference from the chrominance signal, therefore, can be made to have opposite effects on successive scannings of the pattern; that is, a point brightened by the dot interference on one line scan is darkened an equal amount on the next scan of that line, and the net effect of the interference, integrated in the eye over successive scans, is virtually zero. Thus, the monochrome receiver, in effect, ignores the chrominance component of the transmission. It deals with the luminance signal in the conventional manner, producing from it a monochrome image. This monochrome rendition, incidentally, is not a compromise; it is essentially identi-

cal to the image that would be produced by a monochrome television system viewing the same scene.

The channel for colour transmissions, when used by colour receivers, would appear to be affected by mutual interference between the luminance and chrominance components, since these occupy a portion of the channel in common. Such interference is avoided by the fact that the chrominance subcarrier component is rigidly timed to the scanning motions. The luminance signal, as it occupies the channel, is actually concentrated in a multitude of small spectrum segments, by virtue of the periodicities associated with the scanning process. Between these segments are empty channel spaces of approximately equal size. The chrominance signal, arising from the same scanning process, is similarly concentrated. Hence it is possible to place the chrominance channel segments within the empty spaces between the luminance segments, provided that the two sets of segments have a precisely fixed frequency relationship. The necessary relationship is provided by the direct control by the subcarrier of the timing of the scanning motions. This intersegmentation is known as frequency interlacing. It is one of the fundamentals of the compatible colour system, and without it the superposition of colour information on a channel originally devised for monochrome transmissions would not be feasible.

Frequency interlacing

When a colour receiver is tuned to the transmission represented in Figure 14, the picture signal is recovered in a video detector in the usual manner. An amplifier stage, tuned to the 3.58-megahertz chrominance frequency, then selects the chrominance from the picture signal and passes it to a detector that recovers independently the amplitude-modulated and phase-modulated components.

EUROPEAN COLOUR SYSTEMS

The United States colour system has been adopted by Canada, Mexico, Japan, and several other countries. In Europe, two alternative systems have been developed and introduced. The PAL (phase alternation line) system has been adopted in the United Kingdom and most of the countries on the Continent. France, the Soviet Union, and their allied countries and dependencies have adopted the SECAM (*système électronique couleur avec mémoire*) system.

The PAL and SECAM systems embody the same principles as the United States system, including matters affecting compatibility and the use of a separate signal to carry the colour information at low detail superimposed on the high-detail luminance signal. The European systems were developed, in fact, to improve on the performance of the United States system in only one area, the constancy of the hue (tint) of the reproduced images.

It has been pointed out that the hue information in the U.S. system is carried by changes in the phase angle of the chrominance signal, and that these phase changes are recovered in the receiver by synchronous detection. The transmission of the phase information, particularly in the early stages of colour broadcasting in the United States, was subject to incidental errors arising in broadcasting stations and network connections. Errors are also caused by reflections of the broadcast signals by buildings and other structures in the vicinity of the receiving antenna. In recent years, transmission and reception of hue information has become substantially more accurate in the U.S. through care in broadcasting and networking, as well as by automatic hue-control circuits in receivers. The PAL and SECAM systems are inherently less affected by phase errors.

In the PAL and SECAM systems, the nominal value of the chrominance signal is 4.43+ megahertz, a frequency that is derived from and hence accurately synchronized with the frame-scanning and line-scanning rates. This chrominance signal is accommodated within the six-megahertz range of the fully transmitted side band. By virtue of its synchronism with the line and frame scanning rates, its frequency components are interleaved with those of the luminance signal, so that the chrominance information does not affect reception of colour broadcasts by black-and-white receivers.

PAL system. The PAL system resembles the United States system in that the chrominance signal is simultaneously modulated in amplitude to carry the saturation (pastel versus vivid) aspect of the colours and in phase to carry the hue (tint) aspect. In the PAL system, the phase information is reversed during the scanning of successive lines. Thus if a phase error is present during the scanning of one line, a compensating error (of equal amount but in the opposite direction) is introduced during the next line. Thus the average phase information, presented by the two successive lines taken together, is free of error.

Two lines are thus required to depict the corrected hue information, and the vertical detail of the hue information is correspondingly lessened. This produces no serious degradation of the picture when the phase errors are not too great, since, as noted above, the eye does not require fine detail in the hues of colour reproduction, and the mind of the observer averages out the two compensating errors. If the phase errors are more than about 20°, visible degradation does occur. This effect can be corrected by introducing in the receiver (as in the SECAM system described below) a delay line and electronic switch.

SECAM system. In the SECAM system, the luminance information is transmitted in the usual manner, and the chrominance signal is interleaved with it. But the chrominance signal is modulated in only one way. The two types of information required to encompass the colour values do not occur concurrently, and the errors associated with simultaneous amplitude and phase modulation do not occur. Rather, in the SECAM system (SECAM III), alternate line scans carry information on luminance and red, while the intervening line scans contain luminance and blue. The green information is derived within the receiver by subtracting the red and blue information from the luminance signal. Since individual line scans carry only half the colour information, two successive line scans are required to obtain the complete colour information, and this halves the colour detail, measured in the vertical dimension. But, as noted above, the eye is not sensitive to the hue and saturation of small details, so no adverse effect is introduced.

To subtract the red and blue information from the luminance information to obtain the green information, the red and blue signals must be available in the receiver simultaneously, whereas they are transmitted in time sequence. This requirement is met by holding the signal content of each line scan in storage (or "memorizing" it, hence the name *système électronique couleur avec mémoire*). The storage device is known as a delay line; it holds the information of each line scan for 0.000064 second. To match successive pairs of lines, an electronic switch is also needed. When the use of delay lines was first proposed, such lines were expensive devices. Recent advances have reduced the cost, and the fact that receivers must incorporate these components is no longer viewed as decisive.

Since the SECAM system reproduces the colour information with a minimum of error, it has been argued that SECAM receivers do not require receiver controls for hue and saturation. Such adjustments, however, are usually provided to permit the viewer to adjust the picture to his individual taste and to correct for signals that are in error as broadcast, due to such factors as faulty use of cameras, lighting, and networking.

COLOUR CAMERA AND PICTURE TUBE

The terminals of the colour television system, the camera and picture tube, analyze and synthesize, respectively, the colour quantities present at each point in the scanning pattern. The television camera in its current state of development does not produce the luminance, hue, and saturation values directly. Rather it produces three picture signals, representative of the amounts of three primary colours present at each point in the image pattern. From these signals the luminance and chrominance components are then derived by manipulation in electronic circuits.

The typical colour television camera (Figure 15) contains three image orthicon tubes, with an optical system that casts an identical image on the sensitive surface of

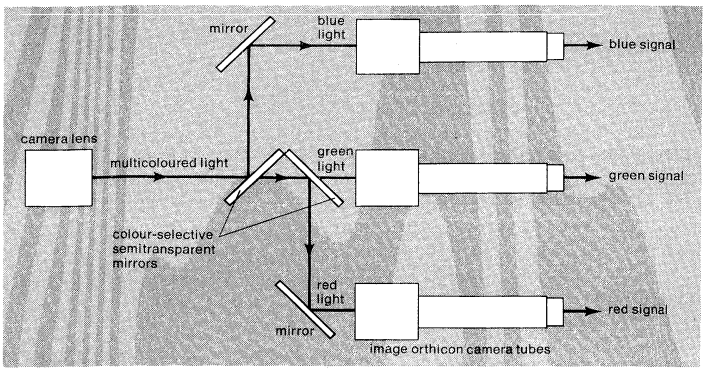

Figure 15: Diagram showing selective separation of light in colour camera.

Optical system of a colour television camera

each tube. The optics comprise a lens and four mirrors that reflect the image rays from the lens onto the three camera tubes, as shown. Two of the mirrors are of a colour-selective type (dichroic mirror) that reflects the light of one colour and transmits the remaining colours. The mirrors, plus colour filters that perfect their colour-selective action, direct a blue image to the first tube, a green image to the second tube, and a red image to the third tube.

The deflection systems of the three camera tubes are arranged to produce identical scanning patterns in each tube, so the picture signals developed by the respective tubes represent images of the same geometrical shape, differing only in colour. The respective primary-colour signals are passed through video preamplifiers associated with each camera tube and emerge from the camera as separate entities. If compatibility were not required, and if sufficient space were available in the radio spectrum, the three signals might be transmitted to the receiver over separate channels. Actually, as mentioned above, the primary-colour signals are recast into luminance and chrominance components; at the receiver the latter are converted back into primary-colour signals before application to the colour picture tube. In the mid-1960s, colour cameras employing four camera tubes were introduced, particularly for studio work. The fourth tube is exposed directly to the scene without an intervening mirror or filter and thus produces a luminance signal of high quality. The three remaining tubes are then confined to the less demanding functions of producing the primary-colour signals. Three-tube cameras based on this principle have also been developed.

Much attention has been paid to the design of camera tubes for colour service, and greatly improved colour rendition, particularly of subtle variations in skin tone, has resulted. The Plumbicon version of the Vidicon, developed in The Netherlands, is particularly noteworthy in this respect.

The colour picture tube (Figure 16) contains three electron guns, which produce three separate electron beams. These are deflected simultaneously in the standard scanning pattern over the viewing screen. One of the beams is controlled by the red primary-colour signal and produces a red image. The second beam produces a blue image and the third a green image.

Colour picture tube screen

To permit three primary-colour images to be formed simultaneously, the screen is composed of three sets of individual phosphor dots, which glow respectively in the three different colours and which are uniformly interspersed over the screen (Figure 16). The "red" beam impinges only on the red-glowing phosphor dots, being prevented from hitting the other two colours, with similar restriction of the other two beams to the blue and green dots, respectively.

The sorting out of the three beams so that they produce images of only the intended primary colour is performed by a mask that lies directly behind the phosphor screen. This mask contains about 200,000 precisely located holes, each accurately aligned with three different coloured phosphor dots on the screen in front of it. Electrons from the three guns pass together through each hole, but at slightly different angles. The angles are such that the electrons arising from the gun controlled by the red primary-colour signal fall only on the red dots, being prevented from hitting the blue and green dots by the shadowing action of the mask. Similarly, the "blue" and "green" electrons fall only on the blue and green dots, respectively. A major improvement consists in surrounding each colour dot with an opaque black material, so that no light can emerge from the portions of the screen between dots. This permits the screen to produce a brighter image while maintaining the purity of the colours. This type of screen (black matrix screen) is more expensive to produce, but in the early 1970s it was widely used in the larger colour tubes.

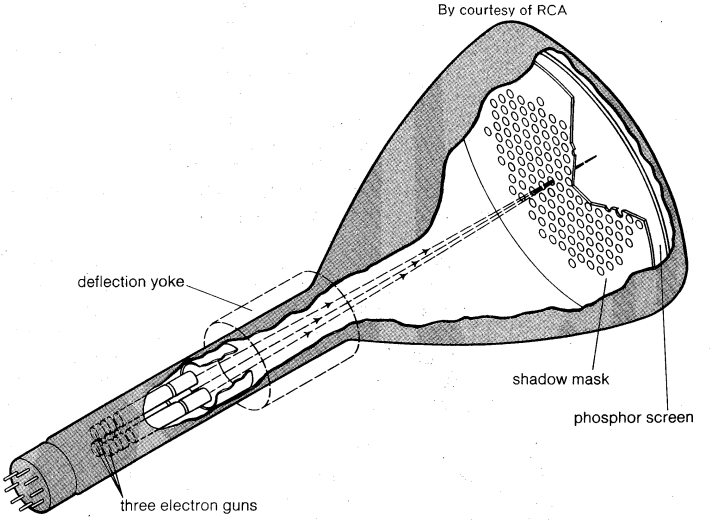

Figure 16: Colour picture tube employing the shadow-mask technique.

Thus three separate primary-colour images are formed simultaneously, as the scanning proceeds. The colour dots of which each image is formed are so small and so uniformly dispersed that the eye does not detect their separate presence, although they are readily visible through a magnifying glass. The primary colours in the three images thereby mix in the mind of the viewer and a full-colour rendition of the image results.

The shadow-mask tube

This type of colour tube is known as the shadow-mask tube. It has several shortcomings: (1) the electrons intercepted by the mask cannot produce light, and the image brightness is thereby limited; (2) great precision is needed to achieve correct alignment of the electron beams, the mask holes, and the phosphor dots at all points in the scanning pattern; and (3) precisely congruent scanning patterns, as among the three beams, must be produced. In the late 1960s a different type of colour tube, the Trinitron, was introduced in Japan. In this tube the shadow-mask is replaced by a metal grille having vertical slits extending from the top to the bottom of the screen. The three electron beams pass through the slits to the coloured phosphors, which are in the form of vertical stripes aligned with the slits. The grille directs the majority of the electrons through the slits, few of the electrons are intercepted by the grille, and a brighter picture results. The electron gun of the Trinitron tube remains in fine focus throughout the scanning of the image, since a major portion of the focus mechanism is common to all three beams.

COLOUR TRANSMITTER AND RECEIVER

Figure 17 shows the essential elements of the colour transmitter, as they differ from the monochrome transmitter shown in Figure 12. Immediately following the colour camera is the colour coder, which converts the primary-colour signals into the luminance and chrominance signals. The luminance signal is formed simply by applying the primary-colour signals to an electronic addi-

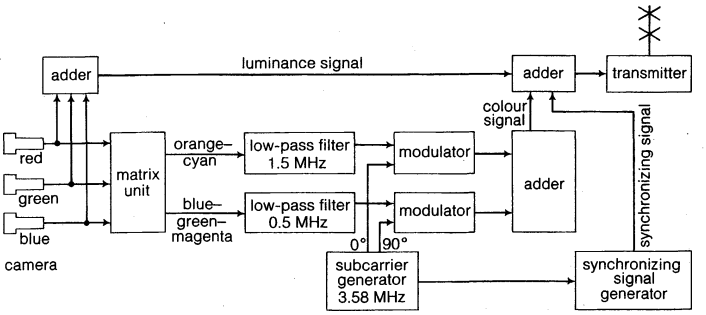

Figure 17: Block diagram of colour transmitter.

tion circuit that adds the values of the three signals at each point along the respective picture signal wave form. Since white light results from the addition, in appropriate proportions, of the primary colours, the resulting sum signal represents the black-and-white (luminance) version of the colour image. The luminance signal thus formed is subtracted individually, in three electronic subtraction circuits, from the original primary-colour signals, and the colour-difference signals are then further combined to produce two signals, which are then applied simultaneously to a modulator, where they are mixed with the chrominance subcarrier signal. The latter is thereby amplitude-modulated in accordance with the saturation values and phase-modulated in accordance with the hues. The luminance and chrominance components are then combined to form the overall colour picture signal, which is then carried to the transmitter over the network or studio–transmitter link.

The chrominance subcarrier is generated in a precise electronic oscillator at the standard value of 3.579545 megahertz. Samples of this subcarrier are injected into the signal wave form during the blank period between line scans just after the horizontal synchronizing pulses. These samples are employed in the receiver to control the synchronous detector, mentioned above. Finally, the horizontal and vertical deflection currents, which produce the scanning in the three camera tubes, are formed in a scanning generator, the timing of which is controlled by the chrominance subcarrier. This common timing of deflection and chrominance transmission produces the dot-interference cancellation in monochrome reception and frequency interlacing in colour transmission, noted above.

At this stage, the colour picture signal can be handled in the same manner as the monochrome signal, except that throughout the network and in the transmitter special precautions must be taken to transmit the chrominance subcarrier at its correct amplitude, with its amplitude and phase modulations preserved against incidental distortions.

Colour receiver components

The colour receiver contains a tuner and intermediate-frequency amplifiers similar to those used in monochrome receivers, but especially designed to preserve the chrominance subcarrier during its passage through these stages. The colour receiver also has power supplies, sound reception circuits, and synchronization and deflection current generators similar to those used in monochrome reception.

The colour reproduction processes are divided into the luminance and chrominance functions. A video detector develops the luminance component and applies it through video amplifiers simultaneously to all three electron guns of the picture tube. This part of the signal thereby activates all three primary-colour images, simultaneously and identically, in the fixed proportion needed to produce white light. When tuned to monochrome broadcasts, the colour receiver produces a monochrome image by means of this mechanism, the chrominance component then being absent.

When the receiver is tuned to a colour broadcast, the chrominance subcarrier component appears in the output of the video detector and it is thereupon operated on in circuits that ultimately recover the primary-colour signals originally produced by the colour camera.

The three colour-difference signals are applied separately to the respective electron guns, where each reduces the strength of the corresponding electron beam to change the white light, which would otherwise be produced, to the intended colour for each point in the scanning line. The net control signal applied to each electron gun bears a direct correspondence to the primary colour signal derived from the respective camera tube at the studio. In this manner, the three primary-colour signals are transmitted as though three separate channels had been used.

The colour receiver controls to be adjusted by the viewer (in addition to the tuning, brightness, contrast, and synchronizing controls present in monochrome receivers) are the hue control and the saturation control. The hue control shifts all the hues in the reproduced image. It is usually adjusted by reference to the colour of the flesh of the performers, since unnatural flesh tone is readily recognized even if the viewer has no knowledge of the intended hues in other parts of the scene. The saturation control adjusts the magnitudes of the colour-difference signals applied to the electron guns of the picture tube. If these magnitudes are reduced to zero, by turning the saturation control to the "off" position, no colour difference action occurs and the reproduction occurs in monochrome. As the saturation control is advanced, the colour differences become more accentuated, and the colours become progressively more vivid. In the late 1960s, the more elaborate colour television receivers began to employ a system known as "automatic hue control." In this system, the viewer makes an initial manual adjustment of the hue control to produce a rendition of flesh tones to suit his preference. Thereafter, the hue control circuit automatically maintains the preselected ratio of the primary colours corresponding to the viewer's choice. Thus the most critical aspect of the colour rendition, the appearance of the faces of the performers, is prevented from changing when cameras are switched from scene to scene or when tuning from one broadcast to another.

Automatic hue control

Since care in tuning is essential in colour receivers to assure correct reception of the chrominance signal, automatic circuits to set the fine-tuning adjustment are provided in the more expensive receivers. A recent development is a single touch-button control that sets the fine tuning and adjusts the hue, tint, contrast, and brightness to preset ranges. These automatic adjustments override the settings of the corresponding knobs, which then function over narrow ranges only. Such refinements permit reception of acceptable quality by viewers who might otherwise be confused by the many misadjustments possible when ordinary manual controls are used.

IV. Applications of television

TELEVISION RECORDING

Commercial systems. Recording of television programs on photographic film or magnetic tape is an important technique, not only to preserve a permanent record of a live-scene program for subsequent rebroadcast but also to perfect a performance prior to its initial presentation. Recorded segments are often used in a "live" studio program when it is impractical to set up the desired scene in the studio. Transmission of films originally produced for motion-picture theatres is also a major activity in broadcasting.

Television film projectors fall into two classes, continuous and intermittent, according to the type of film motion. In the continuous projector, a scanning spot from a flying spot camera tube is passed through a rotating optical system, known as an immobilizer, which focusses the scanning spot on the motion-picture film. As the film moves continuously through the projector, the immobilizer causes the scanning pattern as a whole to follow the motion of the film frame, so that there is no relative motion between pattern and frame. The light passes through the film to a phototube where the light, modified by the transmissibility of the film at each point, produces the picture signal. As one film frame moves out of the range of the immobilizer, the next moves into range and there is a condition of overlap between successive scanning patterns.

The optics are so arranged that the amount of light in the spot focussed on the film is constant at all times and in all positions. This constancy permits the film to be moved at any desired speed, while the pattern scans at the standard rate of 25 or 30 pictures per second. The film is actually moved at the standard rate for motion pictures, 24 frames per second, so the speed of objects and pitch of the accompanying sounds (picked up from the sound track by conventional methods) are reproduced at the intended values.

The intermittent projector

In the intermittent projector, which more nearly resembles the type used in theatre projection, each frame of film is momentarily held stationary in the projector while a brief flash of light is passed through it. The light (which passes simultaneously through all parts of the film frame) is focussed on the sensitive surface of a storage-type camera, such as the Vidicon. The light flashes are timed to occur during the intervals between successive field scans—that is, while the extinguished scanning spot is moving from bottom to top of the frame. The light is strong enough to produce an intense electrical image in the tube during this brief period. The electrical image is stored and is scanned during the next scanning field, producing the picture signal for that field. Light is again admitted between fields and the stored image scanned thereupon by the second field. When one film frame has been thus scanned, it is pulled down by a claw mechanism and the next frame takes its place.

In Europe and other areas where the television scanning rate is 25 picture scans per second, it has been the custom to operate intermittent projectors also at 25 frames per second, or about 4 percent faster than the intended film projection rate of 24 frames per second. The corresponding increases in speed of motion and sound pitch were not so great as to introduce unacceptable degradations of the performance. In the United States and other areas where television scanning occurs at 30 frames per second, it is not feasible to run the film projector at 30 film frames per second, since this would introduce speed and pitch errors of 25 percent. Fortunately, a small common factor, 6, relates the scan rate of 30 and the film projection rate of 24 frames per second. That is, four film frames consume the same time as five scanning frames. Thus, if four film frames pass through the projector while five complete picture scans (ten fields) are completed, both the film motion and the scanning proceed at the standard rates. The two functions are kept in step by holding one film frame for three scanning fields, the next frame for two scans, the next for three scans, and so on.

Television recording tape

Television program recording for rebroadcast is done on magnetic tape, although film is used for longer storage purposes. The tape technique permits prompt rebroadcast of programs the quality of which, when the tape equipment is in good adjustment, is virtually indistinguishable from the original broadcast. The magnetic tape, two inches (five centimetres) wide, is moved at 15 inches (38 centimetres) per second past a magnetic recording head that rotates across the width of the tape, imposing on it a series of crosswise magnetic line patterns that correspond to the lines of the scanning pattern. To keep the pickup and tape motions identical during recording and playback, index signals are imposed during recording, and these are used to control the drive motors during playback. The television signal is recorded by frequency modulation on a carrier signal, thus avoiding the difficult problem of direct recording at the extremely low frequencies present in the picture signal itself.

Magnetic video recording is widely used in broadcast operations, in colour as well as monochrome, not only because of its high quality but because it is immediately available (without subsequent processing) for playback. In the United States, many of the network programs broadcast in and west of Chicago are derived from magnetic recordings, stored for an hour or more after their release along the eastern seaboard to allow for the difference in time in western cities.

Many variations of the basic techniques of recording television program material were introduced in the late 1960s and early 1970s, especially in sports telecasting. The first to be developed was the "instant replay" method, in which a video tape recording is made simultaneously with the live-action pickup. When a noteworthy episode occurs, the live coverage is interrupted and the tape recording is broadcast, followed by a switch back to live action. Often the recording is made from a camera viewing the action from a different angle. Other variations include the slow-motion and stop-action techniques, in which magnetic recording plays the basic role.

Increasing used has been made, particularly in sports broadcasting, of split-screen techniques and the related methods of inserting a portion of the image from another camera into a circular (or rectangular, triangular, etc.) area cut out from the main image. These techniques employ an electronic switching circuit that turns off the signal circuit of one camera for a portion of several line scans, while simultaneously turning on the signal circuit of another camera, the outputs of the two cameras being combined before the signal is broadcast. The timing of the electronic switch is adjusted to blank out, on successive line scans of the first camera, an area of the desired size and shape. The timing may be shifted during the performance and the area changed accordingly. One example of this technique is the wipe, which removes the image from one camera while inserting the image from another, with a sharp, moving boundary between them.

Home recording and playback systems. In the early 1970s several auxiliary systems of television reproduction were under development as adjuncts to the home receiver. These are of two general types, using the "record-plus-playback" and the "playback-only" techniques.

The record-plus-playback systems employ video recording on magnetic tape, including the accompanying sound. They are intended to make a permanent sight-and-sound record of programs, either as broadcast (off-the-air recording) or by using a simple television camera and microphone in the home, as in amateur sound motion pictures. The use of prerecorded programs on tapes purchased or rented was also intended in these systems.

The playback-only systems are analogous to the phonograph record system of sound reproduction. The program material is prerecorded on a disk or on nonmagnetic film and is played back through the home receiver by means of an attachment similar in principle to the phonograph record player. No facilities for the recording are provided, the recording methods being too specialized for use in the home.

Video-cassette systems

By 1971 some 20 different "video-cassette" systems (as they had come to be known by analogy to the cassette sound recorders) were under development. While some were in small-scale production, few were available for use in the home. One of the initial drawbacks was the high cost of the recording material, estimated at from $10 to $35 per hour for the magnetic or nonmagnetic films employed. The video disk was an exception, with a material cost for a one-hour program estimated at $3 or less.

The initial demonstrations were largely confined to black-and-white programs, although all the developers planned the eventual introduction of colour. The high cost led to suggestions that a rental system, similar to the lending-library concept of distributing books, would be essential if widespread public use were to be achieved. The market for such recorded programs was confined in the early 1970s to educational institutions and industrial uses.

The record-plus-playback systems of the early 1970s employed half-inch magnetic tape housed in a cartridge similar to the sound tape cartridge, but larger. These systems, some eight in number, were under development in the United States, Japan, and The Netherlands. The approach of each system was sufficiently different that complete interchangeability of cartridges was not feasible, and the need for standardization was evident. The earliest estimated prices of the recorder-playback units ranged substantially above the cost of the home receiver to which they were attached. The quality of reproduction was highly acceptable, although somewhat poorer than that possible under ideal broadcasting conditions. The video bandwidth employed in playback ranged from two to three megahertz.

Among the playback-only systems, one exciting particular interest because of its low cost-per-hour of recording was a video disk system that originated in Germany. Since the rate of transmitting picture information (three megahertz) is about 400 times greater than that required for sound, the video disk must rotate much faster and possess many more grooves than a phonograph record. In the German system, the disk rotates at 1,500 revolutions per minute (to be increased to 1,800 revolutions per minute for colour), and the grooves are packed on it to the extent of 3,300 per inch. The disk is made of plastic, covered with a thin embossed metal foil. The pickup cartridge does not make physical contact with the grooves, but rides on a thin cushion of air, the information in the groove being transferred to the cartridge by variations in air pressure.

Three different playback-only systems using nonmagnetic film were in evidence; the electronic video recording (EVR) method, the Holotape (Selectavision) system, and systems using conventional eight-millimetre colour motion-picture film (Super-8 techniques).

In the EVR system, the image is prerecorded by electrophotographic means on silver halide emulsion or diazo photosensitive film. Each frame is imposed in two paired images: the luminance (black-and-white) image, used alone for black-and-white material, and a coded image that is decoded by the playback unit to supply the low-detail chrominance information. These are combined into a standard colour-television signal before being fed to the colour receiver. Both images are picked up, in the playback unit, by a flying spot scanner.

The Holotape system makes use of the principles of holography (*q.v.*) to emboss on plastic tape the luminance and chrominance information of each frame. In the playback unit, coherent light produced by a laser picks up the embossed information and directs the visual content of the luminance and chrominance signal to a Vidicon, which translates the light into an electrical signal that is fed to the conventional colour receiver. The anticipated cost of prerecorded programs in this system is reduced, relative to photographic or magnetic means, by the use of the embossing technique, similar in principle to that used for making phonograph records.

The Super-8 systems use conventional eight-millimetre motion-picture film as the source of the prerecorded images, combined with magnetic recording for the accompanying sound. The frames are scanned by a Vidicon or a flying spot scanner, in a simplified version of the film-scanning techniques employed in broadcasting (see also SOUND RECORDING AND REPRODUCING).

TELEVISION BROADCASTING

Transoceanic broadcasts. The initial attempt to interconnect the television networks of Europe and North America came in 1962, when the American Telephone and Telegraph Company used its artificial satellite, Telstar, to relay television signals between Andover, Maine; Goonhilly Downs, Cornwall; and Pleumeur-Bodou, Brittany. The first transmission, of a purely experimental nature, originated in the United States on July 10, 1962, and this was followed the next day by transmissions to the U.S. from France and England; the first colour transmission occurred on July 16. Reception was limited to about 15 minutes, the period during which the satellite was within sight of the sending and receiving stations. To maintain continuous transmissions, the planners of the system proposed using a series of satellites, so that at least one would always be in position to relay signals. In the mid-1960s, however, an alternative technique came to the fore: a single relay satellite in a "stationary" orbit, so adjusted that it would remain always above the same point on the surface of the earth. The first public demonstration of this system was on October 10, 1964, when television coverage of the opening ceremonies of the Olympic Games was relayed from Tokyo to North America via a Syncom satellite positioned above the Pacific Ocean. The so-called "synchronous" communications satellite maintained an altitude of about 23,000 miles (37,000 kilometres), its position fixed with respect to the Earth, their periods of rotation being identical. In the early 1970s, such satellites were so placed that virtually any area of the Earth was within reach of any other by space-relay circuits. The transmitters and receivers used in space are capable of carrying many television channels simultaneously, in addition to telephone and other communications. The landing on the moon by the American astronauts in 1969 was carried by satellite to an estimated audience of more than 100,000,000 viewers (see also BROADCASTING; SATELLITE COMMUNICATIONS).

Broadcasting the Olympic games

Community antenna television (CATV) systems. In 1950 a new method of providing television service to the home was introduced and rapidly gained acceptance in many communities. This involved setting up a "community antenna" in a high and exposed location, where excellent reception is obtainable, and re-transmitting the signals via a local coaxial cable system to homes in the vicinity. The CATV system is particularly advantageous in towns surrounded by hills or other obstructions that prevent high-quality reception by individual antennas at each home. Another, later, application occurred in major metropolitan areas where local reception is degraded by the reflection of signals from tall buildings ("multipath interference"), which produce one or more "ghost" images displaced on the screen from the desired picture. The CATV service is provided, after an initial installation charge of $15–$35, at a monthly charge of about $5. By the early 1970s there were more than 5,400,000 subscribers served by some 2,600 CATV systems in the United States. Similar growth has occurred in Canada and in several other countries.

The plans of the CATV industry have shifted from merely delivering available programs to a more ambitious outlook for services to the home other than from distant broadcast stations. Moreover, under active development in the early 1970s was a system of two-way cable television, which would permit the householder to "call back" over the cable connection to secure all manner of visual and audible information on demand, participate in polls, have access to a computer, etc. The advent of Picturephone (video telephone) service in the United States (described below) has lent impetus to the two-way cable concept. A movement has developed for action by regulatory agencies and the Congress to protect the public interest as the two-way system evolves.

Typical future plans envisage some 20 television channels being available to the home through a single cable connection, far more than existing broadcast programs would require. The additional channels would supply program material produced by community groups and local governments, educational institutions, libraries, and the like. One study estimated that, by 1975, 25 percent of the homes in the United States would be wired for 20 or more channels, and that by 1980 the percentage might rise to 60 percent. Such universal acceptance has suggested the prospect of sending first-class mail visually through the cable network, with delivery time reduced to minutes.

CLOSED-CIRCUIT TELEVISION

The term closed-circuit television, which originally meant a local system consisting of a camera and several monitor receivers connected by a coaxial cable, came to refer to any system, however extensive, in which the televised subject matter is intended for the organization that owns or has hired the system for its exclusive use, as against broadcasting or other general use by the public. Such systems are widely used in industry and commerce and for educational purposes. They range from a single camera and monitor installed in a steam plant to monitor flame condition or water level to a nationwide network hired on a single-occasion basis (*e.g.*, by an automobile manufacturer to present information on new models to dealers assembled in theatres having projection television equipment). Coaxial cable is used in local installations, but microwave relay systems identical to those used in broadcasting may be employed for large closed-circuit hookups.

Since a closed-circuit system is entirely under the control of its proprietor and is not intended to serve the

general public, it is possible to employ scanning standards that differ from those used in broadcasting. Advantage of this freedom in system design is taken in the so-called slow-scan closed-circuit system, which is used to transmit signature records and balances in banks, for example.

Slow-scan system

In the typical slow-scan system, the pictures may be scanned at a rate as slow as one picture every three seconds with a scanning pattern of 180 lines per picture. The maximum frequency in the picture signal then reaches only 8,000 hertz, which can be transmitted inexpensively; *i.e.*, over ordinary telephone lines. In the majority of closed-circuit systems for industry, education, and theatre projection, however, the image-quality requirements are essentially identical to those of broadcasting.

Equipment. Equipment for closed-circuit television is similar to, but generally less elaborate than, that used for broadcast purposes. The Vidicon camera tube is used in industrial television almost to the exclusion of other types, since it is less expensive than the other types and more suitable for compact cameras. In educational television, however, image orthicon tubes and associated equipment very similar to broadcast-station units are widely used. Since closed-circuit installations in industry are seldom operated by television specialists, care must be taken in equipment design to make operation and maintenance simple. An important industrial use is in viewing remote or hazardous events. For such purposes, controls for remote operation of the camera, including adjustment of lens aperture and focus, are provided.

Applications in education. Educational television is often conducted on a public-broadcast basis in cities in which a channel is available for this purpose and in which the expense of the transmitting station can be borne. The simpler and less costly closed-circuit system found increasing favour with educators, however, particularly in larger institutions and in medical schools.

In education, television's most impressive use is extending the range of a gifted teacher beyond a single classroom. When a broadcast system is available, pupils in many schools may be taught simultaneously by a particularly able teacher prior to a more personal instruction and discussion of the subject matter in individual classes with a local teacher in attendance. While motion pictures may also be used in this way, the televised image commands the pupils' attention to a far greater extent. Even when film is used as a program source, the psychological impression on the student is heightened.

Television is also an important teaching aid in bringing to a number of students simultaneously the details of an experiment or operation that otherwise could be viewed only by a single person or small group. Examples include viewing through a microscope and bringing medical students directly into visual contact with operating procedures without interfering with those performing the operation. Use of closed-circuit television for instruction in surgical procedures is widespread; elaborate colour television installations have been made in medical schools and hospitals, colour being an important adjunct in delineating diagnosis and procedure. An important advantage of television in such instruction is that the final outcome is not known as the demonstration proceeds.

Closed-circuit television in medicine

Video telephone. The use of television as an adjunct to telephone service has been planned since the earliest demonstrations of television itself. In 1927, in the first public showing of television in the United States, the pictures were sent in connection with a telephone conversation between Secretary of Commerce (later president) Herbert Hoover and Walter Sherman Gifford, president of the American Telephone and Telegraph Company. In the mid-1930s, a television-telephone service was operated by the German Post Office over coaxial cables between Berlin, Leipzig, Nürnburg, and Hamburg. By the 1960s, slow-scan experimental video-telephone experiments were reported in Italy and Japan. The Soviet Union used the broadcast network for telephone connections outside broadcast hours, and a commercial video telephone was exhibited in London.

The Picturephone system, which became available to subscribers of the American Telephone and Telegraph Company in 1971 in Chicago and Pittsburgh, was first demonstrated at the New York World's Fair in 1964. From 1965 to 1970, tests of the Picturephone system were conducted in large corporation headquarters in New York, Chicago, and Pittsburgh. By the early 1970s, the techniques for local and long-distance service had been established, but acceptance by the public was disappointing. By the end of 1972, only about 100 Picturephone units were in regular use by subscribers. One of the difficulties was the expense of long-distance connections and routing, requiring a bandwidth equivalent to the demands of more than 300 long-distance telephone connections. Research was under way to reduce the required bandwidth for the video service (currently one megahertz) by sophisticated digital-coding techniques.

The Model II Picturephone subscriber set, used in the early 1970s, has a viewing screen 5 by 5.5 inches (13 by 14 centimetres), displaying a 250-line picture at 30 frames per second, with interlaced scanning. The camera tube is of new design, employing a mosaic of tiny photosensitive semiconductor elements. Focus for normal use by the subscriber is set at approximately three feet. The focus can be reset to one foot for viewing graphic materials, which are laid flat on the desk in front of the subscriber set, being reflected into the camera by a 45° mirror.

For the video connection from the subscriber's location to the central office, two conventional wire telephone circuits (pairs) are used in connection with equalizing networks that arrange for the one-megahertz channel to be divided equally between the two circuits. A third circuit is used for the voice connection. The equalization scheme is not adequate for distances beyond six miles (ten kilometres). For long-distance transmission between central offices, wide-band circuits (coaxial cable or microwave relay) were being used in the early 1970s. A future prospect is the use of wire pair circuits at distances of several hundred miles by transforming the video signal into digital form and regenerating it at intervals.

The Picturephone may be used for communication with computers and other sources of digital data. The subscriber uses the 12 keys of a Touch-Tone telephone set to feed data into the system, and receives data visually over the Picturephone screen (see also TELEPHONE AND TELECOMMUNICATIONS SYSTEMS).

Industrial applications. One of the first uses of closed-circuit television in industry was an installation of boiler water-level monitors at the Hell Gate electric generating station in New York, made directly after World War II. This application later was extended to the monitoring of flames in burners and smoke issuing from stacks. Here the justification for television, as against photographic methods, is the need for immediate information without the delay of film processing. Other applications involve the safe handling of nuclear materials, jet fuels, and other hazardous substances. A stereoscopic form of television, comprising two complete systems that present two images separately to the two eyes of the operator, has been used in conjunction with precise remote-handling equipment for packing radioactive substances, disposing of radioactive wastes, and the like. The ability of the television camera to operate in situations hostile to human observers (as outside the fuselage of an airplane in flight, to observe operation of landing gear during engineering tests) also accounts for increasing usage in industry.

The radiation hazard brought industrial television into play in X-ray technology. A fluoroscope or other device for translating X-ray intensities into visible light is viewed by a sensitive television camera and the image brought out at a safe distance from the exposure site. Motion-picture photography might be used, but the television system permits immediate observation without processing delays and avoids the cost of film and processing.

Surveillance applications

Television systems may also be used for surveillance, particularly to assist guards in patrolling restricted areas. Another surveillance application is in reading numbers on freight cars in railway switchyards to aid the yardmaster in making up trains.

Commercial applications. The primary application of closed-circuit television in commerce, as contrasted with

industry, is remote inspection of records in banks and other institutions. In one installation, four branches of a bank were connected with 12 miles (19 kilometres) of coaxial cable to permit any teller to call for the signature card or the current balance of any depositor from a central bookkeeping department. Although the initial and maintenance costs of such a system are substantial, the speed and accuracy with which doubtful accounts may be checked justifies the use of the system. Extension of this technique to remote reading of blueprints and other records depends upon lowering the cost of interconnecting cables and increasing the detail of images so that, for example, a full 8½-by-11-inch page of typewritten material could be read on a monitor without error.

The cathode-ray tube is finding wide use as a display device in applications other than television, particularly in connection with electronic computers. Display of information stored in computer memory, or resulting from calculations, is now widely offered to bank tellers, reservation clerks, inventory managers, and others.

Techniques akin to those of television are finding increased use in other commercial and industrial fields. One application is a scanning technique whereby printed characters are "read" and identified by comparing the character with each of a series of standard templates or matrices. This may be done by storing the video signal arising from scanning in a memory array in the form of voltages that may be compared with a similar array of voltages in a matrix corresponding to each letter or number to be recognized. Either mechanical or electronic scanning may be used in this technique. (D.G.F.)

Television and Radio, Arts of

Radio and television, though they are primarily means of communication, have early made specific contributions to the arts. Through them music, drama, poetry, ballet, and spectacle have all become universally available, reaching audiences that number in the millions. Radio and television have also engendered new art works conceived specifically for them.

By the time radio broadcasting became established in the 1920s, the motion picture had already won recognition as an art form. Sound broadcasting, on the other hand, was recognized only as a potentially powerful uncomplicated medium for the transmission of information, and for relaying certain established art forms such as music. The artistic potential of radio was not explored until the 1930s, that of television not until the 1950s.

BROADCASTING AS A MEDIUM OF ART

Its nature as an art form

The artistic potential of any medium is determined by the unique form it offers and forces on the artist, and its capacity as an effective vehicle of communication in its own right. The form of any art includes the circumstance through which it reaches its public. Shakespeare's stage was little more than an open platform on which any action he cared to represent could be compassed provided he gave his actors the necessary words to indicate the place, circumstance, and atmosphere of the action. But his plays would have been null as practical drama without the circumscribing enclosure of the Elizabethan circular theatre auditorium—the "wooden O"—which gathered the audience around the platform, sealing them off from the outside world and concentrating their attention on the performance. As active auditors they became an integral part of the drama, and one must be constantly aware of them in the very writing, structure, and timing of the plays. Shakespeare's art was born of the discovery of the potentialities of the actor–audience relationship.

The art of radio. In a similar way the art of radio began to be discovered when those engaged in broadcasting became aware of the nature of the medium in which they were working, and of their special relationship to their audience. The discovery took time. Radio was the only medium in which performers were invisible to their audience. Broadcasters tended at first to adopt the manner of the stage or the pulpit: thinking in terms of a mass audience, the inexperienced broadcaster gave his voice and style an artificial inflation totally unsuited to the new medium. His actual audience was composed of small groups and individuals, usually at home or in informal circumstances, often doing other things at the same time. The basic art of radio consisted in adapting manner and style to these new circumstances. Few programs could expect to take their audiences for granted.

News broadcasts were among the exceptions, and news broadcasts in most countries came to be delivered in a fixed, impersonal manner, the newsreader suppressing his personality as far as possible and adopting a "team" voice. Most other spoken radio required using the voice in such a way as to hold the attention of the listener, and this in turn meant recognizing the nature of the microphone as a medium. The public's span of attention was found to be limited. The news summary was allotted five or ten minutes, while a talk might last 15 minutes, or in special instances up to 30 minutes. Much consideration was also given to the appropriate styles for various audiences, depending on the classes of listeners to whom broadcasts were addressed.

The art of radio emerged in Britain—and in certain other countries adopting the same "public service" approach—as a medium nominally addressed to everyone but actually resembling a kind of broad-based national journal with special sections addressed to specific interests and tastes, some more demanding on the intelligence than others. The popular radio talk (a form of spoken journalism, or essay, often excellently composed and delivered) was shorter and more informal in style than that of the "serious" or purely educational talk. Broadcasting offered unique opportunities for bringing the nation's highest intelligences into the living rooms of so-called minority audiences (often amounting to millions) who were prepared to listen to concentrated exposition and argument. From this developed, particularly in Europe, channels specializing for part or all of the day in minority interests. The listeners supported the service by paying an annual license fee. In the United States, on the other hand, privately owned broadcasting companies got their revenues from advertising, and tied their programming to the advertiser's desire to reach the widest possible public. In Japan there were both public and commercial broadcasting services, the former being financed, as in Europe, by license fees from owners of receiving sets. In the Soviet Union broadcasting was recognized, in the words of *Pravda*, as "one of the most powerful weapons of the cultural revolution." Under Stalin virtually all receivers were wired to local exchanges so that the listener could choose only among approved programs. The service had to be regionalized since the U.S.S.R. includes populations speaking some 80 principal languages. Aside from news and commentary, the broadcasts were generally cultural rather than directly propagandistic.

The development of radio as an art form was thus dependent on the way it was organized and financed. There were rich new fields to be opened up in drama, light entertainment, and documentary programming, conceived specifically for the medium, while at the same time some traditional art forms (notably stage drama and music) were transmitted with success. Fiction and poetry reading also became a staple part of sound broadcasting.

The art of television. In the 1950s and 1960s radio was overtaken by television. At first television was considered to be little different as a medium from the film. But although television was a hungry user of film, it needed film in forms that differed from those required by the theatres.

Television compared with film

The difference between film and television as art forms stemmed from the physical and financial conditions governing production, distribution, and exhibition. The relationships between the media and their publics were also quite different. The initial difference lies in the cameras and their function in production. The film camera supplies a record on celluloid in the form of a two-dimensional image, which, suitably edited, can be subsequently projected onto a screen. The television camera accepts and makes available for immediate transmission a two-dimensional image that remains unrecorded and passes with the event, like the image in a mirror (though this image can, by using additional equipment, be recorded on film or videotape). The film camera is associated with a lengthy effort of photographing, cutting, editing, and dubbing—an elaborate process of selection and assembly that may involve months of work. Although television images may also be stored and edited through videotape, the essential television form is the immediate transmission to the public of events occurring at the moment—political and social events, news summaries, commentary, and discussion.

The basic art of television is the control of this immediate flow of images. They can be preselected insofar as the cameras may be set up at chosen vantage points; after that, however, the director must select among the images they give him. The director-editor uses his skill to secure an immediately effective flow of images from the multiple viewpoints his cameras and their lenses collectively represent. In the film the same end is achieved by the quite different process of fragmenting and recording the action piecemeal, thus creating a succession of images that can be subsequently put together by editing and dubbing.

Those who first struggled with the practical aesthetics of television attempted to see the medium on one hand as a kind of visual radio, and on the other as a form of "diluted cinema," a rather poor cousin of the theatrical film. This was in part because they came either from radio or from film making, and saw the medium in relation to their previous occupations. Writers, directors, and performers from radio tended at first to reduce the television image to a "talking head," with the addition of occasional still pictures, film clips, or cut-ins from other broadcasting stations. This was especially the case in countries in which television initially lacked adequate financing (such as France) and directors could not afford costly pictorialization. On the other hand, personnel coming from film making were appalled at the speed with which they were required to prepare and mount their television programs.

Television differs most from film in its relationship to the audience. The film is an event designed for a theatre with an audience specially assembled for the performance. Television, on the other hand, resembles a private performance in the home. The attitude of a person sitting perhaps alone and often for hours on end before a comparatively small picture screened in the familiar surroundings of his living room is quite different from that of a person who has gone out to share the special audience experience of a theatre. The tension is more slack; concentration is constantly threatened by irrelevant interruption. Whereas one is absorbed by a good film in a theatre to the exclusion of all else, one merely "watches" television. The television audience is preoccupied not so much with an individual item as with the free flow of item after item. Television is like a talking picture magazine, going on daily and nightly, asking little, giving out along with its entertainment a quantity of easily assimilated information ranging from formal news coverage to informal, gossipy discussions of the lighter affairs of the day.

Television also differs from film with respect to its visual impact. In the movie theatre a highly magnified image fills the central part of the field of vision in an otherwise darkened hall, exciting curiosity and response to a degree far beyond that obtained by the very small television screen in a relatively undarkened living room. The great, fully loaded images of the big screen, from Griffith's *Intolerance* of 1916 to the Russian *War and Peace* of 1968, have involved the investment of large sums of money in what is called "production value"—the accumulated content of those images with their crowds of people and their elaborate sets. Skilled viewers in the movie theatre perceive and appreciate an astonishing amount of detail. In television, however, one has only to watch a film produced for big-screen theatre to realize the limitations of the small TV screen, in which the actors, speakers, or commentators must occupy most of the visual field.

TECHNIQUES AND BORROWINGS

The various media compared

It is useful to view all of the media together, ranging from the individual performer appearing in the flesh before his audience to the complex presentations of the electronic and allied media. They may be compared in terms of the relationship of the performer to his audience as shown in Table 1. The media also vary in the kind of performance on which they can draw, either derivatively or creatively, as shown in Table 2.

Table 1: Relationship of a Performer to His Audience

performer	audience	relationship
individual speaker, storyteller, or singer	assembled group or audience in any place	direct; performer to audience
company of players, singers, dancers, or musicians	assembled audience in a theatre or concert hall	direct; in an enclosed area
performance by an actor or performer recorded on film; factual film with commentator	assembled audience in a motion-picture theatre, hall, classroom, or other formal place	remote; through a photographed and projected two-dimensional image on either a large or small screen, with recorded sound
radio broadcast by an actor, aural performer, newsreader, or commentator	dispersed audience, located mainly in their own homes	remote; through a signal broadcast in sound only
televised presentation by an actor, singer, dancer, performer, or commentator	dispersed audience, located mainly in their own homes	remote; through a two-dimensional image on a small screen, accompanied by sound

The tables make clear the extent to which the various media borrow from each other. Just as the Greek drama drew on ancient myths and legends, and the Renaissance drama on classical and contemporary material alike, so the voracious demands of the new 20th-century media have driven producers and scriptwriters to acquire the rights to existent material in other media, particularly the novel and the drama. Radio and television have overlapped increasingly with journalism, many journalists becoming broadcasters and commentators.

But much of the borrowing has been mechanical and technical rather than artistic in nature. Radio broadcasting exploited the phonograph record as a means of preserving sound; in a similar way, television drew upon the film. The invention of magnetic tape for recording both sound and video signals has now linked together all of the mechanized media—phonograph, telephone, radio, sound film, and television—and made available a virtually complete record of the sights, sounds, arts, and culture of modern society.

Preservation by recording is in itself not a creative art, but a service to art created elsewhere. A principal func-

Table 2: Relationship of the Medium to the Performance

medium	nature of presentation	type of material
rostrum	visible, audible performance by a single person	oratory, preaching, recital; the speech, sermon, song, reading, monologue, monodrama
live theatre; concert hall	visible, audible performance by a group or company	drama, opera, ballet, revue, circus, *etc.*, with or without music; the concert
motion pictures (silent)	visible, but not audible performance presented by means of cinematograph projection	mimed drama with titles, documentary presentation, news record, or animated film; presented with "live" sound (music, commentator)
motion pictures (sound)	visible, audible performance presented by means of a cinematograph projection	original screenplays or material adapted from theatrical, fictional, or other sources; according to degree of adaptation, the sound film supervenes on the form of its source, making something new; also news, factual, and documentary material
sound radio	audible but not visible broadcast performance	the whole range of human activity, from the news bulletin, report, commentary, discussion, talk, or actuality recording to the complete cycle of the audible arts—story and poetry reading, drama and documentary, music and opera, including material specially created for the medium
television	visible and audible broadcast performance	includes all of the above, but seen as well as heard

tion of radio and television broadcasting has been the dissemination of works of art created for other media. This is particularly true of radio; in television these works are more often transformed to meet the requirements of the medium, and become different art forms. When an opera is performed in a television studio in a way that meets the potentialities of the electronic cameras, the result is television opera—a different form from stage opera. When an opera is commissioned and composed specifically for television (as was Benjamin Britten's *Owen Wingrave*) the television becomes an artistic medium in its own right.

Story-telling

Dramatic techniques. Radio began by restoring the ancient art of the storyteller. Writers for radio next learned how to suggest place and time by word of mouth, accompanied by the impressionistic use of sound and music. Thus was born radio drama. The radio dramatist must address himself to the imagination of listeners who, like blind men, are unable to see what they are experiencing. This limitation carries with it a certain freedom. Just as Shakespeare's independence from stage decor left him free to move his action widely in time and space (*Antony and Cleopatra* has 42 wide-ranging changes of scene), so radio has been free to create its own plastic continuities of action and time-space reference. Radio has been highly creative in the fields of drama and documentary, and also in quite new forms of imaginative light entertainment.

Television, on the other hand, adapted techniques already established by the sound film of the 1930s and 1940s. In the initial rivalry between film and television, economic and technical factors both played a part. The first television plays were like the simplest kind of film dialogues; they avoided elaborate sets or large casts, because the screen was not large enough and because they cost too much. Television material was most expendable, like newspapers and journals that are discarded after a single use. Only gradually did the international distribution of selected television programs, particularly within the large Anglo-American market, permit more money to be spent on "production value" in television.

Television drama came into its own during the 1950s with the emergence of writers and directors who shook themselves free from the old models and began to develop their own techniques—an extension of the two-dimensional image with sound into fields that the cinema could not or would not enter. The creativity of television in the purely artistic sense lies in the unique opportunities it offers the maker. These opportunities were beyond the reach of the film maker, who had no way of impelling his sponsor to finance him in such ventures. Here art and the nature of sponsorship can be said to overlap, as is so often the case in the history of art.

Film techniques. The basic principles that the television image shares with the film image are, of course, its freedom to select the compass of each individual shot and its freedom to determine the nature of the movement within it. The form of presentation depends in both cases on a continuity of such shots in order to build up a narrative flow. Film and television narrative are based on the same principles of mobile composition—the selective (or edited) flow of selective shots of the action. Despite their technological differences they are aesthetically very closely linked and will continue to have a close relationship with each other. This relationship naturally extends into the technical field. Television adopted videotape in order to achieve an immediate high-quality record of the electronic image. This seemed at first a threat to the use of film in television, but that has not proved to be so; the film camera is indispensable in many branches of television production. On the other hand, film makers have found videotape useful in cinema production, since it provides a way of checking the shot before the film is processed.

Use of videotape

The development of television as an art form has not excluded its use as a channel for works produced in other media. On the contrary, production in other media increasingly has been financed out of revenues from its subsequent transmission on television. Since the earliest years of its existence, television has depended on the regular screening of a vast backlog of movie films. The high rentals paid on old films have induced television interests themselves to undertake the production of new films to be shown in theatres and subsequently on the television channels they operate. The feature films they produce often have relatively small casts and a higher ratio of in-close shooting, making them suitable for the smaller TV screen, just as most films now shot for wide screens keep the essential action in the centre so that they can later be shown on television.

FORMS OF RADIO AND TELEVISION BROADCASTING

Drama. Radio and television have provided an entirely new field for the dramatist. The recurrent nature of broadcasting, both radio and television, led to an early adoption of serial forms. The series represents a regular spot in the week filled by standardized blocks of 13, 26, or even 52 successive weekly episodes (covering a quarter, half, or full year). For the writer, director, or actor the series means prolonged employment, though in the actor's case it is also attended by the danger of overidentification with one character. Some of the characters in radio and television serials develop with time, living almost natural life-spans over the years and becoming familiar to a public numbered in millions. An outstanding example is the British television serial *Coronation Street*, which by 1971 had been playing twice weekly for ten years to an average audience large enough to keep a theatre filled for 130 years. To many of its followers, the characters in *Coronation Street* are as real as their friends next door.

The dramatic series

But it is with the nonserial play that the dramatist comes into his own, in both radio and television. In radio, for all but a very few writers of distinction, the nature of the medium (and the comparatively low fees it commands) acts as a deterrent, though some radio plays of high quality have been written, including Dorothy Sayer's *The Man Born to Be King* and Eric Linklater's conversation pieces *The Cornerstone, The Raft,* and *Socrates Asks Why*. In particular, the plays by Louis MacNeice—*Christopher Columbus* and *The Dark Tower*—set to evocative music by William Walton and Benjamin Brit-

ten, respectively, and Dylan Thomas' *Under Milk Wood,* showed how the heightened speech of poetic drama could conjure up a whole world in the imagination of the listener. But radio for the most part has offered only efficient, run-of-the-mill writing by professional radiowriters, or, in a higher level, adaptations of stage plays and classical novels.

Television plays

In television the performance has been more impressive. American writers of the calibre of Paddy Chayefsky (*Marty*) or Reginald Rose (*Twelve Angry Men*) wrote creatively for television as early as the 1950s. But American television turned increasingly to the formula series (though sometimes of high quality, as in *The Defenders*). In Britain the nonserial drama, or the short series by a single writer (such as John Hopkins' four-part series *Quartet*), or the short series by different writers (such as those based on the lives of Henry VIII and Queen Elizabeth I) have provided more opportunity for distinguished writing. Drama is unfortunately the most expensive item in the television repertory (with the exception of light entertainment personalities), and it has constantly to be fought for by its supporters in order to survive in competition with old films and packaged series. Television plays must also be able to hold their own against the competition of news, documentaries, and light entertainment. Television drama has nevertheless proved one of the great creative enterprises of the 20th century. Like the public theatres of Shakespeare's time, television has provided a platform for a whole school of dramatists. It has led to a new kind of dramatic writing, new concepts of character and play structure, new psychological approaches, and new themes. In some instances these have been taken up by the live theatre and the film.

Documentary. Another creative form originating in radio and television is the documentary. Originally a development of the film, it became established on radio in the 1930s. It took many forms, the simplest being a news commentator's presentation backed by selective "on-the-spot" interviewing. This form of broadcasting led to dramatized documentary, with sophisticated scripting and special sound effects, analogous to the newspaper feature story. In the United States it included series such as *March of Time; We, the People;* and *CBS Workshop;* or Norman Corwin's wartime series *This Is War.* Advanced forms of radio documentary were developed during World War II, using radio's full armoury of narrator, scripted dialogue, sound effects, and music to present complex actions—notably in Cecil McGivern's *The Harbour Called Mulberry,* a documentary of the Normandy landings.

Television in its turn offered the documentary film maker an opportunity to develop his art along new and creative lines suitable for the wide-ranging needs of the medium. Documentary, or factual, television can be classified as follows.

The news broadcast. The regular news broadcast in television is supported by illustrations from studio files, videotape recordings, and direct on-the-spot transmissions from the location where events are taking place. The impersonal newscaster eventually gave way to the friendly personality whose warmth makes him a household intimate. An extension of the newscaster is the man in the field, who interprets what is happening, and beyond him the distinguished commentator.

News and current affairs

The news magazine. The effort to provide background to the news led to what may be called the television news magazine. Examples of this format are, in the U.S., *CBS Reports;* in Britain, *Panorama, This Week,* and *World in Action;* and in France, *Cinq colonnes à la une.* The essence of a news magazine is that it should have facilities to send film units and reporters to any part of the world at a moment's notice, as well as to handle home stories as they occur. Coverage can then become fully creative, with the degree of objectivity that may be expected of trusted reporters and commentators.

The documentary of current affairs. Normally filmed rather than videotaped, the current affairs documentary is an investigation in depth of a single subject at home or abroad. Outstanding examples include *See It Now,* which began in the U.S. in 1951, the National Broadcasting system's *White Paper* series of the 1960s, and the British Broadcasting Corporation's *Special Enquiry.* Such documentaries can be highly controversial, as a *See It Now* confrontation with Sen. Joseph McCarthy in 1954 or a Columbia Broadcasting System's *Selling of the Pentagon* of 1971. Made with more leisure than the news magazine, the current affairs documentary shares its techniques with that of the nontheatrical film documentary. More recently, light-weight portable equipment has made possible an intimate, fluid, and mobile technique known as "tele-vérité."

The documentary of general knowledge. Television moved early into the field of general knowledge documentaries, among the first being *Victory at Sea* (NBC), *Air Power* (CBS), and *War in the Air* (BBC). The historical documentary is now used regularly on television, as in NBC's *Project XX,* CBS's *20th Century* series (begun in 1957), and ABC's series *Winston Churchill: The Valiant Years* (1960–61), and the BBC's series *The Great War* and *The Lost Peace.* Some documentaries have been devoted to the sciences, medicine, and the arts—notably in British and Soviet television. Biography is another field. In Britain, Ken Russell's idiosyncratic biographical studies of composers (Debussy, Elgar, Delius, Strauss) caused controversy with their experimental, impressionistic approach, a technique Russell later developed in his feature film *The Music Lovers.*

The personal essay. Some television directors, especially in Britain, have been able to establish highly individual styles. They have used camera and tape on live, unrehearsed subjects in ways that take advantage of new technical developments. Videotape offers more freedom than film, since tape can be erased and reused; tape also can operate with less light than film (to make night shots possible) and can combine coverage from a number of cameras operating in turn on a single, immediate recording.

Educational radio and television. The application of documentary techniques to educational material directed to schools, colleges, and individual students of every kind has become a special field of broadcasting. These services are provided through the public broadcasting networks and through closed-circuit transmissions within school systems.

Other forms. *Music.* Most musical forms may be better suited for radio than for television, since they offer little to the small-screen viewer. Popular singers, however, have become a regular feature on television where they often receive elaborate or fanciful visual presentation—particularly effective on colour television. Opera and ballet are difficult to present effectively on the small screen, though techniques of multicamera coverage have been developed, fragmenting the performance to allow the camera to work more closely with part of the scene at a time.

Popular singers and stars

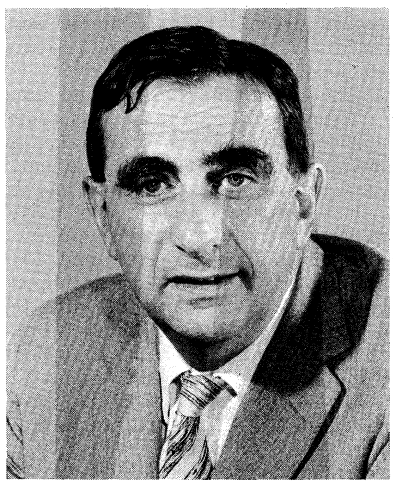
Comedy and satire. A feature of both radio and television is the comedy series; either the half-hour sketch featuring a well-known star or the wholly idiosyncratic show in which burlesque and the verbal or visual gag can be carried to the point of surrealism. In this field radio and television have been strongly creative. Television, notably in Britain, has carried satire to the point of national controversy, as happened with *That Was the Week That Was.*

The television commercial. The television commercial has, at its best, become an art form in its own right. The purest example is the animated commercial, combining its own succinct, witty style and lightning continuity, an art born entirely of television.

THE PROSPECT

The creative use of television in the United States has depended largely on the enlightened sponsor, as in the cases of *Omnibus, Kraft Television Theatre,* and *Playhouse 90.* In Britain the charter of incorporation of the BBC enjoins it to enlighten as well as to entertain, while the Independent Television Authority has the duty to supervise the program content of the commercial televi-

sion companies. But the main hope for more creative television lies in the adoption of new techniques such as the video cassette and cable TV, which will cater to minority interests that cannot be adequately represented in network programming.



BIBLIOGRAPHY. RUDOLF ARNHEIM, *Radio* (1936), was an early evaluation of the broadcast medium; and MARSHALL MCLUHAN, *Understanding Media* (1964), one of the more recent. A definitive history of the BBC appears in ASA BRIGGS, *The History of Broadcasting in the United Kingdom*, 3 vol. (1961–70). In the United States the art of television has generally been discussed in terms of documentary programs, most notably in A. WILLIAM BLUEM, *Documentary in American Television* (1965); a survey of both American and British documentary work occurs in NORMAN SWALLOW, *Factual Television* (1966). The whole field of television art in Britain was covered in PAUL ROTHA (ed.), *Television in the Making* (1956). ROGER MANVELL, *On The Air* (1953), has sections on the arts of radio and television. Among the pioneer manuals on television drama, ARTHUR SWINSON, *Writing for Television* (1955), is among the best. RICHARD LEVIN, *Television by Design* (1961); and WALTER HERDIG and JOHN HALAS, *Film and TV Graphics* (1967), deal respectively with decor and graphics, including animation for titling, commercials, and so forth. A stock-taking of the achievements and limitations of television in Britain is JOAN BAKEWELL and NICHOLAS GARNHAM (eds.), *The New Priesthood* (1970). A. WILLIAM BLUEM and ROGER MANVELL, *Progress in Television* (U.S. title, *TV: The Creative Experience*, 1967), assesses television's development in both the United States and Britain with a selection of articles from the *Journal of the Society of Film and Television Arts* and from the *Television Quarterly*.

(R.M.)

Teller, Edward

The development in 1952 of the world's first thermonuclear weapon, the hydrogen bomb, is generally credited to Edward Teller, who became known in America as "the father of the H-bomb." Although other physicists and mathematicians contributed enormously to the project, his stubborn perseverance in the face of skepticism, and even hostility, from many of his peers played the major role. Teller's work was officially recognized in 1962 when the U.S. Atomic Energy Commission bestowed on him the Enrico Fermi Award.

By courtesy of the University of California Lawrence Radiation Laboratory, Berkeley

Teller.

Born of prosperous Jewish parents in Budapest, Hungary, on January 15, 1908, Edward Teller was encouraged in intellectual pursuits at an early age. A precocious gift for mathematics and curiosity about the natural world characterized his formative years. After attending the Institute of Technology in Budapest, Teller earned a degree in chemical engineering at the Institute of Technology in Karlsruhe, Germany. He then went to Munich and Leipzig to earn a Ph.D. in physical chemistry. While a student in Munich he fell under a moving streetcar and lost his right foot. Despite this tragedy, Teller's robust spirit and sense of fun, as well as his brilliant mind and arresting appearance—an angular face under a shock of unruly black hair and massive eyebrows—have made him a striking figure throughout his life.

Studies in Germany

During the years of the Weimar Republic, Teller was absorbed with atomic physics, first studying under Niels Bohr in Copenhagen and then teaching at the University of Göttingen. In 1935 Teller and his bride, the former Augusta Harkanyi, went to the United States, where he taught at George Washington University, Washington, D.C. Following Bohr's stunning report on atomic fission in 1939 and inspired by the words of President Roosevelt, who had called for scientists and statesmen to act together to defend "our science, our culture, our American freedom and our civilization," Teller resolved to devote his energies to developing nuclear weapons.

By 1941 Teller had taken out U.S. citizenship and joined Enrico Fermi's team in the classic and successful experiment to produce the first nuclear chain reaction. Teller then accepted an invitation from the University of California at Berkeley to work on theoretical studies on the atomic bomb with J. Robert Oppenheimer; and when Oppenheimer set up the secret Los Alamos weapons laboratory in New Mexico in 1943, he was among the first men recruited. Although the Los Alamos assignment was to build a fission bomb, Teller digressed more and more from the main line of research to continue his own inquiries into a potentially much more powerful thermonuclear hydrogen fusion bomb. At war's end he wanted the priority moved to the H-bomb. Hiroshima, however, had had a profound effect on most of the Los Alamos men, and few had the desire to continue in weapons.

Work after World War II

Teller accepted a position with the Institute for Nuclear Studies at the University of Chicago in 1946 but returned to Los Alamos as a consultant for extended periods. The Soviet explosion of an atomic bomb in 1949 made him more determined that the United States have a superbomb, but the Atomic Energy Commission's general advisory committee, headed by Oppenheimer, voted against a crash program. The debate was settled by the confession of the British atomic scientist Klaus Fuchs that he had been spying for the Soviet Union since 1942. Fuchs had known of the U.S. interest in a superbomb. President Truman ordered the go-ahead on the weapon, and Teller laboured on at Los Alamos to make it a reality.

At the Oppenheimer security hearings in 1954, Teller's evidence was decidedly unsympathetic to his former chief. "I would feel personally more secure," he told the inquiry board, "if public matters would rest in other hands." Teller became estranged from Oppenheimer and many other scientists after this.

Teller was instrumental in the creation of the United States' second weapons laboratory, at Livermore, California, concentrating on thermonuclear devices, and was its director for two years from 1958. At the same time he continued as professor of physics at the University of California in Berkeley. Teller resigned from Livermore in 1960 to devote more of his time to his crusade to keep the United States ahead in nuclear arms. He became an influential spokesman in atomic affairs and was a particular champion of Project Plowshare, the Atomic Energy Commission program to find peaceful uses for atomic explosives. He maintained that means could easily be found to guard against radiological pollution from atomic power plants and underground explosions. He advocated nuclear explosions to gain freer access to oil and gas and as a means to create harbours and ship canals.

In a major public statement in December 1970, Teller urged the lifting of secrecy surrounding much of the nation's scientific research, including work in nuclear science, in the interests of clarifying the national debate on the effects of science and technology on society.

BIBLIOGRAPHY. Two works by TELLER are *The Legacy of Hiroshima*, with ALLEN BROWN (1962), the story of the development of the hydrogen bomb; and *The Reluctant Revolutionary* (1964), a discussion of nuclear weaponry and the cold war. For information on Teller, see ROBERT JUNGK, *Heller als tausend Sonnen* (1956; Eng. trans., *Brighter Than a Thousand Suns: The Moral and Political History of the Atomic Scientists*, 1958).

(P.Mi.)

Tennessee

Though classified as an east south central state of the United States, Tennessee is best described as a state of the upper South in its traditions. It entered the Union in 1796 as the 16th member, and, with the disappearance of the Old Southwest in the early 1800s, it became a part of the Old South in spirit and way of life. Such native sons as the frontiersman-legislator Davy Crockett and the soldier-president Andrew Jackson symbolized the state's contribution of a populist political and social philosophy that broke the hold an educated Eastern-Seaboard gentry had maintained on the federal government during the first four decades of the American nation. Unlike the Deep South, in which huge plantations were the symbol of the cotton empire, Tennessee developed largely as an agglomeration of small farms, but most of its people enthusiastically followed the Confederacy into secession and the Civil War.

In the 20th century, however, Tennessee has adapted itself somewhat more readily than most of its sister states to national rather than regional patterns of life. From the beginning, a geography that divided it into three distinct regions tended to soften its Southern cast. East Tennessee always showed marked Northern attitudes, and the two-party political system, which had endured, however weakly, has returned to full flower. Though the state has suffered many of the conflicts of the civil rights struggles since the 1950s, leaders of both whites and blacks hope that an accommodation fully acceptable to both races can be effected.

Four of the state's major cities and their surrounding counties have attained metropolitan size, reflecting Tennessee's growth in population, industry, and urbanization at a generally more rapid pace than its neighbours. Knoxville, the site of the University of Tennessee, and Chattanooga, where in 1863 Confederate and Union soldiers clashed in the famous "Battle above the Clouds" on Lookout Mountain, are the major centres of east Tennessee. Nashville, the state capital and focus of middle Tennessee, is perhaps best known as the national capital of country–western music. Memphis is the hub of west Tennessee, and its history includes its major role in the Mississippi River steamboat traffic and its prominent and colourful position in the development of American jazz.

Tennessee's geography is unique, also, in its extreme breadth of 432 miles (695 kilometres), stretching from the Appalachian Mountain boundary with North Carolina in the east to the Mississippi River borders with Missouri and Arkansas in the west; and its narrow width, only 112 miles (180 kilometres) separating its northern neighbours, Kentucky and Virginia, from Georgia, Alabama, and Mississippi on the south. Its 42,244 square miles (109,411 square kilometres), according to the census of 1970, held a population of 3,923,687 persons, about 16 percent of whom were black. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; CIVIL WAR, U.S.; NORTH AMERICA; APPALACHIAN MOUNTAINS; and MISSISSIPPI RIVER.)

THE HISTORY OF TENNESSEE

From settlement to Civil War. Much of Tennessee's early history consisted of prototypal frontier dramas, for its patterns of exploration and settlement in the late 18th and early 19th centuries were to be repeated in all of the states west of the Appalachians. Tennessee became a sort of mother state for the entire Old Southwest. Its pioneer families fanned out into the newer regions of Alabama, Mississippi, Arkansas, north Louisiana, and east Texas. The bloody, destructive Civil War laid its scourge upon Tennessee, which became a major battleground of the war in the west. The battlegrounds, neatly kept and well-marked, can be found today, but for decades an abiding political and ideological scar kept company with the old fields of conflict.

The long aftermath. The war bound Tennessee closely to the "lost cause" of the Confederacy and to the New South, which became a regional attempt to graft the Old South to the modern trends of the nation. The roaring industrial prosperity of the Eastern and Great Lakes states left the devastated South largely untouched. Though decade by decade Tennessee became a wealthier and growing state, it, like other Southern states, had difficulty in catching up to the booming national standards, despite a diversifying economy and an energetic people. The Great Depression of the 1930s, which came early and ended late in Tennessee, staggered the internal rates of improvement and growth.

Postwar recovery

New directions. After World War II, Tennessee's history again took new directions. The technological revolutions of the 20th century loosened its traditional modes of life. The unities of thought and feeling that sprang from a well-remembered past splintered in the face of the excruciating changes of modern America. In the 1940s and 1950s, the state's economy changed from one dominated by agriculture to one based on manufacturing. Its leaders, with deep conviction, allied themselves with what one observer has called the emerging South, a South less isolated, less rural, less militant, and at the same time more prosperous and more a part of the national scene.

THE LANDSCAPE

The natural environment. East Tennessee comprises rugged mountains and broad valleys of great beauty that give way to the rolling hills and wide basins of middle Tennessee. West Tennessee, on the other hand, is a relatively undulating plain broken by deep gullies.

Geographical regions. Geographers divide the state more scientifically into six natural regions. Sixteen peaks in the Unaka Mountains—a section of which is popularly known as the Great Smoky Mountains—rise above 6,000 feet, the tallest of them, Clingmans Dome, at 6,642 feet (2,024 metres). The Great Appalachian Valley, varying from 30 to 60 miles in width, has within it a series of low ridges that rise 800 feet or more above the intervening valleys. The Cumberland Plateau has a generally flat, slightly undulating surface, but it has been cut by deep and sometimes wide river valleys. The Interior Low Plateau, the largest of the regions, is dominated by the Nashville Basin and its Highland Rim. About 60 miles wide and running roughly north to south across the state, the basin floor is a slightly rolling terrain punctuated by small hills known as knobs. To the west, the Eastern Gulf Coastal Plain undulates only slightly and is laced with meandering, low-banked streams. In the extreme west, the plain ends in the Mississippi Alluvial Plain, a narrow strip of swamp and floodplain alongside the river.

Peaks, plateaus, and plains

Rivers and soils. The land drains directly into three major rivers. The Tennessee River, which flows southward in the east and northward in the west, drains the east, the southern part of the middle region, and a major part of the west. The Cumberland River, dipping into the state from the north, drains the upper middle region, while the Mississippi River directly drains a small portion of the west. The damming of the Tennessee and, to a lesser extent, of the Cumberland has created an impressive chain of slack-water lakes, sometimes known as the Great Lakes of the South, many of which lie in Tennessee. In general, the valleys and upland basins of Tennessee have moderately fertile soil of limestone origins, and the streams have created rich alluvial lands along their beds. The soils of the ridges and the plateau, however, are thin, stony, and moderately acid, while the coastal plain has a sandy, thin soil that does not lend itself to agriculture. Thirty-five percent of the state's soils are unfit for any kind of cultivation.

Climate. Tennessee has a moderate climate featuring cool but not cold winters and warm but not hot summers. The drop in elevation causes temperatures to rise significantly from east to west. Mountain summers in the east are not unlike those of more northerly states. The growing season ranges from 160 days in the east to 260 days in the southwest. The state receives ample precipitation, about 50 inches (1,270 millimetres) a year, rather evenly distributed over the seasons and regions.

Vegetation and animal life. The state's central position in the eastern half of the United States and its diverse elevations have meant that many plants, animals, and fish

identified more with the extremes of north and south can be found in the state. Tennessee is about 52 percent forested by more than 200 species of trees, of which 59 are commercially valuable. Found throughout the state are such common trees as locust, poplar, maple, oak, elm, beech, pine, spruce, walnut, hickory, and sycamore.

Human regionalism. The late settlement of west Tennessee, long an Indian reserve, combined with the obvious geographical separations to create a strong sectionalism within Tennessee. The Civil War further accentuated the differences, with most people in the east remaining Union and loyal, whereas the west and middle became a Confederate stronghold in ideology. The east thereby formed a traditional tie to the Republican Party, as opposed to the equally strong bonds with the southern wing of the Democratic Party that existed in the other regions. The east would also, in legend and partial fact, advertise itself as a fortress for "mountain culture"—independence, small farms, and underemployed mountaineers, poor but proud—whereas middle Tennessee, particularly in the Nashville Basin, allied closely with the New South of the late 19th and early 20th centuries, a South that embraced much of the new technological life but clung mightily to the romanticism of the Old South in its popular lore. The west emphasized a Jacksonian democracy of entrepreneurial yeomen and vigorous Democratic politics for its white majority. Even today, with superhighways and airlines spanning the state, the sense of three different Tennessees influences the politics and thinking of the state. In recent years Memphis and surrounding Shelby County, radically different from agricultural west Tennessee, has increasingly become a distinct section as well.

Sectionalism and sentiment

Small farms and small towns characterize most of the inhabited Tennessee landscape. Its average farm size, 114 acres (46 hectares), is only about one-third of the national size. In 1970 three of the 95 counties had fewer than 4,000 residents, and 57 had fewer than 25,000 people. The urbanization rate of 59 percent represented an increase of only 7 percent during the 1960s. Thus Tennessee continued to urbanize more slowly than the United States in general. The metropolitan areas of the four major cities, however, with their varied industrial bases, spreading suburbs, and urban opportunities and problems, resemble metropolitan areas across the nation. Tennessee's long and traditional rural character, though deeply embedded, is being eroded.

THE PEOPLE OF TENNESSEE

Ethnic and religious composition. At one time, uniformity and homogeneity aptly described Tennessee's white population, relatively untouched as it was by the waves of immigration into the United States. From its beginnings, Tennessee literature and folklore has stressed the Anglo-Saxon tradition celebrated by frontiersmen like Davy Crockett and Andrew Jackson, by such modern heroes as World War I army sergeant Alvin York, and by the entertainers at Nashville's country–western-music mecca known as the "Grand Ole Opry." The state's white population worshipped as Protestants—more than two-thirds of the church members belong to the Southern Baptist and Southern Methodist churches—and had a fundamentalist American approach to such values as patriotism, honesty, courage, work, duty, and personal morality.

Segregation

Yet from the beginning, uniformity and homogeneity pertained only in part. Slavery entrapped more than 280,000 blacks in 1860, some 26 percent of the population. The black percentage has declined consistently since 1880. Black and white Tennesseans, though touching each other in many ways, have lived in most important ways apart and isolated from one another. Blacks grew up and died in a segregated world, separate but very much unequal. In their separate institutions—the church, the lodge, the schools, and other public places—they developed a significant subculture within the general American culture. Beginning in the 1950s, after decades of protest and the slow accumulation of power, many leaders of the black Tennesseans organized and worked for a new, integrated Tennessee: in schools, in factories, and in public places. Their demands for a fair and equal society reverberated across the state. The turns and twists of this black revolution have had a profound impact on the people of Tennessee, creating strains in the social and political life of whites and blacks alike as the legal structure of segregation and some of its habits were broken. The clashes of culture and power probably will continue, but a countertrend of black and white accommodation and understanding is also at work.

Demography. Tennessee's population grew much more slowly than the national rate from 1940 to 1970, but its 8 percent and 10 percent growth in the 1950s and 1960s, respectively, was a faster rate than those of other east south central states. The census of 1970 showed Tennessee with slightly lower percentages of persons in the younger and older age groups and a higher percentage between 18 and 44 years of age. During the 1960s, the birthrate declined well below 20 births per 1,000 of population, and by 1970 the death rate was 9.5 per 1,000 population. The death rate of black Tennesseans, however, was 58 percent higher than that of the white population.

The decades-long trend of greater emigration than immigration was broken in the 1960s, when Tennessee became the only east south central state to have greater inflow than outflow of people. In the same decade, urbanization continued, and a slight movement of population from east to west could be detected. Blacks continued to migrate to the cities in large numbers: by 1970 more than 60 percent of the black population lived in the four metropolitan areas.

THE STATE'S ECONOMY

General economic picture. Tennessee's agricultural resources were always slim: almost 70 percent of the land is unfit or poor for cultivation, and less than 2 percent is classified as good. Until the state's agonizing shift from agriculture to manufacturing began in the 1940s, these weak resources made it appear statistically as an area of high underemployment, low income, low educational levels, substandard housing, and deficient health facilities. The shift to manufacturing has failed to improve Tennessee's position in national rankings, since the nation as a whole has boomed even more, but it has brought about vastly improved standards of living within the state. Regionally, Tennessee became a manufacturing state more quickly and more fully than any other east south central state, and its per capita income, about three-quarters of the national average, is the second highest among these states. It ranks among the top 20 states in value added by manufacture and in industrial employment.

Industry and standards of living

Components of the economy. Though the service industries employed somewhat more persons and provided slightly more personal income, Tennessee's manufacturing employment grew nearly 50 percent during the 1960s. This reflects in part the state government's aggressive policy, over several decades, of enticing industry from other states. The major industries in value added by manufacture were chemicals, food processing, apparel, electrical machinery, and textiles. Agriculture produced less than 4 percent of personal income. The state has moderate coal and stone deposits and is the nation's largest producer of zinc.

Tennessee Valley Authority. The creation of the Tennessee Valley Authority (TVA) in 1933 greatly enhanced a transition to industry in Tennessee as well as neighbouring states affected by it. The growing stock of electricity from the authority's dams, steam plants, and nuclear stations, which made the TVA the nation's largest producer of electricity, attracted such major industries as the Oak Ridge nuclear plant and the works of the Aluminum Company of America. It brought great changes also in rural life throughout much of the South, bringing the first electrification to many areas. The TVA often is looked upon as one of America's major achievements in regional economic development, upgrading the land, industry, and overall standards of living.

Transportation. In the last half of the 19th century, the railroads pushed through the valleys and across the

ridges, but the peak mileage of 1920 had declined by the 1970s. By this time, the more than 70,000 miles of highway had lifted the state out of the mud to dependable all-weather travel. Major airline service to the metropolitan cities and the ever increasing use of barge tows along the Cumberland and Tennessee rivers supplement the transportation network. Tennessee's cities are traffic choked, however, because of their critical need for modern, urban mass transit.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. The constitution of 1870 differed little from the original document formulated in 1796. Reflecting the needs and points of view of an earlier America, it remained unaltered until, beginning in 1953, a series of amendments were passed that have helped to modernize state government.

Among the changes effected were clauses liberalizing the complicated amendment procedure, increasing the terms of the governor and state senators from two to four years (with the provision that the governor cannot succeed himself), increasing the pay of state legislators, providing for annual rather than biennial meetings of the state legislature, abolishing the poll tax, and increasing the power of cities to govern themselves independently of the state.

Today, the structure of the executive, legislative, and judicial branches of government in Tennessee resembles closely that of many other states. The governor is the only popularly elected executive official. The speaker of the state Senate serves as lieutenant governor. Other executive officeholders are elected by the entire legislature, while the attorney general is appointed by the Supreme Court. Executives of major departments and important state commissions are appointed by the governor. The bicameral General Assembly comprises a 33-member Senate and a 99-member House of Representatives. It can override a governor's veto by a simple majority. The legislature is not considered a full-time occupation, for its members receive only token remuneration.

The judicial system consists of a complex of inferior courts—chancery courts, circuit courts, and criminal courts—that try various types of cases. The Supreme Court and the lower Court of Appeals have their judges apportioned among the three traditional sections of the state.

Local government also clings to the national pattern. In some counties, a county court made up of elected trustees collects taxes and maintains most county services. Education and safety forces, however, are administered by an elected or appointed school board and the sheriff, respectively. In several counties, the county court is composed of an elected county judge together with justices of the peace elected by districts. City government includes city manager-council, mayor-council, and commissioners-council forms.

Experimentation in local government

Tennessee has under way a major experiment in local government. In 1962 Nashville and its county, Davidson, began a consolidation into a single governmental unit called Metropolitan Government, or "Metro." Metro has solved some old problems, left others untouched, and created some of its own. As this type of extended-area government frequently has been suggested as a step toward possible improvements in America's urban crises, urban planners across the country are studying Metro closely.

Politics. Tennessee never had the multifactional, one-party politics that characterized so many other Southern states. The Democratic domination was leavened always by the possibility of successful challenges from the Republicans, whose strength remained steady in east Tennessee. The result was a Democratic Party usually made up of two factions, not always ideologically differentiated, that fought in the primary elections and then united for the general election. Since Reconstruction, only four Republican governors have been elected, though two Republican congressmen have been traditional. At the end of the 1960s, this traditional arrangement was shattered badly by the replacement of the two Democratic senators by Republicans. Republicans, though still a minority, dramatically increased their representation in state and local government, and since 1948 Tennessee's presidential vote has gone to the Republicans, except in 1964. In 1970 the Republicans won the governor's chair for the first time in 50 years. With the state's election results no longer certain, they will most likely be disputed hotly by the parties and within the parties' councils as well.

Social services. Tennessee's social needs are many and its wealth slim; its showing in expenditures for public needs in relation to national figures is poor. By the early 1970s, Tennessee's annual budget of about $1,500,000,000 was financed principally by a general sales tax, license and privilege taxes, and several usage taxes, but the tax structures, both state and local, rank among the five lowest states in effort. By 1971 it was one of 12 states that did not have a general income tax. Tennessee's lower living costs are balanced by average weekly and hourly wage rates well below the national average. In 1969, even in the four east south central states, it ranked only third in these rates. Tennessee's population generally ranks very low in educational attainments. Its $560 per student expenditure for public schools in 1970 was 44th in the nation and its per capita expenditure for higher education ranked 50th. By 1970, one of every 16 Tennesseans received welfare funds of some sort, but its per capita payments under such aid programs as for dependent children and the blind or sick ranked in the lower third of the states. Federal and state activity to solve its economic and social problems in the 1960s was almost revolutionary in comparison to previous decades, but Tennessee, hampered by its Appalachian poverty, its low-wage industry, and its depressed west Tennessee agriculture, has not been a national leader in these trends.

CULTURAL LIFE AND INSTITUTIONS

The cultural milieu. Tennessee long has had a national image as the "hillbilly state." The mountaineer—a person of drawling speech dressed in blue-denim overalls, operating an illegal whiskey still—became a figure of national mythology. The image actually was nurtured and sustained by a remarkable institution, the "Grand Ole Opry," founded in Nashville in 1925. This radio broadcast of country-and-western music made Nashville the capital city of country America. Today, Nashville is a leading centre for the production and distribution of popular-music records, particularly country–western, but it is also the seat of Vanderbilt University, founded in 1873, and today one of the most highly regarded universities in the South.

Learning, communications, and the arts

As might be expected, however, Tennessee is in many ways a cultural carbon copy of the greater United States. It has nearly 60 institutions of higher education, both public and private, enrolling more than 130,000 students. More than 200 libraries and branches make books and learning materials available for Tennesseans. All four major cities have active professional symphonic orchestras, and each city supports several art galleries. Museums, such as the American Museum of Atomic Energy at Oak Ridge, help to create a significant educational environment. Sophisticated daily newspapers such as the *Chattanooga Times* (often considered among the finest in the South), the *Memphis Commercial-Appeal*, and the *Nashville Tennessean* circulate across the state. Network and educational television can be seen in every county. Nashville has major publishing houses for the Baptist and Methodist churches. Graceful antebellum architecture dots the landscape, in startling contrast to examples of strikingly modern architecture. The TVA dams and new steam- and nuclear-power plants, symbols of industrial Tennessee, modify considerably the old "hillbilly" image of Tennessee life. In short, Tennesseans participate fully in the great cultural and social movements of their times.

Prospects. Tennessee in the early 1970s offers, somewhat more sharply than some other states, the diversities that make up the United States. The state has a steady drive toward more factories and more people living in congested cities, but a continuing isolated and wooded countryside, a recent rural domination, and many small

towns still link it to an older America. Its political habits have developed a chronic uncertainty as the Republican Party enjoys unprecedented success at the polls. But the shifts in party allegiance over the past 25 years can be deceptive, for both parties tend to be more conservative than their national leadership.

For the most part, Tennessee has not been a leader in effecting change or experimenting with new ways for a new society. Rather, the history of the state shows a people and a set of institutions adjusting slowly to the changes that appear to be working within the nation.

BIBLIOGRAPHY. The most recent, usable history of the state is STANLEY FOLMSBE, ROBERT CORLEW, and ENOCH MITCHELL, *Tennessee: A Short History* (1969). The extensive bibliography on pp. 579–613 directs the reader to the richness of Tennessee's past. JOHN KNOX BALLINGER, *The People of Tennessee* (1949), examines the demography of Tennessee from the 1790s through the 1940s. The best sources of information about the contemporary state may be found in the occasional publications of the TENNESSEE STATE PLANNING COMMISSION, whose studies are directly concerned with the demography, economic and human resources, and social structure of the state, as well as leading problems of government. Information on recent and old publications may be obtained from the State Library and Archives, Nashville.

For the basic physical geography of the state, see HAROLD C. AMICK and L.C. ROLLINS, *The Geography of Tennessee* (1937). A good interpretative work on Tennessee politics in the 20th century may be found in V.O. KEY, *Southern Politics in State and Nation*, pp. 59–81 (1949). See also NORMAN PARKS, "Tennessee Politics Since Kefauver and Reece: A Generalist View," *Journal of Politics*, 28:144–168 (1966). HUGH DAVIS GRAHAM, *Crisis in Print: Desegregation and the Tennessee Press* (1969), gives great insight into racial conflict in the state. See also HARRY HOLLOWAY, *The Politics of the Southern Negro*, pp. 65–90, 272–309 (1969), on race relations in the state.

Tennis and Allied Court Games

Games of the tennis family are played with racket and ball on various sorts of courts and trace their origin back to a 12th–13th century French game *jeu de paume* ("palm game") or, in England, "tennis." Its descendant, lawn tennis, was first played in the early 1870s and has become so popular that to most people tennis means lawn tennis, and throughout this article, unless qualified, tennis refers to lawn tennis. The more ancient game, for purposes of differentiation, is usually called real tennis in Great Britain, court tennis in the U.S., or royal tennis in Australia—much to the annoyance of purists.

The various forms of rackets (including squash rackets) and table tennis are covered in separate articles under those titles. Other modern variations include deck tennis, paddle (or padder) tennis, and platform tennis. This article deals with lawn tennis, real tennis, and badminton.

Lawn Tennis

ORIGINS AND EARLY HISTORY OF LAWN TENNIS

The old game of real tennis had been played in covered courts for many centuries and it is not surprising that from time to time efforts were made to play it in the open air. In the history of the game, various mention is made of such experiments, but none succeeded until the use of rubber resulted in a ball that was able to bounce on a grass surface. Rubber was known to the Aztecs and Columbus saw balls "made of the gum of a tree" being used by the Indians of Haiti. But not until the mid-19th century did Europe learn how to manipulate rubber successfully.

First book of rules

There has been much dispute over the invention of tennis, but certainly it was a Major Walter Wingfield of Nantclwyd in North Wales who first published a book of rules in 1873 and took out a patent on his game in 1874. Wingfield's court was of the "hourglass" shape that had become the rule in badminton (see below). But the publication of his version of "Sphairistikè, or Lawn Tennis" led to a spate of other claims to the invention of the game, most of which involved a rectangular court. R.A. Fitzgerald, secretary of the Marylebone Cricket Club (MCC), then the governing body of real tennis, pointed out that the MCC had only recently revised the rules of real tennis and might be a suitable body to standardize the rules of tennis. Moreover, a distinguished real tennis player, J.M. Heathcote, had developed a better ball, made of rubber but covered with white flannel. And so it came about that the MCC first established the rules of tennis in 1875.

Meanwhile the game spread to the U.S. in 1874 when Miss Mary Outerbridge of New York saw it being played by the British garrison in Bermuda and brought a set of rackets and balls to her brother, a director of the Staten Island Cricket and Baseball Club. Soon afterward, tennis courts were established in Boston, Newport, R.I., Plainfield, N.J., New Orleans, and Philadelphia.

A significant milestone in the history of tennis was the decision of the All-England Croquet Club, in 1875, to set aside one of its lawns at Wimbledon for tennis, which soon proved so popular that the following year the club changed its title to the All-England Croquet and Lawn Tennis Club. In 1877 the club decided to hold a Tennis Championship, open to amateurs only, for a silver Challenge Cup presented by *The Field* magazine. A special championship subcommittee of three was appointed and, probably because two of them were distinguished players of real tennis, they decided on certain rules different from those of Sphairistikè. They decided on a rectangular court, 26 yards (24 metres) long by 9 yards (8 metres) wide; they adopted the real tennis method of scoring by 15s; and they allowed the server one fault (*i.e.*, two chances to deliver a correct service on each serve). These major decisions remain part of the rules today.

Twenty-two entries were received and the first winner of the Wimbledon Championship was Spencer W. Gore, an old Harrovian rackets player, renowned for a heavily cut underhand service and for his net-storming tactics. The scene was very different from that of today. There was no stand for spectators. Players wore white flannel shirts with a tie, long white trousers kept up by a schoolboy belt, and a white cap. Rackets bore traces of their real tennis forebears and were somewhat square-topped with a plain wooden handle. Balls were lighter, weighing 1¼ to 1½ oz (35.4 to 42.5 g), compared with the modern 2 to 2$\frac{1}{16}$ oz (56.7 to 58.5 g).

Two hundred spectators paid a shilling each to watch the final, after which nets, posts, and guy ropes were sold off at 30 shillings a set and the club made a net profit of £10.

The All-England Croquet Club was first in the championship field, but it was followed in 1878 by the Scottish Championship and in 1879 by the Irish Championship, which for many years rivalled Wimbledon in repute.

DEVELOPMENT OF THE SPORT

There were several alterations in some of the other rules (*e.g.*, governing the height of the net) until 1880 when the All-England Club and the MCC published revised rules that approximate very closely those in use today. In 1880, the first American championship of national interest was held at the Staten Island Cricket and Baseball Club. The victor was an Englishman, O.E. Woodhouse. The fast-growing popularity of the game in the U.S. and frequent doubts about rules led to the foundation of the U.S. National Lawn Tennis Association (later renamed the U.S. Lawn Tennis Association [USLTA]), following a meeting of 33 clubs held in New York in 1881.

Founding of national associations and championships

Under the auspices of the USLTA, the first official U.S. National Championship was held in 1881 at the Newport Casino, R.I., next to the real tennis court, which provided a gallery for spectators. It was played under English rules. The winner, R.D. Sears, was U.S. Champion for seven consecutive years.

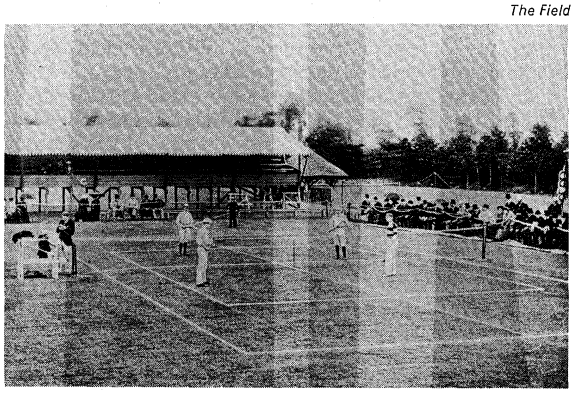
In the United Kingdom the All-England Club was dominant and the British Lawn Tennis Association (LTA) did not come into existence until 1888.

Meantime, lawn tennis had taken firm root in Australia. It started in Victoria in 1880 under the aegis of the Melbourne Cricket Club and in New South Wales in 1885, when the first interstate championships were played. The first New Zealand National Championship was held in 1886. The Lawn Tennis Association of Victoria took over

control from the Melbourne Cricket Club in 1889, but not until 1904 was the Australasia Association founded, to include all the states of Australia and New Zealand.

The National Lawn Tennis Association of France instituted the French National (hard [clay] court) Championship in 1891, but it was not opened to players from other nations until 1925. The National Championship of Canada was instituted in 1890; others included Spain 1910, South Africa 1920, Denmark 1921, Egypt 1925, Italy 1930, and Sweden 1936.

The year 1884 was remarkable for the introduction of a Women's Championship at Wimbledon, as well as the transfer there of the Men's Doubles previously held at Oxford. The first Women's Champion was Maud Watson, who won it two years running. She was succeeded by Miss Blanche Bingley, later Mrs. Blanche Bingley Hillyard, who won the title six times between 1886 and 1900. Lottie Dod, a child prodigy, won her first championship in 1887 at the age of 15 and was victorious every year until 1893 except in 1889 and 1890, when she did not compete. In the U.S., the first Women's Tennis Championship, held in 1887, was won by Miss Ellen F. Hansell.



Ladies' tennis fashions of those early days look very strange to modern eyes. Long white dresses with voluminous skirts, black stockings, black sandshoes (gym shoes), and a white straw hat were considerable obstacles to overcome in order to play an active game.

The first Australian Women's Championship, in 1923, was won by Mrs. B.H. Molesworth. Miss Suzanne Lenglen won the first two French Women's Championships in 1925 and 1926.

Outstanding players

Tennis in the 1880s was dominated by the remarkable twin brothers William and Ernest Renshaw. William won the Wimbledon Championship seven times, on three occasions defeating his brother in the final. Ernest was victorious once, and in partnership they won the British Doubles Championship, first played at Oxford in 1879, seven times. In 1883 they played two exhibition matches at Wimbledon against the U.S. brothers C.M. and J.S. Clark, and defeated them decisively.

The Field

W. and E. Renshaw, England, and C.M. and J.S. Clark, U.S., in the first international match at Wimbledon, 1883.

After the popularity of the Renshaw twins, the 1890s came as an anticlimax and public interest began to wane. The craze for the bicycle was in full swing and some newspapers even predicted that tennis was dying. The Wimbledon Championships showed a financial loss in 1894 and 1895; the All-England Club committee turned back to croquet to revive its flagging fortunes. The situation was saved by the arrival of two more brothers: Reginald F. and H.L. (Hugh) Doherty. R.F. won the Wimbledon Championship in 1897, 1898, 1899, and 1900. H.L. won in 1902, 1903, 1904, 1905, and 1906. H.L. also won the U.S. Singles Championship in 1903 and a Gold Medal at the Olympic Games in Paris in 1900. In partnership they won the Wimbledon Doubles eight times between 1897 and 1905, won the U.S. Doubles in 1902 and 1903, won the Davis Cup in 1903, 1904, 1905, and 1906, and won the Gold Medal for doubles at the 1900 Olympic Games. The crowds flocked back to Wimbledon and the international popularity of the game made rapid progress. Not only were the Dohertys masters of the game; they were also renowned for their charm of manner and good sportsmanship. Their travels abroad throughout Europe and to the U.S. laid the foundations of the worldwide popularity of the game.

The Davis Cup

The first international competition was the Davis Cup, donated by U.S. Doubles champion Dwight Davis, in 1900. Only Great Britain challenged the first year and was defeated by the U.S., Davis himself playing on the victorious team. There was no challenge in 1901, but in 1902 a strong British team that included the Doherty brothers went to America. For some strange reason, the non-playing captain omitted H.L. from the singles, although he was the Wimbledon Champion, and the U.S. retained the trophy. The following year the Doherty brothers swept all before them and won the Cup, which was retained by Great Britain for the next three years.

The Doherty reign ended in 1906. Although H.L. won the Wimbledon Singles, the brothers were defeated in the Doubles by S.H. Smith and F.L. Riseley, who had beaten them once before in 1902. R.F. died in 1910; H.L. retired to play golf and died in 1919. But tennis had become too well established for any falling off in popularity. A new star appeared on the scene, Norman Brookes, the first in a long line of outstanding Australian tennis players. He was vanquished in 1905 by H.L. Doherty, but became Wimbledon Champion in 1907 and again on his next visit in 1914—and was the first left-hander to reach the top. His great friend and doubles partner was Anthony F. Wilding from New Zealand, Wimbledon Champion from 1910 to 1913. In partnership they won the Wimbledon Doubles on both occasions that they entered the event—1907 and 1914. More important, they wrested the Davis Cup from Great Britain in 1907 and held it for the next four years. Their victory in this world-famous international competition and the fact that they defended their title with such success for several years in Australia began there a lively public interest that has never waned.

Of the lady champions of the early 20th century, Mrs. Lambert Chambers was outstanding. As Miss Dorothy K. Douglass, she won her first Wimbledon Championship in 1903 and again in 1904, 1906, 1910, 1911, 1913, and 1914, not competing in 1909 and 1912. She was undoubtedly the outstanding British player of the decade, but in 1905 she met her match in the first U.S. Women's Champion to win at Wimbledon, May Sutton, aged 18, who again defeated her for the Wimbledon Championship in 1907. Like many of her American successors, Miss Sutton possessed a powerful topped forehand drive, more usually associated with the men's game.

The outbreak of World War I in 1914 caused an interruption in tennis activities throughout most of the interested nations, but, with the exception of 1917, American championships continued to be played.

The early postwar years saw the triumph of two outstanding champions, whose prowess in the opinion of many people has never been surpassed—W.T. ("Big Bill") Tilden of the U.S. and Miss Suzanne Lenglen of France.

All-time champions W.T. Tilden and Suzanne Lenglen

Tilden, U.S. Champion from 1920 to 1925 and again in 1929, won the Wimbledon Championship for the first time in 1920, defeating in the final of the all-comers competition Z. Shimizu, the first Japanese player to make a mark at Wimbledon. Tilden retained the title in 1921 and won it again in 1930. In the same period he won 15 Davis Cup singles and contributed largely to the American victories in this competition from 1920 to 1926.

Miss Lenglen dominated the ladies' game from 1919 to 1925; but for the war years she might well have started her international career earlier, for she won the hard-court championship of the world at Saint-Cloud (near Paris) in 1914 at age 15. She won the Wimbledon Championship at her first attempt, in 1919, after a memorable final against Mrs. L. Chambers. She won it again in 1920, 1921, 1922, 1923, and 1925, having retired in 1924 because of illness. In 1920 she won the Gold Medal at the Olympic Games in Antwerp. In 1913 two new championships had been introduced at Wimbledon, for Women's Doubles and Mixed Doubles. In partnership with Elizabeth Ryan of the U.S., Miss Lenglen won the Women's Dou-

William Tilden, U.S., who dominated world tennis from 1920 to 1925, completing an overhead smash.
Culver Pictures

bles six times between 1919 and 1925. Miss Ryan, who never won the Wimbledon Women's Singles, won 19 doubles events at Wimbledon between 1914 and 1934 despite the interruption of the war. Miss Lenglen also won the Mixed Doubles three times, in partnership with G.L. Patterson (1920), P. O'Hara Wood (1922), and Jean Borotra (1925). In 1920 she became the first woman to win all three Wimbledon Championships.

She had developed a powerful game by practicing with men and she needed far more freedom of movement than current fashion allowed. Her first appearance at Wimbledon in a calf-length white dress with short sleeves and without petticoat or suspender belt caused a sensation, but her success soon led to others copying her.

Her only failure was on an American visit in 1921, where she was scheduled to play a series of exhibition matches against Norwegian-born Mrs. M. Bjurstedt Mallory, the U.S. Women's Singles Champion in 1918, 1920, 1921, 1922, and 1926. Mrs. Mallory had won the first set 6–2 and the first game of the second set when Miss Lenglen retired, feeling ill, and cancelled the rest of the tour.

Suzanne Lenglen, France, outstanding player between 1919 and 1925, striding forward to complete a forehand return.

She turned professional in 1926 and made a successful tour of the U.S. before retiring altogether.

Miss Lenglen demonstrated that the English-speaking world had no monopoly of tennis champions and this point was emphasized by four brilliant Frenchmen, Jean Borotra, Henri Cochet, René Lacoste, and Jacques Brugnon. Between them they won the Wimbledon Singles Championship six times in a row from 1924 to 1929 and the Doubles five times; the U.S. Singles three times, and the French Singles 10 times and the Doubles 11 times. They wrested the Davis Cup from the U.S. in 1927 and held it until 1932.

Meanwhile, a new American star had dawned in the ladies' field—Miss Helen Wills, later Mrs. Wills Moody and later still Mrs. Roark. She won her first U.S. Championship in 1923 and won it seven times in all; she won at Wimbledon eight times between 1927 and 1938 and won the French Singles four times between 1928 and 1932. Only once, at the beginning of her career, did she play against Miss Lenglen, at Cannes, where she lost in two straight sets. Her great rival was another young American, Helen Jacobs, Wimbledon Champion in Mrs. Moody's absence in 1936 and U.S. Champion from 1932 to 1935.

Stars of the 1930s, 1940s, 1950s, and 1960s

With the advent of the 1930s, French predominance began to wane and American and British players came to the fore, along with one Australian, J.H. Crawford. For Great Britain, Fred Perry was the principal contender. He won the Wimbledon Championship for three years running (1934–36), the U.S. Championship three times in 1933, 1934, and 1936, the Australian Championship in 1934, and the French in 1935. Thanks to him and H.W. ("Bunny") Austin, the pioneer of short trousers, Great Britain won the Davis Cup from 1933 to 1936.

From America came such champions as S.B. Wood, H. Ellsworth Vines Jr., J. Donald Budge, and Robert L. Riggs. Budge was the first man to score a grand slam by winning all four major championships, the British, American, French, and Australian, in one year, 1938. American predominance regained the Davis Cup for them in 1937 and 1938, although surprisingly they lost it to Australia in 1939. And finally Alice Marble, U.S. Champion in 1936, and 1938–40, won all three championships at Wimbledon (Singles, Doubles, and Mixed) in 1939, a feat accomplished previously only by Miss Lenglen.

The development of the game was interrupted by World War II, although the U.S. Championships continued to be played. International tennis started up again in 1946 and once again U.S. players predominated, led by J.A. Kramer, U.S. Champion in 1946 and 1947 and Wimbledon Champion at Singles and Doubles in 1947.

American women, too, dominated the scene in the early postwar years—Miss P.M. Betz, Miss M.E. Osborne, and, in particular, Miss A. Louise Brough, who had an outstanding record at Wimbledon. She won the Women's Singles three years running, 1948–50, and again in 1955. She won the Women's Doubles from 1948 to 1950 and in 1954, and the Mixed Doubles from 1946 to 1948 and in 1950. At Forest Hills (N.Y.) she won the Women's Doubles with Mrs. du Pont (Miss Osborne) for the 12th time in 1957.

The hegemony of the Americans was soon challenged by their old Davis Cup rivals, the Australians, who regained the cup in 1950 and almost monopolized it for the next 17 years, winning every year except for three American victories in 1954, 1958, and 1963. This was accomplished by a steady stream of outstanding Australian players such as Frank Sedgman, Lew Hoad, Ken Rosewall, Roy Emerson, Rod Laver, and a brilliant doubles player, John Bromwich, who played a two-handed shot on his right, a left-handed forehand on his left, and served and smashed with his right hand. They were led by an outstanding non-playing captain, Harry Hopman.

As well as the names of these brilliant Australians the Wimbledon Championship roll of the 1950s and 1960s contains several outstanding American players and three victors for countries that had not hitherto featured. Jaroslav Drobny, who was born in Czechoslovakia, naturalized Egyptian and then a British subject, won in 1954 at age 32. Alex Olmedo from Peru won in 1959 and the popu-

lar Spaniard Manuel Santana in 1966. The Australians' dominance waned at the end of the 1960s as their best players became professionals.

But if Australia had dominated the field of men's tennis, the U.S. kept a firm hold on the ladies' championships. Not until 1959 did anyone except an American win the Women's Singles at Wimbledon. Among the outstanding players of those years were Doris Hart, Althea Gibson, and the greatest of them all, Maureen Connolly, familiarly known as "Little Mo." She won her first championship at Forest Hills in 1951 at the astonishing age of 16 and remained U.S. Champion in 1952 and 1953. She won the Wimbledon Championship every year she played from 1952 to 1954. In 1953 she achieved the distinction of winning all four major championships—Wimbledon, Forest Hills, Australian, and French—in the same year. It was a tragedy when a serious riding accident in 1954 ended her tennis career.

The first to break the American monopoly of ladies' tennis championships was Maria Bueno from Brazil, Wimbledon Champion in 1959, 1960, and 1964, but American dominance recurred with three consecutive victories by Billie Jean King from 1966 to 1968. There were some outstanding British and Australian players, however, who also won the Championship, such as Angela Mortimer (1961), Ann Jones, and Margaret Court (nee Smith), who won all four major championships in 1970.

PROFESSIONAL AND OPEN TENNIS

In both real tennis and lawn tennis, there had always been professionals. In real tennis they were in charge of the courts, made the rackets and balls, coached amateur players, and "marked" (kept the score). As early as the 15th century, there had been a guild of racket and brush makers in France. By 1571, when Charles IX granted them statutes, they had separated from the brush makers and become known as "Master Professionals."

When lawn tennis began there was an equal need for the professional to coach and organize, but his job remained relatively unknown and, unlike real tennis, there were no competitions in which he could play. All this changed in 1926 when Charles C. ("Cash and Carry") Pyle, a successful football promoter in the U.S., offered Suzanne Lenglen $50,000 to go on a professional tour of America.

Origins of professional circuit

As an opponent he provided Mary Browne, who had won the U.S. Women's Singles Championship from 1912 to 1914. To provide a male spectacle he contracted a Frenchman, Paul Feret, and three Americans, Harvey Snodgrass and Howard Kinsey from California, and Vincent Richards, then ranked third in the world after Tilden, and William "Little Bill" Johnston. The tour was a financial success and the professional tennis circuit was established. The professionals carried their own portable indoor courts with them, set them up in New York's Madison Square Garden or San Francisco's Cow Palace, and brought in large crowds. In the 1930s the professional game received a further significant boost when the greatest player of his day—and many consider of any day—Tilden, turned professional. From that day on Wimbledon champions, including, for example, Vines, Perry, Budge, and Riggs, almost automatically joined the professional ranks.

The pattern was re-established after the war, when in 1947, U.S. and Wimbledon Champion Kramer, then ranked the leading player in the world, turned professional. He took over Tilden's mantle and organized the professional circuit. One by one the leading amateur champions of their day joined the professional ranks. Pancho Gonzales, Frank Sedgman, Tony Trabert, Ken Rosewall, Lew Hoad, Rod Laver, Roy Emerson, and others all signed contracts with guaranteed minimum receipts to play in professional tournaments against one another all over the world.

It was obvious at the same time that even while playing as amateurs the leading players had been making their living from the game. Major championships could afford to follow the amateur (expenses-only) rules, but lesser tournaments, if they were to get the stars, who in turn attracted the crowds, had to hold out offers of pecuniary reward. H.F. David, chairman of the All-England Club, said that the tennis amateur had become "a living lie."

The All-England Club was the first to take action. On November 3, 1959, a resolution was passed by 100 votes to 6 recommending that the Wimbledon Championships should be open to all players, amateurs and professionals alike. That recommendation was rejected by the British LTA. In 1960 a proposal to the International Lawn Tennis Federation (ILTF) that experimental open championships be held in 1961 failed by only 5 votes (134 to 75) to obtain the necessary two-thirds majority. In 1961 a simple majority of 133 to 101 agreed to the principle of experimenting with a limited number of open tournaments, but the resulting recommendations in 1962 failed to get the required majority. Further similar proposals were defeated in 1964 and 1967.

Finally, in December 1967, the British LTA announced that they had abolished the distinction between amateurs and professionals in Great Britain. This unilateral action led to a threat of suspension from the ILTF but it was averted by a decision of that group in March 1968 allowing each country to determine for itself the status of its own players. The ILTF reserved the right to sanction a limited number of open tournaments.

Thus the first Open Championships of tennis were played in Great Britain in 1968, the British Hard Court Championships at Bournemouth, and the first Open Champions there were Rosewall and Virginia Wade. They were followed by the first Wimbledon Open, won by Laver and Mrs. King. The total stake money at this first Wimbledon Open was £26,150, of which £2,000 went to the winner of the Men's Singles and £750 to the winner of the Women's Singles.

Laver successfully defended his Wimbledon title the following year and, duplicating his grand slam as an amateur in 1962 (a feat matched only by Budge, in 1938), became the first Open Champion to win all four major championships in one year—British, U.S., French, and Australian. Laver must be reckoned among the all-time great players and without doubt the best left-hander. The 1969 Wimbledon Championships were also remarkable for the longest match ever played there, in which Pancho Gonzales beat Charlie Pasarell in 5 hours and 20 minutes.

In the meantime, two professional circuits had come into existence in the U.S. in the 1960s: the National Tennis League (NTL) and World Championship Tennis (WCT). Between them they had the world's leading players under contract, all of whom became affiliated with WCT when it absorbed the NTL in 1970. This led to a confused situation in which the ILTF controlled the Open Championships with their historic stadia and their glamorous past, while the commercial sponsors controlled the leading players, whose interests were divided between the relative freedom of competition in Open Championships and the financial security of the professional circuit.

ORGANIZATION AND MAJOR CHAMPIONSHIPS OF TENNIS

The Governing Body of Tennis is the International Lawn Tennis Federation, founded 1912, headquarters at West Kensington, London, to which are affiliated national lawn tennis associations. In the 1970s there were about 65 full members, various members having a different number of votes, and about 25 associate members. The ILTF is responsible for the rules of lawn tennis, for upholding the regulations for the Davis Cup and Federation Cup, for the recognition of official championships, and for the general promotion of the game at the international level. It has been greatly preoccupied with the amateur versus professional controversy and the establishment of open championships.

Categories of players

As from January 1, 1970, the ILTF recognized three categories of players:

1. Amateurs who receive no pecuniary advantage for playing the game.
2. Players who derive material profit for the game but who accept the authority of their national associations and therefore the final authority of the ILTF; sometimes known as independent professionals.
3. Touring professionals under contract to an organiza-

tion other than a national association; the contract professionals.

Categories 1. and 2. may compete in the Davis Cup, Federation Cup, and competitions of all sorts. Category 3. could compete in open tournaments approved by the ILTF. In 1972 the ILTF and WCT announced agreement that all existing contracts would be allowed to expire and no new ones signed, thus eliminating Category 3.

For many years the four major tennis tournaments have been the All-England Championships at Wimbledon, the U.S. Championships at Forest Hills, the French Championships at the Stade Roland Garros (Auteuil), and the Australian Championships, which previously were played alternately in New South Wales, Victoria, South Australia, and Queensland, but since 1970 have been confined to Sydney and Melbourne.

The courts of the Stade Roland Garros on the outskirts of Paris are hard (*i.e.*, clay) courts and the French Championships played there are considered the world's premier hard-court events. Second only to the French Championships on hard courts are ranked the Italian Championships played at the Foro Italico in Rome and the German Championships at the Klub an der Alster in Hamburg.

Of indoor tennis courts, those of the King's Club in Stockholm, Sweden, are considered the most outstanding.

The ILTF recognizes the following major championships:

1. Those held at present in Australia, France, Great Britain, South Africa, and the U.S.
2. The Scandinavian Championships.
3. The South American Championships.
4. The Championships of Asia.

Any national association staging an official championship may make it an open event or hold an open event as well as the official championship. Other national associations may apply to the ILTF for permission to hold open tournaments.

International events

The principal international tennis events are the Davis Cup (Men), the Federation Cup (Women), the King's Cup (European men on covered courts), and the Wightman Cup (Women—Great Britain versus the U.S.). The Davis Cup, as mentioned above, was established in 1900. Each team consists of two singles players, who play each of the two opponents, and a doubles pair, which may or may not include one or both of the singles players. There are thus five matches, four singles and one doubles. With growing interest in the Cup in the 1920s—the 4 nations that had challenged in 1919, increased to 14 in 1922 and to 24 by 1926—the competition was divided in 1923 into two zones, Europe and America, with an inter-zone final to determine who had the right to challenge the holders. At the same time Australasia split into its two constituent parts, Australia and New Zealand, and competed in the American zone. Since 1966 play has been in four zones: European zones A and B, an American zone, and an Eastern zone. Through 1971 the country that held the trophy did not play in the competition but defended its title against the winner of the four zones in the Challenge Round. Beginning in 1972 the holder of the trophy had to participate in the eliminations.

In ladies' tennis the Davis Cup equivalent is the Federation Cup, inaugurated in 1963 and played annually in the spring. Each match consists of two singles and a doubles.

Of longer standing is the annual Great Britain versus U.S. ladies' match for the Wightman Cup. In 1923, Mrs. H.V. Wightman, formerly Miss Hazel Hotchkiss, U.S. Women's Champion in 1909, 1910, 1911, and 1919, gave the cup for annual competition between the ladies of the U.S. and Great Britain to be played alternately in the U.S. and England. The competition consists of seven matches, five singles and two doubles.

The King's Cup dates from 1936 and was presented for competition between European nations on indoor, or covered, courts by King Gustav V of Sweden, himself a first-class player of the game. When Crown Prince, he was one of the first to play in Sweden and his enthusiasm, coupled with a northern climate, led to the building of indoor courts in Stockholm. It was most appropriate, therefore, that he should give a cup for international competition on indoor courts. The Scandinavian countries have been most successful in King's Cup play, Sweden and Denmark each having won it more times than any other country. Other countries that have won one or more times include Great Britain, France, Germany, Yugoslavia, and Czechoslovakia. The early stages of the competition are played as the Davis Cup; *i.e.*, four singles and a doubles, but the semifinals and final take place at a selected venue and each match consists of two singles and a doubles.

Other first-class tournaments within individual countries are too numerous to mention, but, in general, as well as the national championships, there are held indoor court championships and junior championships. In addition, in countries where the national championship is played on grass, there are often hard-court championships as well.

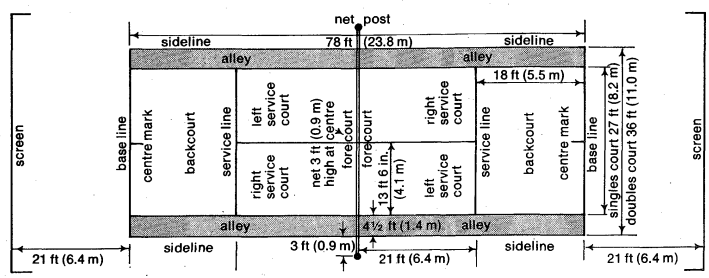
For winners of the major men's and women's championships and of the Davis Cup competition, see SPORTING RECORD in the *Ready Reference and Index*.

PLAYING THE GAME

The court and equipment. As is clear from its history and its name, lawn tennis was originally played on grass, and the world's major tournaments continue to be played on this natural surface. The popularity of the game led, however, to various experiments to produce playing surfaces for winter use for areas where grass did not grow.

Origins of hard (clay) courts

The originator of the hard, or clay, court was Claude Brown, the manager of a brickworks in the English Midlands, a keen tennis player, and a friend of G.W. Hillyard, secretary of the All-England Lawn Tennis Club for 25 years, whose wife was five times Wimbledon champion. Brown had seen various attempts to construct a hard court, but all had failed to provide sufficiently good drainage to combat English climatic conditions. He was also aware of the fact that one of the clays he used for brickmaking was unsatisfactory because it was too porous.



In 1909 he laid down an experimental area 20 x 20 ft (6 x 6 m) with an ash foundation, covered with a 1-in.- (2.5-cm-) thick layer of the porous clay, burned and crushed to a maximum size of ¼ in. Tested by the leading players of the day, it proved a great success.

Since that date many other experiments have been made with different playing surfaces, especially with a view to finding a surface that not only drains well but also requires no upkeep. Asphalt and similar surfaces are widely used for recreational tennis but not for tournament competition. Considerable progress has been made in developing artificial surfaces.

As tennis grew in popularity, those who lived in countries where cold or inclement weather was liable to prevent play, as in Sweden, turned to covered courts. The wheel had turned full cycle and the game that had its origins in a desire to escape into the open air now was provided with indoor facilities. The natural surface for an indoor floor is wood, and indoor court championships throughout the world are played on wooden floors.

In recent years the development of the professional circuit has given rise to a need for a portable court. The most popular of these is a carpet of artificial grass, which can be laid on any smooth surface.

The dimensions of the tennis court are 78 x 27 ft (23.8 x 8.2 m) for singles and 78 x 36 ft (23.8 x 11 m) for doubles. The height of the net at the centre is 3 ft (0.9 m) and it is supported at each side of the court by posts 3 ft 6 in. high at 3 ft outside the court.

Playing area for lawn tennis. The alleys are used only in doubles play.

Rackets and balls

There is nothing in the rules of lawn tennis to specify the type of racket to be used, but in practice it has come to be of uniform shape and size, although various models differ marginally in weight and balance. Traditionally, the racket has consisted of a laminated wood frame, strung with sheep gut. The wood has been chosen from ash, beech, hickory, sycamore, mahogany, and West African obeche, using a combination of these according to the particular quality of each wood. One racket requires 33 ft (10 m) of gut to provide 18 main, or vertical, strings and 20 cross strings. There are also one or more coloured threads at the head and throat of each racket. Synthetic gut and nylon are extensively used. The handle is usually covered with a leather grip. Steel and other metallic-alloy frames have been developed and are used by many leading players.

A tennis ball consists of a pressurized rubber core covered with high-quality cloth, usually wool mixed with up to 35 percent of nylon. Gradual loss of inflation tends to make the ball go soft in the course of time and experiments have been carried out with an unpressurized core. The specific properties for a conventional ball are: diameter, $2^{37}/_{64}$ to $2^{43}/_{64}$ in. (6.55 to 6.8 cm); weight 2 to $2^{1}/_{16}$ oz. (56.7 to 58.47 g); bound when dropped from 100 in. (250 cm), 53 to 58 in. (135 to 147 cm); compression 0.265 to 0.29 in. (.673 to .737 cm), at 18 lb (8 kg) load. World usage of tennis balls is in excess of 25,000,000 per annum.

Principles of play. The following exposition is designed to help a spectator understand a game he may be watching. For information on specific rules or how to play the reader should consult the works listed in the bibliography.

Singles

In singles play, the players spin a racket to decide on side and service. One spins, the other calls "rough" or "smooth," referring to the threading of the small strings at the top and bottom of the racket face. The player who wins the toss may decide to serve or receive service first, in which case his opponent chooses the side, or he may decide on a choice of side, in which case his opponent may choose to serve or receive service first. The players serve alternate games and change sides after every "odd" number of games; *i.e.*, after the first, third, and each subsequent alternate game of each set.

Beginning each game from behind his right-hand court, the server has both feet behind the base line and strikes the ball diagonally across the net and into his opponent's right-hand service court. Should the ball on service strike the top of the net before falling in the correct service court, it is a "let" and does not count. The server is allowed one miss, or "fault." If he fails to deliver a correct service at two attempts, he loses the point.

To return service, the receiver strikes the ball back before it hits the ground a second time, over the net and within the boundaries of his opponent's court. After the service has been correctly returned, either player may volley the ball or hit it after its first bounce and the game continues until one player fails to make a correct return. This may occur either if he fails to hit the ball over the net or if he hits it outside his opponent's boundaries or if he fails to hit it before it strikes the ground a second time on his side of the net.

The winner of each exchange scores 15, the scoring going 15, 30, 40 (abbreviated for 45), game; this system, derived directly from real or court tennis, is medieval in origin and dates from a time when 60 was looked upon as a whole number, rather as 100 has been in modern times; for identification purposes the score of the server is called first. Should both players reach 40, called deuce, a player must then score two consecutive points to win the game. Scoring the first of these is said to be "advantage." A set consists of six games, except that a player must win a set by a margin of two games, so that at five-games-all a set cannot be won before 7–5 at the earliest. Normally a match consists of the best of five sets for men and of three sets for women.

Doubles

The same basic principles apply to doubles, for which the width of the court is enlarged by 4½ feet (1.4 m) on each side. Service alternates between the two opposing teams, but each team must decide at the start of each set which of the two partners shall serve first. Equally the receiving team must decide at the start of each set which of them shall receive the first service and they will then receive service alternately for the rest of that set.

The indeterminate length of matches under the conventional system of scoring has always been inconvenient for those who have to organize tournaments, but recently the demands of television have resulted in some experiments in new methods. In essence these have relied on some form of tie-break system at five games all, usually the best of nine points.

The USLTA allows the use of a tie-break in certain approved tournaments. It has laid down strict rules governing the order of service in a tie-break in order to avoid as far as possible giving an advantage to either side. The 9-point system, in which the first player to score 5 points wins, was first used in the U.S. Open in 1970.

More radical changes in scoring are contained in the VASSS (Van Alen Simplified Scoring System, devised by U.S. tennis buff James H. Van Alen), which has been experimented with in the U.S. The VASSS No-Ad system consists of a 4-point game and a 6-game set. At 5 games all, a 9-point tie-break is played. The VASSS Single Point system is similar to table tennis. The game consists of 31 points, service changing after every 5 points. At 30 points all a tie-break of 9 points is played.

Strategy and technique. Throughout the history of tennis there have been two keys to tactical success. One has been the service, the other, effective play at forward position at the net. The server has a considerable advantage, as he is able to run up to the net immediately after serving. He is vulnerable to a passing shot (a return shot played by the receiver down the side of the court and passing out of his reach), but such a return is not easy from a powerful service, especially if it is also cleverly angled. An effective return is even more difficult in doubles when the server's partner is already at the net.

Advantage of service

The result is that very often, particularly in doubles, games tend to be won by the side that serves. The faster the surface of the court, the more this is true. Some experiments have been tried to counteract the dominance of service by allowing one serve only, for example, or by reducing the size of the service court, but so far none have proved acceptable.

A powerful first service is, therefore, a very considerable asset. For best effect, the server should be able to vary the placing of the service so that his opponent cannot anticipate its direction with certainty. Equally important is the ability to deliver an aggressive second service, which is often the distinguishing mark of a first-class player. Often, in less than first-class tennis, the first service is struck with great ferocity and is usually a fault; there follows either a double fault or a lightly hit second service that gives the attack to the receiver. In first-class tennis, there is much less distinction between first and second service, although often the second service is more controlled, using top or side spin to make up for the slightly reduced speed.

For return of service and in the subsequent play, the ability to play a consistent drive shot on either forehand or backhand is essential. This so-called ground stroke is the foundation of a good player's game. It is a long, smooth stroke in which the racket starts from well behind the body, strikes the ball immediately in front of the body, with the racket at full arm's length, and ends with a long follow through. At the moment of impact, the face of the racket is moving parallel to the ground and this ensures that the ball is struck back with a flat trajectory low over the net and with no loss of speed on its first bounce. Both length and direction are important in the forehand and backhand drive. Ideally, the ball should bounce as near the opponent's base line as possible in order to keep him at the back of the court, and it should be placed down one or the other of his sidelines to pass him if he should attempt to play at the net.

There are of course several variations of the basic drive. Instead of striking the ball with a flat racket, it may be struck with cut to impart back spin to the ball to slow it up on its first bounce (useful for a drop shot) or with top spin

to make the ball dip quickly over the net and bound high and fast (useful in returning a short ball).

Other return strokes are the volley, the half-volley, and the lob. The volley is normally played from the net position or by a player coming up to the net. It requires speed of eye and foot to intercept an opponent's drive and to return it with equal force and good placement or both. The volley is an attacking stroke and is of great significance, especially in men's doubles when both sides are attempting to establish a dominant position at the net.

When an opponent has established himself at the net, there are only two ways around him. One is to play a drive out of his reach down one or the other of his sidelines; the other is to play a lob over his head and deep. Should a lob fall short, it will allow an opponent a chance to execute an overhead volley, or smash, in which the ball is played from as high as possible, allowing it to be smashed down with great force. The smash, like the more usual volley, requires accurate placing to be really effective.

The half-volley is a defensive stroke in most cases. Normally a player will be driving the ball from the base line or volleying it at the net. But on occasions he may be caught between the two and there will be no alternative but to half-volley. This is a difficult stroke to make but doubly difficult to prevent it giving an easy smash to an opponent. Control is therefore most important to ensure that the ball is played as low as possible over the net and placed as far out of reach as possible.

Real tennis (court tennis or royal tennis)

HISTORY

The origins of real tennis lie in medieval France where the game has always been called *jeu de paume* ("palm game"; *i.e.*, the ball was struck with the palm of the hand). The curious layout of the court, with its sloping penthouse roof around three sides, pillared openings below, and wooden hatch (grille), suggests a cloister, and the fact that the earliest mention of the game is usually in ecclesiastical writings confirms the probability that tennis originated when young French priests started playing a form of handball in cathedral cloisters. It would seem to date from the 12th or 13th century.

Origins and early history in France

Its French origins are still apparent in the use of various French words to describe parts of the court; *e.g.*, dedans, grille, tambour, bandeau, and in scoring the use of the word deuce (a corruption of the French *à deux*).

How it came to be called tennis in English is not known for certain. The most likely theory is that the French players were in the habit of calling out "*tenez*!" ("attention!") before serving.

Certainly by the end of the 13th century the game was well established, for it is recorded that in 1292 there were 13 makers of tennis balls in Paris. There is no doubt that it was a popular game with king and court, and Shakespeare's reference to tennis balls sent by the French Dauphin to King Henry V of England was based on historical fact. But the 16th century was the golden age of tennis in France. Francis I, Henry II, Charles IX, and Henry IV were all keen players.

The Bettmann Archive

Copper engraving of a real tennis court, 1612, clearly showing its cloister origins. The net is a fringed cord, called the line, and the rackets are typical of the period. This court is a *jeu carré* without dedans. Winning openings, *la lune* and *le petit trou*, are on the far end wall.

Francis I built a court in his Louvre Palace in Paris in 1530, the plan of which was included in a contemporary Italian book by Antonio Scaino, entitled *Trattato del Giuoco della Palla*, published in 1555. The layout is identical to that of a modern real tennis court and the plan also shows a racket of the time, rather different from the more powerful instrument that is used today, but proving that at least by the middle 16th century the hand had given way to the racket as a means of propelling the ball.

The ball was originally made of hair or wool covered with sheepskin, but as rackets were developed the ball was made harder by using scraps of cloth, moistened, tightly wadded together, bound with string, and covered with white cloth—the same process used today.

Francis I also built a floating court on board the ship "La Grande-Françoise," which was intended to outdo Henry VIII of England's four-masted warship the "Great Harry," but which unfortunately grounded and sank at Le Havre.

François Gregory d'Ierni, who accompanied the Papal Legate to Paris in 1596, reported that there were 250 well-appointed tennis courts in the city and that the game gave employment to 7,000 people. But by 1657 the number of courts had shrunk to 114 according to the Dutch ambassador, who expressed his surprise that there were not more.

Tennis continued to be popular until the French Revolution. In defiance of King Louis XVI, the Third Estate had declared itself to be the National Assembly of France on June 17, 1789. The King retaliated by locking them out of the normal meeting place, but they found an alternative in the tennis court at Versailles, where they proclaimed the famous Tennis Court Oath of June 20th, swearing never to disperse until France had a constitution. The court still stands and is a museum dedicated to the Revolution.

From France tennis spread rapidly all over the continent of Europe and was well known in Italy, Germany, Austria, Sweden, Russia, and the Netherlands. It probably reached Scotland before England, for there were always close links between France and Scotland. In England the game was initially discouraged as it tended to distract men from sports of greater military value such as archery. In fact the earliest mention of the game is in connection with a prosecution in Canterbury about 1396.

The game in England

As in France, tennis flourished in England in the 16th century and it continued to be very popular in the 17th century. Henry VII set an example and he is known to have played on courts at Westminster, Windsor, Woodstock, Sheen, and Wycombe. Henry VIII was especially keen. Having dispossessed Cardinal Wolsey of his palace at Hampton Court, he built there in 1530 a tennis court that is still in use. He also built a tennis court at St. James's Palace and had four courts, two open and two covered, at his palace at Whitehall.

Queen Elizabeth was a keen spectator and planned a new court, which was never completed, at Windsor Castle. King James I recommended the game to his eldest son, Prince Henry. King Charles I was a frequent tennis player and continued to play whenever possible during the Civil War. Oliver Cromwell looked on the game as a frivolity, and, from the beginning of his protectorate in 1653, tennis courts were used for other purposes until the Restoration in 1660.

But then the game was resumed with increased vigour. Charles II was the most enthusiastic player since Henry VIII. He not only restored many of the existing courts but also built a new one at Whitehall, where Samuel Pepys watched him play, and one at Windsor.

The 18th century saw a general decline in tennis playing, and many courts were put to other uses; for example, as theatres, but Victorian England set in train a revival of the game, which spread throughout the English-speaking world. Many famous clubs built courts: the MCC, Queen's Club, and Prince's Club in London; the Manchester Tennis and Racquet Club; and the Leamington Tennis Club. Courts were built at the universities of Oxford and Cambridge; and many private houses could boast of their own courts. There remain 15 courts in use in England and

Modern courts

Scotland. Once more, real tennis became a royal game when H.R.H. the Prince of Wales played at Cambridge in 1967–68.

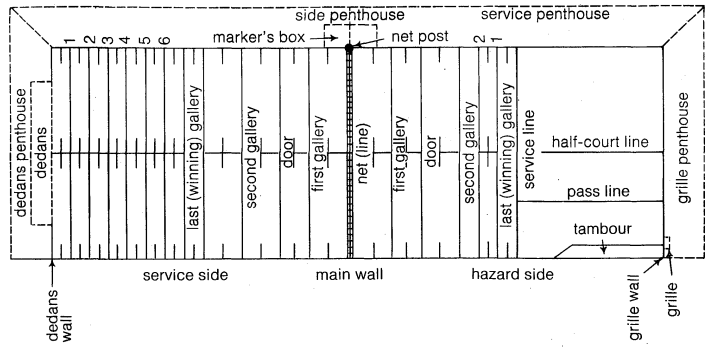
Real tennis spread to the U.S. in 1876 when a court was built at Boston. Seven courts are in use: two at the New York Racquet and Tennis Club, and others at Boston, Philadelphia, Tuxedo Park, N.Y., Greentree (Manhasset, L.I.), and Aiken (S.C.). In Australia there are two courts, one at Hobart, Tasmania, built in 1874 and one at Melbourne, built in 1882. In France only two courts remain in play, one in Paris and one in Bordeaux.

The top honour at real tennis is to be Champion of the World. This title is held until the holder is successfully challenged by a worthy contender. A challenge match is normally the best of 13 sets, played over three days in the reigning champion's court; but when the championship is vacant, the two principal claimants normally play two best-of-13-set matches, one in each of their own home courts. The Championship dates back to 1816, since when the holders have been: 1816, Marchisio (Italy); 1819, Philip Cox (Great Britain); 1829, J.E. Barre (France); 1862, Edmund Tompkins (Great Britain); 1871, George Lambert (Great Britain); 1885, Tom Pettitt (United States); 1896, Peter Latham (Great Britain); 1905, Cecil Fairs (Great Britain); 1907, P. Latham (Great Britain); 1908, C. Fairs (Great Britain); 1912, G.F. Covey (Great Britain); 1914, Jay Gould (United States); 1922, G.F. Covey (Great Britain); 1928, Pierre Etchebaster (France); 1955, James Dear (Great Britain); 1957, Albert Johnson (Great Britain); 1959, Northrup R. Knox (United States); 1969, G.H. Bostwick (United States); 1972, James Bostwick (United States).

Championship competition

Peter Latham also had the distinction of being world champion of rackets. J. Gould, N.R. Knox, and G.H. and James Bostwick are the only amateurs ever to have won the world championship. Pierre Etchebaster, a French Basque and professional at the New York Racquet and Tennis Club, held the title for 27 years until he retired undefeated at the age of 60 and was undoubtedly the outstanding player of the modern era.

The Open Championship in Great Britain is held and challenged for in the same way. In the U.S. it is played for in annual competition. In both countries there are annual Amateur Championships, both singles and doubles, and additional Gold Racket competitions in London (MCC prizes at Lord's Cricket Ground), Tuxedo, and Manchester. The Bathurst Cup, an international competition originally (1922) competed for alternately in London and Paris, has been played also in the U.S. since 1969. Oxford and Cambridge play a university match that dates back to 1859, and since 1956 British and American university teams have competed for the Van Alen Trophy.



In France the Coupe de Paris (1910) and the Coupe de Bordeaux (1909) are amateur championships open to players of all nations. The Raquette d'Or (1899) and the Raquette d'Argent (1899), played alternately in Paris and Bordeaux, are open only to French nationals.

In Australia the principal competition, the Open Championship, is played annually in Hobart or Melbourne. The Royal Melbourne Tennis Club (RMTC) holds an annual championship for the Gold Racquet and the Hobart Tennis Club annual championships for the H.J. Hill Cup (singles), the Captain James Johnson Cup (doubles), and the Bendena Cup (women's singles). There is also an annual match between the two clubs for the Percy Finch Trophy (singles) and the RMTC Trophy (doubles).

There is no international authority and the game is controlled in each country by its own national association.

THE GAME OF REAL TENNIS

The court and equipment. The real tennis court is an enclosed area with a paved or artificial stone floor measuring approximately 96 by 32 ft (29 by 10 m). Around three sides of the court is a sloping roof (penthouse) starting about 7 ft (2 m) from floor level. At certain points beneath the penthouse roof there are netted openings known as "galleries" (see diagram). Two of these galleries are winning openings and a ball entering them immediately wins a point. These are the dedans and the winning gallery, where the ball rings a bell to mark a successful shot. Another winning opening is the grille.

Playing area for real tennis.
Adapted from *The Lonsdale Book of Sporting Records;* Seeley, Service & Co.

There was a variation of this court, the *jeu carré*, of which the only remaining example is at Falkland Palace in Scotland. The *jeu carré* had no dedans, but instead two other winning openings, *la lune* and *le petit trou.*

The court is divided in two by a net, technically called the line, since originally it was only a piece of cord. Service is always delivered from the dedans side of the court; the other side is known as the hazard side. On the main wall on the hazard side is a projecting buttress, called the tambour, which, since it deflects balls that chance to hit it, adds to the difficulty of the game.

The earliest balls were stuffed with hair and in Shakespeare's *Much Ado About Nothing* occur these lines: "... the barber's man hath been seen with him; and the old ornament of his cheek hath already stuffed tennis-balls." But for very many years balls have been made of cloth. Around a small central cloth core are coiled further strips of cloth until the ball is about 2 in. (5 cm) in diameter. It is then placed in a special wooden "cup" and gently hammered until perfectly round. The subsequent tying of the ball is a work of great artistry; 16 turns of string are made round the ball to hold it securely in shape. It is then covered with two pieces of white cloth, firmly sewn together. The final ball must be not less than 2$\frac{7}{16}$ in. (6.2 cm) and not more than 2$\frac{9}{16}$ in. (6.5 cm) in diameter. It must weigh between 2½ and 2¾ oz (71 and 78 g). A set of balls normally consists of nine dozen.

Early balls and rackets

The great skill required to make real tennis balls has led to a recent and not unsuccessful experiment to produce real tennis balls by a process similar to that used in the manufacture of lawn tennis balls.

The racket is made of ash, strung with sheep gut. It has 18 main (vertical) strings and 26 cross strings, of which the top 3 are usually of thinner gut. It has a characteristic lopsided head, designed to impart greater cut to the ball. The handle is usually bare wood, although it may be covered with a leather or towelling grip if desired.

Principles of play. Scoring is as in lawn tennis. There are normally six games in a set, although in France there are sometimes eight. Play follows the same principles as in most other games except for the additional complication of "chases." In most other ball games a ball is dead when it bounces a second time on the ground. In tennis it makes a chase at the point where it strikes the floor on the second bounce and the floor is marked out with painted lines that enable the marker (scorer) accurately to describe the exact point (see diagram). Equally, a chase is made when the ball enters one of the galleries, other than a winning gallery or dedans.

When a chase is made, neither side scores and the chase is held in the marker's memory until either a second chase is made or one player comes within a point of winning a game. In either case the players then change sides and play off the one or two chases. The player who made the chase (*i.e.*, who would have won the point in most other games) now defends it and his opponent attacks it. To win the chase the attacker must make a better chase—and "better" in real tennis means nearer the back wall. In other words, the attacker must ensure that each stroke that he plays will cause the ball, if allowed to bounce

twice, to hit the floor on its second bounce nearer the back wall than the line of the chase being played. If he fails, the defender will allow the ball to bounce a second time and thereby win the point. The defender may also win the chase by hitting the ball into any of his opponent's galleries.

Strategy and technique. The great merit of real tennis lies in the chase, explained above. This medieval device tends to favour skill rather than brute force. In very few other games is it possible for a player to allow the ball to hit the ground a second time without necessarily losing the point. The skill required, therefore, is to play a normal stroke that will always make a "short" chase, if allowed to bounce a second time. In other words, ideally every ball should strike the floor on its second bounce within half a yard of the opponent's back wall.

This is obviously impossible, but in order to make as short a chase as possible, it is important that on striking the opponent's back wall the ball should come down sharply toward the floor to strike it on second bounce as near the back wall as possible. This means that the best stroke is one that is heavily cut. The familiar top spin shot of lawn tennis would bound far out from the back wall of a real tennis court and make a very poor chase. The classic real tennis shot bounces first somewhere about chase 4, strikes low on the back wall and comes down sharply to strike the floor on its second bounce within a yard or two of the wall. The need for this heavily-cut stroke led to the curious design of the racket.

Cutting the ball for a short chase

The server undoubtedly has an advantage, although not nearly so dominant a one as in lawn tennis. An unreturnable service is much more difficult in real tennis, but the server has the advantage of being able to play at two winning openings (the grille and the winning gallery), or at the tambour. Moreover, there are no chases at the back of the hazard side and the server can win a point outright in that area.

Real tennis is a complicated game to watch for the uninitiated, but its very complication is its attraction to those who play it.

Badminton

HISTORY

Badminton is descended from the old children's game of battledore and shuttlecock. Rackets of one sort or another developed over the centuries as a means of improving the striking power of the human hand, but the invention of the shuttlecock is less clear. This weird object is a variation on the more usual ball, consisting of a cork base fitted with a crown of feathers. The racket, or battledore, is a primitive form of racket, the head of which was normally covered with vellum or, latterly, strung like a racket.

One rainy day in the 1860s, so the story goes, a house party at Badminton in Gloucestershire, home of the Duke of Beaufort, got hold of the children's battledores and shuttlecocks, stretched a cord across the hall, and invented the game that has come to be called badminton. One member of the house party subsequently found himself in India, where he introduced the game to others and where the first attempt to formulate rules was made in 1877 at Karāchi. The hall at Karāchi where the game was played was not much wider than the court and access to it was gained from doors at the centre that opened inward. To make allowance for this, the court was laid out in "hourglass" form, the width at the net being shorter than at the base line. This curious feature provided the reason why Major Wingfield adapted the "hourglass" shape for his first lawn tennis courts. Soon after badminton became popular, the primitive battledore was replaced by a lightweight racket.

The hour-glass court

Two Americans, Bayard Clark and E. Langdon Wilkes, were impressed by seeing badminton in England and formed The Badminton Club of the City of New York during the winter of 1878–79. There were about 40 members originally, limited to men and "good-looking" single girls.

In 1893 the Badminton Association was formed in England and the rules were codified—including the hourglass court, which was finally abolished in 1901. The All-England Championships were instituted in 1899 and were soon followed by Irish Championships in 1902 and Scottish in 1907. The game gradually achieved worldwide popularity, and in 1925 and 1930 an English team visited Canada. In 1936 the American Badminton Association was formed.

The governing body of badminton is the International Badminton Federation (IBF), formed originally in 1934 by nine founder-members—Canada, Denmark, England, France, Ireland, The Netherlands, New Zealand, Scotland, and Wales. In the 1970s there were more than 50 affiliated "National" organizations, affiliated "International" organizations, and temporary "Associate Members." The IBF is responsible for the laws of badminton and for the organization of the International Badminton Championships, the Thomas Cup for men and the Uber Cup for women.

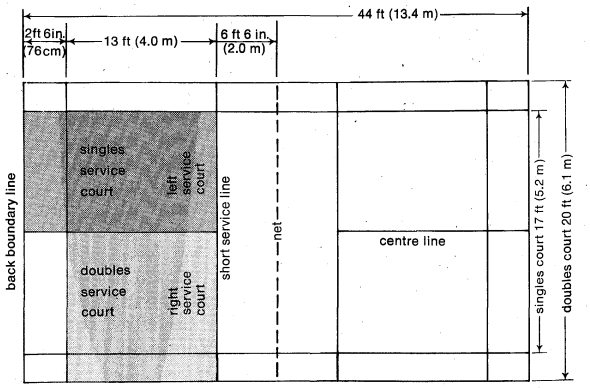
The Thomas Cup was presented in 1939 by the founder-president of the IBF, Sir George Thomas, Baronet, one of the most distinguished figures in the game. It is played on similar lines to the Davis Cup, zone winners meeting in interzone ties (competitions) and the final winner having the right to challenge the holder for the cup. The 1969–70 competition was organized in four zones—American, Australasian, Asian (east and west sections), and European, covering an entry of 25 nations. A change in the rules required the 1969–70 and subsequent holder nations to compete at the interzone stage.

Each tie consists of nine matches—five singles and four doubles—and the players must be selected from a nominated team of not less than four and not more than six bona fide amateurs.

The competition, which has been held every three years since 1948–49, has been dominated by Malaya and Indonesia.

The Uber Cup was presented by Mrs. H.S. Uber and first played for in 1956–57. It is organized on similar lines to the Thomas Cup, except that each tie consists of seven matches—three singles and four doubles. The U.S. and Japan have been predominant in Uber Cup competition. For listing of Thomas and Uber Cup winners, see SPORTING RECORD in the *Ready Reference and Index*.

National championships and outstanding players



Numerous national championships are held annually all over the world, some reserved for nationals, others open to any competitor, but all of them restricted to bona fide amateurs. The All-England Championships, held at the Empire Pool, Wembley, in March, are open to all amateurs and enjoy the highest prestige. These championships began in 1899 as the Badminton Association Tournament and the title of All-England was assumed in 1902. There was no competition in 1899 and the first winners in 1900 were S.H. Smith and Miss E. Thomson, both of England. The rules provide that three consecutive victories or four victories in all win the cup outright and this has been achieved in the singles by the following great players; the total number of their victories is shown in parentheses:

Sir G.A. Thomas, Baronet, England (4)	Miss E. Thomson, England (5)
J.F. Devlin, Ireland (6)	Miss M. Lucas, England (6)
R.C.F. Nichols, England (5)	Miss Kathleen McKane, England (4)
Wong Peng Soon, Malaya (4)	Mrs. F.G. Barrett, England (5)
Eddy B. Choong, Malaya (4)	Mrs. G.C.K. Hashman (*nee* Judy Devlin) U.S. (10)
Erland Kops, Denmark (7)	
R. Hartono, Indonesia (5)	

Although he visited Europe only once, winning the All-England Championship in 1949, David Freeman is generally regarded as the best-ever singles player of the game. He was singles champion of the U.S. from 1939 until American participation in World War II put an end to the championship in 1943. When it was resumed, he won it again in 1947 and 1948 before retiring from active competition. He returned, however, to win once again in 1953.

THE GAME OF BADMINTON

Since the slightest wind affects the flight of the shuttle, competitive badminton is played indoors, though the game is popular out-of-doors as a recreational pastime. It consists essentially of the striking of a shuttle over a 5-ft-

Badminton court.

(1.5-m-) high net and within the boundaries of the court (see diagram). The shuttle does not bounce and therefore has to be kept in play without touching the ground. A point is lost if it is allowed to strike the ground, provided it lands within the court or if it fails to cross the net. A doubles or men's singles game consists of 15 or 21 points with an option to play a further 5 points at 13-all or 19-all and a further 3 points at 14-all or 20-all. A ladies' single consists of 11 points with an option to play a further 3 points at 9-all or 2 points at 10-all. A match is the best of three games; players change ends after each game and in the middle of the third game, if there is one.

General principles

Before starting, the players toss for choice of service or side. Service is delivered from one service court diagonally across the net into the opponent's service court, starting from the right-hand court. In singles players serve from the right-hand court when their own score is 0 or an even number and from the left-hand court when it is an odd number. The shuttle when struck for service must be below the server's waist at the head of the racket below his hand; both the server's and receiver's feet must be on the ground and entirely within the lines of the service court.

Unlike tennis, only one service is allowed and a single fault loses a point. A service in which the shuttle hits the top of the net and still falls within the correct service court is "good"—not a "let" as in tennis.

After service a rally takes place until one side fails to return the shuttle within the bounds of his opponent's court. If the server wins the rally, a point is added to his score. If the receiver wins it, the service passes to him, but no point is scored. In doubles each partner serves in turn (except for the first service of a game when only one partner of the side that serves first has an inning), and the service passes to their opponents only when they have both been "put out" by the loss of two rallies.

Rackets and shuttles

As in tennis, there are no rules governing the racket. It is desirable that it should be as light as possible, consistent with the required strength, and it normally consists of a wooden head frame, made from hickory and strung with gut of nylon, and a metal handle; its weight is about 5 to 5½ oz (142 to 156 g). Experiments have been made with an all-metal racket.

The shuttlecock, shuttle, or bird weighs from 73 to 85 gr (5 to 6 g) and is made of 14 to 16 goose feathers fixed in a piece of cork. It is 3½ in. (9 cm) in length. Variations to the exact specifications are permitted when climatic or other conditions make this necessary. Plastic shuttles have come into use, but feathers are used in major tournaments.

The skill of badminton depends on four principal strokes, which bear some resemblance to tennis strokes but are different in effect with a shuttle. This is due to the fact that the speed of the shuttle declines very rapidly and it falls, therefore, much more steeply.

First, the high drop or "clear" is a shot struck hard and high into the air to clear any opponent at the net and to fall as near the back of the court as possible. Second, the smash is an overhead volley as in tennis, struck as hard as possible down into an opponent's court. Third, the drive, also as in tennis, is a hard-hit shot, passing as low as possible over the net and usually aimed along one or other of the sidelines. Fourth, the drop shot, as its name implies, is a gentle stroke, which just clears the net and falls almost vertically beyond it.

These four shots are played in an infinite variety of combinations and it is the skill and control required to vary them and to develop a suitable shot in reply that makes the game so fascinating to play and to watch. The ability to disguise the type of shot to be played until the very last moment is of great importance to the highly skilled player and it demands even greater finesse; for example, to shape up for a smash and finally to play a gentle drop shot requires complete control and masterful skill.

Ball badminton

An interesting variation of the game, known as ball badminton, is played in India and is particularly popular in the southern states there. Its name derives from the fact that a ball, made of wool and coloured yellow, is used instead of a shuttlecock. The racket is similar to a normal racket, but is heavier in the head and the frame is normally made of bamboo or steel. Ball badminton is played out-of-doors on a large court, 80 ft (24 m) long by 40 ft (12 m) wide, with five players on each side, two forward, two back, and one in the centre. Singles and doubles are also played on a smaller court 80 ft x 20 ft. The game consists of 21 points with a set of 7 points at 20-all, but on reaching 6-all in the set one player has to establish a lead of two points to win the game.

The open air and the woollen ball give great opportunity for high spinning shots, particularly in the service, and the wrist is used to a large extent.

Tennyson, Alfred, Lord

Alfred, Lord Tennyson, the leading poet of the Victorian Age in England, had come by the middle of the 19th century to occupy a position similar to that of Pope in the 18th. Tennyson was generally regarded by his contemporaries both as a consummate poetic artist, consolidating and refining the traditions bequeathed to him by his predecessors in the Romantic movement—especially Wordsworth, Byron, and Keats—and as the pre-eminent spokesman for the educated middle class Englishman, in moral and religious outlook and in political and social consciousness no less than in matters of taste and sentiment. His poetry dealt often with the doubts and difficulties of an age in which the old religious sanctions and the traditional assumptions about man's nature and destiny were increasingly called into question; it dealt with them, moreover, as the intimate personal problems of a sensitive and troubled individual inclined to melancholy. Yet through his poetic mastery—the spaciousness and nobility of his best work, its classical aptness of phrase, its distinctive harmony—he conveyed to sympathetic readers a feeling of implicit reassurance, even serenity. Tennyson may be seen as the first great English poet to be fully aware, and qualified to speak, of the new picture of man's place in the universe revealed by modern science. While the contemplation of this unprecedented human situation sometimes evoked his fears

and forebodings, it also gave him a larger imaginative range than most of the poets of his time and added a greater depth and resonance to his art.

Early life and work. Tennyson was born in England at Somersby rectory, Lincolnshire, on August 6, 1809, into an old Lincolnshire family. The fourth of 12 children, Alfred, with two of his brothers, Frederick and Charles, was sent in 1815 to Louth grammar school—where he was unhappy. He left in 1820, but, though home conditions were difficult, his father managed to give him a wide literary education. Alfred was precocious, and before his teens he had composed in the styles of Pope, Scott, and Milton. To his youth also belongs *The Devil and the Lady* (first published in 1930), which shows an astonishing understanding of Elizabethan dramatic verse. Byron was a dominant influence; at the news of his death (1824) Tennyson flung himself on the ground in a passion of grief and carved on sandstone, "Byron is dead."

By courtesy of the National Portrait Gallery

Tennyson, oil painting by Samuel Laurence, c. 1840. In the National Portrait Gallery, London.

At the lonely rectory the children were thrown upon their own resources. All writers on Tennyson emphasize the influence of the Lincolnshire countryside on his poetry: the plain, the sea about his home, "the sand-built ridge of heaped hills that mound the sea," and "the waste enormous marsh."

In 1824 the health of Tennyson's father began to break down, and he took refuge in drink. Alfred, though depressed by unhappiness at home, continued to write, collaborating with Frederick and Charles in *Poems by Two Brothers* (1826; dated 1827). His contributions (more than half the volume) are mostly in fashionable styles of the day.

In 1827 Alfred and Charles joined Frederick at Trinity College, Cambridge. There Alfred made friends with Arthur Hallam, the gifted son of the historian Henry Hallam. This was the deepest friendship of Tennyson's life. The friends became members of the "Apostles," an exclusive undergraduate club of earnest intellectual interests. Tennyson's reputation as a poet increased at Cambridge. In 1829 he won the Chancellor's gold medal with a poem called *Timbuctoo*. In 1830 *Poems, Chiefly Lyrical* was published; and in the same year Tennyson, Hallam, and other "Apostles" went to Spain to help in the unsuccessful revolution against Ferdinand VII. Tennyson took away many vivid memories, especially of the scenery of the Pyrenees. In the meantime, Hallam had become attached to Tennyson's sister Emily but was forbidden by her father to correspond with her for a year.

Early publications

In 1831 Tennyson's father died. Alfred's misery was increased by his grandfather's discovery of his father's debts. He left Cambridge without taking a degree, and his grandfather made financial arrangements for the family. In the same year, Hallam published a eulogistic article on *Poems, Chiefly Lyrical* in *The Englishman's Magazine*. He went to Somersby in 1832 as the accepted suitor of Emily.

In 1832 Tennyson published another installment of his poems (dated 1833), including "The Lotos-Eaters," "The Palace of Art," and "The Lady of Shalott." Among them was a satirical epigram on the critic "Christopher North" (pseudonym of the Scottish writer John Wilson), who had attacked *Poems, Chiefly Lyrical* in *Blackwood's Magazine*. Tennyson's sally prompted a scathing attack on his new volume in the *Quarterly Review*. The attacks distressed Tennyson, but he continued to revise his old poems and compose new ones.

In 1833 Hallam's engagement was recognized by his family, but while on a visit to Vienna in September he died suddenly. The shock to Tennyson was severe. It came at a depressing time; three of his brothers, Edward, Charles, and Septimus, were suffering from mental illness, and the bad reception of his own work added to the gloom. Recent research has shown that his frustrated courtship of Rosa Baring and his attachment to Sophie Rawnsley increased his psychological difficulties. Yet it was in this period that he wrote some of his most characteristic work: "The Two Voices" (of which the original title, significantly, was "Thoughts of a Suicide"), "Ulysses," "St. Simeon Stylites," and, probably, the first draft of "Morte d'Arthur." To this period also belong some of the poems that became constituent parts of *In Memoriam* and lyrics later worked into *Maud*.

In May 1836 his brother Charles married Louisa Sellwood of Horncastle, and at the wedding Alfred fell in love with her sister Emily. For some years the lovers corresponded, but Emily's father disapproved of Tennyson because of his bohemianism, addiction to port and tobacco, and liberal religious views; and in 1840 he forbade the correspondence. Meanwhile the Tennysons had left Somersby and were living a rather wandering life nearer London. It was in this period that Tennyson made friends with many famous men, including Gladstone, Thomas Carlyle, and the poet Walter Savage Landor. Carlyle, writing to Ralph Waldo Emerson in 1842, described him as

Friendships with Gladstone and Carlyle

> a man solitary and sad, dwelling in an element of gloom, carrying a bit of Chaos about him, which he is manufacturing into Cosmos . . . one of the finest-looking men in the world. A great shock of rough, dusky, dark hair; bright, laughing hazel eyes; massive aquiline face, most massive yet most delicate; of sallow brown complexion, almost Indian looking, clothes cynically loose, free-and-easy, smokes infinite tobacco. His voice is musically loose, fit for loud laughter and piercing wail, and all that may lie between; speech and speculation free and plenteous; I do not meet in these last decades such company over a pipe!

In 1840 Tennyson invested his patrimony in a project for wood carving by machinery. Its failure plunged him into financial difficulty; and family worries, besides his ill health and nervous instability, brought him near to a breakdown. But the then fashionable "water cure," which he took several times during the 1840s, seems to have done him good, for one hears of his resuming his port-and-tobacco regime.

Major literary work. In 1842 he published *Poems*, in two volumes, one containing a revised selection from the volumes of 1830 and 1832, the other, new poems. The new poems included "Morte d'Arthur," "The Two Voices," "Locksley Hall," and "The Vision of Sin" and other poems that reveal a strange naïveté, such as "The May Queen," "Lady Clara Vere de Vere," and "The Lord of Burleigh." The new volume was not on the whole well received. But the grant to him at this time, by Sir Robert Peel, of a pension of £200 helped to alleviate his financial worries.

The year 1850 marked a turning point. Tennyson resumed his correspondence with Emily Sellwood, and their engagement was renewed and followed by marriage. Meanwhile, Edward Moxon offered to publish the elegies on Hallam that Tennyson had been composing over the years. They appeared, at first anonymously, as *In Memoriam*, which had a great success with both reviewers and the public, won him the friendship of Queen Victoria, and helped bring about, in the same year (1850), his appointment as poet laureate.

Appointment as laureate

After his marriage, which was happy, Tennyson's life

became more secure and outwardly uneventful. There were two sons: Hallam (1852–1928) and Lionel (1854–86). The times of wandering and unsettlement ended in 1853, when the Tennysons took a house, Farringford, in the Isle of Wight. Tennyson was to spend most of the rest of his life there and at Aldworth (near Haslemere, Surrey), which he built as a summer home in 1868.

His position as the national poet was confirmed by his ode on the death of Wellington (1852)—though some critics at first thought it disappointing—and the famous poem on the charge of the Light Brigade at Balaklava, published in 1855, first in the press and then in the *Maud* volume. *Maud* itself, a strange and turbulent "monodrama," provoked a storm of protest; many of the poet's admirers were shocked by the morbidity, hysteria, and bellicosity of the hero. Yet *Maud* was Tennyson's favourite among his poems.

The Arthurian project he had long considered at last issued in *Idylls of the King* (1859), which had an immediate success. Tennyson, who loathed publicity, had now acquired a sometimes embarrassing public fame. The *Enoch Arden* volume of 1864 perhaps represents the peak of his popularity. New Arthurian *Idylls* were published in *The Holy Grail, and Other Poems* in 1869 (dated 1870). These were again well received, though some readers were beginning to show discomfort at the "Victorian" moral feeling that Tennyson had imported into his source material from Sir Thomas Malory.

Poetic drama

In 1874 Tennyson decided to try his hand at poetic drama. *Queen Mary* appeared in 1875, and an abridged version was produced at the Lyceum in 1876 with only moderate success. It was followed by *Harold* (1876; dated 1877), *Becket* (not published in full until 1884), and the "village tragedy" *The Promise of May*, which proved a failure at the Globe in November 1882. This play—his only prose work—shows Tennyson's growing despondency and resentment at the religious, moral, and political tendencies of the age. He had already caused some sensation by publishing a poem called "Despair" in *The Nineteenth Century* (November 1881). It evoked a parody by Swinburne and a stream of pamphlets, lectures, and sermons. A more positive indication of Tennyson's later beliefs appears in "The Ancient Sage," published in *Tiresias and Other Poems* (1885). Here the poet records his intimations of a life before and beyond this life.

Tennyson accepted a peerage (after some hesitation) in 1884. In 1886 he published a new volume containing "Locksley Hall Sixty Years After," consisting mainly of imprecations against modern decadence and retracting the earlier poem's belief in inevitable human progress. This challenge to the liberal thought of the day prompted Gladstone to write a protesting article in *The Nineteenth Century* for January 1887.

In 1889 Tennyson wrote the famous short poem "Crossing the Bar," during the crossing to the Isle of Wight. In the same year he published *Demeter and Other Poems*, which contains the charming retrospective "To Mary Boyle," introducing "The Progress of Spring," a fine lyric written much earlier and rediscovered, and "Merlin and the Gleam," an allegorical summing-up of his poetic career. In 1892 his play *The Foresters* was successfully produced in New York. Despite ill health, he was able to correct the proofs of his last volume, *The Death of Oenone, Akbar's Dream, and Other Poems*. He died at Aldworth on October 6, 1892.

Assessment. Tennyson's ascendancy among Victorian poets began to be questioned even during his lifetime, when Browning and Swinburne were serious rivals. And 20th-century criticism, influenced by the rise of a new school of poetry headed by T.S. Eliot (though Eliot himself was an admirer of Tennyson) has proposed some drastic devaluations of his work. Undoubtedly much in Tennyson that appealed to his contemporaries has ceased to appeal to many readers today. He can be mawkish and banal, pompous and orotund, offering little more than the mellifluous versifying of shallow or confused thoughts. The rediscovery of earlier poets like Donne or Hopkins (a poet of Tennyson's own time who was then unknown to the public), together with the widespread acceptance of Eliot and Yeats as the leading modern poets, opened the ears of readers to a very different, and perhaps more varied, poetic music. A more balanced estimate of Tennyson has begun to prevail, however, with the recognition of the enduring greatness of "Ulysses," the unique poignancy of Tennyson's best lyrics, and, above all, the stature of *In Memoriam* as the great representative poem of the Victorian Age. It is now also recognized that the realistic and comic aspects of Tennyson's work are more important than they were thought to be during the period of the reaction against him. Finally, the perception of the poet's awed sense of the mystery of life, which lies at the heart of his greatness, as in "Crossing the Bar" or "Flower in the Crannied Wall," unites his admirers in this century with those in the last. Though less of Tennyson's work may survive than appeared likely during his Victorian heyday, what does remain—and it is by no means small in quantity—seems likely to be imperishable.

MAJOR WORKS

VERSE: *Poems, Chiefly Lyrical* (1830), includes "Mariana," "The Poet," "Love and Death," "Oriana," and "Claribel"; *Poems* (1832, dated 1833), includes "The Lady of Shalott," "The Dream of Fair Women," "Oenone," "The Lotos-Eaters," "The Palace of Art," and "The Miller's Daughter"; *Poems*, 2 vol. (1842), includes "Locksley Hall," "Ulysses," "Sir Galahad," "Morte d'Arthur," "The Two Voices," and "The Vision of Sin"; *The Princess* (1847); *In Memoriam* (1850); *Ode on the Death of the Duke of Wellington* (1852); *Maud and Other Poems* (1855), includes "The Charge of the Light Brigade"; *Idylls of the King* (1859); *Enoch Arden* (1864), includes "Sea Dreams," "Aylmer's Field," and "The Northern Farmer"; *The Holy Grail and Other Poems* (1869, dated 1870); *The Window, or the Song of the Wrens* (privately printed 1867, first published edition 1870, dated 1871), music by Arthur Sullivan; *Gareth and Lynette* and *The Last Tournament* (1872); *Ballads and Other Poems* (1880), includes "Rizpah," "The Revenge," and "The Defence of Lucknow"; *Tiresias and Other Poems* (1885), includes "To Virgil," "Balin and Balan," and "The Ancient Sage"; *Locksley Hall Sixty Years After* (1886); *Demeter and Other Poems* (1889), includes "To Mary Boyle," "The Progress of Spring," and "Merlin and the Gleam"; *The Death of Oenone, Akbar's Dream, and Other Poems* (1892).

DRAMA: *Queen Mary* (published 1875); *Harold* (1876, dated 1877); *The Promise of May* (1882); *The Cup* and *The Falcon* (1884); *Becket* (1884); *The Foresters* (1892).

BIBLIOGRAPHY. CHRISTOPHER RICKS (ed.), *The Poems of Tennyson* (1969), presents all the known poetry, published and unpublished, with full textual, bibliographical, and explanatory notes. *Alfred Tennyson*, by the poet's grandson, SIR CHARLES TENNYSON (1949, reprinted 1968), is the most authoritative modern biography, revealing much that was previously unknown about his early life. R.W. RADER, *Tennyson's Maud: The Biographical Genesis* (1963), explores the relationship between the poet's private life and his art. Victorian criticism of Tennyson is extensively represented in J.D. JUMP (ed.), *Tennyson: The Critical Heritage* (1967). Some of the best modern criticism is collected in JOHN KILLHAM (ed.), *Critical Essays on the Poetry of Tennyson* (1960).

(W.W.R.)

Terence

Distinguished primarily for the purity of his Latin and the urbane realism of his plays, Terence ranks as one of the two masters of classical Roman drama, along with the more boisterous and popular Plautus. Like the other comic dramatists of classical Rome, Terence based his plays on Greek originals: his skillful interrelation of character and plot, his subtle handling of situation, and the limpidity of his style are also seen in the Athenian playwright Menander, his main source. It is chiefly from Terence's application of these qualities, however, that the modern comedy of manners derives its essential character.

Terence—the anglicized form of the name of Publius Terentius Afer—wrote six verse comedies, all extant, for the Roman stage in the 2nd century BC. Reliable information about his life and dramatic career is defective. There are four sources of biographical information on him: a short, gossipy life by the Roman biographer Suetonius, written nearly three centuries later; a garbled

version of a commentary on the plays by the 4th-century grammarian Aelius Donatus; production notices prefixed to the play texts recording details of first (and occasionally also of later) performances; and Terence's own prologues to the plays, which, despite polemic and distortion, reveal something of his literary career.

Terence was born, probably in 186/185 BC, in the North African town of Carthage. He was taken to Rome as a slave by Terentius Lucanus, an otherwise unknown Roman senator who was impressed by his ability and gave him a liberal education and, subsequently, his freedom.

The plays

Most of the available information about Terence relates to his career as a dramatist. During his short life he produced six plays, to which the production notices assign the following dates: *Andria* (*The Andrian Girl*), 166 BC; *Hecyra* (*The Mother-in-Law*), 165 BC; *Heauton timoroumenos* (*The Self-Tormentor*), 163 BC; *Eunuchus* (*The Eunuch*), 161 BC; *Phormio*, 161 BC; *Adelphi* (or *Adelphoe*; *The Brothers*), 160 BC; *Hecyra*, second production, 160 BC; *Hecyra*, third production, 160 BC. These dates, however, pose several problems. The *Eunuchus*, for example, was so successful that it achieved a repeat performance and record earnings for Terence, but the prologue that Terence wrote, presumably a year later, for the *Hecyra*'s third production gives the impression that he had not yet achieved any major success. Yet alternative date schemes are even less satisfactory.

From the beginning of his career, Terence was lucky to have the services of Lucius Ambivius Turpio, a leading actor who had promoted the career of Caecilius, the major comic playwright of the preceding generation. Now in old age, the actor did the same for Terence. Yet not all of Terence's productions enjoyed success. The *Hecyra* failed twice: its first production broke up in an uproar when rumours were circulated among its audience of alternative entertainment by a tightrope walker and some boxers; and the audience deserted its second production for a gladiatorial performance nearby.

Attacks on his dramatic method

Terence faced the hostility of jealous rivals, particularly one older playwright, Luscius Lanuvinus, who launched a series of accusations against the newcomer. The main source of contention was Terence's dramatic method. It was the custom for these Roman dramatists to draw their material from earlier Greek comedies about rich young men and the difficulties that attended their amours. The adaptations varied greatly in fidelity, ranging from the creative freedom of Plautus to the literal rendering of Luscius. Although Terence was apparently fairly faithful to his Greek models, Luscius alleged that Terence was guilty of "contamination"—*i.e.*, that he had incorporated material from secondary Greek sources into his plots, to their detriment. Terence sometimes did add extraneous material. In the *Andria*, which like the *Eunuchus*, *Heauton timoroumenos*, and *Adelphi* was adapted from a Greek play of the same title by Menander, he added material from another Menandrean play, the *Perinthia* (*The Perinthian Girl*). In the *Eunuchus* he added to Menander's *Eunouchos* two characters, a soldier and his "parasite"—a hanger-on whose flattery of and services to his patron were rewarded with free dinners—both of them from another play by Menander, *The Kolax* (*The Parasite*). In the *Adelphi*, he added an exciting scene from a play by Diphilius, a contemporary of Menander. Such conservative writers as Luscius objected to the freedom with which Terence used his models.

A further allegation was that Terence's plays were not his own work but were composed with the help of unnamed nobles. This malicious and implausible charge is left unanswered by Terence. Romans of a later period assumed that Terence must have collaborated with the Scipionic circle, a coterie of admirers of Greek literature, named after its guiding spirit, the military commander and politician Scipio Africanus the Younger. Though he may have been friendly with the Scipio household, Terence also may have died before this circle existed. The younger Scipio was about Terence's age, and intimacy with him could have led to the presentation of the *Adelphi* and the *Hecyra* for production at the funeral games of Lucius Aemilius Paulus, Scipio's father.

Terence died young. When he was 25, he visited Greece and never returned from the journey. He died either in Greece from illness or at sea by shipwreck on the return voyage. Of his family life, nothing is known, except that he left a daughter and a small but valuable estate just outside Rome on the Appian Way.

Modern scholarship

Modern scholars have been preoccupied with the question of the extent to which Terence was an original writer, as opposed to a mere translator of his Greek models. Positions on both sides have been vigorously maintained, but recent critical opinion seems to accept that, in the main, Terence was faithful to the plots, ethos, and characterization of his originals: thus, his humanity, his individualized characters, and his sensitive approach to relationships and personal problems all may be traced to Menander, and his obsessive attention to detail in the plots of *Hecyra* and *Phormio* derives from the Greek models of those plays by Apollodorus of Carystus of the 3rd century BC. Nevertheless, in some important particulars he reveals himself as something more than a translator. First, he shows both originality and skill in the incorporation of material from secondary models, as well as occasionally perhaps in material of his own invention; he sews this material in with unobtrusive seams. Second, his Greek models probably had expository prologues, informing their audiences of vital facts, but Terence cut them out, leaving his audiences in the same ignorance as his characters. This omission increases the element of suspense, though the plot may become too difficult for an audience to follow, as in the *Hecyra*.

Striving for a refined but conventional realism, Terence eliminated or reduced such unrealistic devices as the actor's direct address to the audience. He preserved the atmosphere of his models with a nice appreciation of how much Greekness would be tolerated in Rome, omitting the unintelligible and clarifying the difficult. His language is a purer version of contemporary colloquial Latin, at times shaded subtly to emphasize a character's individual speech patterns. Because they are more realistic, his characters lack some of the vitality and panache of Plautus' adaptations (Phormio here is a notable exception); but they are often developed in depth and with subtle psychology. Individual scenes retain their power today, especially those presenting brilliant narratives (*e.g.*, Chaerea's report of his rape of the girl in the *Eunuchus*), civilized emotion (*e.g.*, Micio's forgiveness of Aeschinusin the *Adelphi*, Bacchis' renunciation of Pamphilus in the *Hecyra*), or clever theatrical strokes (*e.g.*, the double disclosure of Chremes' bigamy in the *Phormio*).

Influence

The influence of Terence on Roman education and on the later European theatre was very great. His language was accepted as a norm of pure Latin, and his work was studied and discussed throughout antiquity.

MAJOR WORKS

VERSE COMEDIES (WITH PROLOGUES): Dating of first production follows the production notices, but is problematic. *Andria* (166 BC; *The Andrian Girl*; *The Lady of Andros*; *The Girl from Andros*); *Heauton timoroumenos* (163 BC; *The Self-Tormentor*; *The Self-Punisher*); *Eunuchus* (161 BC; *The Eunuch*); *Phormio* (161 BC); *Adelphi* (160 BC; *Adelphoe*; *The Brothers*); *Hecyra* (three productions, two unsuccessful in 165 and 160 BC, the third later in 160 BC; *The Mother-in-Law*).

BIBLIOGRAPHY. The best edition of the complete Latin text is that by R. KAUER and W.M. LINDSAY, Oxford Classical Texts (1926; reprinted with supplementary critical information, 1958). Notable English translations are those by LAURENCE ECHARD *et al.*, *Terence's Comedies* (1689, reprinted 1963); GEORGE COLMAN THE ELDER, *The Comedies of Terence Translated into Familiar Blank Verse* (1765 and later editions); and BETTY RADICE, *The Brothers and Other Plays* (1965), and *Phormio and Other Plays* (1967), both Penguin Classics. For a survey of the extensive Terentian bibliography, see H. MARTI, "Terenz 1909–1959," *Lustrum*, 6:114–238 (1961) and 8:5–93 (1963). For general comment, see G.E. DUCKWORTH, *The Nature of Roman Comedy* (1952); H. HAFFTER, *Terenz und seine künstlerische Eigenart* (1967; reprinted from *Museum Helveticum*, vol. 10, 1953); W. BEARE, *The Roman Stage*, 3rd ed. rev. (1965). For comment on particular aspects, see O. RIETH, *Die Kunst Menanders in den Adelphen des Terenz* (1964); W. LUDWIG, "The Originality of Terence and His

Greek Models," *Greek, Roman and Byzantine Studies*, 9:169–192 (1968); and W.G. ARNOTT, "Phormio Parasitus: A Study in Dramatic Methods of Characterization," *Greece and Rome*, 17:32–57 (1970).

(W.G.A.)

Terrestrial Ecosystem

A terrestrial ecosystem basically is a landscape that supports life; its components include earth materials at least as deep as roots extend, boundary layers of air, films of water, and interacting organisms. It is not simply these components but the interactions and diverse relations among them that fulfill the concept of an ecological system. Facing the complexity of his environment, man seeks first to analyze the various components; later he attempts to synthesize a broader perspective to understand how the components relate functionally to each other. This synthesis implies, first, an understanding of processes and roles—hence also measures of performance and of subsystems within larger systems. The conceptual basis for ecological systems is dealt with in the article ECOSYSTEM; particular ecological systems in watery environments are considered in the article AQUATIC ECOSYSTEM.

Tables, which list major terrestrial ecosystems, also include preliminary estimates of area and of productivity in live organic carbon for areas of major terrestrial ecosystems. For a perspective on the functions that all ecosystems perform, terrestrial ecosystems are contrasted briefly with aquatic ecosystems. After this review of constraints of life on land, consideration is given to corresponding adjustments of life-forms and the kinds of ecological roles, or niches, that have become available in both natural and modified ecosystems.

THE LAND ENVIRONMENT

Land as a medium for life. The complexes of ecosystems in Table 1 may be compared with the temperature–moisture array of plant types in the article COMMUNITY, BIOLOGICAL to give an impression of the wide range of temperatures and precipitation encountered in different communities throughout the world. If monthly or hourly extremes of these and other climatic variables are considered, as well as the conditions at different levels (micro-environments) above or below the ground, some idea may be gained of the constraints that land organisms had to overcome, during their evolution, after leaving the confines of water. Organisms that are available to colonize a given area and the local physical factors of soil, topography, and moisture availability limit what can arrive, survive and thrive.

Pioneer organisms

Pioneer organisms may change a bare land surface, thus making it suitable for other species, which, in turn, further modify the local ecosystem and prepare the way for still later generations of mutually compatible species. Some combinations of species persist for hundreds or thousands of years if average rates of change of soil and other internal system conditions are slow enough. For intervals of more than a few thousand years, however, gradual shifts in the boundary conditions are imposed from larger systems (*e.g.*, climatic changes bringing on glaciers and major relocation of populations and life zones; gradual shifts and extinctions of species available over wide regions). Undisturbed natural systems adjust accordingly on a time scale that is long by comparison with the recovery times of communities resulting from perturbations of both human and natural impacts. Organisms along the evaporating fringes of the ice cap creeping into Antarctica's dry valleys may encounter water during only a few days in summer when temperatures rise enough to melt ice. Mountains—from Antarctica, along many Andean summits, around the Tibetan Plateau, and locally elsewhere—reach altitudes above which only windborne, wind-nourished life (with few or no vascular plants) persists. These and other extreme outposts of Earth's life were colonized from places where the obstacles to survival were not so severe.

The use of studies of successively smaller ecosystems and subsystems—not in isolation from one another but as nested in the progressively large systems—provides the breadth of data needed to comprehend fully the workings of the global ecosystem.

Smaller systems are dependent on larger ones in many ways. Like space vehicles or stations, some fascinating natural ecosystems depend on the importation of outside energy and some nutrients (see CAVES AND CAVE SYSTEMS; SPRINGS AND WELLS).

Land and water. Shore waters, especially, depend on materials flowing in from the land as well as solar energy penetrating the surface. Deep, dark waters depend on what is produced and transformed in the shallow, sunlit waters. Yet the local upwelling of deep waters, with mineral nutrients released by the decay of sinking organic debris, strongly influences the amounts and kinds of plankton and, hence, of fishes and birds, which return some small fraction of the continents' nutrient loss back to the streams or shore areas.

More or less natural ecosystems on land convert solar energy to organic material by incorporating the carbon of atmospheric carbon dioxide. Man's crops deflect an increasing fraction of this energy and carbon into foods and other products for society. Agriculture and industry, however, consume not only the human energy refueled by foods but also fossil fuels stored long ago in the coal beds and oils of sediments by ecosystems of past ages.

Land, sea, and boundary zones

Fewer than 133,000,000 square kilometres (51,000,000 square miles) are accounted for by glacier-free land, compared with 362,000,000 square kilometres (140,000,000 square miles) by the oceans and adjacent waters. Small but important fractions of these areas lie in shifting boundary zones between land and water. Floodplain, swamp, and delta complexes include some of the world's most productive landscapes. Tides and currents, however, wash away some nutrients from these complexes—and from grassy salt marshes—fertilizing shallow marine waters and stimulating the aquatic food-chain growth.

Even regions so dry that they have no exterior outlets of water to the sea gather saline waters in some rare storms or during moist years. Adjacent flatlands of sodium chloride and even sodium carbonate may be mostly barren but yet support salt-tolerant plants at certain times and places after water flows in from surrounding highlands.

Such cases of shifting boundary conditions of land and water are of interest partly because special displays of clear-cut environmental control of life can be sorted out in the extremes. Similarly, bogs and mires receive widespread interest as wetlands dispersed widely, from the vast lowland Arctic tundras through boreal forest (taiga) belts to a few places further south.

The ancestors of present land life evolved in fresh and salt waters with the appropriate membranes and metabolic processes for selecting the scarce elements and compounds that each cell requires for survival, possible genetic change (mutation), and further evolution.

Adaptation to land living

Limiting factors to living on land. Many adaptations were required before organisms could leave the seas and live on the land. Most green plants evolved from algae that had fluid sacs (vacuoles) inside cells that helped maintain water and chemical balances in the living cell substance. Vascular conducting systems help pipe water to all tissues. Impermeable outer coverings control outgoing water and incoming carbon dioxide through special openings called stomates, which are regulated by guard cells. Specialized adaptations have allowed desert succulents to take in carbon dioxide at night, when temperature and stress of moisture loss are low. Certain organisms have drought-resistant cytoplasm. Lichens, fungi that enclose algal cells in a biological partnership, survive far into the polar regions and into temperate and tropical deserts. The right species can photosynthesize for brief periods under favourable conditions of moisture or humidity, while resisting attrition of their accumulated assets of water and organic compounds during the long times of intervening aridity. In the dry as well as in fairly wet areas of tundra and taiga and especially in the rocky parts of mountain landscapes, other lichens and many mosses illustrate the patchwork patterns of coloni-

Table 1: Approximate Zonal Distribution of Major Pre-agricultural Ecosystems

major bioclimatic zones, temperature, relief	moisture	ecosystem type	area* (000,000 sq km)
Polar to subpolar area			
Polar	arid to humid	tundra, barren	7.86
Polar to boreal	wet peat	open bog and mire	1.30
Boreal alpine	mostly humid	"tundra" meadow	1.58
Subpolar	mostly humid	scrub, herb, bog–woods	2.80
Total			13.54
Boreal and semiboreal area			
Boreal	mostly humid	taiga	10.10
Semiboreal or montane	mostly humid	mostly coniferous	6.91
Total			17.01
Temperate forest complexes			
Cool or montane	mostly humid	mostly coniferous	3.77
Cool	humid	mostly deciduous	3.76
Warm	humid	evergreen, deciduous	5.76
Warm or montane	mostly semi-arid	woodland, scrub	3.83
Warm (moist site)	arid to semi-arid	herb–woods mix	1.07
Total			18.19
Grassland area			
Alpine	mostly humid	mountain meadow	1.81
Temperate	humid	tallgrass, marsh	1.05
Temperate or montane	semi-arid	grass, scrub, puna	9.43
Cold tropical montane	humid	paramo, scrub	0.94
Tropical, subtropical	mostly semi-arid	grassy savanna	9.73
Total			22.96
Desert and semidesert area			
Temperate and tropical	semi-arid to arid	sandscapes	5.77
Cold montane	semi-arid to arid	mountain desert	3.20
Other temperate	arid	desert	10.45
Tropical and subtropical	very arid to arid	desert	9.93
Total			29.35

Hot (moist site)	arid to semi-arid	herb–woods mix	0.32
Hot	humid–dry	woodland, savanna	8.93
Hot	dry–humid	scrub, wood, savanna	5.12
Total			14.37

*Areas regrouped after N.I. Bazilevich, L.E. Rodin, and Rozov.

zation such as might have occurred as the continents first became populated by green plants. Microbes and animals were ready to follow, consuming dead or live organic matter, or both.

Major divisions of the land environment. *Polar regions and tundra.* The colder divisions of the land environment can be grouped broadly as tundra and polar barrens, which include cold "deserts" and spotty tundra (Table 1). Bogs and mires accumulate dead carbon wherever decomposition fails to match production over a long period. Altitudinal and local mixtures of tundra dwarf scrub and meadow extend to many boreal mountains (and also to Alpine temperate and tropical areas tabulated under grassland in Table 1). Sub-polar areas also include cold maritime herb meadow and scrub, bogs with dwarf woods, and open wooded or tall-shrub "tundra" (see POLAR BIOMES; TUNDRA).

Boreal forest (taiga). The boreal forest is here differentiated between northern (transitional to tundra), middle (open woodland to closed forest), and southern (denser forest). Estimates of typical forest area (and total carbon in living organisms) are separated from figures for unwooded and sparsely wooded bogs on peaty soils. Although "boreal" is frequently used in the general sense to refer to anything northern, it is best distinguished from several other predominantly coniferous zones here called semiboreal. These include the sub-alpine and montane zones of mountains, as in the western American Cordillera. A mixed forest zone in eastern and western Eurasia has some broad-leaved species besides the usual poplar and birch that are common in boreal and its grassland fringe zone of western Siberia and south central Canada. Except in these and a few other areas in which aridity and local relief complicate the pattern, a broad climatic outline around most boreal and semiboreal ecosystems is bounded on the north by the farthest extent of the 10° C (50° F) July average temperature and on the south by areas with more than four months above this temperature.

Temperate areas. Temperate areas include some predominantly coniferous forests; *e.g.*, from the central British Columbian interior to lower elevations around alpine–sub-alpine–montane complexes farther inland in North America. Except in parts of a cool coastal belt and some other local rain forests, conifer growth is usually limited by droughts as well as by sporadic insect outbreaks. These repeated disturbances, plus sporadic lightning fires before man began burning and logging, have influenced the extent of most conifer stands. Giant evergreen forests locally attain much greater than average carbon mass. Evergreens of lesser stature, dwarfed in areas of salt–wind exposure, may line these and other vegetation belts in coastal strips too narrow to map on a global scale.

The summer-green forest

Temperate summer-green or cold-deciduous forest, in contrast to the drought-deciduous forest of tropical monsoon regions, prevailed originally in the now industrialized areas of northeastern United States, midlatitude Europe, central eastern Asia, and locally elsewhere. Conifers peculiar to special habitats, especially in mountains and sand plains, also may have been part of the original vegetation and certainly have been extended in plantings in much of the cool temperate zone. In North America, for example, below the latitudes or altitudes where spruce-fir was common, pines were important pioneer species on burned-over forest land and abandoned clearings; eastern hemlock, which is more shade-tolerant, persists or even expands in areas protected from fire, especially in the Great Lakes and Appalachian regions (see FORESTS).

The warm temperate zone, as generally understood in English, is referred to as subtropical in Soviet atlases and literature (which provided many of the preliminary esti-

mates in the tables accompanying this article). Broad-leaved forests are partly deciduous but increasingly evergreen near the southern coasts of the United States, Japan, and China. Only a few conifers are important. Forest and woodland areas include also maquis and garigue scrub in the Mediterranean area, chaparral in California, and similar vegetation capable of maintaining its leaves through dry summers or wet winters or spring seasons (see SCRUBLANDS).

Mostly evergreen broad-leaved forests prevailed in humid portions of the Southern Hemisphere areas: *Eucalyptus* in Australia, *Nothofagus* in New Zealand and the southern Andes. Here oceanic climates moderate winter cold. Wet hard-leaved (sclerophyll) forest and temperate rain-forest ecosystems are quite localized on favourable sites; dry sclerophyll communities of varied height and tree spacing are especially prominent in both temperate and subtropical parts of Australia. Monterrey pine outgrows other planted conifers and the several native evergreen genera.

Wetlands with mixtures of floodplain or swamp herbs are locally important in semi-arid to arid lands. They provide grazing and watering places for animals and invited man's early agriculture and irrigation.

Grasslands. In the same manner that the cool temperate forests interfinger with grassland in the Soviet Union and the northern United States, so the warm temperate forest alternates with grassland on different substrates west of 95° W longitude in the south central United States. As in tropical savannas, burned fringes of all the foregoing forests included open woodlands (*e.g.*, burr oak and post oak openings) and sparser groupings of trees. Semi-arid grassland is here typical throughout, but gradations to cold alpine vegetation and semidesert are also evident.

Tall grassland includes the belt of meadow steppe south of the Eurasian forest and the North American prairie. Short or mixed grassland prevails in the next drier belt. From Mongolia westward, barely interrupted by the mountain meadows and terraced conifer forests of the Altai and other mountains, the shortgrass steppes offered a corridor for Asian horsemen to the Caucasus, the Crimea, and central Europe.

In the Southern Hemisphere occur the pampas of Uruguay and Argentina and the grassy parts of the South African veld, which share the scattered parklike tree growth of the subtropical savannas. With woodland or scrub mixed in, these latter are marked by seasonal moisture and fire (see GRASSLANDS).

Arid regions. Arid lands, climatically defined, include mixtures of grassy and open scrub or special life forms. Cool semidesert steppes typically are marked in the north by silvery *Artemisia* species. Extremes of hot and cool temperatures, in addition to low moisture, further constrain plant growth in the warm semidesert. Saline deserts are interspersed among both of the above arid lands and even in some grasslands but occur in greatest extent in central Asia (see DESERTS).

In Table 1, sandy landscapes, especially those with dunes, are probably estimated conservatively, but biomass is not great even in semi-arid, grassy sand hills or in the *Haloxylon* sand woodlands actively cultivated in the Kara-Kum Desert. Almost 10,000,000 square kilometres (4,000,000 square miles), from semidesert savanna to absolute barren deserts of several kinds, are included as tropical desert.

Tropical forests. When these and transitional semideciduous and semi-evergreen forest or woodland are taken into account, the area of completely evergreen tropical forest is more limited than many maps suggest. Massive tropical or equatorial rain forests occupy only a fraction of this total area. Sites that are enriched by nutrients from upstream or upslope give the exceptionally high production noted on Table 3—but only over still more limited areas, which have long been the first to attract shifting cultivation (see JUNGLES AND RAIN FORESTS).

Woodlands. Below the highest snowfields are equatorial mountains that include treeless zones with temperatures near freezing on most days of the year. These areas, with a peculiar combination of low and exceptionally tall cold-resistant herbs, are called paramo in Colombia and Ecuador. Far less localized are elfin woodlands and scrub vegetation, widespread near the summit of mountains in both the tropics and subtropics. Evergreen subtropical mountain forests are typical of monsoon regions that have drought-deciduous forests in the lowlands.

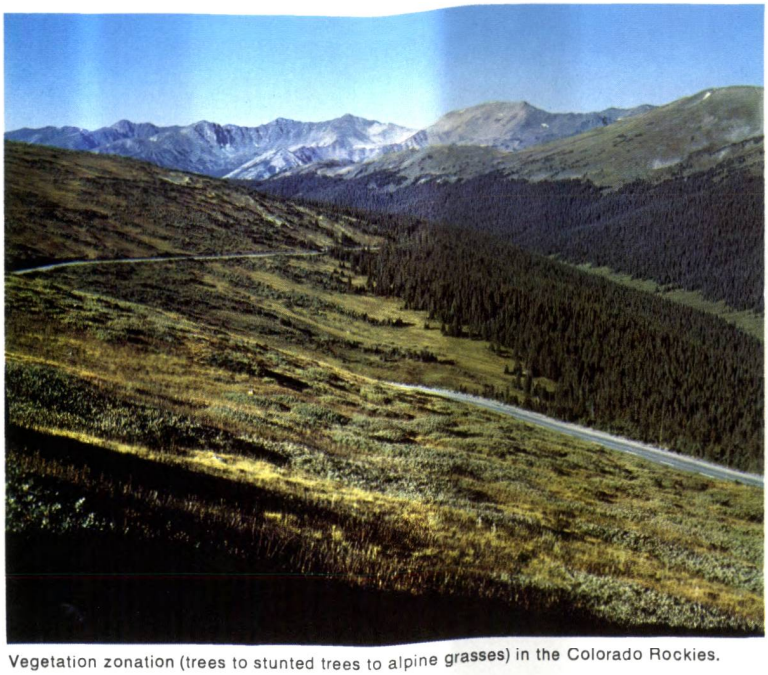
Development of savanna and scrub

Natural deterioration by leaching of nutrients and by clearing and erosion have already created much savanna and scrub in the coastal rain forest belt of eastern Brazil and in many areas of the Amazon Basin. In West Africa, rain forest and moist evergreen forest appear to be more vulnerable to conversion to grassy savanna than are drier types of ecosystems because fire-resistant trees are not already present. Moist semideciduous forest, dry deciduous forest, and woodland are considered more likely for conversion to savanna woodlands through selection favouring resprouting of resistant trees already mixed in the vegetation or available for invasion from the vegetation of surrounding regions. Original savanna woodland maintains resistant trees but has opened up to allow more grass or scrub since burning has become an annual management tool—especially where fires are mostly started late in the dry season.

MAJOR LIFE FORMS AND CLASSES

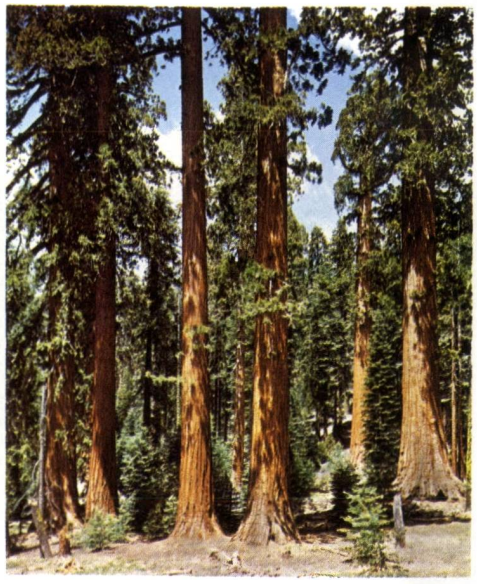
Growth habits and indicator organisms. A classic ecological approach to interpreting environmental constraints on regional plant formations or local community and site types within regions is based on the kind of plant group, or life-form, that predominates (see Table 2). Anglo-American and Soviet forestry traditions have tended to emphasize the indicator value of such life-forms and, where possible, the genus and species of the main community or perhaps each of several layers (strata) approximating a class. Preliminary indications of community change are based on the prevailing heights of plants constituting the class and include the appearance of very different species combinations in seedling or other young strata as compared with currently dominant vegetation.

In a complex ecosystem, however, the species of greatest abundance is frequently not such a sensitive indicator of habitat conditions as are others having lesser abundance but greater fidelity or differential occurrence. Several Eurasian schools of ecosystem classification and newer techniques of statistical analysis have introduced the relative importance of various combinations of factors distinguishing one ecosystem type from another.



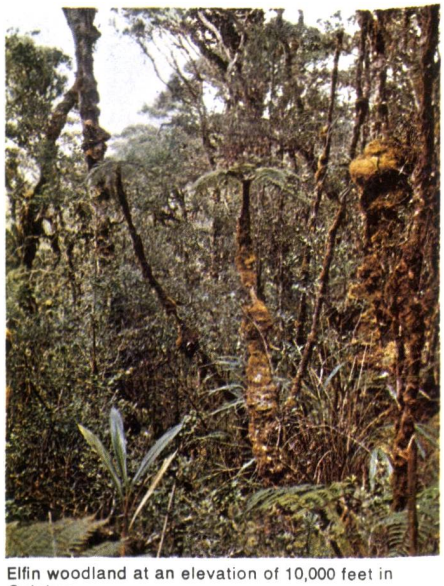
Ecologically similar species within major genera are recognizable among quite distant areas—especially in the Northern Hemisphere. On the other hand, the physical constraints of water relations and energy balance have led to convergent evolution of similar life-forms from genetically distant stock. Notable examples among plants include the hard-leaved (sclerophyll), mostly evergreen scrub and woodland or forest in the winter-rain, summer-drought (Mediterranean-type) climates of Chile, Australia, and California, as well as southernmost Europe, northernmost and southwest (Cape) Africa, and areas of southwest Asia.

The evolution, successional change, and seasonal movements of animals are related directly to plants that provide them food and shelter. In the very cold or dry regions noted earlier, herbivorous and especially predatory and scavenging animals may have to range widely to survive and reproduce. Warmer, humid regions include migrants but also allow a wide variety of other organisms within almost any habitat.



Habitats and niches

Classification by habitat. The habitat—where an organism lives—is frequently used to categorize the living things in an ecosystem. The types of habitat may be divided broadly as soil organisms, rooted plants, organisms attached to plants, and free-moving animals.



Soil organisms include a size range from microbiota (micro-organisms and minute animals) through mesobiota (arthropods and smaller larvae) to macrobiota (roots of plants, larger invertebrates and burrowing vertebrates). Plants provide an aboveground layer consist-

Table 2: Life-Forms of Primary Producers

plant life-form group	height	Raunkaier categories*
Epiphytes (growing on plants of the following groups)		
Woody or evergreen perennials (bud-bearing shoots above ground)	buds more than 0.25 metre above ground	Phanerophytes
Trees (one to few stems; self-pruning)	taller than 30 metres	Megaphanerophytes
	10–30 metres	Mesophanerophytes
	less than 10 metres	Microphanerophytes
Shrubs (smaller woody plants, often with many stems and with shoot replacement)	taller than 0.5 metre	Microphanerophytes
	less than 0.5 metre	Nanophanerophytes
subshrubs	less than 0.25 metre	Chamaephytes
semishrubs	partly dying annually	Chamaephytes
Lichen-moss layer(s)	buds near ground surface	bryoid-chamaephyte
Perennial (or biennial) herbs		
Grass-like (including sedge, rush, etc.)	buds near ground surface	Hemicryptophytes
Forbs (including non-grassy herbaceous plants)	buds below ground	Geophytes
Water plants	buds or bulbs below water	Hydrophytes
Marsh plants	buds or bulbs in wet ground	Helophytes
Annuals		
Summer, winter, and facultative perennial	"buds" in seed	Therophytes
Special forms†		

*A traditional standard terminology for life-forms as devised about 1900 by C. Raunkaier, a Danish botanist. †Including: bamboos (woody grasses); tuft plants; climbers (lianas); succulents (stem and leafy).
Source: After H. Ellenberg, D. Mueller-Dombois, A. Kuchler, W. McGinnies, and others.

ing of prostrate herbaceous plants, shrubs, vines, and trees. The organisms that attach to such plants are called epiphytes; those that cling but can move are often called periphytes. The freely moving animals—both walking and flying—are referred to as permeants.

Classification by niche. Not only the habitats but the niches (operating roles of organisms throughout their life) are involved in a careful consideration of ecosystems and their evolving populations. Just as persons "find their own niches" in a complex society and adapt, through learning, to their own special vocations, an indefinitely large number of species possibilities have been narrowed down during the course of evolution to those especially adapted to definite and perhaps discrete "vocations" in a natural ecosystem.

Considering first the environment as conditioning a local ecosystem through climate, the presence of other organisms, pre-existing surface, surrounding relief, and related moisture factors, then within a specified local area, or volume, on the Earth's surface, the range of variables is seen to be much smaller than in the entire biosphere, or zone of life.

If each available species in neighbouring ecosystems is allotted a dimension, for example, those that never become established in a local ecosystem in question measure zero. Whatever the measure used, pioneer species are those scoring high soon after a bare or disturbed area has opportunity for recovery but declining—usually to zero—as waves of replacement species arrive. Self-perpetuating (climax) species may have more dimensions than the pioneer species or those that typically rise and disappear in stages of succession.

If the individual species and its niche be examined, the organisms with which a species coexists at one time or another (a kind of intersection set) constitute part of its niche. Microclimatic variables within the local habitat occupied by the species limit the range of favourable conditions. Soil conditions, microtopography, and moisture conditions, all of which change with the other variables, are additional ecosystem properties that influence most of its inhabitants directly or indirectly. Also upper and lower limits of physiological tolerance influence where and how long a species can persist—either locally, on the time scale of a species life cycle, of succession, or globally, on the time scale of evolution.

Not only mere survival but the probable rates of intake of resources, of elimination, of growth and reproduction, and of death for each kind of organism are influenced by the other variables. An organism can fill any of three niches at any given time in its life: it can be a producer of goods, like green plants; a consumer of goods, like most animals; or a decomposer of goods, like many micro-organisms. The entire complex constitutes a food web or network. Energy passes along this net as in a power grid, and is dispersed as heat along the way.

The three types of niches

Producers. With minor exceptions (chemosynthetic bacteria) green plants fulfill the prime role of providing energy for all other organisms by means of the process of photosynthesis, the conversion of sunlight and raw materials to sugars and other foods. Roots and other underground parts of plants replenish water losses and also withdraw mineral nutrients from substrates. Both for plants with and plants without above-ground woody parts, storage of photosynthetic products underground may be very important. Above-ground stems provide the support for displaying the photosynthetic machinery through as great a vertical column of air as the habitat, life form, and stand age will permit.

Consumers. Under optimal conditions well over 10 percent of the net primary production may be channelled through various consumers, but a lower percentage is the usual case. Plant-eating animals (herbivores) are the primary consumers; they extract their varied food needs from the predominant carbohydrate storage of plants, accumulating large stores of protein. Predators consume other animals, thus taking advantage of the concentrations of protein already accumulated by the prey. Direct feeding on other animals is accomplished also in diverse ways by parasites. Disease organisms represent extreme cases, in which the host is not actually consumed but is debilitated or even killed by gradual depletion of its resources.

Table 3: Net Primary Production,* Carbon Pool, and Turnover

ecosystem complexes	production† (10^9 metric tons of carbon per year)	live carbon pool (10^9 tons)	turnover fraction‡ per year
Non-woodland			
Tundra and bog (treeless)	0.88	8.08	0.109

Total forest, woodland	59.37	1,009.41	0.059
Total land	75.35	1,070.00	0.07

*Equivalent to the gross primary production less the respiration of all parts of green plants. †Includes carbon tied up in all living plants. ‡Annual loss of carbon from the live carbon pool to dead organic matter/live pool.

Omnivores have kept more feeding options open: they can consume both plants and animals. Certain birds and mammals switch readily between these foods according to season and abundance of food types.

Decomposers. Plant parts and animals die and pass on to organisms called decomposers, which break down organic structure—using and dispersing energy from the compounds left over by other organisms. This important functional role has the further consequence of releasing mineral nutrients for eventual recycling through succeeding generations of plants.

Various decomposers are adapted to diverse microhabitats within an ecosystem and create and modify new kinds of niches for other organisms as well.

PRODUCTIVITY IN TERRESTRIAL ECOSYSTEMS

Ecologists use the word production in a strict sense to mean the processes by which plants and animals convert nutrients to their own kind of body substance. Production can be carefully measured in terms of production rate per unit of time, or it can be expressed graphically as a generally rising curve of cumulative increase of input with time. Sometimes the word productivity is used specifically to indicate a short-term or instantaneous rate or derivative of change rather than a long-term average. Productivity of dry matter or economic products from a given ecosystem is frequently given as a prediction rather than a measurement, varying with the intensity and kind of management. Here the meaning is broad enough to cover the phenomena related to all the aspects of production.

Net primary production. Relatively refined physiological studies are necessary for estimating what is termed gross primary production of an ecosystem. This measurement is usually expressed as the total amount of carbon absorbed by plants as carbon dioxide and converted to organic matter. Subtracting the compounds returned in any form of respiration by green plants gives net primary production. If expressed instead as the dry matter equivalent of carbon, this and the following terms must include an appropriate additional few percent for mineral elements (*e.g.*, nitrogen, sulfur) that accompany the carbon, hydrogen, and oxygen of all organic compounds. Energy equivalents are often preferred.

Carbon as a measure of productivity

On the basis of the best data available in the early 1970s, Table 3 provides estimates of net primary production. Metric tons of organic carbon per square kilometre per year (which equals grams per square metre per year and 0.1 kilogram per hectare per year) is multiplied by the areas from Table 1 to give the current approximation of the contribution of each ecosystem to worldwide net primary production (first column of Table 3).

Both the inventory, or "pool," of carbon in the biosphere and its distribution are judged according to pre-agricultural conditions; *i.e.*, before extensive forest clearing and widespread modification of natural vegetation.

If the annual income of carbon were approximately balanced by annual losses from all sources under natural conditions (*i.e.*, if the pool were neither increasing nor declining in comparison with the annual atmospheric exchange of photosynthesis), the following equation would hold true:

$$\frac{\text{production}}{\text{live pool}} = \frac{\text{sum of losses}}{\text{live pool}} = \text{turnover fraction per year.}$$

Among the groups of tundra-like ecosystem complexes in Table 3, about 11 percent of the vegetation is replaced each year. The production of about 170 grams of organic carbon per square metre per year averages over a wide variance between polar deserts (near zero) and mountain-meadow ecosystems, which approximate values for grasslands, noted below.

Grassy ecosystems turnover is about 30 percent of the plant life per year. Production rates average 450 grams of carbon per square metre per year—from about 60 percent or less for shortgrass prairies to 140 percent or more for wet prairies and marshes.

Desert-like ecosystems average consistently lower—about 100 grams of carbon per square metre per year—but this aveage obscures a wide variance from near zero to values approaching grassland production where moisture is frequently replenished. Turnover of plant material also varies widely, perhaps near 20 percent per year where woody or underground parts are prominent, to nearly 60 percent where short-lived vegetation is relatively more prominent.

Special moist sites having small area but high production per unit area have been purposely treated separately so as not to influence disproportionately the estimates for the surrounding widespread landscapes of arid, semi-arid, and temperate humid regions. These wetlands have high turnover (25–30 percent per year) because herb growth is prominent, and the ratio of shrub and tree growth to biomass is higher than in other woodlands and forests.

By contrast, true forests of the boreal and temperate zones have a consistently low annual turnover—averaging slightly over 3 percent per year if the data in Table 3 are widely representative. Primary production rates per

unit area vary widely. Sub-alpine and other semiboreal coniferous ecosystems average only slightly higher than tundra margin or bog woodlands. Warm temperate forests, such as those in the southeastern United States, are only slightly more productive than tropical and subtropical woody savanna, thorn forest and scrub; 600–800 grams of carbon per square metre per year.

Production estimates for tropical forests are high relative to those for other forests. For the nutritionally enriched forests, estimates of roughly 2,500 grams of carbon per square metre per year production are given. The turnover rate of 13 percent per year is only half that attributed to wetlands of the cooler and drier areas, where more of the vegetation is killed and replaced each year.

While future research may modify the estimated areas and carbon pools of Table 1 and production rates of Table 3, the general trends of turnover fraction outlined above and the following interpretations of world totals are not expected to change too drastically.

Ecosystems of low productivity

Tundra-like ecosystems and deserts must have contributed low production and live pool of organic carbon, although wetter parts of the tundra have stored much former live material as dead peat or meadow humus (not listed in Table 3). Grasslands and grassy savanna-like ecosystems probably had higher production rates and pools of live carbon than did tundra and deserts together, and they probably had accumulated deep humus in mineral soils.

The same table suggests that moist, cold, and seasonally dry categories of open or low woodland and scrub combined produce more carbon than either tundra or grasslands and several times as much stored carbon in live plants. It suggests further that denser forests (boreal, temperate, and tropical together) contributed more than half of the land's annual carbon fixation, and more than 75 percent of its carbon storage in live organisms—mostly plants and, more specifically, the woody parts of trees. Of course much of this wood is physiologically dead, but its entry into the decomposer food chains is mostly delayed while the outer trunk of the tree remains alive even if heartrot and cavities begin to break down the inner wood. As reflected also in the low turnover fractions for forest and some woodlands, these ecosystems evolved a life-form and structure that allows their photosynthetic machinery to operate through a considerable depth of atmosphere as compared with all the other kinds of ecosystems.

Secondary production and decomposition. Only a fraction of the plant material lost each year in the biosphere is consumed by animals; much of this vegetation falls to the decomposer organisms. Food that is consumed is only partly assimilated in the digestive tract and becomes part of the secondary production in an ecosystem; the remainder may be fairly promptly regurgitated, defecated, or excreted in other fluids.

Equations used for balancing incomes and losses for major decomposers as well as aboveground consumers help to identify the environmental control of each major transfer in the ecosystem. It is likely, however, that there is a significant remaining group of decomposers that cannot be analyzed independently of the surfaces in which they are inextricably dispersed. For this remaining group or for a summary equation expressing the joint action of all decomposers and the surfaces on which they act in a combined subsystem, the net change in mass can be summarized in a balance equation combining the terms for income of dead organic materials and respiration rates of the decomposers concerned.

If the last line of Table 3 fairly approximates the preagricultural annual income and inventory of live organic carbon on land, the long-lived and short-lived compounds together averaged about 7 percent replacement per year. Losses were less than income for the entire biosphere for certain long periods because there was a downhill washing from lands to waters and a net accumulation of dead organic materials in peat, coal, and petroleum. This represents a net storage of solar energy fixed ages ago, over geologically long periods, by the photosynthesis of past ecosystems.

Man-influenced ecosystems and their productivity. A growing international research effort is attempting to understand ecosystems well enough to improve upon estimates heretofore given and to predict the consequences of changes in income and loss rates. The uncertainty in present agricultural and man-modified landscape production rates is large, but several assessments made in 1968–70 added up to incomes around 56,000,000,000 metric tons of live carbon per year, compared with an inventory or live pool about ten times as large. It is clear that a real decrease has occurred in the inventory and that much of this is the result of forest clearing. Roughly 70 percent of the former forest–woodland area remains and about 70 percent of the mass per unit area on this remaining area is probably a generous estimate. Less than half as much organic carbon, mass, and energy is carried on remaining forests when compared to the natural ecosystems. These cleared areas were subsequently replaced by pastures and almost 15,000,000 square kilometres (6,000,000 square miles) of agricultural land.

Disruption of natural ecosystems

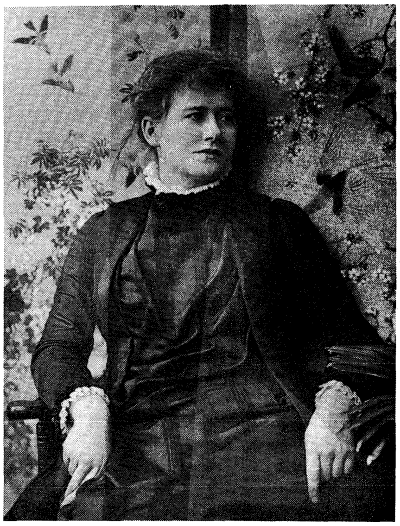
Intense and efficient agricultural practices—constituting the "Green Revolution"—have drastically increased carbon fixation rates on some fairly small fraction of this land, but soil deterioration has probably decreased it on other cropland and on many semiwild ecosystems. Overgrazing and other misuse have diminished biological and economic productivity of large areas and have allowed the sand or dust in some desert fringe areas to encroach on formerly arable landscapes and, in Mediterranean areas, on cities that were formerly supported by better biological production.

Glowing hopes have been raised about optimizing the mixture of material and intangible values of the landscapes that are left, but it remains far from clear that constraints of the real world will permit a bare maintenance of present living standards as populations rise—much less the higher living standards to which much of the world aspires. The growth of industry and cities—and of mechanized agriculture to support both—has been tapping fossil fuel reserves (coal, oil, and gas) at rates that are still rising and measurably increasing the atmosphere's carbon dioxide faster than it is absorbed by vegetation. It will take much collective wisdom to foresee the consequences of all these changes and even more determination than man has yet shown for his environment in order to steer the Earth's future in the most beneficial manner (see AGRICULTURE, TECHNOLOGY OF; FORESTRY; and URBANIZATION).

BIBLIOGRAPHY. Information on terrestrial ecosystems can be found in the voluminous literature of biology and Earth sciences.

Methods and results of research are provided in *Ecological Studies*, the first volumes of which are: D.E. REICHLE (ed.), *Analysis of Temperate Forest Ecosystems* (1970), and HEINZ ELLENBERG (ed.), *Integrated Experimental Ecology* (1971).

Forest ecosystems are emphasized in the two volumes cited above and in V.N. SUKACHEV and N. DYLIS, *Fundamentals of Forest Biogeocoenology* (1968). This text-reference book and the following on a wider variety of world ecosystems are translations of major Russian sources: L.E. RODIN and N.I. BAZILEVICH, *Production and Mineral Cycling in Terrestrial Ecosystems* (1967); N.I. BAZILEVICH and L.E. RODIN, "Geographical Regularities in Productivity and the Circulation of Chemical Elements in the Earth's Main Vegetation Types," *Soviet Geography: Review and Translation*, 12:24–53 (1971), which includes maps derived from the foregoing data.



These and several other results from the two were incorporated in Reichle's book cited above, and in maps distributed by the organization, Students of Earth's Future, Oak Ridge, Tennessee.

The relation of terrestrial animal production to ecosystems is treated in diverse entomological and zoological as well as ecological literature, but the following highlight some important problems of integration: K. PETRUSEWICZ and A. MACFADYEN, *Productivity of Terrestrial Animals*, IBP Handbook No. 13 (1970); R.V. BELL, "A Grazing Ecosystem in the Serengeti," *Scient. Am.* 225:86–93 (1971), which together with G.M. VAN DYNE, *Analysis of Structure and Function of Grassland Ecosystems* (1970), offers a diverse sampling of studies or syntheses describing very different ecosystem groups, and their practical importance or unsolved questions.

(J.S.O.)

Terry, Ellen

For decades Ellen Terry's beauty, charm, vivacity, and immediate, sincere command of sentiment and pathos made her one of the most popular stage performers in both Britain and North America; an actress whose success was based essentially on her personality that imbued even the dullest part with a stirring vitality, she was most celebrated during her long partnership (1878–1902) with Sir Henry Irving. Although her career became desultory after his death, she never lost her hold on the public imagination and continued to be loved and admired, more for her great warmth of personality than for her infrequent theatrical performances after Irving's death.

Ellen Terry, *c.* 1878.

Alice Ellen Terry was born in Coventry, Warwickshire, on Feb. 27, 1847, the second surviving daughter in a large family of which several were to become well-known on the stage. She had no formal schooling, but trained by her parents, she rapidly developed into a celebrated child actress. At the age of nine she made her debut in the child's part of Mamillius in *The Winter's Tale*, which Charles Kean, son of the actor Edmund Kean, produced in London in April 1856. She remained in Kean's company until 1859 and later joined the stock company playing at the Theatre Royal, Bristol, where she played leading parts in Shakespeare and in repertory theatre.

In 1864, at the age of 16, she left the stage to marry the painter G.F. Watts, whose model she had been. Watts, a melancholic man almost three times her age, made many fine portraits and sketches of her, but the marriage survived a bare ten months; his rich patroness was determined that Ellen should go. In her despair, she could scarcely be induced to return to the stage but eventually did so, though playing with little of her former distinction. It was in 1867 that she first appeared, by chance, with Sir Henry Irving, playing Katherine in *The Taming of the Shrew*.

The following year she left the stage abruptly to live for six years in Hertfordshire with the architect and theatrical designer Edward Godwin (1833–86), whom she had met in Bristol and who became the father of her children, Edith and Edward Gordon Craig (1872–1966), who was to become a renowned actor, stage designer, and producer. When her association with Godwin began to fail, it was the author, dramatist, and producer Charles Reade who found her and brought her back to the stage. In the role of Portia she showed new maturity in a striking production of *The Merchant of Venice* (1875), designed by Godwin. On parting from Godwin (who married in 1876), she became responsible for maintaining their children. Before joining Irving at the Lyceum Theatre in 1878, she completed a successful season at the Court Theatre. In 1877 she received a divorce from Watts and married an actor, Charles Kelly, mainly to give her children a "name." They soon separated, and Kelly died in 1885.

Career with Irving

When Ellen Terry joined Irving, she was 31 and he 40. It was the beginning of a close association with a man of genius whose life and resources were to be dedicated to the theatre and who was to make the Lyceum a centre for new, striking interpretations—of Shakespeare in particular. His approach to sponsorship of new plays was that of a great stage visualizer and star actor who required a scenarist to assemble a script that would give him a framework for compelling performance and spectacular stage effects. As part of his *mise-en-scène,* he needed a beautiful woman to lend her own glamour to his productions. Ellen Terry responded to his needs with selfless dedication, playing many great Shakespearean parts—Portia (1879), Juliet and Beatrice (1882), Lady Macbeth (1888), Queen Katharine (1892), Imogen (1896), Volumnia (1901), Ophelia (1878), Desdemona (1881), and Cordelia (1892). She willingly undertook such humble roles as Rosamund in Tennyson's *Becket* (1893), in which all the limelight shone upon the master.

Whether in London or on arduous provincial tours, in New York or on exhausting excursions across North America, Ellen Terry acted as Irving's leading lady until she had grown too old for most of the parts in his repertory. They severed their partnership only in 1902, three years before his death. Their relationship was as close in private as in public life, and it was only when his affection began to wane in the 1890s that she entered into her famous "paper courtship" with Bernard Shaw. This correspondence is one of the most brilliant in the history of English letter writing. In 1907 she married the American actor James Carew, some 30 years her junior; although they soon parted, he remained her friend.

It was in comedy and in plays of tender sentiment, as well as in Shakespeare, that Ellen Terry's talent shone. When she left Irving it was to appear with Sir Herbert Beerbohm Tree in *The Merry Wives of Windsor* (1902), and Shaw eventually persuaded her to appear as Lady Cecily Wayneflete in *Captain Brassbound's Conversion* (1905), one of several parts he wrote with her in mind. When she celebrated her golden jubilee in 1906 at the Theatre Royal, Drury Lane, all the theatrical personalities of the day shared the stage with her.

Bernard Shaw saw Ellen Terry as a shining example of a modern, intelligent actress, capable alike of naturalistic and intellectual performance. During the 1890s he constantly urged her to leave Irving, whom he regarded as reactionary, and to dedicate herself to promoting the modern drama, represented in the work of Ibsen and himself. But unlike Sarah Siddons, her 18th-century predecessor as undisputed queen of the English theatre for a whole generation, Ellen Terry was ill suited by temperament to become a theatrical leader in her own right. Her particular, instinctual genius flowered only through her long service with Irving.

Although Irving had paid her £200 a working week for most of 20 years, she still had to earn a living in her later years. She worked in the theatre, last appearing on stage in 1925; in films; and as a Shakespearean lecturer-recitalist, reinterpreting her successes on tours in the U.S., Britain, and Australia. Her warm, generous personality made her a favourite wherever she went, but eyesight and memory began to fail. Belatedly, in 1925, she was made a Dame Grand Cross of the British Empire. She died on July 21, 1928, at her cottage, Small Hythe, Kent, which became the Ellen Terry Memorial Museum and in 1939 was given to the National Trust by her daughter Edith Craig.

BIBLIOGRAPHY. The principal biography is ROGER MANVELL, *Ellen Terry* (1968). See also her *Story of My Life* (1908; as *Ellen Terry's Memoirs*, with preface, notes, and additional biographical chapter by E. CRAIG and C. ST. JOHN, 1932); her *Four Lectures on Shakespeare* (1932); EDWARD GORDON CRAIG, *Ellen Terry and Her Secret Self* (1931); and EDWARD A. CRAIG, *Gordon Craig* (1968), in which the relationship between Ellen Terry and her son is developed by Gordon Craig's son, Ellen Terry's grandson. The correspondence with Shaw was edited by C. ST. JOHN (1931; 2nd ed. as *Ellen Terry and Bernard Shaw: A Correspondence*, 1949). Other important works are: LAURENCE IRVING, *Henry Irving, the Actor and His World* (1951), which gives a full account

of Irving's and Ellen Terry's place in the Victorian theatre; GEORGE BERNARD SHAW, *Dramatic Opinions and Essays*, 2 vol. (1906), which contains the articles in which Shaw attacked Irving and praised Ellen Terry; and ROGER MANVELL, *Sarah Siddons, Portrait of an Actress* (1971), which provides insight into the theatrical tradition from which Ellen Terry emerged.

(R.M.)

Tertiary Period

The Tertiary Period is the geological time interval from 65,000,000 to about 2,500,000 years ago, after the Cretaceous Period and before the Quaternary Period. The name Tertiary was first used in 1760 for younger rocks that rest on the "Secondaries" or Mesozoic strata (from 225,000,000 to 65,000,000 years ago) in northern Italy. It is derived from the Latin *tertiarius*, meaning "belonging to the third part." In 1811 the deposits in the Paris Basin, and soon thereafter all the rocks younger than Mesozoic, were called Tertiary in western Europe.

Subdivision of Tertiary time

The Tertiary faunas of western Europe that were known in the 19th century consisted mostly of mollusca of modern aspect. By 1830 those of the Paris Basin were being intensively studied and compared with those of other parts of Europe. Sir Charles Lyell proposed four subdivisions of the Tertiary. These were, from oldest to youngest: the Eocene, with its type deposits in the Paris Basin; the Miocene, with its type deposits, the "Faluns (shelly marls) of the Loire" of southwestern France; older Pliocene, with its type deposits, the "Subapennine formations" of northern Italy; and the newer Pliocene, with its type deposits, the strata in the Val di Noto of Sicily. The fauna of the Eocene was characterized by 3.5 percent of living species, the Miocene by slightly less than 18 percent, and the undifferentiated Pliocene (including both older and newer) by 49 percent. It also was noted that the fauna of the newer Pliocene included an immense preponderance of Recent (synonymous with Holocene Epoch—the last 10,000 years, approximately) species. The name Pleistocene was substituted for the newer Pliocene in 1839, and in 1846 it was applied to glacial deposits of post-Pliocene and pre-Recent age.

Lyell expressly provided for the recognition of intermediate divisions of Tertiary time. A study of the Tertiary deposits of the Mainz Basin of West Germany in 1854 led to the suggestion that the time interval between the Eocene and Miocene be termed the Oligocene. This was to include the Tongrian and Rupelian stages (Table 1) as well as strata that subsequently formed the basis of the Chattian Stage. In 1874 "Paleocene" was proposed for an interval characterized by a flora intermediate between that of the Cretaceous and that of the Eocene; the "Sands of Bracheux," "the Travertines of Sezanne," and the "Lignites and sandstones of Soissonais" (Suessonian) from the Paris Basin were cited as typical. The Paleocene as thus defined included strata now assigned to the Ypresian Stage, which is here accepted as basal Eocene. In 1846 the Danian Stage was proposed and was assigned to the Cretaceous on the basis of contained megafossils. In the last two decades, however, micropaleontologists have found that the planktonic foraminifera (floating, one-celled, marine organisms) of the Danian are more nearly related to those of the overlying Montian Stage of the Paleocene than to those of the underlying Maastrichtian; for this reason, the Danian is considered by some authorities as the earliest stage of the Tertiary.

The name Paleogene was proposed in 1856 for the three older Tertiary epochs, and Neogene for the two younger epochs, but this twofold division of the Tertiary has not been as widely used as the fivefold.

In 1948 the 18th International Geological Congress decided to place the base of the Pleistocene at the base of the marine strata of the Calabrian Stage of northern Italy, at the first appearance of northern or cool-water invertebrates. As thus defined, the base of the Pleistocene would fall within the Pliocene, according to original usage. There is much disagreement about the subdivisions and their time significance. Table 1 shows the most widely used subdivisions of the Tertiary Period and their diverse usage; recommended usages are starred.

This article treats Tertiary rock deposits, life-forms, and aspects of stratigraphic correlation of deposits. It also presents a synopsis of the paleogeography and paleoclimatology of Tertiary time. For information on previous and subsequent intervals of geological time, see CRETACEOUS PERIOD; PLEISTOCENE EPOCH; see also CENOZOIC ERA for an overview of Tertiary, Pleistocene, and Holocene events. Additional detail on relevant life-forms and stratigraphy is presented in the articles FOSSIL RECORD; STRATIGRAPHIC BOUNDARIES.

TERTIARY ROCK DEPOSITS

Distribution of deposits

Within the continents Tertiary marine deposits are mostly found along continental margins (except in western Europe), along the Tethyan Seaway (see map), and in the Mississippi Valley of North America. Marine Tertiary deposits are known *in situ* in Antarctica only on Seymour Island in the Palmer Peninsula area, but marine fossils recently have been recorded from glacial erratics (ice-transported rocks) in the Ross Sea area.

In Europe, western Asia, and the Near East, the marginal seas and the various branches of Tethys expanded greatly at times during Early and Middle Tertiary time, and marine and brackish deposits are widespread in these regions. In most regions the Paleocene–Eocene seaways extended farther inland than they did later in the Tertiary. Deposits of Tertiary age also are widely exposed on the sea floor of all ocean basins. Nonmarine deposits of both sedimentary and volcanic origin are widespread in North America west of the Mississippi River, and in the Neogene extend westward almost to the coast. In South America, very thick nonmarine clastic sequences (conglomerates, sandstones, and shales) are known in the Andes Mountains and along their eastern front; these extend eastward for a considerable distance into the Amazon Basin. Nonmarine sediments are also widely distributed in the interior of Asia, and similar sequences are present in northeastern Africa.

Volcanism and orogenesis. Evidence of Tertiary volcanism is absent in western Europe and most of Africa, except in Northern Scotland and Ireland during the Early Tertiary; in central Germany and the Massif Central of France during the Oligocene; in Algeria during the Middle Tertiary; and in the rift zone of East Africa during the Middle and Upper Tertiary. It also is largely absent in Asia, except in the Caucasus during the Early and Middle Tertiary. The rim of the Pacific, from the Philippine Islands in the southwest to California in the southeast, except for a segment around the head of the Gulf of Alaska, was the site of much volcanism through the Tertiary. Extensive volcanism occurred, however, in the Indonesian area after the middle Miocene. The Deccan Plateau of India was the site of extensive outpourings of lava at the onset of the Tertiary. In the Miocene, similar outpourings of basaltic rocks occurred over an extensive area of eastern Washington and Oregon, southern Idaho, and northeastern California. The northern Rocky Mountains of North America were the site of active volcanism during the Early Tertiary, but in the southern Rockies volcanism was more common during the Middle and Late Tertiary. In Central America, volcanic activity began near the end of the Oligocene and has continued to the present. In South America, volcanism is almost exclusively confined to the Andean Belt; most of it occurred during the Middle and Upper Tertiary. The North Island of New Zealand was also the site of much volcanic activity during the Middle and Upper Tertiary, but in Australia notable volcanic activity occurred only during the Early Tertiary, and was largely restricted to Queensland and adjacent areas of the continent. Within the Pacific Ocean Basin, the major island groups, such as the Hawaiian and Galápagos, basically are composed of volcanoes that rise from the sea floor. The ancestral Hawaiian Islands probably had their inception in Late Mesozoic time, whereas the Galápagos seem to date from the Miocene. The Caribbean area was the site of volcanism throughout the Tertiary, with the locus of activity shifting from time to time. Greenland and Iceland in the Atlantic Ocean were the site of much Cenozoic volcanism, whereas on

Outpourings of lava on land and beneath the sea

Table 1: Comparison of Some Tertiary Classification Schemes

the sea floor the Mid-Atlantic Ridge was the site of volcanic outpourings throughout the Tertiary.

Mountain building

In North America, the Laramide orogeny (mountain-building episode) that formed the Rocky Mountains began in the late Cretaceous and continued into the Eocene. Along the Pacific Coast, the Sierra Nevada and the Coast Ranges of British Columbia, which had been involved in a mid-Cretaceous orogeny, were the site of recurrent movement during Late Tertiary and Pleistocene time. The Andean Geosyncline (depositional trough) of South America was broken up by the late Cretaceous orogeny; activity was renewed near the end of the Miocene. Final uplift occurred during Pliocene and Pleistocene time.

Complex tectonic activity occurred in Asia and Europe in the Tethyan Sea area during the Tertiary. The main Alpine orogeny began in the Oligocene and continued throughout the Tertiary. The Apennines of Italy are the culmination of a series of movements that began in the Tyrrhenian Sea during the Oligocene and moved eastward until near the end of the Miocene. The last of the recurrent orogenies that affected the Pyrenees occurred in the late Eocene. On the south side of the Tethys, the coastal Atlas of North Africa underwent its major uplift in late Eocene time, but minor orogenic movements continued through most of the Tertiary. Along the Tethyan Belt in the Near East and India, tectonic activity began during the Eocene and continued recurrently throughout the Tertiary, with the seaway being disrupted at the end of the Oligocene. The most intensive Himalayan orogeny occurred in the middle Miocene, but tectonic activity continued until the middle Pleistocene. In the Malaysian–Indonesian–Japanese region, major orogenic episodes occurred in the Miocene, and lesser episodes continued on into the Pleistocene. In New Zealand, the principal Cenozoic orogeny occurred during the Miocene and continued intermittently thereafter.

Marine sediments of the Paris Basin and Gulf of Mexico

Sedimentary sequences. Compared to those of geosynclinal areas, the Tertiary rocks of the Paris Basin are relatively thin, are nearly horizontal, and often are highly fossiliferous. The sediments occur in a roughly oval area, about 125 by 225 kilometres (78 by 140 miles) in maximum dimensions, with Paris near the centre. They show marked lateral changes in facies (all aspects of a geological unit, including rock type and contained fauna), and, in consequence, the local stratigraphy is highly complex. The sequence has a maximum thickness of less than 300 metres (less than 1,000 feet) and is composed of sands, clays, marls, limestones, and gypsum, which reflect numerous alternations of marine, brackish, lacustrine, and terrestrial environments during their deposition. Approximately 50 stratigraphic units are commonly recognized in the interval from the beginning of the Paleocene through the Burdigalian, and about 25 of these comprise the restricted typical Eocene.

In contrast, the Tertiary deposits of the Gulf of Mexico embayment cover a much larger area, extending from Yucatan in the southwest to Florida in the southeast, a distance of around 3,000 kilometres (2,000 miles) along

the present coastline. At its maximum, during the Paleocene, this embayment extended inland to southwestern North Dakota, a distance of about 2,000 kilometres (1,250 miles) from the present shoreline. In southwestern North Dakota the Cannonball Formation, with a maximum thickness of about 90 metres (300 feet), is marine, and although formerly referred to the Late Cretaceous, it is now known to correlate with part of the Midway Group of the Gulf Coast; it represents the maximum encroachment of the Tertiary seas in North America. Marine deposits of Tertiary age have been eroded from the intervening area between northwestern South Dakota and southern Illinois, but from this latter locality marine deposits continue southward and underlie the Gulf of Mexico. At the margin of the Gulf these sediments are estimated to be more than 12,000 metres (40,000 feet) thick and range in age from Paleocene to Pleistocene. Most of the exposed rocks are of Paleogene age, but as the present shoreline is approached, great thicknesses of Neogene sediments occur in deep wells and are suggested by geophysical data. The sediments vary from dominantly calcareous in the Florida area to arenaceous (sandy) in the west. Individual units may thin, pinch out, and disappear, and then recur; they are generally thin in the east and thick near the deltas of the Mississippi River and the Rio Grande. An immense number of local stratigraphic names are in use, but in the central region the outcropping Paleogene sediments are often assigned, in ascending order, to the Midway, Wilcox (or Sabine), Claiborne, Jackson, and Vicksburg stages. The overlying Neogene sediments, which are best known in the subsurface, may be assigned to the Chickasawhay, Anahuac, Napoleonville, Duck Lake, Clovelly, and Foley Stages.

In contrast to the preceding geosynclinal region, there was a series of local basins in the Utah–Colorado–Wyoming area of the Rocky Mountains in which nonmarine sediments were laid down. In northeastern Utah–southwestern Wyoming the Paleocene–Eocene is represented, from oldest to youngest, by: North Horn Formation, about 550 metres (1,800 feet) of sandstone, conglomerates, and shale of lacustrine and fluviatile origins; Flagstaff Limestone, 100 to 500 metres (330 to 1,600 feet) of limestone with minor thicknesses of sandstone and shale, of late Paleocene–lower Eocene age; the Colton Formation, 500 metres (1,600 feet) of sandstone, siltstone, and shale, of lower Eocene age; Green River Formation, 1,000 to 1,670 metres (3,300 to 5,480 feet) of lacustrine beds, mostly shales, of middle Eocene age; Uinta Formation, 500 to 600 metres of variegated shale with interbedded sandstone, of Upper Eocene Age; Duchesne River Formation, about 500 metres (1,600 feet) of fluvial sandstone, shale, and conglomerate, of latest Eocene or Oligocene age; Bishop Conglomerate, 30 metres (100 feet) of conglomerate that is unconformable on older formations (deposition was interrupted), of Oligocene or Miocene age. The North Horn, Flagstaff Limestone, and Colton Formations were formerly known as the Wasatch Formation or Group. The typical mammal-bearing beds of the North American Provincial Uintan and Duchesnean land mammal ages are in this sequence.

Deposits on seamounts

In the Pacific Ocean Basin numerous truncated seamounts known as guyots, now sunk below sea level, have been found. Guyots represent former volcanoes that rose or were built up from the sea floor, were truncated by wave action at sea level, and subsequently depressed below sea level. Marine sediments, representing various stages of the Tertiary, occur on the summits of many of the guyots. On some of these peaks, formation of coral limestones has kept pace with the sinking, and coral atolls have been formed. At Eniwetok Atoll in the Marshall Islands more than 1,400 metres (4,610 feet) of limestone was drilled before basalt was encountered. The sequence ranged in age from late Eocene to Recent (see CORAL ISLANDS, CORAL REEFS, AND ATOLLS).

In the last few years a number of wells have been drilled in the deep-sea floor. A well in the Equatorial Pacific at 0°28.9′ N and 133°13.7′ W penetrated 481 metres (1,578 feet) of calcareous ooze and chalk, eventually stopping in basalt. The oldest sediments were of late Eocene age.

TERTIARY LIFE

The biota of the Tertiary has a distinctly modern aspect. No major taxa except the belemnites and discoasters became extinct, although much evolution took place and minor lineages disappeared or evolved into others. Some early Tertiary species are closely similar to their living descendants, although because of modern refined taxonomic practices few if any Paleocene and Eocene organisms are now assigned to living species. In the sea, the "larger" foraminifera (nummulitids, discocyclinids, miogypsinids, lepidocyclinids, and so forth), the planktonic foraminifera, coccolithids, discoasterids, gastropods, and clypeastroid echinoids were evolving rapidly, but in other invertebrate groups evolution generally was not as marked. On land, the pulmonate gastropods and especially the mammals, underwent rapid evolution; some groups (pinnipeds and cetaceans) returned to the sea. Among the plants, the grasses appear in the Eocene, the Compositae in the Paleocene, and the Leguminosae are recorded in the early part of the late Cretaceous. All these plant families underwent rapid evolution, diversification, and dispersal during the Tertiary. Presumably the Orchidaceae (with no known fossil record), which are numerically one of the most diverse of living plant families, also arose in the Tertiary and had a similar history.

Evolution and distribution of foraminifera. In the last two decades, detailed studies have shown that, during the Cenozoic, planktonic foraminifera (Superfamily Globigerinacea) evolved rapidly and were dispersed widely. As a result, they are excellent organisms to use for correlation of marine deposits. Data on the rate of evolution of Cenozoic planktonic foraminifera indicate that evolution does not proceed at a consistent rate, but that it may change markedly at any time during phyletic evolution. As a result, the duration of individual species may vary markedly. Conical members of the genus *Globorotalia* have stratigraphic ranges that vary from about 1,500,000 to 5,000,000 years per species. The average duration of species in different phyletic groups of this superfamily varies from 700,000 years in rapidly evolving lineages to 9,000,000 years in slowly evolving lineages.

Among the larger foraminifera, the genus *Nummulites* (which occurs in limestones used to build the Pyramids) presents a peculiar distribution pattern. In the Eurasian Tethyan Province it occurs throughout the middle and upper Paleocene, Eocene, and lower and middle Oligocene, but only a few nummulitids reached the New World. Their rarity in the Neotropical region is puzzling in view of current concepts of continental drift (*q.v.*). One of the notable trends in the nummulitids was an increase in size up to the middle Eocene, at which time individuals with a diameter of 150 millimetres (six inches) are known. In the Oligocene only small types are known. The Miogypsinids are an important group that range from the late Oligocene to the middle Miocene, generally showing an increase in complexity of the test (structural hard parts) by the addition of lateral chambers and changes in the arrangement of the embryonal apparatus and first subsequent chambers.

The extinct discoasters are minute (around ten microns) radiate skeletal remains of organisms that presumably were members of the oceanic nannoplankton. The skeletal unit is a single calcite crystal, in contrast to that of the coccoliths, which have a radiating fibrous structure. Discoasters appear in the Late Cretaceous and become extinct at about the Pliocene–Pleistocene boundary.

Other marine invertebrates. Mollusca are the most conspicuous and diversified of Tertiary marine megafossils (in contrast to foraminifera and other microfossils). Among the various classes, the Gastropoda are the most diversified and evolved the most rapidly. Most of the early Tertiary genera are extinct, and most living species are assigned to genera that arose in the Middle Tertiary. Some genera, such as *Velates* and *Athleta*, are known only in the Paleocene and Eocene. The New World genus *Orthaulax* is found only in the late Oligocene and early Miocene. Others, such as *Pseudoliva* and *Rimella* (in a broad sense), are worldwide in distribution during the Pa-

Gastropods, pelecypods, and echinoderms

leocene–Eocene and later become restricted geographically. *Pseudoliva* lives only along the west coast of Africa, and *Rimella* lives only in the Indonesian area. It has been estimated that there are about 40,000 living species of gastropods in the marine environment. They were presumably as diverse throughout the Tertiary.

The Bivalvia (mollusca), or clams, are much less diversified than the gastropods, with only about 12,000 living marine species. Many of the Paleocene–Eocene species are assigned to extant genera, and relatively few new genera appeared during this interval. Some genera of the Pectinidae, such as *Lyropecten* and *Patinopecten*, evolved rapidly during the Tertiary and make good index fossils, particularly in the Neogene. In the Paleocene–Eocene, large-sized species of the genus *Venericardia* are common and evolved rapidly; they also make good index fossils.

Among the echinoderms, the order Clypeasteroida begins its rapid evolution and diversification in the middle Eocene. Two genera are known from the latest Cretaceous and 36 from the Miocene, but only 24 in the Recent fauna. About 75 genera are recognized in the Cenozoic, with a number of them, such as the sand dollars *Astrodapsis* and *Dendraster*, existing for periods of only 10,000,000 to 15,000,000 years, or less, during the Neogene, but yet undergoing much speciation. Five species in an evolutionary lineage can be recognized in the extinct genus *Scutellaster* during the Pliocene, spanning an interval of less than 5,000,000 years.

In the nonmarine environment, snails of the superorder Pulmonata diversified as much as all other gastropods. The first accepted records are of aquatic forms in the Middle Jurassic (about 170,000,000 years ago), whereas the purely terrestrial types appear in the Late Cretaceous (about 70,000,000 years ago). It is estimated that there are around 40,000 living species in the Recent fauna. It appears that most of this diversification followed the appearance of angiospermous plants in the mid-Cretaceous, and, by inference, largely within the Tertiary, even though their fossil record has not been well studied.

Vertebrates. In the terrestrial environment the most spectacular event of the Cenozoic has been the diversification and rise to dominance of the Mammalia. Nineteen families of marsupials are known in the Tertiary, with only one (Didelphidae) extending back into the Cretaceous. Among the placental mammals, 25 orders are recognized in the Tertiary, and only three originated in the Cretaceous. Inasmuch as there are about 4,400 living species, it is apparent that mammalian evolution has been very rapid. In many lineages there was a trend toward larger size. The early horse *Hyracotherium*, a browser, was about the size of a fox, but most of its descendants increased in size, leading up to horses the size of a mustang. While the legs were increasing in length, the ancestral four front toes and three hind toes were gradually being lost until only one remained, producing a more cursorial animal. Meanwhile, the cheek teeth were becoming higher crowned, giving a longer-lasting tooth, more suitable for grazing.

Mammalian evolutionary change

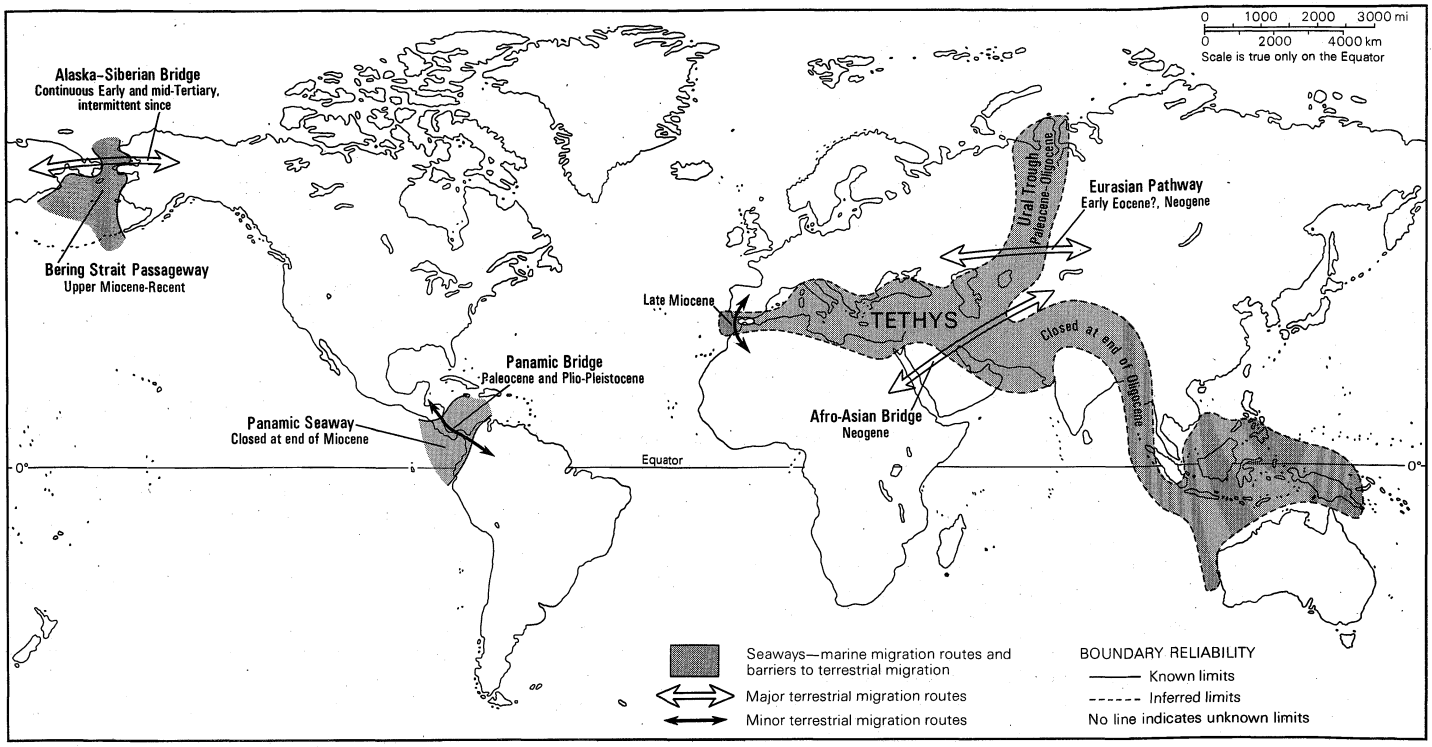
Among the carnivores, early members of the Felidae (cat family) are present in the lower Oligocene and lead up to the modern large cats. During this interval, marked enlargement of the upper canine tooth occurred at least three separate times, producing three unrelated groups of sabre-toothed cats, the last of which culminated in the Pleistocene *Smilodon*, well known from the tar pits of Rancho La Brea, California. In the Middle Tertiary one branch of the Carnivora adopted an aquatic habitat, producing the seals and sea lions. In the Early Tertiary one of the generalized creodonts entered the sea and gave rise to the whalelike zeuglodonts.

In contrast to the rapidly evolving groups of mammals, the Insectivora, which had appeared in the Cretaceous, were conservative and underwent little marked change during the Tertiary. A modern shrew resembles its Cretaceous ancestors.

The Primates diverged from the Insectivora during the latest Cretaceous and went on to give rise to such diverse types as the spider monkeys, the great apes, and man. Recognizable early hominoids are known from sites in East Africa such as Rusinga Island, for which a radiometric (potassium–argon) date of 18,500,000 to 22,000,000 years has been established.

CORRELATION

The subdivisions of the Tertiary originally were based on percentages of living species in the different faunas (largely Mollusca) of western Europe. Early correlations were made by direct comparison with the faunas of the type areas in Europe, when in the same general faunal region, or by utilization of the percentage method when in different faunal regions. Because of the faunal isolation of the region, an independent set of percentages for the Indonesian region was proposed in 1919. In Europe, the need for improved means of correlation was recognized, and the concept of stages was introduced in 1842 for stratigraphic sequences recognized by a characteristic assemblage of fossils. The methodology was modified and improved, and it provides the basis for modern biostratigraphic correlation. Unfortunately, these methods did not come into extensive use on a worldwide basis until the last few decades.



Radiometric dating and foraminiferal zones. During the last three decades it has been widely recognized that the products of radioactive decay of the elements may be retained in certain minerals, and that by measurement of these products the age of formation of these minerals and the containing rocks may be calculated (see DATING, RELATIVE AND ABSOLUTE). The method utilizing the decay of potassium-40 to argon-40 has proved to be the most useful, and numerous dates are now available. During the same interval, it has been demonstrated that the Earth's magnetic field has undergone numerous reversals in the past, and that most rocks take on and retain the magnetic orientation of the Earth's field at the time of their formation (see ROCK MAGNETISM). With the development of techniques for measuring this original magnetization, a sequence (see Table 2) of geomagnetic reversals has been dated and built up for the later Mesozoic and Cenozoic. If an appropriate sequence of reversals is available, the age of the rock sequence can be determined.

Utility of planktonic foraminifera

In the last two decades it has been recognized that many marine planktonic organisms have evolved rapidly and are widely distributed geographically. In the late Mesozoic and Cenozoic eras the planktonic foraminifera, coccoliths, and discoasters are particularly useful, and a very refined worldwide zonation utilizing the foraminifera has been built up. For convenience the zones are numbered, from the oldest, P1, P2, and so forth, in the Paleogene and N1, N2, and so forth, in the Neogene. A chart comparing several different chronologies and possible correlations between them is shown in Table 2. Radiometric dates are used to control the vertical allocation of the units wherever possible. A considerable number of radiometric dates are tied into the planktonic foraminiferal zones. Other radiometric dates are tied into the sequence of North American land mammal ages. The planktonic foraminiferal zonation has been used as far as possible to establish equivalencies between the different schemes applicable to the marine environment.

Boundaries and chronologies. The base of the Saucesian Stage in California is about 22,500,000 years old. This horizon corresponds to the base of the planktonic foraminiferal zone N4 or the *Globigerinoides quadrilobatus primordius—Globorotalia kugleri* zone, which is also recognized at the base of the Aquitanian Stage in France. Inasmuch as the base of the Aquitanian Stage is currently accepted as the base of the Miocene, this also dates the Oligocene–Miocene boundary at 22,500,000 years before the present. The boundary between the Relizian and Saucesian stages is set at about 14,000,000 years ago. Because this horizon closely approximates the first appearance of the foraminiferan *Orbulina*, this gives a slightly younger age for this datum than previously accepted. The base of the Calabrian Stage in Northern Italy corresponds to the base of the planktonic foraminiferal zone N22, which has been determined by correlation with geomagnetic reversals to be about 1,860,000 years old.

The boundaries of the Tertiary

Principal Cenozoic migration routes and barriers.

By definition, this is the base of the Pleistocene. A radiometric date of 64,800,000 years has been obtained for the base of the North American basal Paleocene land mammal age; this date is usually rounded out to 65,000,000 years and is used for the Cretaceous–Tertiary boundary.

Precise stratigraphic positions for the boundaries of the various Tertiary epochs were not specified by early workers, and as a result there has been much variation in usage (see Table 1). In recent years the International Geological Congress has specified that the base of the marine Calabrian Stage be taken as the Pliocene–Pleistocene boundary, and it has been recommended to them that the base of the Pliocene be accepted as the base of the Zanclian Stage in Italy, and that the base of the Miocene be placed at the base of the Aquitanian in southwestern France. The base of the Lattorfian is usually taken to mark the base of the Oligocene, as defined by Beyrich. Current usage usually places the base of the Eocene at the base of the Ypresian Stage of the Paris Basin, although the Ypresian was included in the original type Paleocene.

PALEOGEOGRAPHY AND PALEOCLIMATOLOGY

By the inception of the Tertiary, the continents had nearly attained their present positions, although current notions of continental drift and plate tectonics indicate that the Atlantic Ocean was still spreading, with the continents moving away from the Mid-Atlantic Ridge.

Land–sea distribution and continental movements. Some of the available data from the North Atlantic suggest that during the last 40,000,000 years the North American and African plates, two of the major segments of the Earth's crust that move above the mantle, have been rotating about a position south of Greenland near 52° N and 34° W, at a relatively uniform spreading rate of between one and 1.4 centimetres per year. A rate of 1.3 centimetres per year would result in 520 kilometres (325 miles) of opening between the two plates for this interval. If this rate prevailed throughout the Cenozoic, the total amount of Tertiary spreading would be about 845 kilometres (528 miles). Similar rates of spreading presumably prevailed between the North American and European plates. Northward movement of India is responsible for the closure of Tethys near the end of the Oligocene and the formation of the Himalayan Mountains. Australia and New Zealand were completing their northward movement during the Cenozoic. On the Pacific Coast of North America the formation of the Gulf of California is attributed by many to plate tectonics, as is the documented lateral displacement of 300 kilometres (189 miles) on the San Andreas Fault in the last 23,500,000 years.

Rates of sea-floor spreading

The Mediterranean Sea is a remnant of the essentially east–west Tethyan Seaway (see map) that formerly separated Africa and India from the northern continents, and was broken up at the end of the Oligocene. An arm of it extended northward to the Arctic along the east side of the Ural Mountains throughout most of the Paleocene–Eocene–Oligocene, although there was a temporary retreat during the Eocene. This seaway effectively prevented migration of terrestrial mammals between Africa and Europe–Asia until the early Miocene. By Burdigalian time, proboscideans with an Early Tertiary African origin had migrated to Asia and western Europe. During the late Miocene the old portal to the Atlantic was closed and evaporites (mineral deposits formed by the evaporation of saline waters) were deposited throughout much of the Mediterranean. At the beginning of the Pliocene the present western portal opened.

In the North Pacific region there was no seaway through the Bering Strait region to the Arctic until near the end of the Miocene. This seaway was open for a short time and then closed again until near the end of the Pliocene. Thus, migration of terrestrial animals between Asia and America was possible throughout most of the Tertiary, and until late Pliocene marine organisms were not able to move from the Pacific to the Arctic to the North Atlantic or vice versa, except for a short interval in the late Miocene. In the Central American–northwest Colombian region there was a seaway, at times rather wide, that connected the Caribbean and Pacific oceans throughout the Tertiary until the end of the Miocene; one interval in the Paleocene is a possible exception. It was not until after this that a land bridge permitted free terrestrial migration between North and South America. As a result, the differences between the faunas of the Caribbean and Panamic (Central American) marine provinces did not arise until the Pliocene, and the pre-Pliocene marine faunas of these areas were part of a large unified biotic province that included the tropical Eastern Pacific and the tropical Western Atlantic–Caribbean regions.

Early Tertiary climates. Much evidence shows that during the Early Tertiary warm climates extended much farther poleward (see Table 2) than now. Reef corals

and tropical molluscs occur at 48° N on the Pacific Coast of North America, and ecologically similar faunas occur in the correlative beds of the Paris Basin. On land, palms and similar warmth-requiring plants grew in southern Alaska, Washington, and western Europe during the Paleocene–Eocene. In the Northern Hemisphere there was a slow climatic deterioration until the middle Miocene, then a short interval of warming in middle latitudes, followed by a climatic deterioration until the onset of continental glaciation in middle latitudes in the Pleistocene. It is worth noting, however, that there is clear evidence of local glaciation at sea level in the Gulf of Alaska (60° N latitude) in the Miocene, and continental glaciation prevailed in Antarctica during much, if not all, of the Cenozoic. Oxygen isotope ratios from marine shells indicate that there was a general warming in southern Australia until the Oligocene, followed by a gradual cooling from the Miocene on. This Early Tertiary warming trend in Australia may be correlated with the northward drift of the continent into lower latitudes. Similar data for the oceans suggest that deep-sea temperatures in the Pacific were 8° to 10° C warmer in the Eocene–Oligocene than they are today.

Effect of climatic changes on faunas

The wider distribution of warm climates, combined with the existence of the Tethyan Seaway and the Panamic Passageway, resulted in much more cosmopolitan marine faunas during the Early Tertiary. Subsequent breakup of Tethys and closure of the Panamic Passageway, together with a more restricted tropical zone, combined to produce the Late Cenozoic provinciality of marine faunas. On land, the barriers presented by the Tethyan Sea produced largely endemic mammalian faunas in Africa, western Europe, and the Asia–North American area in the Early Tertiary. Once Tethys was broken up, the African–western Europe–Asian areas lost much of the faunal provinciality that had characterized them previously. Meanwhile, the isolation of South America and Australia permitted the development of their peculiar Tertiary mammal faunas, and it was not until the Pliocene that migration of North American mammals into South America caused the extinction of many of its endemic mammals.

BIBLIOGRAPHY. The literature on the Tertiary Period tends to be both diverse and specialized. For general coverage of geology, stratigraphy, and paleontology, the interested reader should consult the following works: B.M. FUNNEL, "The Tertiary Period," in W.B. HARLAND *et al.* (eds.), *Phanerozoic Time Scale*, pp. 179–191 (1964); MAURICE GIGNOUX, *Géologie stratigraphique*, 4th ed. (1950; Eng. trans., *Stratigraphic Geology*, 1955); and W.B. HARLAND *et al* (eds.), *The Fossil Record* (1967). Important papers on Tertiary climates and foraminiferal zonation include: W.O. ADDICOTT, "Tertiary Climatic Change in the Marginal Northeastern Pacific Ocean," *Science*, 165:583–586 (1969); W.A. BERGGREN, "Cenozoic Chronostratigraphy, Planktonic Foraminiferal Zonation and the Radiometric Time Scale," *Nature*, 224:1072–1075 (1969); W.H. BLOW, "Late Middle Eocene to Recent Planktonic Foraminiferal Biostratigraphy," *Proceedings First International Conference on Planktonic Microfossils*," 1:199–421 (1969); J.F. EVERNDEN *et al.*, "Potassium-Argon Dates and Cenozoic Mammalian Chronology of North America," *Am. J. Sci.*, 262:145–198 (1964); D.L. TURNER, "Potassium-Argon Dating of Pacific Coast Miocene Foraminiferal Stages," *Spec. Pap. Geol. Soc. Am.*, 124:91–129 (1970); J.A. WOLFE and D.M. HOPKINS, "Climatic Changes Recorded by Tertiary Land Floras in Northwestern North America," in *Tertiary Correlation and Climatic Changes in the Pacific* (Eleventh Pacific Science Congress, Tokyo, 1966), pp. 67–76 (1967); and M.G. WILMARTH, "Geologic Time Classification of United States Geological Survey Compared with Other Classifications," *Bull. U.S. Geol. Surv.*, no. 769 (1925).

Tertullian

Tertullian (Quintus Septimius Florens Tertullianus), an early Christian author and polemicist, helped to establish Latin—rather than Greek, which was the most widely used language at that time—as an eccesiastical language and as a vehicle for Christian thought in the West. He coined many new theological words and phrases and gave currency to those already in use, thus becoming a significant thinker in forging and fixing the vocabulary and thought structure of Western Christianity for the next 1,000 years. Because he was a moralist rather than a philosopher by temperament—which probably precipitated his famous question, "What has Athens to do with Jerusalem?"—Tertullian's practical and legal bent of mind expressed what would later be taken as the unique genius of Latin Christianity.

The life of Tertullian is based almost wholly on information written by men living over a century after him and from obscure references in his own works. On this basis a general outline of his life has been constructed, but most of the details have been continually disputed by modern scholars.

Education and conversion

Tertullian was born in Carthage in the Roman province of Africa, present Tunisia, a little over 100 years after the beginning of Christianity; *i.e.*, approximately AD 155–160. Carthage at that time was second only to Rome as a cultural and educational centre in the West, and Tertullian received an exceptional education in grammar, rhetoric, literature, philosophy, and law. Little is known of his early life; in fact, most of the details of his life are unknown and disputed. His parents were pagan, and his father may have been a centurion (*i.e.*, a noncommissioned officer) in an African-based legion assigned to the governor of the province. After completing his education in Carthage, he went to Rome, probably in his late teens or early 20s, to study further and perhaps begin work as a lawyer. He is most likely not the jurist Tertullian mentioned in the Digest, a collection of Roman legal opinion compiled under the aegis of the 6th-century Byzantine (Eastern Roman) emperor Justinian, though this is disputed.

While in Rome, he became interested in the Christian movement, but not until he returned to Carthage toward the end of the 2nd century was he converted to the Christian faith. He left no account of his conversion experience, but from his early works, *Ad martyras* ("To the Martyrs"), *Ad nationes* ("To the Nations"), and *Apologeticum* ("Defense"), he indicated that he was impressed by certain Christian attitudes and beliefs: the courage and determination of martyrs, moral rigourism, and an uncompromising belief in one God. By the end of the 2nd century the church in Carthage had become large, firmly established, and well organized and was rapidly becoming a powerful force in North Africa. By the year 225 there were approximately 70 bishops in Numidia and Proconsularis, the two provinces of Roman Africa. Tertullian emerged as a leading member of the African church, devoting his talents as a teacher in instructing the unbaptized seekers and the faithful and as a literary defender (apologist) of Christian beliefs and practices. According to Jerome, a 4th-century biblical scholar, Tertullian was ordained a priest. This view, however, has been challenged by some modern scholars.

Literary activities

During the next 20 to 25 years—*i.e.*, from his early 40s to mid-60s—Tertullian devoted himself almost entirely to literary pursuits. Developing an original and unprecedented Latin style, the fiery and tempestuous Tertullian became a lively and pungent propagandist though not the most profound writer in Christian antiquity. His works abound with arresting and memorable phrases, ingenious aphorisms, bold and ironic puns, wit, sarcasm, countless words of his own coinage, and a constant stream of invectives against his opponents. Yet, he could be gentle and sensitive, as in a treatise to his wife (*Ad uxorem*), and he could be self-critical and reflective, as in his treatise on patience (*De patientia*), a virtue that he admitted was conspicuously absent in his life.

As a historical personage Tertullian is known less for what he did than for what he wrote. The range of his interests and the vigour with which he pursued them, however, encouraged other Christians to explore previously uninvestigated areas of life and thought. Like his contemporaries, he wrote works in defense of the faith (*e.g.*, *Apologeticum*) and treatises on theological problems against specific opponents: *Adversus Marcionem* ("Against Marcion," an Anatolian heretic who believed that the world was created by the evil god of the Jews),

Adversus Hermogenem ("Against Hermogenes," a Carthaginian painter who claimed that God created the world out of pre-existing matter), *Adversus Valentinianos* ("Against Valentinus," an Alexandrian Gnostic, or religious dualist), and *De resurrectione carnis* ("Concerning the Resurrection of the Flesh"). He also wrote the first Christian book on Baptism (*De Baptismo*), a book on the Christian doctrine of man (*De anima* ["Concerning the Soul"]), essays on prayer and devotion (*De oratione* ["Concerning Prayer"]), and a treatise directed against all heresy (*De praescriptione Haereticorum* ["Concerning the Prescription of Heretics"]). In addition to apologetical and polemical works, he addressed himself to a whole range of moral and practical problems on issues facing Christians of his day: what is appropriate dress, the wearing of cosmetics (*De cultu feminarum* ["Concerning the Cult of Femininity"]), service in the military (*De corona* ["Concerning the Crown"—a military decoration]), whether one should flee under persecution (*De fuga in persecutione* ["Concerning Flight in Persecution"]), on marriage and remarriage (*De exhortatione castitatis* ["Concerning the Exhortation to Chastity"]; *De monogamia* ["Concerning Monogamy"]), on the arts, theatre, and civic festivals (*De spectaculis* ["Concerning Spectacles"]; *De idololatria* ["Concerning Idolatry"]), on repentance after Baptism (*De poenitentia* ["Concerning Repentance"]), and others.

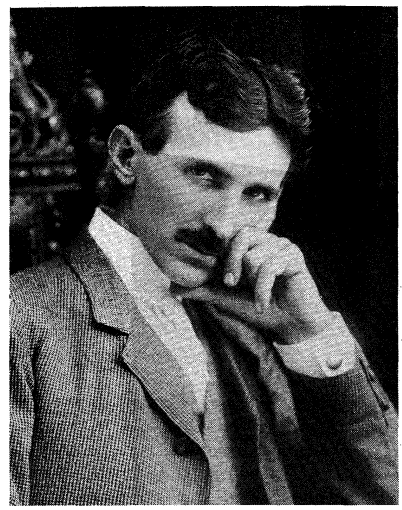
Tertullian is usually considered the outstanding exponent of the outlook that Christianity must stand uncompromisingly against its surrounding culture. Recent scholarship has tended to qualify this interpretation, however. Like most educated Christians of his day, he recognized and appreciated the values of the Greco-Roman culture, discriminating between those he could accept and those he had to reject.

Tertullian as a Montanist

Sometime before 210 Tertullian left the orthodox church to join a new prophetic sectarian movement known as Montanism (founded by the 2nd-century Phrygian prophet Montanus), which had spread from Asia Minor to Africa. His own dissatisfaction with the laxity of contemporary Christians was congenial with the Montanist message of the imminent end of the world combined with a stringent and demanding moralism. Montanism stood in judgment on any compromise with the ways of the world, and Tertullian gave himself fully to the defense of the new movement as its most articulate spokesman. Even the Montanists, however, were not rigorous enough for Tertullian. He eventually broke with them to found his own sect, a group that existed until the 5th century in Africa. According to tradition, he lived to be an old man. His last writings date from approximately 220, but the date of his death is unknown.

In antiquity most Christians never forgave him for his apostasy (rejection of his earlier faith) to Montanism. Later Christian writers mention him only infrequently, and then mostly unfavourably. Somewhat grudgingly, however, they acknowledged his literary gifts and acute intelligence. Modern scholars, however, do not share this earlier view. In the 19th and 20th centuries Tertullian has been widely read and studied and is considered one of the formative figures in the development of Christian life and thought in the West.

BIBLIOGRAPHY. For a complete listing of Tertullian's works, see JOHANNES QUASTEN, *Patrology*, vol. 2, pp. 246–319 (1953), with extensive bibliography. Editions of his work appear in *Corpus scriptorum ecclesiasticorum Latinorum*, vol. 20 (1890), and *Corpus Christianorum*, 2 vol. (1953–54), the latter with bibliography. English translations of all his works are in the "Ante-Nicene Fathers," vol. 3 and 4 (1869–70, reprinted 1957). Modern English translations of individual treatises are by ERNEST EVANS, WILLIAM P. LE SAINT, and others in the various series of translations of the Fathers. There is no modern critical biography. For continuing bibliography, see the annual listing in WILHELM SCHNEEMELCHER, *Bibliographia Patristica*. For a recent study with an up-to-date bibliography of Tertullian that considers anew the evidence of his life and the chronology of his writings, disputing the opinions of many modern scholars, see TIMOTHY D. BARNES, *Tertullian: A Historical and Literary Study* (1971).



(Ro.W.)

Tesla, Nikola

Nikola Tesla, who discovered the rotating magnetic field, which is the basis of practically all alternating-current machinery, has been called the genius who ushered in the power age.

Tesla was born on July 9/10, 1856, in Smiljan, Croatia (Yugoslavia), of a family of Serbian origin. His father was an Orthodox priest; his mother was unschooled but highly intelligent. A dreamer with a poetic touch, as he matured, Tesla added to these earlier qualities those of self-discipline and a desire for precision.

Culver Pictures

Tesla.

Training for an engineering career, he attended the Technical University at Graz, Austria, and the University of Prague. At Graz he first saw the Gramme dynamo, which operated as a generator and, when reversed, became an electric motor (see ELECTRIC MOTOR); and he conceived a way to use alternating current to advantage. Later, at Budapest, he visualized the principle of the rotating magnetic field and developed plans for an induction motor, that would become his first step toward the successful utilization of alternating current. In 1882 Tesla went to work in Paris for the Continental Edison Company, and while on assignment to Strassburg in 1883, he constructed, in after-work hours, his first induction motor. Tesla sailed for America in 1884, arriving in New York with four cents in his pocket, a few of his own poems, and calculations for a flying machine. He first found employment with Thomas Edison, but the two inventors were far apart in background and methods, and their separation was inevitable.

In May 1885, George Westinghouse, head of the Westinghouse Electric Company in Pittsburgh, bought the patent rights to Tesla's polyphase system of alternating-current dynamos, transformers, and motors. The transaction precipitated a titanic power struggle between Edison's direct-current systems and the Tesla-Westinghouse alternating-current approach, which eventually won out.

Tesla's laboratory experiments

Tesla soon established his own laboratory, where his inventive mind could be given free rein. He experimented with shadowgraphs similar to those that later were to be used by Wilhelm Röntgen when he discovered X-rays in 1895. Tesla's countless experiments included work on a carbon button lamp, on the power of electrical resonance, and on various types of lighting.

Tesla gave exhibitions in his laboratory in which he lighted lamps without wires by allowing electricity to flow through his body, to allay fears of alternating current. He was often invited to lecture at home and abroad.

The Tesla coil, which he invented in 1891, is widely used today in radio and television sets and other electronic equipment. That year also marked the date of Tesla's United States citizenship.

Westinghouse used Tesla's system to light the World Columbian Exposition at Chicago in 1893. His success

was a factor in winning him the contract to install the first power machinery at Niagara Falls, which bore Tesla's name and patent numbers. The project carried power to Buffalo by 1896.

In 1898 Tesla announced his invention of a teleautomatic boat guided by remote control. When skepticism was voiced, Tesla proved his claims for it before a crowd in Madison Square Garden.

In Colorado Springs, where he stayed from May 1899 until early 1900, Tesla made what he regarded as his most important discovery—terrestrial stationary waves. By this discovery he proved that the earth could be used as a conductor and would be as responsive as a tuning fork to electrical vibrations of a certain pitch. He also lighted 200 lamps without wires from a distance of 25 miles (40 kilometres) and created man-made lightning, producing flashes measuring 135 feet (41 metres). At one time he was certain he had received signals from another planet in his Colorado laboratory, a claim that was met with derision in some scientific journals.

Returning to New York in 1900, Tesla began construction on Long Island of a wireless world broadcasting tower, with $150,000 capital from the U.S. financier J. Pierpont Morgan. Tesla claimed he secured the loan by assigning 51 percent of his patent rights of telephony and telegraphy to Morgan. He expected to provide worldwide communication and to furnish facilities for sending pictures, messages, weather warnings, and stock reports. The project was abandoned because of a financial panic, labour troubles, and Morgan's withdrawal of support. It was Tesla's greatest defeat.

Tesla's work shifted to turbines and other projects. Because of a lack of funds, his ideas remained in his notebooks, which are still examined by engineers for unexploited clues. In 1915 he was severely disappointed when a report that he and Edison were to share the Nobel Prize proved erroneous. Tesla was the recipient of the Edison Medal in 1917, the highest honour that the American Institute of Electrical Engineers could bestow.

Tesla allowed himself only a few close friends. Among them were the writers Robert Underwood Johnson, Mark Twain, and Francis Marion Crawford. He was quite impractical in financial matters. An eccentric, driven by compulsions and a progressive germ phobia, Tesla had a way of intuitively sensing hidden scientific secrets and employing his inventive talent to prove his hypotheses. He was a godsend to reporters who sought sensational copy, but a problem to editors who were uncertain how seriously his futuristic prophecies should be regarded.

Criticism of Tesla's prophecies

Caustic criticism greeted his speculations concerning communication with other planets, his assertions that he could split the earth like an apple, and his claim to having invented a death ray capable of destroying 10,000 airplanes, 250 miles (400 kilometres) distant.

Tesla demanded much of his employees but inspired their loyalty. Though he admired intellectual and beautiful women, he had no time to become involved.

Tesla died on January 7, 1943. The Custodian of Alien Property impounded his trunks, which held his papers, his diplomas and other honours, his letters, and his laboratory notes. These were eventually inherited by Tesla's nephew, Sava Kosanovich, and later housed in the Nikola Tesla Museum, Belgrade, Yugoslavia. Hundreds filed into New York City's Cathedral of St. John the Divine for his funeral services, and a flood of messages acknowledged the loss of a great genius. Three Nobel Prize recipients addressed their tribute to: ". . . one of the outstanding intellects of the world who paved the way for many of the technological developments of modern times."

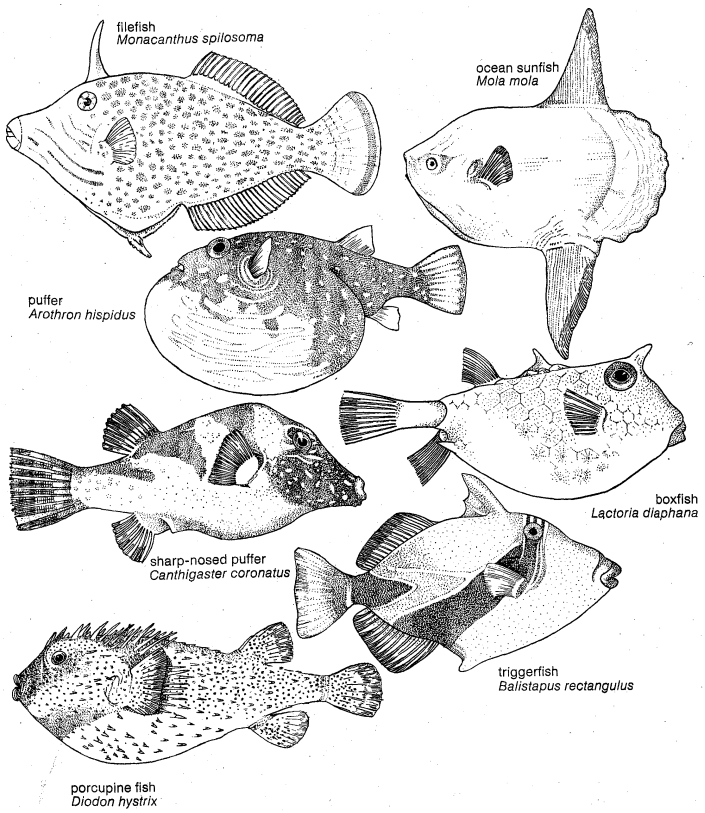
Tetraodontiformes



The order Tetraodontiformes is a group of primarily tropical marine fishes that evolved from the Perciformes (the typical advanced spiny-rayed fishes) during the Eocene Period of the Cenozoic Era, about 50,000,000 years ago. The approximately 320 species of modern tetraodontiforms are notable for a high degree of diversity in anatomical structure and way of life. The great diversity evident among the 11 families of the order is also seen within some families, but not in others. Members of the deepwater, bottom-dwelling Triacanthodidae, the most primitive family, for example, range from relatively normal configurations to weirdly specialized forms with extremely long tubular snouts; the shallow-water members of the Triacanthidae, closely related and derived from the Triacanthodidae, are of rather uniform configuration. Likewise, the balistids are rather uniform in body plan; but monacanthids, which evidently evolved from them, include a series of species ranging from the normal to the exceedingly elongated and highly specialized.

General features. The tetraodontiforms make up about 5 percent of the tropical marine fishes of the world. Most species range in size from about eight to 60 centimetres (three to 24 inches) in length, but one ocean sunfish reaches more than three metres (11 feet). They are often strikingly patterned or gaudily coloured. With the exception of the relatively deepwater Triacanthodidae and Triodontidae, the members of this order are usually found in waters less than about 65 metres (200 feet) in depth and are especially prominent around coral or rocky reefs and on open sand and grass flats.

Poisonous flesh

Importance to man. Many species, especially of puffer fishes (Tetraodontidae), have poisonous flesh, at least during certain seasons of the year, but most of the highly poisonous substance (tetraodontoxin) responsible for the numerous annual fatalities in Indo-Pacific regions is contained in the viscera. The flesh of the poisonous species can be safely eaten only when the freshly caught specimen has been carefully cleaned and washed in the exacting manner of fugu (or puffer fish) chefs in Japan. But the majority of tetraodontiforms are palatable, and, in numerous tropical regions, the flesh of various triggerfishes and trunkfishes is highly esteemed. Other than as food in tropical coastal areas, man makes little direct use of tetraodontiforms, except for the dried bodies of the hard-cased boxfishes and the spine-studded, inflated puffers as curios. In fact, the order Tetraodontiformes contains so many strangely specialized species that the group has intrigued mankind from early times; a 1st-century Roman author, Pliny the Younger, for example, discussed puffer fishes and ocean sunfishes in his *Naturalis Historiae*. While most adult tetraodontiforms have thick, spiny skins or other defensive mechanisms that protect them from most predacious fishes, the young, relatively defenseless stages are eaten in great quantities by certain game fishes—dolphin, marlin and other billfishes, tunas, and various jacks.

Natural history. *Feeding habits.* As one would suspect from their usually well-developed and massive dentition, often with the teeth fused together in a parrotlike beak, most tetraodontiforms feed on hard-shelled crustaceans, mollusks, and echinoderms. But some, with massive, crushing jaws and teeth, such as the ocean sunfishes, often feed extensively on such soft-bodied invertebrates as jellyfishes (medusae). Some, such as boxfishes, blow a jet of water out of their mouths onto sand bottoms to expose burrowing invertebrates; others (such as some triggerfishes) specialize in eating spiny sea urchins or even clams and oysters. A few species, especially the long-snouted Triacanthodidae, have reduced or even rudimentary teeth, some apparently feeding on the scales of other bottom fishes. Other species probably feed on soft-bodied invertebrates, probing with the snout into holes in the bottom or into recesses in outcroppings to obtain food unavailable to less specialized fishes. Although many species have specialized feeding habits, the order as a whole can be considered as comprised of opportunistic predators on invertebrates.

Body plans of representative tetraodontiform fishes.
From Spencer W. Tinker, *Hawaiian Fishes* (1944)

Locomotion. Most tetraodontiforms swim by the rather unusual method of rapid undulations or complex scullings of the soft dorsal and anal fins (in the midline of the back and underside, respectively); the powerful caudal fin (except in the Molidae) is reserved for rapid bursts of speed. The paired pectoral fins (just behind the gills) are in an almost constant state of rapid vibration, which gives a delicacy of control to their movements that is unusual even among fishes.

Activity cycle. Those tetraodontiforms for which data are available are diurnal, feeding or otherwise active during daylight but quiescent at night, often retiring to holes or crevices in coral or rocky reefs to sleep. When disturbed during the day, as by a potential predator, some species take rapid flight; others dive into reef crevices. Other species avoid the attention of predators by remarkable colorations or patternings that permit them to blend into the environment, which may be anything from a coral reef to a bed of bottom sea grass. One relatively defenseless species (a filefish), moreover, is an excellent mimic in body form and bright coloration of a spiny-skinned, inflatable, and perhaps poisonous puffer.

Form and function. The Tetraodontiformes are distinguished externally by a small gill opening restricted to a relatively short slit on the side of the head and a small mouth, usually equipped with massive teeth. The scales of the body are typically highly modified into overlapping (in triacanthoids and balistoids) and even sutured (in ostraciontoids) plates, or into sharp, projecting spines (in tetraodontoids and diodontoids); in some cases, the skin itself may be thickened and hardened by deep layers of connective tissues (molids). There are no anal fin spines, and the dorsal fin spines are either absent or present only in reduced number (never more than six). The pelvic fin, which in the perciforms has one spine and five soft rays, in tetraodontiforms is either absent or reduced to no more than one spine and two small soft rays. The skeleton of tetraodontiforms is notable for a reduced number of bones, a number of the separate bony elements of the ancestral perciforms having been lost through the processes of reduction, consolidation, fusion, or failure to develop. The hallmark of the evolution and diversification of the tetraodontiforms, in fact, has been the reductive tendencies in some parts—number of skeletal elements, number of fin spines, size of mouth and gill opening, and number of teeth—with the simultaneous elaborative tendencies in other systems—scale and skin development, inflation apparatus, size of teeth and fusion with jawbones, and poisonous flesh.

Fin and skeletal features

Classification. *Annotated classification.* The Tetraodontiformes are classified as follows, with only the most obvious external differences that distinguish the groups mentioned.

ORDER TETRAODONTIFORMES (PLECTOGNATHI)
Small mouth and gill openings; reduced dorsal and pelvic fin spines; no anal fin spines; skin usually tough or spiny.

Suborder Balistoidei (Scleroderm)
Teeth separate, discrete, individual units.

Superfamily Triacanthoidea

Six dorsal spines and a large pelvic spine.

Family Triacanthodidae (spikefishes). The most primitive members of the order; deepwater species with a truncated or rounded tail; deep caudal peduncle; nonstreamlined body; soft dorsal and anal fins of about same length along their bases; Indo-Pacific and Caribbean.

Family Triacanthidae (triple spines). Shallow-water derivatives of the spikefishes; deeply forked caudal fin; slender caudal peduncle (the region between the end of the anal fin and the front of the tail); relatively streamlined body for rapid swimming; soft dorsal fin base much longer than anal fin base; Indo-Pacific.

Superfamily Balistoidea

Two or 3 dorsal spines, the 2nd spine serving to lock the 1st in an erected position; pelvic spine rudimentary or absent.

Family Balistidae (triggerfishes). Three dorsal spines; 8 outer teeth in each jaw; worldwide.

Family Monacanthidae (filefishes). Two dorsal spines; 6 or fewer outer teeth in each jaw; worldwide.

Superfamily Ostraciontoidea

No dorsal spines, body encased in a turtle-like cuirass (carapace) of sutured, platelike scales.

Family Aracanidae (keeled boxfishes). Carapace open behind the dorsal and anal fins and bearing a ventral keel; usually in deeper water than the ostraciontids; Indo-Pacific.

Family Ostraciontidae (boxfishes, trunkfishes, cowfishes). Carapace closed behind anal and usually behind dorsal fin, no ventral keel; worldwide.

Suborder Tetradontoidei (Gymnodontes)
Teeth more or less fused to the jawbones, forming a parrot-like beak.

Superfamily Triodontoidea

Three tooth plates, 2 in upper and 1 in lower jaw.

Family Triodontidae (pursefish). Most primitive member of the suborder, the only species to retain even the pelvic bone of the pelvic fin apparatus (completely lost by all other members of suborder); 1 species; deep water; Indo-Pacific.

Superfamily Tetraodontoidea

Four tooth plates, 2 in each jaw; the skin bearing small erectile spines.

Family Tetraodontidae (puffer fishes). A large number of species, differing from the sharp-nosed puffers mainly in osteological structure, but always having a prominent nasal apparatus; worldwide.

Family Canthigasteridae (sharp-nosed puffer fishes). Single, inconspicuous nostril on each side of head; snout more laterally compressed than in the tetraodontids; worldwide.

Superfamily Diodontoidea

Two tooth plates, 1 in each jaw; the skin bearing huge spines; caudal fin normal.

Family Diodontidae (porcupine fishes and burrfishes). Characteristics of superfamily. Spines erectile (porcupine fishes) or fixed (burrfishes); worldwide.

Superfamily Moloidea

Two tooth plates, 1 in each jaw. Skin relatively smooth but often exceptionally thick; caudal fin highly modified or absent.

Family Molidae (ocean sunfishes). Three species, 2 of which reach enormous size, 1 up to 3.3 metres (11 feet) in length and 1,900 kilograms (4,000 pounds) in weight; worldwide.

Critical appraisal. The classification of the order is still in a state of flux, and some authorities recognize as families only those listed above as superfamilies. More important, the ostraciontoids are often recognized as a third suborder of Tetraodontiformes rather than, as above, a superfamily of the suborder Balistoidei. Only recently has the ordinal term Tetraodontiformes come into use; the group still is often called the Plectognathi and its two suborders the Sclerodermi and Gymnodontes.

BIBLIOGRAPHY. JAMES E. BOLHKE and CHARLES C.G. CHAPLIN, *Fishes of the Bahamas and Adjacent Tropical Waters* (1968), includes an excellent combination of scientific and popular accounts of the Caribbean tetraodontiforms, with all species well illustrated. BRUCE W. HALSTEAD, *Poisonous and Venomous Marine Animals of the World,* vol. 2, *Vertebrates* (1967), contains a comprehensive review of the poisonous properties of the tetraodontiforms, with numerous illustrations of poisonous species. JAMES C. TYLER, *A Monograph on Plectognath Fishes of the Superfamily Triacanthoidea* (1968), is a technical monograph on the two most generalized families of tetraodontiforms but also includes general accounts of the way of life, distribution, and relationships of these families, as well as an extensive bibliography on related articles.

(J.C.T.)

Texas

The vastness and diversity of Texas, the largest of the 48 coterminous states of the United States, are evident in nearly all aspects of the state's physical character, of its history, and of the economic and social life of its people. As a classic example, January temperatures in the Rio Grande Valley have registered well over 90° F (32° C) while, at the same time, nearly halfway to Canada, blizzards were blocking highways in the Panhandle. The image of the state was of a raw and lawless frontier when, in 1845, it surrendered its status as an independent nation to become the 28th member of the Union. This picture has altered drastically to incorporate Texas' present-day combinations of agricultural wealth with high national rankings in industry and finance, of huge urban centres that foster a cosmopolitan cultural life with seemingly unending stretches of high prairie and range devoted to cattle and cotton.

Image and heritage of Texas

Texas, with the forth-longest seacoast among the coterminous states and a shipping industry to match, occupies the south central segment of the nation. Its 267,338 square miles (692,379 square kilometres) make it larger than any nation in Europe except the Soviet Union. Water delineates many of its borders: the Rio Grande carves a shallow channel separating Texas from Mexico on the southwest; the Gulf of Mexico laps its crescent-shaped coast on the southeast; the Sabine River forms most of the eastern boundary with Louisiana (where by land it bounds Arkansas as well); and the wriggling course of the Red River on the north makes up two-thirds of the boundary with Oklahoma. The Panhandle juts northward, forming a counterpart in western Oklahoma, and New Mexico lies to the west.

The Texan who talks endlessly about the marvels of his native state can be justified by many facts. To talk of Texas is to talk more of a region than of a state, and the articles of its admission to the Union allow it the option —unlikely to be taken up—of dividing itself into as many as four states. Texans are keenly conscious, also, of their land's unique location at the confluence of four deep and diverse streams of human development: the underlying influx of Indian culture from the northwest; the passionate involvement of Spanish patterns of life moving northward from Mexico; the pragmatic outlook brought by the Anglo-Saxon and later European immigrants; and the sensitive and brooding tide of black history that has flowed increasingly stronger out of the past of slavery. They will note proudly that, counter to the usual idea that all American history originated with the colonies of the Eastern seaboard, Texas looked southward as well for its beginnings and that the National Autonomous University of Mexico was awarding degrees almost 70 years before the Pilgrim Fathers set foot on Plymouth Rock in 1620.

Like other Southern states, however, Texas has been struggling in recent decades to right inequities in education, economic opportunity, and housing that have mitigated in particular against the personal advancement of Mexican-Americans—or Chicanos, as many of them prefer to call themselves—and of blacks, who made up about 15 and 13 percent, respectively, of the 11,196,730 Texans counted in the census of 1970. The economic expansion since World War II has spread its benefits unequally, widening the gap between the affluent and the marginal-income families. The sturdy concept that those who fail simply have not exerted the necessary will power or zeal for work long helped to keep Texas among the lowest ranking states in welfare and other social services, and the notion is fading only reluctantly. The Republican Party in Texas has gained unusual strength for a Southern state, perhaps through a recognition that its more conservative stance on the national level may provide a more appropriate voice for many Texans than does the national Democratic Party. Recognition has come, also, that the economic growth of the state to date has come primarily from the exploitation of its natural resources, an avenue that cannot continue to offer ever-increasing rates of expansion. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; MEXICO, HISTORY OF; CIVIL WAR, U.S.; NORTH AMERICA; RIO GRANDE; GREAT PLAINS; and MEXICO, GULF OF.)

THE HISTORY OF TEXAS

The forerunners of the west Texas Indians lived in camps whose remains indicate they were made perhaps as much as 37,000 years ago. Possessing only crude spears and flint-pointed darts, these hunters survived primarily on wild game. In the more fertile areas of east Texas, tribes established permanent villages and well-managed farms and evolved political and religious systems. Forming a loose federation to preserve peace and provide mutual protection, they came to be known as the Caddo confederacies. By 1528, when the first white man set foot on Texas soil, the area was sparsely settled, but Indian culture and habitation exerted measurable influence on the later history of the region.

Settlement. By the 1730s, the Spanish had sent more than 30 expeditions into Texas. San Antonio, which by 1718 housed a military post and one or more missions, had become the administrative centre. Missions, with military support, were established in Nacogdoches in east Texas, Goliad in the south, and near El Paso in the far west. The French poked their way briefly into Texas. The explorations of Robert Cavelier, sieur de La Salle, and his colony at Matagorda Bay were the bases of French claims to east Texas.

Anglo-American colonization gained impetus when the United States purchased the Louisiana Territory from France in 1803 and claimed title to lands as far as the Rio Grande. By 1819, however, the United States had accepted the Sabine River as the western boundary of the Louisiana Territory. Moses Austin secured permission from the Spanish government to colonize 300 families on a grant of 200,000 acres. When Mexico became an independent country in 1821, his son, Stephen F. Austin, received Mexican approval of the grant. He led his first band of settlers to a site named San Felipe de Austin near the Gulf Coast. By 1832, Austin's several colonies had about 8,000 inhabitants. Other impresarios with similar grants brought the territory's Anglo-American population to about 20,000.

Spanish-Anglo confrontations

Revolution and the republic. Unrest throughout Mexico, including Texas, resulted in a coup by Antonio López de Santa Anna, who assumed the presidency in 1833. Texans, hopeful for relief from restrictive governmental measures, supported Santa Anna. Austin expected a friendly hearing about these grievances but instead was imprisoned in Mexico City for encouragement of insurrection. Freed in 1835, he returned home to find that skirmishes had already developed between colonists and Mexican troops and that Santa Anna was preparing to send reinforcements. Texans formed a provisional gov-

ernment in 1835 and in 1836 issued a declaration of independence at Washington-on-the-Brazos. David G. Burnet was chosen provisional president of the Republic of Texas, Sam Houston was appointed military commander, and Austin became commissioner to the United States to secure strategic aid and enlist volunteers.

The famous siege of the Alamo in San Antonio lasted from February 23 to March 6, 1836. The strategic objective of the stand was to delay Mexican forces and thereby permit military organization of the Texas settlers. As the battle climaxed with a massive attack over the walls, the defenders (about 187) were all killed. Among the dead were the famous frontiersmen Jim Bowie and Davy Crockett. On April 21, Sam Houston led a surprise attack on the Mexican troops at San Jacinto, and he succeeded in capturing Santa Anna and also securing victory for the Texans.

The Texan revolution was not simply a fight between Anglo-American settlers and Mexican troops; it was a revolution of all people living in Texas against what was regarded as tyrannical rule from a distant source. Many of the leaders in the revolution and many of the armed settlers were Mexicans.

The Republic of Texas was officially established with Sam Houston as president and Stephen Austin as secretary of state. Cities already had been named in their honour: Houston was the capital until 1839, when Austin was approved as the permanent capital.

The republic led a difficult ten-year life. Financing proved critical, and efforts to secure loans from foreign countries were unsuccessful. Protection against raids from Mexico and occasional attacks by Indians required a mobile armed force. Before the revolution certain commissioned officers in the colonies had been called Rangers. During the republic a squad of armed men, the famous Texas Rangers, was maintained to ride long distances quickly to repel or punish raiding forces.

Annexation and statehood. As early as 1836, Texans had voted for annexation by the United States, but the proposition was rejected by the Van Buren administration. Great Britain favoured continued independence to block further westward expansion of the United States, but this attitude swung Americans toward annexation. A treaty of annexation was approved by the Texas and the U.S. congresses in 1845, and the transfer of authority from the republic to the state of Texas took place in 1846. A feature of the annexation agreements was a provision permitting Texas to retain title to public lands, a situation unique among the 50 states.

Civil War and aftermath

The U.S. Civil War brought intense disruption. Gov. Sam Houston strongly opposed secession, and, after refusing to take the oath of allegiance to the Confederacy, he was removed from office. During the war, Texans had to defend themselves from Indian attacks, from Mexican encroachments, and from Federal gunboats and invading soldiers. Federal forces ultimately gained control of much of the Gulf Coast but were unable to move far inland.

The last three decades of the 19th century saw rapid developments in population and economy. The state was readmitted to the Union under a new constitution in 1869. By 1874 the Comanches had been forced into a reservation in present-day Oklahoma. Under waves of immigration from North and South as well as from Europe, towns were established, farming spread throughout the central areas, and the cattle industry began to thrive on the plains of west Texas. Railroad building and increased shipping fashioned new links with the rest of the world. Manufacturing, forced into life by the isolation of Civil War years, continued to grow. The population had climbed to more than 3,000,000 by 1900.

The 20th century. In 1901 the oil well that blew in at Spindletop redirected the entire economy of the state. By the early 1970s Texas was the nation's major petroleum producer, but already the state had begun to diversify its economic base. In the same period population increased nearly fourfold, creating several metropolises, and the state system of education became one of the nation's largest.

THE NATURAL AND HUMAN LANDSCAPE

Physical regions and exploitation. Far from being merely wide, arid plains filled with cattle and cowboys, Texas comprises a series of gigantic steps, from the fertile and densely populated Coastal Plains in the southeast to the high plains and mountains on the west and northwest.

Coastal Plains. Stretching inland from the Gulf Coast, the Coastal Plains range from sea level to about 300 feet (90 metres). These flat, low prairies extend inland to form a fertile crescent, varying in width from 50 to 200 miles (80 to 320 kilometres), that is well adapted to farming and cattle raising. Near the coast much land is marshy, almost swamp, except where drained by man-made devices.

Agriculture on the coast

The western anchor of the Coastal Plains is the Rio Grande Valley, where a heavy investment in citrus farming was damaged by rare but disastrous freezes. It now features diversified farming, with vegetables intermingled with citrus. The low coastal lands between Port Lavaca and Port Arthur are ideal for rice cultivation. Inland from Houston the flatlands provide grazing for fine-breed cattle. Forests of pine and cypress grow extensively from Beaumont to the Red River and spill into Louisiana and Arkansas, making lumbering and paper mills important industries.

Access to water transportation, reservoirs of natural gas and oil, and availability of raw materials have made the coastal area the centre of industry in Texas. It is also the most densely populated part of the state. Houston, Texas' largest city, is a focal point, while Fort Worth, Dallas, Waco, Austin, and San Antonio form a line at the inner edges of the Coastal Plains. Corpus Christi, Galveston, and the Beaumont–Port Arthur–Orange complex augment the Port of Houston, one of the nation's largest.

The North Central Plains, the Hill Country, and the Edwards Plateau. The Coastal Plains, encompassing about one-third of the land area, break abruptly when they encounter the Balcones Escarpment, where in the distant geological past the surface of the earth cracked and slipped. Northwest of the fault, the land rears up into the Texas Hill Country and then into the tablelands of the Edwards Plateau to the south and the North Central Plains to the north. The last two regions generally are considered extensions of the Great Plains. The entire region varies from about 750 to 2,500 feet (230 to 760 metres) above sea level. Farming and cattle raising constitute the basic economy. The Hill Country mixes orchard crops with ranching, small industries, summer camps, and tourism.

The High Plains and the Trans-Pecos region. At the western edge of the North Central Plains lies the Cap Rock Escarpment, an outcropping of rock that stretches north and south for about 200 miles. Protruding above the plains like a huge barricade, it is starkly visible in some places in cliffs of 200 to 300 feet. Beyond that escarpment lies the third big step of Texas: the High Plains country and, to the south, the Trans-Pecos region.

The Staked Plains

From the High Plains country emerged many of the legends of Texas weather and of the Texas cowboy. In this region lies the flat, dry area known as the Staked Plains (Llano Estacado). Legend has it that, as it moved westward, the Coronado expedition laid down stakes to serve as guides for the return trip and that even Indian tribes hesitated to venture across these lands. On these plains, sandstorms can cut down vision in midday, filter tiny bullets of sand into the best-built homes, and scour the paint from exposed automobiles. Many wide, flat riverbeds remain dry most of the year, but they can become sluiceways for flash floods. Through the northern portal, beyond Amarillo, "blue northers" sweep out of the Rocky Mountains with a frenzy of freezing wind, ice, and snow. In the 19th century such famous ranches as the XIT, the Yellow Horse, and the Matador spread their cattle over these ranges.

The North Plains subdivision, centred around Amarillo, depends economically on grain farming, ranching, oil, and small industries. The South Plains subdivision, with Lubbock the principal city, has large underground water reservoirs that allow large-scale irrigated cotton farming.

The state's most rugged terrain lies west of the Pecos River. Trailing down from the Rockies, the Guadalupe Mountains lead into mountains of the Big Bend country, a name derived from a loop of the Rio Grande. The highest peak in Texas is Guadalupe Peak, at 8,751 feet (2,667 metres). Big Bend National Park preserves the native ruggedness of the region.

Climate. Generalizations about Texas weather on a statewide basis are almost meaningless. The Gulf Coast area around Houston has an average annual temperature of about 70° F (21° C) and rainfall of 45 inches (1,143 millimetres), whereas the Panhandle registers about 60° F (16° C) and less than 19 inches (483 millimetres) of rain. The driest region is the Trans-Pecos country, and the wettest is the northeast. Southern areas have freezing weather only rarely. In Brownsville, the southernmost city, no measurable snow has fallen in more than 70 years, but the northwest corner averages 23 inches (584 millimetres) annually.

THE TEXANS

Texas has been a huge reservoir for diverse streams of race and culture. For the bands of prehistoric hunters, for the waves of Indian tribes, for the Spanish and Mexicans pushing northward, for the Anglo-Americans from the North and East, and for colonizers direct from Europe, there was more than enough room for settlement and opportunity for their influence on the institutions of the state. Some churches still conduct services in Swedish, Czech, or Spanish, and, throughout the south and west, Spanish remains the family language of much of the populace.

The Indians. Census reports show only about 18,000 Indians living in Texas today, but this figure fails to account for the many families with some Indian blood. By contrast, more than 20 tribes existed when the first Europeans entered Texas. In following centuries other tribes, including Comanche and Kiowa, were driven into the area; and expanding American colonies pushed Choctaw, Chickashaw, and Alabama-Coushatta westward across the Mississippi. They remained an intermittent threat to white settlements, though many tribes sought peace with the settlers. Military campaigns often failed to distinguish between friend and foe.

Indian tribal diversity

In 1867 representatives of the federal government and of the Comanche, Kiowa, and Apache tribes signed a treaty restricting the Indians to a 3,000,000-acre reservation in Indian Territory (present-day eastern Oklahoma). Indian parties broke the treaty with fierce raids in the Panhandle, but in 1874–75 were pushed back to the reservation. Most present-day Indians are unobtrusive city dwellers, but two tribes remain cohesive units. The Alabama-Coushatta Indians occupy the only reservation in the state, in east Texas. About 300 Tiguas live in a site now enveloped by El Paso.

The Chicanos. Though subtle differences exist between such terms as Mexican-American and Chicano, popular usage has tended to fuse them, and the federal census distinguishes only a single group through the criterion of Spanish surnames. This measurement fails to account, however, for the intermingling of Spanish with Indian and European bloodlines, including families whose surnames have lost all Mexican-American flavour. Up to 20 percent of Texans probably are of Mexican-American descent.

Many communities along the American side of the southwestern border are almost totally Mexican-American, and larger cities such as Brownsville, Laredo, Corpus Christi, El Paso, and San Antonio carry the mark of Spain and Mexico in architecture, in names of streets and parks, in homes shaped around patios and flower gardens, and in the ever-present flow of the Spanish language on street corners. With the urbanization of the state and the decrease in demand for agricultural workers, large Chicano populations have converged on the major metropolitan centres farther from the border.

Many Mexican-Americans have won distinction as scholars, artists, writers, and business leaders—as well as active revolutionaries against Mexico in 1836. The lands north of the Rio Grande, however, have always attracted subsistence-level families fleeing the harshness of northern Mexico, and over many decades easy entry into the United States, both legal and illegal, provided a flow of Mexicans who served as poorly paid harvesters for landowners in Texas and other states. The Anglos owned the land and dominated political life, so the Mexican-Americans remained the tillers, the unskilled labourers, and the holders of jobs for which education was not an essential requirement.

In spite of improved conditions since World War II, Chicanos remain at the bottom of all ethnic groups in terms of education, income, and political power. To overcome these deficiencies has become an increasingly strong goal of the Chicanos. School systems that once barred Spanish and seemed in many ways to belittle the home life and cultural patterns of the Chicano have begun to adopt new approaches.

Community control by Anglo minorities has been challenged with considerable success by voter-registration drives and balloting. Occasional violence has erupted, and charges have been made that law-enforcement officers show favouritism for the Anglos, but Mexican-Americans have gained control of some local political offices. Some Chicano leaders have proved too inexperienced, and various factions have quarrelled among themselves, but further gains in municipal, county, and state elections are likely.

The blacks. From the earliest European penetration, the Southwest offered a haven for Negro slaves. When the United States purchased Louisiana in 1803, the Spanish rulers of Mexico declared that any slave who escaped into Texas would be a free man. Many sought this opportunity. Runaway slaves also intermarried with Indian populations, and many eventually established homes near the Rio Grande. The Civil War brought freedom for thousands of slaves within the state. In recent decades the black population has clustered in the central parts of the larger cities, and nearly 50 percent of the black Texans are concentrated in the urban areas of Dallas and Houston.

Despite the constant existence of racial discrimination, blacks have gained many positions of significance. Many black Texans have gained fame as athletes, while others have become educational leaders in both the black and larger communities.

The civil rights movements of recent years and the actions of federal courts have brought the black greater access to the ballot. Black candidates have been elected to some school boards, to a few city councils, and to the state legislature. In many ways, however, the position of the black in Texas resembles his position nationwide. Moving from rural communities and clustering in the central city, while whites move to suburbs in which mere lip service is paid to the open-housing principle, he is faced with subtle discrimination in education and employment.

The European-Americans in Texas. The 19th century witnessed streams of migration into Texas. Between 1821 and 1836 an estimated 38,000 settlers, on promises of 4,000 acres per family for small fees, trekked from the United States into the territory. In the 30 years before the Civil War came shiploads of Germans, Poles, Czechs, Swedes, Norwegians, and Irish, suffering many hardships but establishing footholds in the frontier land. By 1850, about 33,000 Germans, one-fifth of the state's population, had settled here.

Land ownership—difficult to acquire in Europe—provided an impelling motive for many immigrants. Many families fled Europe to seek personal and religious freedom, including many intellectuals, believers in suffrage, human rights, and education. Turning generally to farming, they were frugal, hardworking, and civic-minded, with a large reservoir of fortitude. Church-oriented, they brought with them a stern dedication to Catholic or Protestant faith.

Post-Civil War years brought numerous families from devastated southern plantations to farms and ranches of the Southwest. From the North Central states came com-

munities of farming families with Swedish, Polish, and Irish backgrounds seeking relief from the tight economy. Others came from Europe, including Belgians, Danes, and Greeks, to become city dwellers, craftsmen, keepers of small shops.

THE STATE'S ECONOMY

Cotton, cattle, and oil—all based on land resources—dominated the successive stages in Texas' economic development until the mid-20th century, and they still undergird the state's basic wealth. Retailing and wholesaling, banking and insurance, and construction have been among activities reflecting a general affluence and urbanization and the semblance of a diversifying economy.

The unequal spread of affluence, however, has produced the phenomenon of a statewide per capita income further below the national average in the late 1960s than it was 20 years earlier. The legislature has paid scant attention to minimum-wage laws, and only federal standards have supported those jobs not subject to union–management bargaining.

Economic optimism

For the future, greater optimism is found in the moves to Texas by numerous national corporate headquarters and the exploration by petroleum companies for new sources of energy to continue their leadership in the fuelling of the nation. The National Aeronautics and Space Administration (NASA), headquartered in Houston, is among many federal air installations in Texas. In addition, tourism has become a major business, and Dallas is attracting worldwide attention as a fashion centre—generally a low-wage industry, however, for most employees. Texas also has become eminent in its oceanographic investigations into uses of the continental shelf and in the relatively unpublicized areas of medicine and surgery. The economic consequences of these activities cannot as yet be estimated fully.

Resources of the land. The fertile lands of east Texas attracted cotton farmers before the Civil War, and, following that struggle, cotton became the state's major crop. As mechanized farming developed, production shifted to the High Plains country of west Texas, where irrigation and fertilizer fostered bountiful crops and maintained Texas' national leadership in cotton production. Occasional crop failures due to drought led to crop diversification. In total value of farm crops, Texas consistently has ranked third or fourth among the states in recent years and has been the leading producer of grain sorghums, rice, grapefruit, peanuts, and watermelons.

Sixty percent of the world's mohair and 95 percent of the U.S. total comes from the Angora goats of Texas. The state leads all states in beef cattle and sheep. The vast cattle empires of the 19th century have tended to shift to coastal areas during the 20th century, reversing the path of cotton.

The average farm size has doubled since 1940, absentee ownership has increased, and the farmer has encountered increasing difficulty in surviving. Farm labourers dropped sharply in number during the 1960s, and migrant workers were left jobless for long periods, facing problems of education for their children, fair-employment treatment, and overall economic survival.

Mineral wealth

New uses for oil were being developed when in 1901 the Spindletop gusher blew in near Beaumont. Today, Texas leads all other states in oil and natural-gas production and oil-refining capacity, and it has more than 40 percent of the nation's proved reserves. Oil deposits have been found under more than two-thirds of the state's area, though many finds seem too light for commercial development. Sixty percent of the nation's sulfur comes from large primary deposits and as a by-product of oil and gas refining.

Manufacturing. Manufacturing began naturally with the processing of local raw materials: cotton gins and cotton-seed mills, meat-packing plants, flour mills, and fruit- and vegetable-canning plants. Food processing remains the largest manufacturing employer and ranks third in value added by manufacture.

Oil refining is a major processor of raw materials, though the manufacture of oil-field equipment has proved profitable. The Gulf Coast area is the centre for the petrochemical industrial complexes. About 40 percent of the basic petrochemicals that are produced in the United States come from plants ranging from Beaumont to Corpus Christi.

Reflecting a maturing economy, manufacturing has moved toward the fabrication of finished consumer products. In this category, the growth of the electronics industry has been outstanding. Other finished goods now manufactured in quantity include air conditioners, furniture, boats, household appliances, machinery, leather goods, and clothing.

Transportation. The vastness of Texas and its contrasts in terrain posed great difficulties for transportation yet greatly stimulated its development. The desire to develop inland areas was one factor leading to the establishment of Austin as the capital. In 1852 the legislature granted public lands to railroads for each mile of track constructed, and in 1883 it authorized a county road tax for farm-to-market dirt roads. By 1900 railroads crisscrossed the state, and dirt roads straggled between most communities.

Recent estimates indicate that automotive vehicles are driven more than 62,000,000,000 miles annually over Texas highways and roads. By 1970 the state had 66,970 miles of highways, and its annual expenditures for building and maintenance were more than $500,000,000. In addition, counties and cities maintained more than 164,000 miles of public roads.

As in other states, the actual mileage of mainline railroads has diminished, and passenger transportation by the early 1970s had been discontinued over most lines. Operating freight revenues, however, have increased tremendously over recent decades.

Texas pioneered in the development of the airplane. In or near San Antonio alone were the first army flying schools, established at Ft. Sam Houston in 1910; Kelly Field, which became a training camp for pilots in 1917; and Randolph Field, which by 1931 was serving as "the West Point of the Air." The need for air power in World War II brought air training to more than 40 military bases in Texas.

Focal centres for civil air travel are Dallas–Fort Worth, Houston, and San Antonio. Intercity rivalries have been resolved, and by 1976 the Dallas–Fort Worth complex will be served by one of the nation's major airports. In 1969 Houston unveiled a new Intercontinental Airport, encompassing 7,300 acres and providing a computer-run train to carry passengers from each of four terminals to flight gates.

The discovery of oil and gas necessitated the cheaper avenue of water transportation to markets in the East and North. Federal aid permitted harbour improvements at Galveston, Sabine Pass (opening water routes to Port Arthur and Beaumont), Aransas Pass, and Corpus Christi. The opening of a 50-mile channel has made Houston an international port, the third-largest in the nation in tonnage moved in the early 1970s. In the 1930s an Intercoastal Canal was completed from New Orleans to Sabine Pass and from Galveston to Corpus Christi, and in 1946 the Gulf Intracoastal Canal was opened from Brownsville to Florida. Continuous dredging operations have opened lanes of ocean commerce to many smaller ports. Galveston, oldest among the major ports, is headquarters port for extensive commercial fishing enterprises.

In exports, agricultural products generally are first: in 1970, Texas ranked fourth nationally in this respect. Petroleum products, petrochemicals, sulfur, and basic chemicals were the second-largest category of export.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. The constitution of 1876 outlines the prevailing structure of Texas government. The governor, elected for a two-year term, may initiate legislation, call special legislative sessions, veto bills, and appoint boards and commissions. His power is limited, however, because numerous officials and executive boards are elected rather than appointed. The bicameral

legislature comprises a Senate of 31 members who serve for four years and a House of Representatives with 150 members elected for two years. The top court for civil matters is the Supreme Court, with a chief justice and eight associate justices elected for six-year terms. The highest court for criminal matters is the Court of Criminal Appeals, with five justices elected for six-year terms. There are 14 courts of civil appeal and 183 state district courts, with judges elected for four-year terms. Lower courts comprise county courts, justice of peace courts, and corporation courts.

Local government and taxation

Texas comprises 254 counties ranging in size from Brewster County, with 6,208 square miles—equal to the combined areas of Connecticut and Rhode Island—to Rockwall County, with 147 square miles. Within constitutional limitations, the legislature may create new counties. Each county is administered by a commissioners' court, which is an administrative rather than a trial body. Cities of more than 5,000 population may adopt their own charters; by 1969 there were 188 such home-rule cities with varying forms of executive and legislative government.

The more critical problems of local government inevitably involve finances. The traditional source of local financing has been the property tax, but the movement of workers to suburbs and a hodgepodge of governmental agencies with taxing power has complicated the scene.

The functioning of government operates against a political backdrop at all levels.

Politics. Traditionally, the Democratic Party has dominated elections since the Reconstruction period. Except on rare occasions the Democratic primary, pitting the many splinters of the party against one another, has determined the eventual winners of state offices. Within the one party, the political philosophies of candidates have ranged from extreme liberalism to extreme conservatism.

Emergence of two-party political life

Certain new trends have emerged. The influx of new businesses and industries has brought many Republicans into Texas. The conviction that a two-party system would allow elections based on issues rather than personalities has led some Democrats into the Republican camp, and strong support of civil rights by the national Democratic Party has caused widespread defections by ultraconservatives. In addition, many strong Texas liberals have begun subtly to lend influence to Republicans whom they consider more liberal than the old-time Democratic leaders. Thus, by the early 1970s, the Republican Party, gaining strength by playing upon the divisions within the Democratic Party, had its first senator since Reconstruction, several representatives, and numerous local officeholders.

Political campaigning also has changed. It was possible once for W. Lee "Pappy" O'Daniel, a little-known flour salesman, to burst upon the electorate in the late 1930s with a whirlwind of country music and a slogan of "pass the biscuits, Pappy!" and emerge as governor. The public-relations expert, however, has replaced the entertainer. Old-fashioned oratory has yielded to a soft-voiced message, loaded with sincerity, speaking personally and intimately from the television set.

Politics also is becoming more organized. Both Chicanos and blacks have discovered the power of the ballot to elect city officials, to influence state decisions, and to move upward in the power structure. The increasing tempo of party rivalry and the efforts of the minorities to gain power may stimulate a citizenry that often is apathetic at election time.

Education. Efforts to meet, understand, and solve educational problems arising from the multitudinous social, economic, and other changes since World War II have brought mixed results. An observer may visit a school in which an environment of library self-study and a building designed to accommodate innovation place the educational emphasis upon individual growth rather than grade classification. Conversely, he may sit in a formal classroom in which Mexican-American children are forbidden to utter a word in their family language, the teacher is an autocrat, and dogmatic instruction is regarded as the bridge to wisdom.

Historical factors have helped to shape Texas' present-day educational system. In the 19th century, Texas retained many vestiges of colonial culture. Many communities were colonized by European settlers who brought the concept that public education was only for orphans and children of indigents. In such localities parochial schools were common, and often English remained a second language. The Indians, the labourers from northern Mexico, and the freed slaves, however, had no family tradition of education. In the early years of the republic, leaders tried to reconcile private and free schools. Lacking adequate financial support, the concept of public education became blurred, and, for the populace at large, privately supported education remained the way to secure a sound education.

Another restraining factor has resulted from the divided responsibility between local and state authorities. Local school systems, despite minimum standards established by the state, vary greatly in accordance with local financial resources, prevailing adult educational levels, and demands for equal education for all segments of the population.

Public lands have been used to support education from the years of the Texas Republic. The Texas Congress in 1839 set aside lands in each county to support schools and a university. Railroad building was encouraged in 1854 by land grants for each mile of track—with the proviso that an equal amount be set aside for education. The constitution of 1876 affirmed the endowment of 52,000,000 acres for public schools, another 2,000,000 for a state university and agricultural college. Oil discoveries on these lands by the early 1970s had accumulated well over $1,000,000,000 in permanent endowment funds that can be used to swell legislative appropriations for public education at all levels.

Education of minorities. Most of the 58,000 freed slaves in 1865 were illiterate or barely able to read and write. Despite honest efforts in many communities, the separate but equal principle contained in the constitution of 1876 proved inadequate, though the number of black children enrolled in accredited schools continued to rise. In a test case in 1950 the U.S. Supreme Court ordered the admission of a black student to the University of Texas School of Law, a decision that opened the doors of public colleges and universities in the South to Negro enrollment. Following the Supreme Court's rejection of the separate but equal principle in 1954, public school systems prepared to integrate, but the legislature in 1957 made it illegal for school boards to abolish segregation without approval by local election. Nevertheless, the federal Civil Rights Act and the threat of withholding federal funds from schools that do not integrate adequately have conquered resistance in most areas.

School integration

In the early 1970s, the major obstacles to school integration resulted from discrimination in housing. In addition, black youths from segregated schools find it difficult to gain admission to better colleges or to survive if admitted. These problems are by no means peculiar to Texas, of course, nor to the South, but pervade all urban centres in the nation.

Some of the Mexican-American families have been Texans since the Spanish and Mexican regimes, and many of them are scholars of distinction or wealthy leaders in professional life. But the majority are not, and, hoping to break the barriers of language and culture, schools in heavily Mexican-American areas long forbade the use of any language but English in the classroom and pursued curricula oriented toward Anglo-Saxon social institutions. Recently, however, increased recognition of the cultural heritage has made the family language a springboard into learning experiences.

In spite of these brights spots, a far greater proportion of Mexican-Americans and blacks than Anglos remain outside the educational structure, fail to reach high school, or receive an inadequate education.

Higher education. In 1971–72 the University of Texas system enrolled nearly 70,000 students, more than half of them on the main campus in Austin. Among the 115 colleges and universities are 22 public senior institutions

and 40 public junior colleges. Seven new institutions have been authorized for the state university system, with completion scheduled for 1975.

The University of Texas regularly confers more doctoral degrees than any other Southern university, and 13 of its Ph.D. programs are ranked among the nation's top 20. Rice University, a private institution, in Houston, long has been recognized for the scholarly excellence of its faculty and its high academic standards.

Texas has more than 50 private or church-supported colleges and universities. Baylor University, in Waco, founded in 1845, is the only remaining university of the five established during the republic. In 1970 the state legislature was approached by 50 private institutions with requests to provide financial support through contractual arrangements.

Health and welfare. Among the states Texas ranked 43rd in 1970 in average per capita aid from state and local funds for all categories. In that year voters defeated a measure that would have permitted raising the ceiling on state welfare spending. By the early 1970s, 23 percent of the individuals over 65 in the state were receiving old age assistance, one of the highest percentages in the nation; but the average monthly payment ranked 33rd among such averages in all states. The average payment of $67 monthly to persons totally or permanently disabled ranked 42nd among the states.

Programs for the mentally ill and mentally retarded have been slow to develop in Texas; but increasing public concern has been making itself felt in the legislature. There are six mental health hospitals within the state. Likewise, for aged senile patients there are two geriatric centres, and a neuropsychiatric institute. Increasing attention is being given to outpatient clinic services. Nine state schools care for the mentally retarded.

Annual family incomes demonstrate that the Mexican-American and black families suffer by comparison with Anglo families. The 1960 census figures revealed that over one-half of the Mexican-American and the nonwhite families, as compared with about one-fifth of the Anglo families, had an annual income of less than $3,000. Stimulated by federal antipoverty programs, efforts are increasing to provide adequate employment and equal salary treatment to all segments of the population.

In medical education, research, and preventive medicine the state ranks among national leaders. The University of Texas Southwestern Medical School, in Dallas, is typical of these vigorous programs. It planned to double enrollment by 1975 and to develop a Life Sciences Center emphasizing prevention, cure, and control through combining medicine with the social sciences.

CULTURAL LIFE AND INSTITUTIONS

Preservations. Entering the Institute of Texan Cultures in San Antonio is like walking back into history. The visitor is enveloped quickly in large panoramas of coastline and prairie and in sounds of wind and animal life that contribute to a sense of reality. Moving along, he stands before recreated scenes of Indian life, then of pioneer dwellings, with drawings, dioramas, and preserved objects. The emphasis is upon the various nationalities and cultures that converged to form the life of the Southwest.

Appreciation of cultural diversity

The sense of the past has traditionally been strong in born and bred Texans. The emphasis long was based upon the heroics of living in a frontier land, upon individuals and their deeds, but in recent decades an increasing appreciation of the diverse cultures that have enriched the life of Texas has helped to preserve and strengthen those customs. Throughout the state, regional historical associations quietly search out and help to restore striking examples of 19th-century homes. San Antonio has recreated the early-18th-century Mexican-Spanish flavour in both restoration and in public shopping and walking areas in the heart of the city. Fredericksburg, with its historic German background, preserves many 19th-century customs and continues to cling to German as a family tongue. Even a metropolitan city like Houston has found space adjacent to its downtown area for restored historic homes. Brownsville vividly dramatizes the marriage of Mexican and Anglo cultures with an annual Washington's birthday parade and fete. Particularly evident are influences from Mexican culture, from the deep-rooted impact of the cattle country, and from the newer yet vibrant life fashioned by oil booms, wildcatting, refineries, and pipelines.

The arts. Art, music, and literature occupy significant places in the lives of many communities in Texas. The Amon G. Carter Museum of Western Art in Fort Worth, dedicated to "the visual documentation of the culture of western North America," houses many paintings and bronzes of Western artists and maintains a microfilm collection of Western newspapers published before 1900. With the Fort Worth Art Center, the William Edrington Scott Theatre, the Kimbell Art Museum, and the Fort Worth Children's Theater, the Amon G. Carter Museum provides a cultural centre for study and appreciation of the arts.

The Civic Center nestles in 150 acres amid the tall buildings of downtown Houston. It serves as the home for the Houston Symphony Orchestra and the Grand Opera Association. The world-famous Alley Theater has moved into new quarters nearby. Dallas has developed diverse centres for cultural activities. The Margo Jones Theatre was opened in the 1960s, and the Dallas Theater Center provides an outlet for cultural and educational groups. The Dallas Symphony Orchestra is among the better known classical ensembles in the nation. Such interests, however, are not restricted to large metropolitan areas. Odessa, for example, with an area population of about 100,000, supports the unique Museum of the Presidents, showing extensive memorabilia of the American presidents, as well as an accurate replica of London's Globe Theatre, in which a summer program of Shakespearean and other Elizabethan plays is produced. Colleges and universities in the state are active in all areas of the arts.

Recreation. Water has added new dimensions to popular recreation. In 1913 there were only eight major lakes or reservoirs in Texas, but by the early 1970s there were 200 or more, many built to husband water against periodic droughts. Several national parks and some 70 state parks dot the state, many of them providing fishing, swimming, camping, and picnicking. An increasing tourist trade has turned sports fishing into a major recreation along the Gulf Coast.

Sports and amusements

Other dimensions of entertainment—for tourists and Texans alike—include Six Flags Over Texas, a Westernized amusement park halfway between Dallas and Fort Worth, and, near the Dallas suburb of Mesquite, a reservation into which motorists can drive, as on an African safari, and watch apparently free-roaming elephants, giraffes, and other African wildlife. In Houston the well-publicized Astrodome has become a centre of professional sports, rodeos, bullfights (with no killing), circuses, and other spectaculars.

Literary resources. Book publishing, though not as yet a big business within the state, has gained a strong foothold. The University of Texas Press has gained national acclaim through its scholarly and historical works, and the Southern Methodist University Press likewise has established discriminating standards. Several commercial publishing companies have concentrated on books and monographs related to the history of the Southwest.

The university libraries, art galleries, and special collections contain remarkable treasures. The Armstrong Browning Library at Baylor houses more than 5,000 books and manuscripts by and about Robert and Elizabeth Barrett Browning. At the University of Texas in Austin, the new Presidential Library, dedicated in 1971 and operated as a branch of the Library of Congress, will house about 34,000,000 documents on public affairs since the mid-1930s, related to the public career of former President Lyndon B. Johnson. At this university, also, the Latin-American collection, the Michener Collection of Art, and a number of other special collections are available to scholars, historians, and the public.

Press and broadcasting. From colonial days, the news media have played a special role in the development of

Texas. Gail Borden, Jr., founded the *Telegraph and Texas Register* in 1835 in San Felipe and used the newspaper to advocate the cause of Texas freedom and to strengthen support for the republic. In the years before the Civil War, Texas editors were combinations of educators, newsmongers, and chamber of commerce promoters for their communities, characteristics that persisted until modern times.

Interactions of newspapers and communities

In nearly every city or town a newspaper has grown up with the community, influencing decisions and promoting community virtues to outsiders. The *Fort Worth Star-Telegram* thus became a major force in stirring Fort Worth to leadership in the cattle business, in browbeating railroad officials into routing more trains through the town, and in attracting investment capital from the East. In a similar way, the *Dallas Morning News* and later the *Dallas Daily Times Herald*, the *Houston Post* and the *Houston Chronicle*, and the *San Antonio Express* and the *San Antonio Light* similarly shaped the destinies of their cities, until in many ways the cities and the newspapers came to reflect one another. Austin's *Texas Observer* has gained distinction through its dogged stabs at racial inequities, political dealings, and other injustices throughout the state. Newspapers in smaller communities—the *Victoria Advocate*, the Beeville *Bee-Picayune*, or the *Smithville Times*—are as deeply embedded as the county courthouse. In the early 1970s, the fastest growing segment of the press was in suburban communities.

The first radio station in Texas began operating in 1920 under the ownership of the city of Dallas. The first television station went on the air in 1947. In 1970 Texas had more than 400 AM and FM radio stations and about 70 television stations. By 1970, cable television had established itself firmly in most Texas cities and had reached out to some of the smaller communities. Educational television, or "public broadcasting," also reached a large audience in Texas.

Prospects. Certain trends that will continue into the future emerge logically from the developments of post-World War II Texas. In ensuing decades it seems likely that the population of the state will increase at a rate faster than that of the nation as a whole. Industry and business must certainly diversify, to place greater emphasis upon end products rather than natural resources. Mexican-American and black minorities will become more cohesive and more politically astute, thereby exerting greater influence upon government and politics. As a consequence, educational integration will progress with decreasing friction as new schools are built between neighbourhoods, rather than in the centre of homogeneous residential areas. In addition, integration will become more realistic and less token in public life, in churches, and eventually in housing. The struggle to establish additional bases for taxation will remain acute, as governmental bodies within the state assume greater burdens and voters become convinced of the necessity for increasing expenditures for the improvement of society. These upgraded programs inevitably will fall in such areas as public health and welfare, the salaries of public employees, education, mental-health programs, and law enforcement.

BIBLIOGRAPHY. The single most valuable volume of facts about various aspects of Texas life and industry is *The Texas Almanac*, ed. by WALTER B. MOORE and published every two years. The *Handbook of Texas*, ed. by WALTER PRESCOTT WEBB (1952), provides encyclopaedic information about individuals, ranches, Indians, colonizations, education, government, and other glimpses into Texas development. The comprehensive *Texas: A Guide to the Lone Star State*, rev. ed., ed. by HARRY HANSEN (1969), is particularly helpful in its guide to the large and middle-size cities of the state. CLIFTON MCCLESKEY, *The Government and Politics of Texas*, 3rd ed. (1969), is the most authoritative book on Texas government, emphasizing the social and economic contexts. Lively glimpses of 20th-century Texas, written with attention to human interest and colour, include STANLEY WALKER, *Texas* (1962); and GEORGE M. FUERMANN, *Reluctant Empire* (1957). Both authors examine the people and their doings with the eyes of an interpretative reporter. The student of the West, seeking authentic information of frontier days, will find information in such books as J. FRANK DOBIE, *The Mustangs* (1952), which recaptures the smells, sounds, and sights of the Western plains and the wild horses that once lived there. WALTER PRESCOTT WEBB, *The Texas Rangers*, rev. ed. (1965), is the best book about the subject. W.W. NEWCOMB, JR., *The Indians of Texas from Prehistoric to Modern Times* (1961), is a scholarly and lucid report. FRED B. GIPSON, *Cowhand: The Story of a Working Cowboy* (1953), is a day-by-day real-life story that has the movement and feeling of fiction. R. HENDERSON SHUFFLER *et al.*, *From Many Texans: A Gathering of Cultures* (1970), relating colourful stories of the mixture of cultures in the Southwest; and CURTIS and GRACE BISHOP, with C.I. MARTIN, *Trails to Texas* (1965), recreating the cattle decades, are written for young people but appealing to adults as well. The INSTITUTE OF TEXAN CULTURES in San Antonio has begun the production of a series of monographs depicting the various ethnic or immigrant streams of life that have flowed into the Southwest, including *The Indian Texans* and *The Norwegian Texans* (both 1970).

(DeW.C.R.)

Textile Industry

The term textile, derived from the Latin *texere* ("to weave"), originally applied only to woven fabrics, is now a general term for fibres, yarns, and other materials that can be made into fabrics and for fabrics produced by interlacing or any other construction method. Thus threads, cords, ropes, braids, lace, embroidery, nets, and fabrics made by weaving, knitting, bonding, felting, or tufting are textiles. Some definitions would also include those products obtained by the paper-making principle that have many of the properties associated with conventional fabrics.

This article is concerned with the development of the textile industry, the conversion of fibres to yarn, fabric construction, finishing processes applied to textiles, end uses of textile materials, and the relationship between the producer and the consumer. Specific textile fibres are treated in the articles FIBRES, MAN-MADE; and FIBRES, NATURAL. Other related articles include FLOOR COVERINGS and DYES AND DYEING. Aesthetic aspects are discussed in the articles RUGS AND CARPETS and TAPESTRY. This article is divided into the following sections.

I. Development of the textile industry
  History to the 19th century
    Early textile production
    Effects of the Industrial Revolution
  From the 19th century to the present
    Application of scientific methods
    The modern industry
II. Production of yarn
  Textile fibres
  Conversion to yarn
    Treatment of raw fibre
    Spinning
    Yarn packages
  Types of yarn
    Classification based on number of strands
    Novelty yarns
    Classification based on use
    Measurement systems
III. Production of fabric
  Woven fabrics
    The weaving process
    Development of the loom
    Basic weaves
    Complex weaves
  Knitted fabrics

I. Development of the textile industry

HISTORY TO THE 19TH CENTURY

Early textile production. Textile structures derive from two sources, ancient handicrafts and modern scientific invention. The earliest were nets, produced from one thread and employing a single repeated movement to form loops, and basketry, the interlacing of flexible reeds, cane, or other suitable materials. The production of net, also called limited thread work, has been practiced by many peoples, particularly in Africa and Peru. Examples of prehistoric textiles are extremely rare because of the perishability of fabrics. The earliest evidence of weaving, closely related to basketry, dates from Neolithic cultures of about 5000 BC. Weaving apparently preceded spinning of yarn; woven fabrics probably originated from basket weaving. Cotton, silk, wool, and flax fibres were used as textile materials in ancient Egypt; cotton was used in India by 3000 BC; and silk production is mentioned in Chinese chronicles dating to about the same period. The history of spinning technology will be touched on below in the section *Production of yarn: Spinning* and that of weaving technology in the section *Production of fabric*.

Early fabrics. Many fabrics produced by the simple early weaving procedures are of striking beauty and sophistication. Design and art forms are of great interest, and the range of patterns and colours is wide, with patterns produced in different parts of the world showing distinctive local features.

Yarns and cloth were dyed and printed from very early times. Specimens of dyed fabrics have been found in Roman ruins of the 2nd century BC; tie-and-dye effects decorated the silks of China in the T'ang dynasty (AD 618–907); and there is evidence of production of printed textiles in India during the 4th century BC. Textiles found in Egypt also indicate a highly developed weaving craft by the 4th century AD, with many tapestries made from linen and wool. Persian textiles of very ancient origin include materials ranging from simple fabrics to luxurious carpets and tapestries.

Textiles in the Middle Ages. By the early Middle Ages certain Turkish tribes were skilled in the manufacture of carpets, felted cloths, towels, and rugs. In Mughal India (16th–18th centuries), and perhaps earlier, the fine muslins produced at Dacca in Bengal were sometimes printed or painted. Despite the Muslim prohibition against representation of living things, richly patterned fabrics were made in Islamic lands.

In Sicily, after the Arab conquest in AD 827, beautiful fabrics were produced in the palace workshops at Palermo. In about 1130, skilled weavers who came to Palermo from Greece and Turkey produced elaborate fabrics of silk interlaced with gold.

Growth of the textile industry in Italy

Following the conquest of Sicily in 1266 by the French, the weavers fled to Italy; many settled in Lucca, which soon became well-known for silk fabrics with patterns employing imaginative floral forms. In 1315, the Florentines captured Lucca, taking the Sicilian weavers to Florence, a centre for fine woven woollens from about 1100 AD, also believed to be producing velvet at this time. A high degree of artistic and technical skill was developed, with 16,000 workers employed in the silk industry and 30,000 in the wool industry at the close of the 15th century. By the middle of the 16th century a prosperous industry in velvets and brocades (see below *Production of fabric*) was also established in Genoa and Venice.

Textile industries of France and Germany. French manufacture of woven silks began in 1480, and in 1520 Francis I brought Italian and Flemish weavers to Fontainebleau to produce tapestry under the direction of the King's weaver. Others were brought to weave silk in Lyons, eventually the centre of European silk manufacture. Until 1589, most of the elaborate fabrics in France were of Italian origin, but in that year Henry IV founded the royal carpet and tapestry factory at Savonnières. Flemish weavers were brought to France to produce tapestries in workshops set up by Jean Gobelin in the 16th century. By the time of Louis XIII (1610–43), French patterned fabrics showed a distinctive style based on symmetrical ornamental forms, lacelike in effect, perhaps derived from the highly regarded early Italian laces. In 1662, the French government, under Louis XIV, purchased the Gobelin factory in Paris. Rouen also became known for its textiles, with designs influenced by the work of Rouen potters. French textiles continued to advance in style and technique, and under Louis XVI (1774–93) design was refined, with classical elements intermingled with the earlier floral patterns. The outbreak of the French Revolution in the 1790s interrupted the work of the weavers of Lyons, but the industry soon recovered.

Flanders and its neighbour Artois were early centres of production for luxurious textiles: Arras for silks and velvets; Ghent, Ypres, and Courtrai for linen damasks; and Arras and Brussels for tapestries. The damasks, characterized by heraldic motifs, were especially well known, and linen damasks of very high quality were produced in the 18th century. In Germany, Cologne was an important medieval cloth centre, renowned for Orphrey webs (narrow cloths of gold bearing richly embroidered woven inscriptions and figures of saints).

Textile manufacture in England. English textiles of the 13th and 14th centuries were mainly of linen and wool, and the trade was influenced by Flemish fullers (finishers) and dyers. Silk was being woven in London and Norwich in 1455, and in 1564 Queen Elizabeth I granted a charter to Dutch and Flemish settlers in Norwich for production of damasks and flowered silks. The revocation of the Edict of Nantes in 1685, renewing persecution of French Protestants, caused many weavers to move to England, settling in Norwich, Braintree, and London. The most important group of refugees, some 3,500, lived in Spitalfields, a London settlement that became the chief centre for fine silk damasks and brocades. These weavers produced silk fabrics of high quality and were known for their subtle use of fancy weaves and textures. Norwich was also famous for figured shawls of silk or wool.

Textiles in the New World. Weaving and dyeing were established in the New World before arrival of the Europeans. Weaving was in an advanced state in North and South America during prehistoric times; both the Peruvians and Mexicans had fine woven fabrics. The Peruvian fabrics were much like those of ancient Egypt, although contact between the two civilizations is generally considered unlikely. Inca cotton and wool fabrics were brilliantly coloured, with patterns based on geometric and conventionalized human forms. Fabrics, especially blankets, made by the Navajos of Arizona and New Mexico had exceptionally close texture and brilliant colour.

American Indian textiles

English settlers established a cloth mill in Massachusetts in 1638. There Yorkshire weavers produced heavy cotton fustians; cotton-twill jeans; and linsey-woolsey, a coarse, loosely woven fabric of linen and wool. Fulling mills were operating in Massachusetts by 1654, freeing the community from dependence on England for fine linen and worsted. The industry developed steadily, and received a major impetus from Eli Whitney's invention of the cotton gin in 1793.

Effects of the Industrial Revolution. The textile industry, although highly developed as a craft, remained essentially a cottage industry until the 18th century. The advantages of cooperative operations were realized much earlier, and numbers of workers occasionally operated together under one roof, with one such group operating a mill in Zurich in 1568 and another in Derby, England, in 1717. Factory organization became most advanced in the north of England, and the Industrial Revolution, at its height between 1760 and 1815, greatly accelerated the growth of the mill system.

John Kay's flying shuttle, invented in 1733, increased the speed of the weaving operation, and its success created pressure for more rapid spinning of yarn to feed the faster looms. Mechanical spinners produced in 1769 and 1779 by Sir Richard Arkwright and Samuel Crompton encour-

aged development of mechanized processes of carding and combing wool for the spinning machines (see below *Production of yarn: Carding and combing*). Soon after the turn of the century the first power loom was developed. The replacement of water power by steam power increased the speed of power-driven machinery, and the factory system became firmly established, first in England, later in Europe and the United States.

FROM THE 19TH CENTURY TO THE PRESENT

Throughout the 19th century a succession of improvements in textile machinery steadily increased the volume of production, lowering prices of finished cloth and garments. The trend continued in the 20th century, with emphasis on fully automatic or nearly fully automatic systems of machinery.

Application of scientific methods. The mechanical developments in textile production associated with the Industrial Revolution resulted from the application of comparatively simple engineering and physical principles. Further progress required a clear understanding of the scientific principles of textile processing. Lack of basic information on the structure and properties of fibres limited understanding, delaying a scientific approach to textile processing. In the late 19th century, however, increasing knowledge of the physical and chemical properties of fibres led to application of scientific methods. Applications of chemistry originally attracted the greatest attention, largely because of the production of new compounds and the realization that fibres could be considered the result of chemical activity. In the 20th century, with the development of electronics and computers, new physical and engineering concepts were employed in textile research and development. An outstanding application of science to the textile industry was the development of man-made fibres, providing new textile materials and leading to the application of new processes to traditional fibres, thereby providing faster processing methods and introducing a wider variety of new techniques. The man-made fibre industry originally employed textile expertise developed through years of experience with natural fibres, but the excellent results obtained by the scientific approach encouraged increased industrial use of applied science, and information was soon accumulated on the behaviour of fibres under a variety of conditions.

Effects of development of man-made fibres

The modern industry. Both industrialized and developing countries now have modern installations capable of highly efficient fabric production. In addition to mechanical improvements in yarn and fabric manufacture, there have been rapid advances in development of new fibres, processes to improve textile characteristics, and testing methods allowing greater quality control.

The modern textile industry is still closely related to the apparel industry, but production of fabrics for industrial use has gained in importance. The resulting wide range of end uses demands a high degree of specialization. In the most technically advanced communities, the industry employs technicians, engineers, and artists; and a high degree of consumer orientation leads to emphasis on marketing operations. Some manufacturing operations, usually serving specialized or local markets and dependent on a limited number of firms for product consumption, still employ many hand operations, however.

Modern fabrics. The many types of modern textile fabrics, produced from both traditional and man-made materials, are often classified according to structure. Fabrics made by interlacing include woven and knitted types, lace, nets, and braid; fabrics produced from fibre masses include bonded types, wool felt, and needle-woven types; composite fabrics are produced by uniting layers of various types. Conventional weaving and knitting methods are currently the major textile manufacturing techniques, but newer construction methods are achieving acceptance, and may replace certain long-established products as costs of conventional textiles continue to rise and rapid technological advances continually develop new materials.

Quality control. Textile fabrics are judged by many criteria. Flexibility and sufficient strength for the intended use are generally major requirements, and industrial fabrics must meet rigid specifications of width, weight per unit area, weave and yarn structure, strength and elongation, acidity or alkalinity, thickness, and porosity. In apparel fabrics design and colour are major considerations, and certain physical properties may be of secondary importance. In addition, the various tactile properties of a fabric, described as its "hand," "handle," or "feel," influence consumer acceptance.

Criteria for evaluating textile fabrics

The textile industry increasingly employs research and development in the area of quality control. Medieval craft guilds were concerned with maintaining high quality standards, and later textile mills established rigid systems of inspection, realizing that a reputation for supplying fault-free goods encouraged repeat orders. Modern quality control has been assisted by development of techniques and machines for assessing fibre, yarn, and fabric properties; by the introduction of legislation regarding misrepresentation in many industrialized countries; and by the establishment of rigid specifications by a growing number of buyers. Specifications have been established for the purchase of industrial fabrics, for textiles used by the military and other branches of governments, and for similar purchasing methods adopted by some retailers and other large buyers. In consumer-oriented areas, the public is becoming aware of product testing, and is beginning to require proof that products have met certain test standards.

Many modern textile organizations test product quality at every major stage of processing. Yarns are tested for uniform thickness and other characteristics; fabric pieces are checked for defects; and the fastness of finishes and colours to various conditions is determined. Although it would not be feasible to test each yarn or fabric piece produced, statistical techniques allow maintenance of quality within previously specified limits, and the introduction of automatic testing devices has greatly reduced testing time and cost. Methods for assessing such properties as dimensions, strength, and porosity have been established, and their validity is generally accepted within the industry. Standards are available for colour fastness, although such important properties as water-repellency, resistance to creasing, and flame resistance are presently more difficult to define, and various organizations have adopted their own test procedures. It is important, for example, that a fabric described as flame resistant should conform to some specification in which the meaning of flame resistance is clearly defined.

Some manufacturers attach trademarks and quality labels to tested goods, and licensed trademarks are often associated with particular processes for which the manufacturer has been granted a license. The terms of the license require the manufacturer to ensure that his products meet the standards laid down by the proprietors of the particular process.

II. Production of yarn

Yarn is a strand composed of fibres, filaments (individual fibres of extreme length), or other materials, either natural or man-made, suitable for use in the construction of interlaced fabrics, such as woven or knitted types. The strand may consist of a number of fibres twisted together; a number of filaments grouped together but not twisted; a number of filaments twisted together; a single filament, called a monofilament, either with or without twist; or one or more strips made by dividing a sheet of material, such as paper or metal foil, and either twisted or untwisted. The properties of the yarn employed greatly influence the appearance, texture, and performance of the completed fabric.

TEXTILE FIBRES

Raw materials. Fibres are units of matter having length at least 100 times their diameter or width. Fibres suitable for textile use possess adequate length, fineness, strength, and flexibility for yarn formation and fabric construction, and for withstanding the intended use of the completed fabric. Other properties affecting textile fibre performance include elasticity, crimp (waviness), moisture

Qualities required in textile fibres

absorption, reaction to heat and sunlight, reaction to the various chemicals applied during processing and in the dry cleaning or laundering of the completed fabric, and resistance to insects and micro-organisms. The wide variation of such properties among textile fibres determines their suitability for various uses.

The first fibres available for textile use were obtained from plant and animal sources. Over a long period of experimentation with the many natural fibres available, cotton, wool, jute, flax, and silk have become recognized as the most satisfactory. The commercial development of man-made fibres began late in the 19th century, experienced much growth during the 1940s, expanded rapidly after World War II, and in the 1970s was still the subject of extensive research and development. This group includes regenerated fibres, such as rayon, made from fibre-forming materials already existing in nature and manipulated into fibrous form, and synthetic fibres, with the fibre-forming substance produced from chemicals derived from such sources as coal and oil, and then made into such fibres as nylon and polyester.

Factors affecting cost. The cost of fibres is determined by availability, the kind and amount of processing required, and their versatility. Natural fibres usually require extensive land area for their production, are affected by climatic conditions, and must frequently be transported long distances to the point of manufacture. Because quantity and quality are not easily controlled, prices tend to fluctuate. Recent research has been directed toward improving various properties during the manufacturing processes.

Man-made fibres can usually be produced near the point of use; their production does not require large land areas; they can be manufactured quickly, in desired quantities, with specific built-in properties; and they require little advance preparation for conversion to yarn. Initial costs are high because of the production equipment employed, but prices tend to be stable and may be reduced as production expands. Recent research has been directed toward improving the properties of man-made fibres and developing types suitable for specific purposes.

Although the major natural fibres continue to dominate the textile industry, production and consumption of man-made fibres are growing.

CONVERSION TO YARN

Because filaments, such as silk and the man-made fibres, have extreme length, they can be made into yarn without the spinning operation necessary for the shorter staple fibres. When grouped together in a loose, continuous rope without twist, man-made filaments are called tow. Filaments may be loosely twisted together to form yarns of a specified thickness. Staple fibres, such as cotton, only a few inches long, must be tightly twisted together to produce satisfactory length.

Tow

Filament yarns are usually thin, smooth, and lustrous; staple yarns are usually thicker, fibrous, and without lustre. Man-made filaments cut to a predetermined short length become staple fibres, usually described by combining the fibre name with the term staple, as in rayon staple.

Treatment of raw fibre. In modern mills, most fibre-processing operations are performed by mechanical means. Such natural fibres as cotton, arriving in bales, and wool, arriving as fleece, are treated at the mill to remove various foreign materials, such as twigs and burrs. Wool must also be treated to remove suint, or wool grease; silk must be treated to remove sericin, a gum from the cocoon, and the very short silk fibres, or waste silk. Raw linen, the fibre of flax, is separated from most impurities before delivery. Man-made fibres, since they are produced by factory operations, rarely contain foreign materials. Blending, frequently employed for natural fibres, involves mixing fibres taken from different lots to obtain uniform length, diameter, density, and moisture content, thus assuring production of a uniform yarn. Blending is also employed when different fibres are combined to produce yarn. Man-made fibres, which can be cut into uniform tow, do not require blending unless they are to be mixed with other fibres.

Cotton, wool, waste silk, and man-made staple are subjected to carding, a process of separating individual fibres and causing many of them to lie parallel, and also removing most of the remaining impurities. Carding produces a thin sheet of uniform thickness that is then condensed to form a thick, continuous, untwisted strand called sliver.

Carding

When very fine yarns are desired, carding is followed by combing, a process that removes short fibres, leaving a sliver composed entirely of long fibres, all laid parallel, and both smoother and more lustrous than uncombed types. Slivers may be loosely twisted together, forming roving. Hackling, a process applied to straighten and separate flax, is similar to combing.

Spinning. *Early spinning methods.* Spinning is the process of drawing out and twisting fibres to join them firmly together in a continuous thread or yarn. Spinning is an indispensable preliminary to weaving cloth from those fibres that do not have extreme length. From early times through the Middle Ages spinning was accomplished with the use of two implements, the distaff and the spindle. The distaff was a stick on which the mass of fibres was held. The drawn-out length of fibre was fastened to the weighted spindle, which hung free. The spinner whirled the spindle, causing it to twist the fibre as it was drawn from the distaff. As a length was drawn out the operation was halted, the new yarn wound on the spindle and secured by a notch, and the operation repeated. The spinning wheel, invented in India and introduced to Europe in the Middle Ages, mechanized the process; the spinning of the wheel supplanted the whirl of the weighted spindle, and after each operation the spinner wound the new yarn on the spindle. This was accomplished simply and speedily by holding the yarn outstretched with the left hand and feeding it as the wheel was spun in the reverse direction.

An important advantage conferred by the spinning wheel was the fact that it tended to add more twist at thin places in the forming yarn and to draw out the thicker places, giving a more uniform yarn.

Improvements on the spinning wheel

The spinning wheel continued in use into the 19th century, receiving an important improvement in the 16th century in the form of the Saxony wheel, which made possible continuous spinning of coarse wool and cotton yarn. With this improvement in speed, three to five spinning wheels could supply one loom with yarn, but Kay's flying shuttle (described below under *Woven fabrics*) greatly increased the output of the loom and created a demand for spinning machinery. James Hargreaves' spinning jenny (patented 1770) operated a number of spindles simultaneously, but was suitable only for making yarn used as filling. Sir Richard Arkwright, making use of earlier inventions, produced a better machine, capable of making stronger yarn than Hargreaves' jenny. Still a third machine, Samuel Crompton's "mule" (1779), vastly increased productivity, making it possible for a single operator to work more than 1,000 spindles simultaneously; and it was capable of spinning fine as well as coarse yarn. Several further modifications were introduced in Britain and the United States, but the Crompton mule effectively put yarn spinning on a mass production basis.

Modern spinning. In modern spinning, slivers or rovings are fed into machines having rollers that draw out the strands, making them longer and thinner, and that insert the amount of twist necessary to hold the fibres together. The tightness of the twist determines the strength of the yarn, although too much twist may eventually cause weakening and breakage. Yarns twisted to the right, or clockwise, are described as Z-twist; yarns twisted to the left, or counterclockwise, are described as S-twist. Crepe yarns, producing a crinkled effect in fabrics, are made with a very high degree of twist, producing a kink. Shadow effects can be produced in finished fabrics by the use of yarns combining opposing twists, producing differing light reflections. The spinning process is completed by winding the yarn on spools or bobbins.

Reeling and throwing. Reeling is the process of unwinding raw silk filament from the cocoon directly onto a holder. When several filament strands, either raw silk or man-made, are combined and twisted together, producing yarn of a specified thickness, it is called throwing.

Yarn packages. The intended use of a yarn usually determines the packaging method employed. Bobbins are wood, cardboard, or plastic cores on which yarns are wound as they are spun, and have holes in their centres allowing them to fit on spindles or other holding devices. Spools are cylindrical, with end flanges. Cones, having a conical-shaped core, produce a package of conical shape; tubes, with cylindrical-shaped cores, produce cylindrical packages. Cheeses are cylindrical yarn packages wound on a tube, and unlike most other packages, they have greater diameter than height. Skeins are coils of yarn wound with no supporting core.

Pirns are large barrel-shaped packages used to hold the weft, or filling, yarn supply for the shuttle in weaving; quills are small tapered tubes holding the weft yarns for weaving. Beams are wood or metal cylinders, about five feet long and up to ten inches in diameter, on which yarns used as warp in weaving are wound.

For detailed information on individual fibres, including their production, processing, individual properties, and uses, see FIBRES, MAN-MADE and FIBRES, NATURAL.

TYPES OF YARN

Classification based on number of strands. Yarns can be described as single, or one-ply; ply, plied, or folded; or as cord, including cable and hawser types.

Single yarns. Single, or one-ply, yarns are single strands composed of fibres held together by at least a small amount of twist; or of filaments grouped together either with or without twist; or of narrow strips of material; or of single man-made filaments extruded in sufficient thickness for use alone as yarn (monofilaments). Single yarns of the spun type, composed of many short fibres, require twist to hold them together and may be made with either S-twist (clockwise) or Z-twist (counterclockwise) (see Figure 1). Single yarns are used to make the greatest variety of fabrics.

From Evelyn E. Stout, *Introduction to Textiles* (© 1970); John Wiley & Sons, Inc.

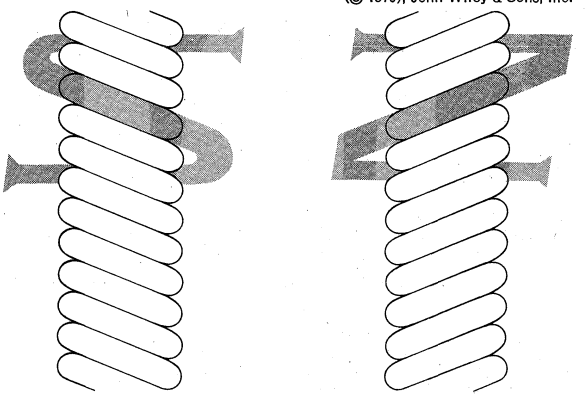

Figure 1: (Left) S- and (right) Z-twist yarns.

Ply yarns. Ply, plied, or folded, yarns are composed of two or more single yarns twisted together. Two-ply yarn, for example, is composed of two single strands; three-ply yarn is composed of three single strands. In making ply yarns from spun strands, the individual strands are usually each twisted in one direction and are then combined and twisted in the opposite direction. When both the single strands and the final ply yarns are twisted in the same direction, the fibre is firmer, producing harder texture and reducing flexibility. Ply yarns provide strength for heavy industrial fabrics and are also used for delicate-looking sheer fabrics.

Cord yarns. Cord yarns are produced by twisting ply yarns together, with the final twist usually applied in the opposite direction of the ply twist (see Figure 2). Cable cords may follow an SZS form, with S-twisted singles made into Z-twisted plies that are then combined with an S-twist, or may follow a ZSZ form. Hawser cord may follow an SSZ or a ZZS pattern. Cord yarns may be used as rope or twine, may be made into very heavy industrial fabrics, or may be composed of extremely fine fibres that are made up into sheer dress fabrics.

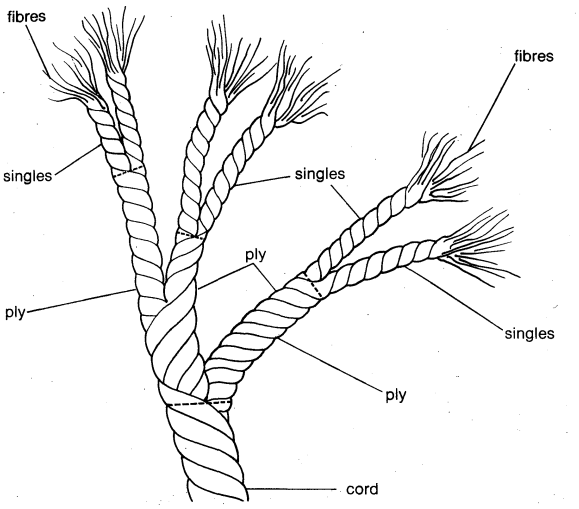

Figure 2: Single, ply, and cord yarns.

Novelty yarns. Novelty yarns include a wide variety of yarns made with such special effects as slubs, produced by intentionally including small lumps in the yarn structure, and man-made yarns with varying thickness introduced during production. Natural fibres, including some linens, wools to be woven into tweed, and the uneven filaments of some types of silk cloth are allowed to retain their normal irregularities, producing the characteristic uneven surface of the finished fabric. Man-made fibres, which can be modified during production, are especially adaptable for special effects such as crimping and textures.

Textured yarns. Texturizing processes were originally applied to man-made fibres to reduce such characteristics as transparency, slipperiness, and the possibility of pilling (formation of small fibre tangles on a fabric surface). Texturizing processes make yarns more opaque, improve appearance and texture, and increase warmth and absorbency. Textured yarns are man-made continuous filaments, modified to impart special texture and appearance (see Figure 3). In the production of abraded yarns, the surfaces are roughened or cut at various intervals and given added twist, producing a hairy effect.

Bulking creates air spaces in the yarns, imparting absorbency and improving ventilation. Bulk is frequently introduced by crimping, imparting waviness similar to the natural crimp of wool fibre; by curling, producing curls or loops at various intervals; or by coiling, imparting stretch. Such changes are usually set by heat application, although chemical treatments are sometimes employed. Bulking

From G.E. Linton, *Applied Basic Textiles*, 2nd ed. (1973)

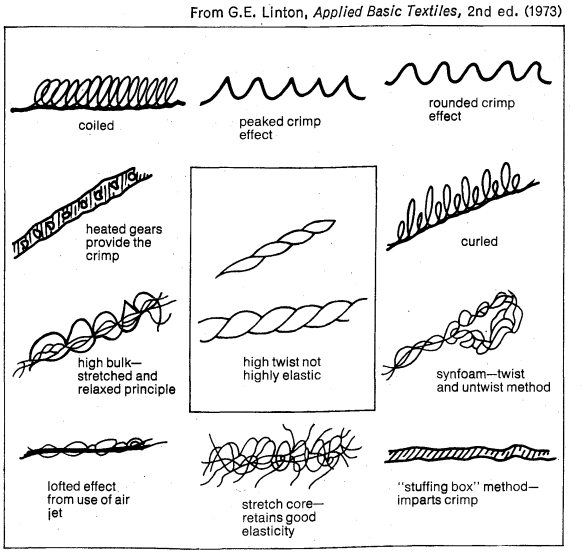

Figure 3: Examples of textured yarns.

In the early 1970s bulky yarns were most frequently produced by the "false twist" method, a continuous process in which the filament yarn is twisted and set, and then untwisted and heated again to either stabilize or destroy the twist. The "stuffing box" method is often applied to nylon, a process in which the filament yarn is compressed in a heated tube, imparting a zigzag crimp, then slowly withdrawn. In the knit de knit process, a synthetic yarn is knitted, heat is applied to set the loops formed by knitting, and the yarn is then unravelled and lightly twisted, producing the desired texture in the completed fabric.

Bulk may be introduced chemically by combining filaments of both high and low shrinkage potential in the same yarn, then subjecting the yarn to washing or steaming, causing the high shrinkage filaments to react, producing a bulked yarn without stretch. Such regenerated yarns as rayon and acetate, which are not made malleable by heat, may be air-bulked by enclosing the yarn in a chamber where it is subjected to a high-pressure jet of air, blowing the individual filaments into random loops that separate, increasing bulk.

Stretch yarns. Stretch yarns are frequently continuous-filament, man-made yarns that are very tightly twisted, heat-set, then untwisted, producing a spiral crimp giving a springy character. Although bulk is imparted in the process, a very high amount of twist is required to produce yarn that has not only bulk, but also stretch.

Elastomeric fibres

Spandex is the generic term for a highly elastic synthetic fibre composed mainly of segmented polyurethane. Uncovered fibres may be used alone to produce fabrics, but they impart a rubbery feel. For this reason, elastomeric fibre is frequently used as the core of a yarn, and covered with a nonstretch fibre of either natural or man-made origin. Although stretch may be imparted to natural fibres, other properties may be impaired by the process, and the use of an elastic yarn for the core eliminates the need to process the covering fibre.

Metallic yarns. Metallic yarns are usually made from strips of a synthetic film, such as polyester, coated with metallic particles. In another method, aluminum foil strips are sandwiched between layers of film. Metallic yarns may also be made by twisting a strip of metal around a natural or man-made core yarn, producing a metal surface.

The article FIBRES, MAN-MADE provides more information about the production, characteristics, and uses of modern man-made novelty yarns.

Classification based on use. *Fabric construction yarns.* Almost any textile yarn can be used to produce such interlaced fabrics as woven and knitted types. In weaving, the warp, or lengthwise, yarns are subjected to greater stress, and are usually stronger, smoother, more even, and have tighter twist than the weft, or crosswise, yarns. A sizing (stiffening) material such as starch may be applied to warp yarns, increasing their strength to withstand the stresses of fabric construction operations. Weft yarns, subjected to little stress during weaving, may be quite fragile.

Warp and weft threads used in the same fabric may be of differing diameter, producing such special effects as ribbing or cording in the fabric. Special effects may also be obtained by combining warp and weft yarns of fibre from differing origin, or with different degrees of twist, or by introducing metallic threads into weaves composed of other fibres.

Yarns for machine knitting are usually loosely twisted because softness is desired in knit fabrics.

Yarns used in handwork. Yarns used in hand knitting are generally of two or more ply. They include such types as fingering yarns, usually of two or three plys, light to medium in weight and with even diameter, used for various types of apparel; Germantown yarns, soft and thick, usually four-ply and of medium weight, frequently used for sweaters and blankets; Shetland yarns, fine, soft, fluffy, and lightweight, frequently two-ply, used for infants' and children's sweaters and for shawls; worsted knitting yarn, highly twisted and heavy, differing from worsted fabric by being soft instead of crisp, and suitable for sweaters; and zephyr yarns, either all wool, or wool blended with other fibres, very fine and soft, with low twist, and used for lightweight garments.

Embroidery floss, used in hand embroidery, generally has low twist, is of the ply or cord type, and is made of such smooth filaments as silk and rayon. Yarn used for crocheting is frequently a loose cotton cord type; and darning yarns are usually loosely spun.

Sewing thread. Sewing threads are tightly twisted ply yarns made with strands having equally balanced twist, producing a circular cross section. Thread for use in commercial or home sewing machines and for hand sewing should allow easy movement when tension is applied and ease in needle threading; should be smooth, to resist friction during sewing; should have sufficient elasticity to avoid the breaking of stitches or puckering of seams; and should have sufficient strength to hold seams during laundering or dry cleaning and in use.

Threads for special uses may require appropriate treatment. Garments made of water-repellent fabrics, for example, may be sewn with thread that has also been made water-repellent. Thread is usually subjected to special treatment after spinning, and is then wound on spools. Thread size is frequently indicated on the spool end, and systems for indicating degree of fineness vary according to the textile measurement system used locally.

Silk, cotton, and nylon threads

Silk thread has great elasticity and strength combined with fine diameter. It can be permanently stretched in sewing, and is suitable for silks and wools. Buttonhole twist is a strong, lustrous silk about three times the diameter of normal sewing silk, and is used for hand-worked buttonholes, for sewing on buttons, and for various decorative effects.

Cotton thread is compatible with fabric made from yarn of plant origin, such as cotton and linen, and for rayon (made from a plant substance), because it has similar shrinkage characteristics. It is not suitable for most synthetics, which do not shrink, or for fabrics treated to reduce shrinkage. Its low stretch is useful for woven fabrics, but not for knits, which require more stretch.

Nylon thread is strong, with great stretch and recovery, does not shrink, and is suitable for sheers and for very stretchy knits. Polyester thread has similar characteristics, and is appropriate for various synthetic and preshrunk fabrics, and for knits made of synthetic yarns.

Measurement systems. Yarn measurements are expressed as yarn number, count, or size, and describe the relationship of length and weight (or approximate diameter). Because methods of measurement were developed in various areas of the world, there has been a lack of uniformity in such systems.

Indirect systems. Indirect measuring systems are those employing higher number to describe finer yarns, and are based on length per unit weight. Most countries measure yarns made from staple fibres according to the weight of a length of yarn. If one pound is used as a standard unit, for example, a very fine yarn will have to be much longer than a coarser yarn to weigh a pound, so higher counts indicate finer yarns. The size number is an indication of the length of yarn needed to reach a weight of one pound.

In the United States, the system is based on the number of hanks per pound, with a hank of 840 yards for cotton and spun silk, 300 yards (a lea) for linen, 256 yards for woollen yarns, and 560 yards for worsted yarns. A widely used continental system is based on the number of hanks of 1,000 metres (one kilometre) required to reach a weight of one kilogram.

Denier system. The denier system is a direct-management type, employed internationally to measure the size of silk and man-made filaments and yarns, and derived from an earlier system for measuring silk filaments (based on the weight in drams of 1,000 yards). Denier number indicates the weight in grams of 9,000 metres of filament or filament yarn. For example, if 9,000 metres of a yarn weigh 15 grams, it is a 15-denier yarn; if 9,000 metres of a yarn weigh 100 grams, it is a 100-denier yarn, and much coarser than the 15-denier yarn. Thus a smaller number indicates a finer yarn. This system is not convenient for measurement of staple yarns because their greater weight would require the use of very large numbers.

Tex system. The tex system, originally devised in 1873, is a universal method developed for the measurement of staple fibre yarns, and is also applicable to the measurement of filament yarns. It is based on the weight in grams of one kilometre (3,300 feet) of yarn. Although representatives of ten nations voted to adopt the system in 1956, tex was still not widely used in the early 1970s.

III. Production of fabric

Fabric construction involves the conversion of yarns, and sometimes fibres, into a fabric having characteristics determined by the materials and methods employed. Most fabrics are presently produced by some method of interlacing, such as weaving or knitting. Weaving, currently the major method of fabric production, includes the basic weaves, plain or tabby, twill, and satin, and the fancy weaves, including pile, Jacquard, dobby, and gauze. Knitted fabrics are rapidly increasing in importance and include weft types and the warp types, raschel and tricot. Other interlaced fabrics include net, lace, and braid. Nonwoven fabrics are gaining importance and include materials produced by felting and bonding. Laminating processes are also increasing in importance, and fairly recent developments include needle weaving and the sewing-knitting process.

WOVEN FABRICS

Woven fabrics are made of yarns interlaced in a regular order called a binding system, or weave. Weaving is the process of combining warp and weft components to make a woven structure. The components need neither be parallel to each other nor cross each other at right angles, but most woven structures are comprised of two sets of components, both flexible and crossing at right angles. Weaving is differentiated from warp and weft knitting, braiding, and net making in that these latter processes make use of only one set of elements. In addition, there are geometrical differences, one of the most significant being the small angles through which the components of a woven structure are, in general, bent, in contrast with the components of other structures.

Weaving is a widely used constructional method because it is cheap, basically simple, and adaptable. Woven fabrics have valuable characteristics resulting partly from the geometrical conformation of their components and partly from the fact that the components are held in position not by rigid bonding but by friction set up at the areas where they make contact. Woven fabrics are used in household, apparel, and industrial textiles.

Textile designers can produce a very large variety of cloths by their selection of yarns, finishing processes, and binding systems. Yarns vary in thickness, smoothness, fibre content, twist, and colour, all of which have a profound influence on the finished cloth. Finishing processes range from such simple treatment as brushing up the nap on a woven fabric to such a complicated chemical process as that employed to change opaque cotton fabric to transparent, permanently stiffened organdy.

The binding system, or weave, however, is the basic factor in determining the character of a woven fabric. The three basic systems are plain or tabby, twill, and satin. In complex binding systems, the basic weaves are combined or enriched by hand manipulation or mechanical loom attachments; these include multiple-plane, pile, inlaid, and gauze weaves. Regardless of the binding system, other devices—manipulation of warp spacing, beating in, or tension—can be used to alter the appearance of any weave, to make it looser or more compact, to make it more or less regular.

Weave drafts

As musical notation conveys a composer's ideas, so weave drafts or point paper plans communicate a textile designer's directions for constructing woven fabrics. The draft is a plan on graph paper showing at least one repeat or weave unit of the fabric to be woven. This information enables the weaver or mill specialist to plot the drawing in of the warp, tie up of harnesses to shedding mechanism, and shedding order.

The weaving process. Woven cloth is normally much longer in one direction than the other. The lengthwise threads are called the warp; the other threads, which are combined with the warp and lie widthwise, are called the weft (synonyms are "filling," "woof," and "shoot," or "shute"). An individual thread from the warp, of indefinite length, is called an end; each individual length of weft, extending from one edge of the cloth to the other, is called a pick, or shot. Consecutive picks are usually consecutive lengths of one piece of weft yarn that is repeatedly folded back on itself.

In all methods of weaving cloth (except the rudimentary form of darning), before a length of weft is inserted in the warp, the warp is separated, over a short length extending from the cloth already formed, into two sheets. The process is called shedding and the space between the sheets the shed (Figure 4A). A pick of weft is then laid between the two sheets of warp, in the operation known as picking (Figure 4B). A new shed is then formed in accordance with the desired weave structure, with some or all of the ends in each sheet moving over to the position previously occupied by the other sheet. In this way the weft is clasped between two layers of warp.

Shedding, picking, and beating in

Since it is not possible to lay the weft close to the junction of the warp and the cloth already woven, a further operation called beating in, or beating up (Figure 4C), is necessary to push the pick to the desired distance away

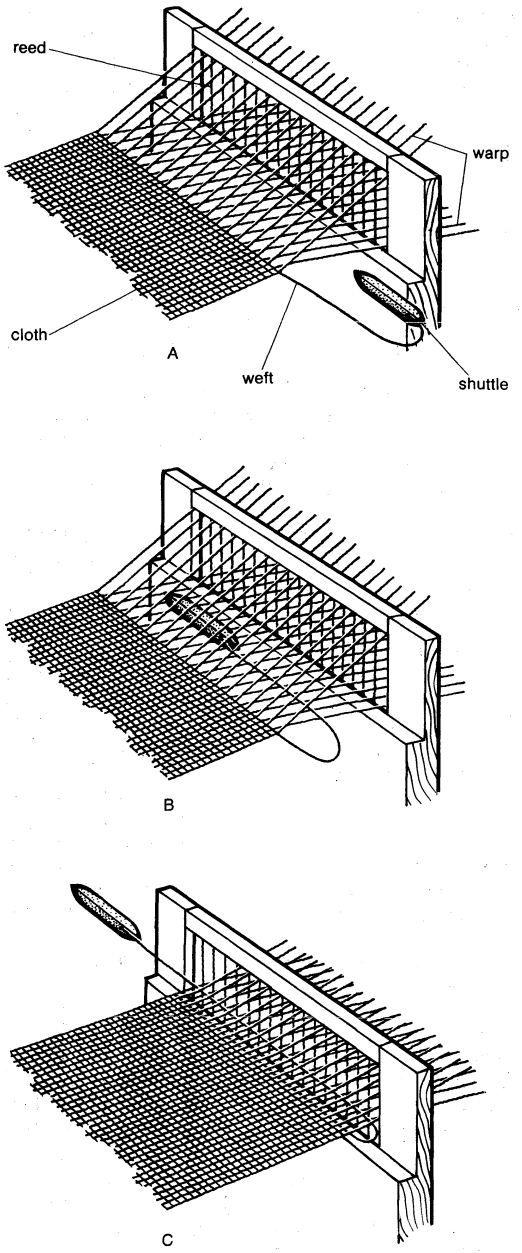

Figure 4: *The three basic motions of weaving:* (A) shedding, (B) picking, and (C) beating in.

from the last one inserted previously. Although beating in usually takes place while the shed is changing, it is normally completed before the new shed is fully formed.

The sequence of primary operations in one weaving cycle is thus shedding, picking, and beating in. At the end of the cycle the geometrical relation of the pick to the warp is the same as it would have been if the pick had been threaded through the spaces between alternate ends, first from one side of the cloth and then from the other, as in darning. This is the reason the weaving process is considered an interlacing method.

Development of the loom. The word loom (from Middle English *lome*, "tool") is applied to any set of devices permitting a warp to be tensioned and a shed to be formed. Looms exist in great variety, from the bundles of cords and rods of primitive peoples to enormous machines of steel and cast iron.

Except on certain experimental looms, the warp shed is formed with the aid of heddles (or healds). Usually one heddle is provided for each end, or multiple end, of warp thread, but on some primitive looms simple cloths are produced with heddles provided only for each alternate end. A heddle (Figure 5A) consists of a short length of cord, wire, or flat steel strip, supported (in its operative position) roughly perpendicular to the unseparated sheet of warp threads and provided, in modern looms, with an eyelet at its midpoint, through which the warp end is threaded. By pulling one end of the heddle or the other, the warp end can be deflected to one side or the other of the main sheet of ends. The frame holding the heddles is called a harness.

In most looms, the weft is supplied from a shuttle, (Figure 5B), a hollow projectile inside which a weft package is mounted in such a way that the weft can be freely unwound through an eyelet leading from the inside to the outside. The shuttle enters the shed and traverses the warp, leaving a trail of weft behind.

Beating in is generally effected by means of a grating of uniformly spaced fine parallel wires, originally made of natural reeds and thus called a reed (Figure 5C), which, mounted at right angles to the warp, oscillates between the heddles and the junction of the warp and the cloth. The ends pass, one or more at a time, through the spaces between consecutive reed wires, so that the reed, in addition to beating in, controls the spacing of the ends in the cloth.

Early looms. The earliest evidence of the use of the loom (4400 BC) is a representation of a horizontal two-bar (or two-beamed—*i.e.*, warp beam and cloth beam) loom pictured on a pottery dish found at al-Badārī, Egypt. The warp is stretched between two bars or beams, pegged to the ground at each of the four corners. Lease (or laze) rods are used to separate the warp yarns, forming a shed and aiding the hands in keeping the yarns separated and in order. Lease rods were found in some form on every later type of improved loom, and their use at this very early date indicates that the loom already had been in use long enough to have reached a stage of improvement by addition of devices to aid the hands.

Lease rods

Before lease rods were added, it would have been necessary for the fingers to separate each odd from each even warp thread to create the shed through which the weft yarn was passed. A third rod also seen in this early drawing may be a heddle rod. If so, this loom represents a still more advanced stage of development.

The heddle rod rests on top of the warps. To produce a plain weave, alternate warp yarns are tied to the rod, and when it is raised, the shed is formed quickly and accurately. Some authorities consider the heddle to be the most important step in the evolution of the loom. A shed stick is ordinarily used with the heddle, forming the second, or countershed, opening for the return of the weft.

In addition to the horizontal two-bar loom, there are two other primitive varieties, the warp-weighted and the vertical two-bar loom. The warp-weighted loom consists of a crossbar supported by two vertical posts. The warp threads hang from the crossbar and are held taut by weights of clay, ceramic, or chalk tied to their free ends. Loom weights have been found at archaeological sites

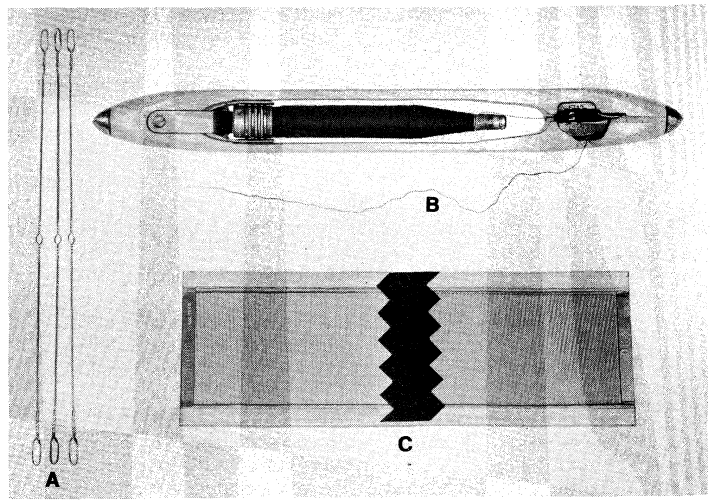

Figure 5: *Loom devices and their functions:* (A) heddles, used for shedding; (B) the shuttle, used for picking; (C) the reed, used for beating in (see text).

dating from 3000 BC, but this type of loom may have originated even earlier. The earliest picture of a vertical two-bar loom is from the Egyptian 18th dynasty (1567–1320 BC). It coincides with the appearance of more intricate textile patterns, the earliest known tapestries (datable between 1483 and 1411 BC) having been found in the tomb of Thutmose IV at Thebes. (Even today the vertical loom is preferred for tapestry weaving.) In the vertical two-bar loom the ends of the warp yarns are attached to a second crossbar, thus combining features of both the horizontal two-bar and the warp-weighted looms.

The heddle rods and shed sticks are used in a similar way on all three types.

Counterparts of these very early looms have been used through the ages in many cultures. The Navajo Indians, probably the best known of the American Indian weavers, have used the simple two-bar vertical loom for several centuries to produce their beautiful rugs and blankets. A form of the horizontal two-bar loom was the backstrap loom, in which one bar was tied to a tree or other stationary device, the second being attached to the weaver's waist by a strap. The weaver could control the tension of the warp yarns by applying pressure as necessary. The backstrap loom was used in pre-Columbian Peru, in other cultures of Central and South America, in Asia, and elsewhere.

Horizontal frame looms. By about 2500 BC a more advanced loom was apparently evolving in the Far East. Fragments of silk fabrics found adhering to bronzes of the Shang (or Yin) period (1766–1122 BC) in China, show traces of a twill damask pattern, suggesting an advanced weaving knowledge, since such fabrics could not practicably be woven on the looms described above. These fabrics were probably produced on a horizontal frame loom with treadles. The logical connecting link between the horizontal two-bar and the horizontal frame loom with treadles would have been a loom with a heddle rod that was controlled by one foot, for which no early illustrations have been found.

Early horizontal two-bar treadle looms

The earliest European pictorial record of the horizontal frame loom with a treadle dates from the 13th century, when it appears in a highly developed form, almost certainly introduced from the East. This two-bar loom was mounted in a frame; to this was connected a treadle operated by the feet, moving the heddles, an improvement of the heddle rod or cord controls now mounted between bars and called a shaft. The advantages of this type of loom were many. First, in the two-bar loom, though more than two heddle rods could be used, the number of groupings of warp threads was limited. Although highly complex patterns could be woven, it was not practical to do so in producing any but very small

quantities of cloth. The shaft loom allowed as many as 24 shafts to be set up easily, enabling the weaver to produce comparatively intricate patterns. Second, the weaver's sword or comb formerly used to beat the weft into place was replaced by the batten, supported in a heavy wooden frame from the main frame of the loom; its weight and free-swinging motion improved the beating-in action and made it easier. Third, use of the foot treadle freed both hands to throw the shuttle and swing the batten. The loom remained virtually unchanged for many centuries thereafter.

Drawlooms. The shaft loom was adequate for plain and for simply patterned fabrics, but a more complex loom was needed for the weaving of intricately figured fabrics, which might require 100 or more shafts. This kind of weaving was accomplished on the drawloom. Its origin is unknown, but it probably was first used in the Far East for silk weaving and was introduced into the silk-working centres of Italy during the Middle Ages. The drawloom had two devices for shedding: in addition to the shafts, which the weaver operated by treadles, cords were also used to raise the warp threads, gathered into groups as required by the pattern. The cords were worked by an operator (called a drawboy) seated on top of the loom.

The drawloom was improved in Italy and France in the early 17th century by the addition of a type of mechanical drawboy, allowing the assistant to stand on the floor at the side of the loom and increasing the control of the cords. The continued inconvenience of employing an assistant, however, who might also make errors, led to a search for an automatic mechanism that would perform all work of the drawboy. Most of the later developments in automatic mechanisms to control the shedding operation originated in France, which had become one of the leading countries in the weaving of figured silks.

The mechanical drawboy

In 1725 Basile Bouchon added to the mechanical drawboy a mechanism that selected the cords to be drawn to form the pattern. Selection was controlled by a roll of paper, perforated according to the pattern, which passed around a cylinder. The cylinder was pushed toward the selecting box and met with needles carrying the warp-controlling cords; the needles that met unperforated paper slid along, and the others passed through the holes and remained stationary. The selected cords were drawn down by a foot-operated treadle.

The mechanical drawboy made the proper selection of warp threads, eliminating errors, but still required an operator. The mechanism was improved in 1728 by increasing the number of needles and using a rectangular perforated card for each individual shedding motion, the cards being strung together in an endless chain. In 1745 Jacques de Vaucanson constructed a loom incorporating a number of improvements. He mounted the selecting box above the loom, where it acted directly on hooks fastened to the cords that controlled the warp yarns. The hooks passed through needles and were raised by a strong metal bar. The needles were selected by perforated cards passing around a sliding cylinder, without the aid of a second operator or assistant. The cylinder was very complex, and the mechanism is not known to have been adopted, but it served as the foundation for the successful Jacquard attachment.

The Jacquard attachment. The French inventor Joseph-Marie Jacquard, commissioned to overhaul Vaucanson's loom, did so without any of the directions, which were missing. In 1801, at the Paris Industrial Exhibition, he demonstrated an improved drawloom, and in 1805 he introduced the invention that ever since has caused the loom to which it is attached to be called the Jacquard loom.

The Jacquard attachment is an automatic, selective shedding device, mounted on top of the loom and operated by a treadle controlled by the weaver. As in the drawloom, every warp yarn runs through a loop in a controlling cord, held taut by a weight. Each cord is suspended from a wire ("hook") that is bent at the bottom to hold the cord and bent at the top in order to hook around the blades or bars of the griff, the lifting mechanism. To allow only those warp threads that are needed to form the pattern to be raised, some hooks must be dislodged from the rising griff. This is accomplished by horizontally placed needles connected to the hooks. As the perforated pattern card moves into place on the cylinder (which is, in fact, a quadrangular block), the needles pass through the holes in the card, and the warps are raised; where there are no holes, the needles are pushed back (by a spring action on the opposite end of each), pulling the hooks away from the rising griff bar, and the warps are not raised.

Each card represents one throw of the shuttle, and the pattern is transferred to the cards from the designer's weave draft. Although each Jacquard attachment is limited in the number of hooks it can control and, therefore, in the size of the repeat pattern, by adding several Jacquard attachments to one loom, the weaver not only can produce intricately figured fabrics but also can weave pictures of considerable size.

The flying shuttle. The first decisive step toward automation of the loom was the invention of the flying shuttle patented in 1733 by the Englishman John Kay. Kay was a weaver of broadloom fabrics, which because of their width required two weavers to sit side by side, one throwing the shuttle from the right to the centre, the other reaching between the warps and sending it on its way to the left and then returning it to the centre. The stopping of the shuttle and the reaching between the warps caused imperfections in the cloth. Kay devised a mechanical attachment controlled by a cord jerked by the weaver that sent the shuttle flying through the shed. Jerking the cord in the opposite direction sent the shuttle on its return trip. Using the flying shuttle, one weaver could weave fabrics of any width more quickly than two could before. A more important virtue of Kay's invention, however, lay in its adaptability to automatic weaving.

Power-driven looms. The first power-driven machine for weaving fabric-width goods, patented in 1785 by Edmund Cartwright, an English clergyman, was inadequate because it considered only three motions: shedding, picking, and winding the woven cloth onto the cloth beam. Cartwright's second patent (1786) proved too ambitious, but his concept of a weaving machine became the basis for the successful power loom.

Early difficulties of the power loom

One of the great obstacles to the success of the power loom was the necessity to stop the loom frequently in order to dress (*i.e.*, apply sizing to) the warp, an operation that, like many others, had been done in proportionately reasonable time when the weaving was done by hand. With the power loom a second man had to be employed continuously to do this work, so there was no saving of expense or time. In the early 19th century a dressing machine was developed that prepared the warp after it had been wound onto the warp beam and as it was passed to the cloth beam. Although later superseded by an improved sizing apparatus, this device made the power loom a practical tool.

Advances made by William Horrocks of Scotland between 1803 and 1813 included an improvement in the method of taking up the cloth (*i.e.*, winding the woven fabric onto the cloth beam) and making a more compact machine of iron, requiring little space as compared with wooden handlooms.

Francis Cabot Lowell, of Boston, experimented with the power loom, adding improvements to increase the weaving speed, and also improved the dressing machine.

A valuable improvement was that of the let-off and take-up motions, to maintain uniform warp tension automatically. The principle of holding at the beat (*i.e.*, not permitting the warp to be let off until the pick was beaten into place) first applied by Erastus Brigham Bigelow in the carpet loom, was successfully applied to all kinds of weaving. Another Bigelow invention, applicable to power looms in general, although first used on a carpet loom, was the friction-brake stop mechanism, allowing the loom to be stopped without a shock.

These developments were primarily concerned with the power loom used for weaving plain goods. William Crompton, an English machinist working in the machine

shop attached to a cotton factory in Massachusetts, undertook the development of a loom that could weave fancy goods, patented in both the U.S. and England in 1837. The loom was later much improved by his son George Crompton. Such 19th-century inventions made possible the production of textile goods for every use in great volume and variety, and at low cost.

Modern looms. Modern looms still weave by repeating in sequence the operations of shedding, picking, and beating in, but within that framework there has been considerable development during the 20th century. Several new types of loom have come into industrial use, whereas older types have been refined and their scope extended. Two main influences have been the rising cost of labour and the increasing use of man-made, continuous-filament yarns. The first has led to an increase in automatic control, in automatic handling of yarn packages, and in the use of larger packages; the second, to greater precision and finish in loom construction, because deficiency in these qualities is readily reflected in the quality of the cloth made from these yarns.

Modern looms can be grouped into two classes according to whether they produce cloth in plane or tubular form (see Figure 6). Looms of the first kind, comprising

From E. M. Pritchard, *A Short Dictionary of Weaving;* reproduced by permission of The Philosophical Library, Inc.

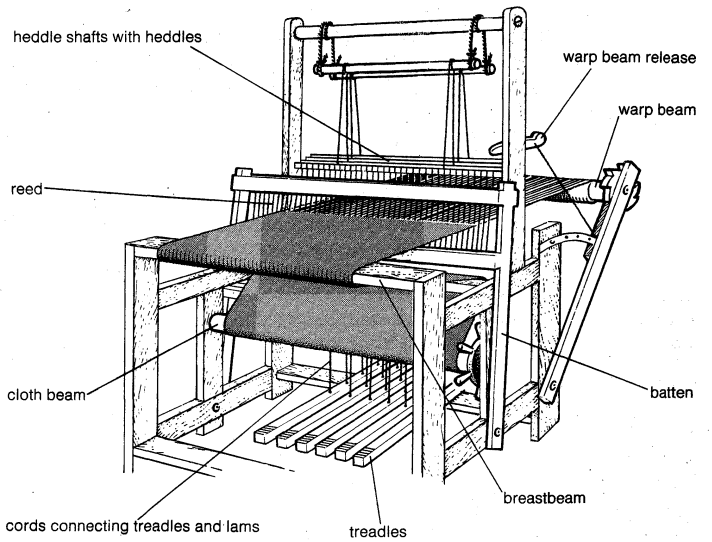

Figure 6: Principal parts of a modern handloom.

The two classes of modern looms

all but a few, are called flat looms; the others are described as circular. Since the majority are flat looms, the adjective is used only when a distinction has to be drawn. Flat looms fall into two categories: those that employ a shuttle and those that draw the weft from a stationary supply, usually called shuttleless looms. (This term is not entirely satisfactory, as some primitive looms make no use of a shuttle, merely passing through the shed a stick with weft wound on it.) Shuttle looms fall into two groups according to whether the shuttle is replenished by hand or automatically. The second kind is often described as an automatic loom, but, except for shuttle replenishment, it is no more automatic in its operation than the hand-replenished or so-called nonautomatic loom, which, like all modern looms, is power-operated by electric motor. With both types of loom the actual weaving operation is entirely automatic and is performed in exactly the same manner.

Hand replenished, or nonautomatic, looms are used only where particular circumstances—of yarns, fabrics, or use—make automatically replenished looms either technically unsuitable or uneconomic. Basically they differ little from the power looms of the latter half of the 19th century. They do not run appreciably faster but are better engineered, making use, for example, of machine-cut instead of cast gear wheels. Often there is no superstructure, which makes for cleanliness and improved illumination; frequently rigid heddle connectors are employed, leading to precise and stable setting of the shed; and usually the overpick mechanism has been replaced by the cleaner and safer underpick.

Automatically replenished flat, or automatic, looms are the most important class of modern loom, available for a very wide range of fabrics. In virtually all such looms, the shuttle is replenished by automatically replacing the exhausted bobbin with a full one. In principle they are thus the same as the automatic looms introduced at the end of the 19th century. Since that time, automatic shuttle-changing looms have also been introduced but have largely become obsolete, because bobbin-changing looms have been developed to a point where they can deal with most of the yarns for which it was once thought necessary to use shuttle-changing looms.

Apart from the general engineering refinements, automatic looms have advanced mainly in respect of the weft supply. Alternatives to the hand-replenished bobbin now exist in the form of the automatic bobbin loader, the loom being supplied with boxes of pirned (reeled) weft; and the automatic loom winder, the loom being fed with large cones of yarn, which is wound onto pirns at the loom. These alternatives are technically feasible and economic only with certain yarns. Therefore, all three types of weft supply continue to be used. An alternative to the rotary battery, when weft of more than one colour is used, is a series of vertical stacks.

The principle of shuttle replenishment is the same for all three systems. When the shuttle is stationary in the shuttle box, and the bar carrying the reed is farthest forward, a feeler enters the shuttle and senses whether the weft is on the point of exhaustion. Feelers may be mechanical or electrical, relying, respectively on the change in friction or the change in electrical resistance brought about by the absence of weft. Alternatively, with delicate wefts, an optical feeler may be used that depends for its action on the change in the amount of light reflected when the bare pirn is revealed.

When the feeler has sensed that the bobbin is nearly empty, mechanical or electrical signals are transmitted to the transfer mechanism that, when the shuttle is appropriately positioned and momentarily at rest, both as regards warp-way and weft-way motion, hammers a new bobbin into position, simultaneously ejecting the empty one through the open base of the shuttle. The loom continues to run at its normal speed throughout.

In the course of this operation, there are created unwanted lengths of weft extending from the nearer selvage. These, if not controlled and disposed of, may find their way into the cloth and appear as defects. Modern looms supplement the earlier mechanical methods by pneumatic suction, with the result that the most delicate fabrics can be woven on automatic bobbin-changing looms without any loss of quality. To make certain of removal of the remnant of weft on the old bobbin, extending to the eye of the shuttle, a cutter moves forward into the shuttle box and cuts the weft close to the eye just before the bobbin is ejected.

High speed, often combined with the use of large and heavy shuttles, means that these modern looms are noisier than ever. The noise level in a typical textile mill is above the level at which deafness occurs following prolonged exposure.

Types of shuttleless looms

Shuttleless looms are of three kinds, of which the first predominates: dummy shuttle, rapier, and fluid jet. The dummy-shuttle type, the most successful of the shuttleless looms, makes use of a dummy shuttle, a projectile that contains no weft but that passes through the shed in the manner of a shuttle and leaves a trail of yarn behind it.

The rapier type coveys a pick of weft from a stationary package through the shed by means of either a single rapier or a pair of rapiers. Rapiers are either rigid rods or flexible steel tapes, which are straight when in the shed but on withdrawal are wound onto a wheel, in order to save floor space. Rapier looms are, on the whole, simpler and more versatile than dummy-shuttle looms, but they have failed to achieve such high rates of weft insertion, the maximum being not more than 400 yards (365 metres) per minute. They differ in respect of the number

of rapiers employed and the type of selvage provided; some of them operate by gripping the free end of the weft and conveying that through the shed rather than by starting with a loop. Fluid-jet looms, most recently developed of the shuttleless types, are produced and used on a much smaller scale than the two other types described above. They are of two kinds, one employing a jet of air, the other a water jet, to propel a measured length of weft through the shed. The significance of this development is that for the first time nothing solid is passed into the shed other than the weft, which eliminates the difficulties normally associated with checking and warp protection, and reduces the noise to an acceptable level.

In addition to those looms that have established themselves industrially, there are looms still in the experimental stage. Loom development is always slow: some of the looms just gaining favour had their origins in inventions made 50 or even 100 years earlier. The most intense activity is in the field of shuttleless looms, because these offer the greatest prospect of achieving increased rates of weft insertion and of avoiding the drawbacks of noise, danger, vibration, high power consumption, and wear attendant on the use of a shuttle. The ultimate in direct projection is a method, still experimental, in which the weft is projected longitudinally at high speed and traverses the warp under its own momentum, nothing entering the shed but the pick of weft. The name inertial has been given to this method. Another experimental loom employs multiple rapiers for weft insertion and, in addition, eliminates the heddles and the reed.

Basic weaves. The basic weaves include plain (or tabby), twills, and satins (see Figure 7).

From Evelyn E. Stout, *Introduction to Textiles*, (© 1970); John Wiley & Sons, Inc.

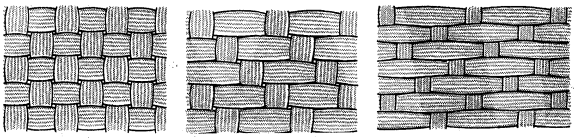

Figure 7: *Types of weaves:* (Left) plain, (centre) twill, (right) satin.

Plain weave. Plain, or tabby, weave, the simplest and most common of all weaves, requires only two harnesses and has two warp and weft yarns in each weave unit. To produce it, the warp yarns are held parallel under tension while a crosswise weft yarn is shot over and under alternate warps across the width of the web. The weave unit is completed at the end of the second row, when the weft has been inserted over and under the opposite set of warps, thus locking the previous weft in place. Fabric length is increased with the insertion of each succeeding weft yarn. When warp and weft yarns are approximately equal in size and quantity, the finished fabric is balanced and potentially stronger than cloth made of the same kind and number of warp and weft yarns in any other basic weave. Tabby woven with different-sized warp and weft yarns results in such fabrics as taffeta and poplin, in which many fine warps are interlaced with proportionately fewer thick weft yarns to form cloths with crosswise ridges or ribs.

The term extended tabby describes any weave in which two or more warps or wefts, or both, are interlaced as a unit. The group includes fabrics with basketry effects and fabrics with ribs formed by groups of warps or wefts in each shed.

Tapestry weave

Tapestry weave is a tabby in which a variety of coloured weft yarns is interlaced with the warp to form patterns. It is usually an unbalanced weave, with wefts completely covering a proportionately low number of warps. These cloths are sturdy and compact. Although they are flat and generally do not drape well, they have been used for centuries to make ceremonial and decorative dress and costumes.

Twill weave. Twill weave is distinguished by diagonal lines. The simplest twill is that created by the weft crossing over two warp yarns, then under one, the sequence being repeated in each succeeding shot (pick), but stepped over, one warp either to the left or right. Twills with more warps than wefts floating on the fabric's face are called warp faced; those with wefts predominating, weft faced. The angle of the twill can also vary.

Twills can be varied by changing the relative number of warps and wefts in each repeat (2:1, 2:3, 3:1, 6:2, etc.); by stepping the repeat in one direction; by breaking the direction of the diagonals formed by the twill at regular intervals; by reversing the direction of the diagonal at regular intervals to form chevrons or lozenges; or by combining several twills or modifying them to create a pattern.

Twills drape better than plain weaves with the same yarn count because twills have fewer interlacings. Twill weaves have been used throughout history in many weights and textures, from wool serges mentioned in medieval French manuscripts to English diapered (diamond patterned) table linens, patterned bed coverlets, and Indian shawls.

Satin weave. Although satin-weave drafts superficially resemble those of twills, satin weave does not have the regular step in each successive weft that is characteristic of twills. Thus, there is no strong diagonal line, and the fabric is smooth faced, with an unbroken surface made up of long floating warp yarns. A true satin must have at least five warp and weft yarns in each complete weave repeat and thus requires at least five harnesses. Most satin fabrics are made of smooth, lightly twisted yarns that heighten the effect of light unbroken by visible crosswise bindings. The limited number of interlacings allows the weaver to use a proportionately large number of warp yarns and thus produce a heavy textured cloth that can be arranged in smooth, shadowed folds. Satins, having long floats, are susceptible to the wear caused by rubbing and snagging and are, therefore, generally regarded as luxury fabrics.

Damask

Among the variations of satin weave are damask and sateen, a weft-faced satin. Damask is the most important variation of basic satin weave. Classic damask is a patterned, solid-coloured fabric with figures in warp-faced satin and background in weft-faced satin weave. The pattern is created by the difference in light reflection between the warp-faced and weft-faced areas. Silk damasks probably originated in China and came to Europe through Italy, the centre of European silk manufacture between the 13th and 17th centuries. During this period drawloom weavers from the Netherlands and Belgium also developed the art of linen damask weaving. Pictorial linen damasks, unlike most silk damasks of the time, often consisted of a single large repeat, picturing biblical scenes, contemporary events, or the arms of nobles and kings.

Complex weaves. Complex weaves include multiple plane, pile, inlaid, Jacquard, dobby, and gauze (or leno) weaves.

Multiple plain weave. Reversible double-woven cloth is produced by multiple plain weaving. It is woven in two layers, which may be completely independent, may be joined at one or both selvages, may be held together along the edges of a pattern, or may be united by a separate binding weft. Though often tabby weave is employed on both surfaces, any of the basic weaves may be used, depending on the intended use of the fabric.

Double-woven cloths have been used for clothing, but, though warm, they tend to be heavy and to drape poorly. They are most often used as bedcovers or wall hangings. German 18th-century *Beiderwand* is an example of antique double-woven cloth consisting of two layers of tabby weave joined only along the edges of the pattern. A dark-coloured pattern in one layer is set against the light-coloured ground of the other layer; the pattern is seen in negative or the reverse side of the cloth.

Nonreversible cloth with two or more sets of warp and sometimes of weft can also be produced. These cloths have an intricately patterned face, and all warps and wefts that do not appear on the face are carried along and bound into the web on the reverse side. This class includes important historic textiles, such as early Persian and Byzantine figured fabrics, as well as more recent Jacquard-woven imitation tapestries and a wide range of imitation brocaded fabrics.

Pile weave. Pile weaves have a ground fabric plus an extra set of yarns woven or tied into the ground and projecting from it as cut ends or loops. A great range of textures is included in this binding system, from terry pile towelling and corduroy to silk velvets and Oriental rugs.

In warp-pile fabrics the pile is formed by an extra set of warp yarns. To create such a fabric, first one set (sheet) of ground warps is raised, and the weft makes its first interlacing with the ground warp. Next, pile warps are raised, and a rod is inserted through the entire width of the web. The remaining ground warps are raised to form the third shed; then the ground weft is shot across again. This sequence is repeated several times; then the rods are slipped out, leaving a warp pile. To form cut-pile velvet, a knife on the end of the rod cuts the pile warps it passes, creating two fine rows of cut pile. Although the system has many technical variations, the same basic process can be applied to most warp-pile weaving.

If the pile is not cut when the rod is removed, a loop pile fabric results. In weaving terry pile fabrics, the ground warp is under tension, and the pile warp stays slack. When wefts are beaten in, the slack yarns are pushed into loops on both sides of the cloth.

To make velvets by double-cloth construction, two layers of cloth are woven simultaneously face-to-face, with long pile warp yarns connecting the two layers. After the cloth is woven, a knife slices the two layers apart.

Corduroy and velveteen are weft-pile constructions. Weft yarns having long floats are inserted between ground-weave picks. The floats are slit longitudinally after the fabric is completed, thus forming a ribbed surface of cut pile. In manufacture of velveteen the floats are formed over the whole surface of the fabric and cut evenly to imitate velvet.

Hand-knotted Oriental and Scandinavian rugs are constructed on a tabby-weave ground, with each row of knots followed by tightly beaten-in wefts. The pile of fine Oriental rugs may contain 160 knots per inch, thus completely obscuring the knots in the rug's foundation.

Inlaid weave. In all of the fabrics of this class, designs are created by inserting pattern warp or weft yarns between ground warps or wefts.

Brocaded fabric

Brocaded fabric has a pattern of coloured or metallic threads, or both, set in low relief against the ground weave. The ground weave can be any basic weave, since the brocaded pattern is merely inserted between ground wefts and is bound by ground warps. Until the advent of the Jacquard mechanism in the early 19th century, brocaded fabrics were woven by drawloom weavers who inserted the pattern wefts by hand. These weft yarns were wound on small brocading shuttles that travelled across the width of each pattern repeat, a separate shuttle being used for each colour in the repeat. Generally, these extra wefts were found only in the area in which the pattern was located and usually formed long floats on the reverse side of the fabric.

A mechanical process closely corresponding to hand brocading is called swivel, a system of figuring fabrics by using mechanically controlled pattern shuttles. The figures, inserted between ground-weft picks, interlace with the warp. The lappet system produces figured fabrics resembling those made by swivel figuring, but the pattern yarns are extra warps (rather than wefts) brought into play from separate warp beams. Lappet weaving is generally confined to coarse pattern yarns and can be distinguished from swivel by its interlacing with weft rather than with warp yarns.

Jacquard weave. The Jacquard weave, used to make allover figured fabrics such as brocades, tapestries, and damasks, is woven on a loom having a Jacquard attachment to control individual warps. Fabrics of this type are costly because of the time and skill involved in making the Jacquard cards, preparing the loom to produce a new pattern, and the slowness of the weaving operation. The Jacquard weave usually combines two or more basic weaves, with different weaves used for the design and the background.

Dobby weaves. Dobby weaves also produce allover figured fabrics. They are made on looms having a dobby attachment, with narrow strips of wood instead of Jacquard cards. Dobby weaves are limited to simple, small geometric figures, with the design repeated frequently, and are fairly inexpensive to produce.

Gauze or leno weave. Gauze weaving is an open weave made by twisting adjacent warps together. It is usually made by the leno or doup, weaving process, in which a doup attachment, a thin hairpin-like needle attached to two healds, is used, and the adjacent warp yarns cross each other between picks. Since the crossed warps firmly lock each weft in place, gauze weaves are often used for sheer fabrics made of smooth fine yarns. Although gauze weaving, with its multitude of variations, has been adapted to modern production, it is an ancient technique.

KNITTED FABRICS

Knitted fabrics are constructed by the interlocking of a series of loops made from one or more yarns, with each row of loops caught into the preceding row. Loops running lengthwise are called wales, those running crosswise courses. Hand knitting probably originated among the nomads of the Arabian Desert about 1000 BC and spread from Egypt to Spain, France, and Italy. Knitting guilds were established in Paris and Florence by the later Middle Ages. Austria and Germany produced heavily cabled and knotted fabrics, embroidered with brightly coloured patterns. In the Netherlands, naturalistic patterns were worked on fabric in reverse stocking stitch, and several Dutch knitters went to Denmark to teach Danish women the Dutch skills. The craft of hand knitting became less important with the invention of a frame knitting machine in 1589, although production of yarns for hand knitting remains an important branch of the textile industry.

The frame knitting machine allowed production of a complete row of loops at one time. The modern knitting industry, with its highly sophisticated machinery, has grown from this simple device.

Nomenclature of knitted fabrics

Knitted fabrics were formerly described in terms of the number of courses and wales per unit length and the weight of the fabric per unit area. This system is limited, however, and there is a shift to use of the dimensions and configuration of the single loop, the repeating unit determining such fabric characteristics as area, knitting quality, and weight. The length of yarn knitted into a loop or stitch is termed the stitch length, and in a plain knitted structure this is related to the courses per inch, wales per inch, and stitch density. The two basic equilibrium states for knitted fabrics are the dry-relaxed state, attained by allowing the fabric to relax freely in the air, and the wet-relaxed state, reached after static relaxation of the fabric in water followed by drying.

Knitting machines. The needle is the basic element of all knitting machines. The two main needle types are the "bearded" spring needle, invented about 1589, and the more common latch needle, invented in 1847.

The bearded needle, made from thin wire, has one end bent, forming an operating handle; the other end is drawn out and bent over, forming a long flexible tipped hook resembling a beard. A smooth groove, or eye, is cut in the stem or shank of the needle just behind the tip. In use this needle requires two other units, a sinker to form a loop and a presser to close the needle beard, allowing the loop to pass over the beard when a new stitch is formed. Bearded needles can be made from very fine wire and are used to produce fine fabrics.

The latch needle is composed of a curved hook, a latch, or tumbler, that swings on a rivet just below the hook, and the stem, or butt. It is sometimes called the self-acting needle because no presser is needed; the hook is closed by the pressure of a completed loop on the latch as it rises on the shaft. Needles differ greatly in thickness, in gauge, and in length, and appropriate types must be selected for specific purposes. A 4-gauge needle, for example, is used for heavy sweaters, but an 80-gauge needle is required for fine hosiery.

Weft knitting. The type of stitch used in weft knitting affects both the appearance and properties of the knitted fabric. The basic stitches are plain, or jersey (see Figure

8) rib; and purl. In the plain stitch, each loop is drawn through others to the same side of the fabric. In the rib stitch, loops of the same course are drawn to both sides of the fabric. The web is formed by two sets of needles, arranged opposite to each other and fed by the same thread, with each needle in one circle taking up a position between its counterparts in the other. In a 2:2 rib, two needles on one set alternate with two of the other. The interlock structure is a variant of the rib form in which two threads are alternately knitted by the opposite needles so that interlocking occurs. In the purl stitch, loops are drawn to opposite sides of the fabric, which, on both sides, has the appearance of the back of a plain stitch fabric. Jacquard mechanisms can be attached to knitting machines, so that individual needles can be controlled for each course or for every two, and complicated patterns can be knitted. To form a tuck stitch, a completed loop is not discharged from some of the needles in each course, and loops accumulating on these needles are later discharged together. The plaited stitch is made by feeding two threads into the same hook, so that one thread shows on the one side of the fabric and the other on the opposite side. A float stitch is produced by missing interlooping over a series of needles so that the thread floats over a few loops in each course.

Types of knitting machines

Knitting machines can be flat or circular. Flat machines have their needles mounted in a flat plate or needle bed or in two beds at right angles to each other and each at a 45° angle to the horizontal. The knitted fabric passes downward through the space between the upper edges of the plates, called the throat. In the knitting process, the needles are pushed up and down by cams attached to a carriage with a yarn guide, which moves over the length of the machine. The width of the fabric can be altered by increasing or decreasing the number of active needles, allowing production of shaped fabrics, which when sewn together make fully fashioned garments. Although flat-bed machines are suited for hand operation, they are power driven in commercial use, and, by selection of colour, type of stitch, cam design, and Jacquard device, almost unlimited variety is possible. The cotton frame, designed to knit fine, fully fashioned goods, shaped for improved fit of such items as hosiery and sweaters, is fitted with automatic narrowing and widening devices.

Circular machine needles are carried in grooves cut in the wall of a cylinder, which may be as small as one centimetre (0.4 inch) in diameter and as large as 1.5 metres (five feet). Some circular machines have two sets of needles, carried in concentric cylinders, so that the needles interlock. During the knitting operation the butts of the needles move through cam tracks, the needles sliding up and down to pick up yarn, form a new loop, and cast off the previously formed loop. In the least complicated of these machines, yarn is supplied from one package, each needle picking up the yarn once per revolution of the cylinder. Modern machines may have as many as 100 feeders, allowing each needle to pick up 100 threads per revolution. Both latch and spring needles are used, with the former more common. Modern, large, circular, plain or jersey machines having 90–100 feeders are frequently used to produce medium-weight fabric. Small bladelike units, or sinkers, are inserted between every two needles to engage and hold the completed fabric, preventing it from riding up with the needles as they are lifted to form new stitches. Machines may be fitted with pattern wheels controlling needle action to produce tuck and float stitches, and a Jacquard mechanism may also be attached. Stop motions are essential to stop the machine when a thread breaks. Because yarn tension affects fabric uniformity, various tension controllers have been devised. An alternative method, positive feed, feeding precisely measured amounts of yarn into the machine, is now considered more satisfactory.

Circular rib machines consist of a vertical cylinder, with needle slots on the outside, and a horizontal bed in the form of a circular plate or dial with needle slots cut radially, so that the two sets of needles are arranged at right angles to each other.

Seamless hosiery, knitted in tubular form, is produced by circular knitting machines. Modern hosiery machines, such as the Komet machine employ double-hooked needles directly opposite each other in the same plane to knit the leg and foot portions, the heel and the toe. The toe is later closed in a separate operation. In the Getaz toe, the seam is placed under the toes instead of on top of them.

Underwear fabrics are usually knitted on circular machines, and—except for fully fashioned underwear, tights, and leotards, which are knitted to pattern and sewn together—underwear making is a cut, make, and trim operation. Tights or panty hose are a combination of hosiery and underwear and can be fully fashioned. Seamless panty hose are made on circular hose machines modified to make very long stockings with open tops, two of which are cut open at opposite sides and seamed together front and back. The wearing quality and fit of modern panty hose have been greatly improved with the development of stretch nylon and spandex, and greater variety has been introduced with the development of texturized yarn.

Much hosiery is finished by washing, drying, and a boarding process in which the hosiery is drawn over a thin metal or wooden form of appropriate shape and pressed between two heated surfaces. The introduction of nylon fibre led to the development of a preboarding process, setting the loops and the fabric in the required shape before dyeing and finishing. The article, fitted on a form of appropriate shape, is placed in an autoclave or passed through a high-temperature setting unit. Fabric treated in this way does not distort during dyeing.

Circular knitting machines can be adapted to make simulated furs. One type intermeshes plush loops with the plain-stitch base fabric then cuts the loops, producing a pile. A more common method forms the pile with a carded sliver. A plain-stitch fabric is used as the base and loose fibres from a sliver, fed from a brushing or carding device, are inserted by a V-shaped claw, forming the pile. Pile depth is determined by the length of the fibres in the sliver.

One of the most sophisticated knitting machines incorporates electronic selection of sinkers in a Jacquard circular knitting machine.

Warp knitting. The two types of warp knitting are raschel, made with latch needles, and tricot, using bearded needles.

Raschel. Coarser yarns are generally used for raschel knitting, and there has recently been interest in knitting staple yarns on these machines. In the Raschel machine, the needles move in a ground steel plate, called the trick plate. The top of this plate, the verge, defines the level of the completed loops on the needle shank. The loops are prevented from moving upward when the needle rises by the downward pull of the fabric and the sinkers between the needles. Guide bars feed the yarn to the needles. In a knitting cycle, the needles start at the lowest point, when the preceding loop has just been cast off, and the new loop joins the needle hook to the fabric. The needles rise, while the new loop opens the latches and ends up on the shank below the latch. The guide bars then swing through the needles, and the front bar moves one needle space sideways. When the guide bar swings back to the front of the machine, the front bar has laid the thread on the

hooks. The needles fall, the earlier loops close the latch to trap the new loops, and the old loops are cast off. Raschels, made in a variety of forms, are usually more open in construction and coarser in texture than are other warp knits.

Tricot. Tricot, a warp knit made with two sets of threads, is characterized by fine ribs running vertically on the fabric face and horizontally on its back. The tricot knitting machine makes light fabrics, weighing less than four ounces per square yard. Its development was stimulated by the invention of the so-called FNF compound needle, a sturdy device that later fell into disuse but that made possible improved production speeds. Although approximately half of the tricot machines in current use make plain fabrics on two guide bars, there is increasing interest in pattern knitting. In this type of knitting, the warp-knitting cycle requires close control on the lateral bar motion, achieved by control chains made of chunky metal links.

Special effects in warp knits. The scope of warp knitting has been extended by the development of procedures for laying in nonknitted threads for colour, density, and texture effects (or inlaying), although such threads may also be an essential part of the structure. For example, in the form called "zigzagging across several pillars," the ground of most raschel fabrics, the front bar makes crochet chains, or "pillars," which are connected by zigzag inlays.

An extension of conventional warp knitting is the Co-We-Nit warp-knitting machine, producing fabrics with the properties of both woven and knitted fabrics. The machines need have only two warp-forming warps and provision for up to eight interlooped warp threads between each chain of loops. These warp threads are interlaced with a quasiweft, forming a fabric resembling woven cloth on one side.

OTHER INTERLACED FABRICS

Net and lace making. The popularity of handmade laces led to the invention of lace-making machines. The early models required intricate engineering mechanisms, and the development of the modern lace industry originated when a machine was designed to produce laces identical with Brussels lace. In the Heathcot, or bobbinet, machine, warp threads were arranged so that the threads moved downward as the beams unwound. Other threads were wound on thin, flat spools or bobbins held in narrow carriages that could move in a groove or comb in two rows. The carriages carrying the bobbins were placed on one side of the vertical warp threads and given a pendulum-like motion, causing them to pass between the warp threads. The warp threads were then moved sideways, so that on the return swing each bobbin thread passed around one of them. Then the warp threads moved sideways in the opposite direction, thus completing a wrapping movement. In addition, each row of bobbins was moved by a rack-and-pinion gearing, one row to the left and one to the right. As these movements continued, the threads were laid diagonally across the fabric as the warp was delivered. Improvements on the Heathcot machine followed through the 19th century: Nottingham-lace machines, used primarily for coarse-lace production, employ larger bobbins, and the pattern threads are wound independently on section spools; in another type, the Barmens machine, threads on king bobbins on carriers are plaited together, sometimes with warp threads.

Early machine-made laces

Schiffli lace, a type of embroidery, is made by modern machines, evolved from a hand version, using needles with points at each end. Several hundred needles are placed horizontally, often in two rows, one above the other. The fabric to be embroidered is held vertically in a frame extending the full width of the machine, and the needles, supplied with yarn from individual spools, move backward and forward through the fabric. At each penetration a shuttle moves upward and interlaces yarn with the needle loop. Movement of both fabric and needles is controlled by Jacquard systems.

Many types of machine-made laces are made, frequently with geometrically shaped nets forming their backgrounds. Formerly made only of cotton, they are now frequently made from man-made fibre yarns. Bobbinet lace, essentially a hexagonal net, is used as a base for applique work for durable non-run net hosiery, and, when heavily sized, for such materials as millinery and veilings. Barmens lace has a fairly heavy texture and an angular pattern; flowing lines, heavy outline cords, and fine net backgrounds are not usually made on Barmens machines. The introduction of light-resistant polyester yarns led to a revival of Nottingham machine-made curtains. Leavers lace is available in an infinite variety of patterns, since the manufacturing technique allows use of almost any type of yarn. The high strength and comparatively low cost of man-made fibre yarns has made sheer laces widely available.

Net, an open fabric having geometrically shaped, open meshes, is produced with meshes ranging from fine to large. Formerly made by hand, the various types are now made on knitting machines. Popular types include bobbinet, made with hexagonal-shaped mesh and used for formal gowns, veils, and curtains, and tulle, a closely constructed, fine net having similar uses. Fishnet, a course type with knots in four corners forming the mesh formerly made by fishermen, is now a popular machine-made curtain fabric.

Braiding or plaiting. Braid is made by interlacing three or more yarns or fabric strips forming a flat or tubular narrow fabric. It is used as trimming and for belts and is also sewn together to make hats and braided rugs. Plaiting, usually used synonymously with braiding, may be used in a more limited sense, applying only to a braid made from such materials as rope and straw.

NONINTERLACED FABRICS

With the exception of felt, nonwoven materials are in the early stages of development. There is controversy about the precise meaning of the term nonwoven, but one authority defines nonwoven fabrics as textile fabrics made of a fibrous layer having randomly laid or oriented fibres or threads.

Felt. Felts are a class of fabrics or fibrous structures obtained through the interlocking of wool, fur, or some hair fibres under conditions of heat, moisture, and pressure. Other fibres will not felt alone but can be mixed with wool, which acts as a carrier. Three separate industries manufacture goods through the use of these properties. The goods produced are wool felt, in rolls and sheets; hats, both fur and wool; and woven felts, ranging from thin billiard tablecloths to heavy industrial fabrics used for dewatering in the manufacture of paper. Felts of the nonwoven class are considered to be the first textile goods produced, and many references may be found to felts and their uses in the histories of ancient civilizations. The nomadic tribes of north central Asia still produce felts for clothing and shelter, utilizing the primitive methods handed down from antiquity.

Bonding. Several methods for making nonwoven materials are now firmly established, and others are being developed.

In adhesive bonding, fabrics are made by forming a web of fibres, applying an adhesive, then drying and curing the adhesive. The web can be produced by a garnetting machine or a conventional card, several layers being piled up to obtain the required thickness. Such webs are weak across the width, but this does not limit their use for certain end products. A more uniform product results from cross laying the web. Other machines, such as the Rando-Webber, lay down the fibres by an airstream.

Adhesive and mechanical bonding

The fibres in the web may be stuck together in various ways. The web may be sprayed with an emulsion of an adhesive—*e.g.*, a latex based on synthetic rubber, acrylic derivatives, or natural rubber—or, alternatively, may be carried on a mesh screen through a bath of latex, the excess being squeezed out by a pair of rollers. Adhesives may also be applied as a foam or a fine powder. Thermoplastic fibres can be incorporated in the blend and on heating will bond together, giving strength to the mass of fibres.

Mechanically bonded nonwoven products (or fibre-

bonded nonwovens) are webs strengthened by mechanical means. The web, sometimes reinforced by a thin cotton scrim in the middle or by texturized yarns distributed lengthwise through it, is punched by barbed needles mounted in a needle board. The fibres in the web are caught up by the needle barbs, and the resulting increased entanglement yields a compact product sufficiently strong for many purposes. Modern needle-felting or punching machines perform 900 punches per minute, and selection of appropriate needles is based on the fibre being processed and the desired product.

Stitch bonding

The Arachne machine, the best known unit for stitch bonding, operates much like a warp-knitting machine. Fibrous web is fed into the machine, and stitches are made by a series of needles placed about eight millimetres apart, giving the web longitudinal strength; lateral strength is provided by the fibre interactions. The products are attractive for many purposes and can be improved by treatment with polyester resins to increase their wear resistance and with thermosetting precondensates to reduce their tendency to pill (*e.g.*, to form small tangles). A new device attached to the Arachne machine permits introduction of weft ends at every single course, making colour effects possible. Araloop machines yield loop-pile fabric suitable for towels and floor coverings.

Three sewing-knitting machines were invented in East Germany in 1958. In the Malino machine process, warp yarns are placed on top of filling yarns and stitched together by a third yarn. The Maliwatt machine interlaces a web of fibres with a sewing thread, giving the effect of parallel seams. The Malipol machine produces a one-sided pile fabric by stitching loop pile through a backing fabric. A new British process makes double-sided terry fabric, called Terrytuft, by inserting pile yarn into a backing and knotting it into position.

Webs made of yarns having a core of one polymer and an outer sheath of another material having a lower softening point, may be lightly pressed and then heated to an appropriate temperature. The core yarn will "spot weld" together at the junction points, binding the mass of fibres together. Products made in this way find uses as industrial fabrics, coatings, and interlinings.

Laminating. The joining of one fabric to another by an adhesive such as natural rubber has long been practised in rainwear manufacture. Composite materials were later joined by bonding a layer of polyurethane or other foam to a conventional textile fabric. The two components were stuck together by flame bonding or by an adhesive in the form of a continuous coating, in spots, or as a powder. This laminating process has been extended to the joining of two layers of fabric. Each fabric layer can be quite thin, and the amount and type of adhesive are chosen to add only minimum stiffening. Such materials offer a variety of applications. A coating fabric, for example, may be joined to a lining; dimensionally stable composites can be made from cloth layers that are in themselves dimensionally unstable. Acetate knitted fabrics are frequently used as backing material in laminates.

IV. Textile finishing processes

BASIC METHODS AND PROCESSES

The term finishing includes all the mechanical and chemical processes employed commercially to improve the acceptability of the product, except those procedures directly concerned with colouring. The objective of the various finishing processes is to make fabric from the loom or knitting frame more acceptable to the consumer. Finishing processes include preparatory treatments used before additional treatment, such as bleaching prior to dyeing; treatments, such as glazing, to enhance appearance; sizing, affecting touch; and treatments adding properties to enhance performance, such as preshrinking. Newly formed cloth is generally dirty, harsh, and unattractive, requiring considerable skill for conversion into a desirable product. Before treatment, the unfinished fabrics are referred to as gray goods, or sometimes, in the case of silks, as greige goods.

Finishing formerly involved a limited number of comparatively simple operations evolved over the years from hand methods. The skill of English and Scottish finishers was widely recognized, and much British cloth owed its high reputation to the expertise of the finisher. More sophisticated modern finishing methods have been achieved through intense and imaginative research.

Preparatory treatments. It is frequently necessary to carry out some preparatory treatment before the application of other finishing processes to the newly constructed fabric. Any remaining impurities must be removed, and additives used to facilitate the manufacturing process must also be removed. Bleaching may be required to increase whiteness or to prepare for colour application. Some of the most frequently used preparatory processes are discussed below.

Burling and mending. Newly made goods, which frequently show imperfections, are carefully inspected, and defects are usually repaired by hand operations. The first inspection of woollen and worsted fabrics is called perching. Burling, mainly applied to woollen, worsted, spun rayon, and cotton fabrics, is the process of removing any remaining foreign matter, such as burrs and, also, any loose threads, knots, and undesired slubs. Mending, frequently necessary for woollens and worsteds, eliminates such defects as holes or tears, broken yarns, and missed warp or weft yarns.

Scouring. When applied to gray goods, scouring removes substances that have adhered to the fibres during production of the yarn or fabric, such as dirt, oils, and any sizing or lint applied to warp yarns to facilitate weaving.

Bleaching. Bleaching, a process of whitening fabric by removal of natural colour, such as the tan of linen, is usually carried out by means of chemicals selected according to the chemical composition of the fibre. Chemical bleaching is usually accomplished by oxidation, destroying colour by the application of oxygen, or by reduction, removing colour by hydrogenation. Cotton and other cellulosic fibres are usually treated with heated alkaline hydrogen peroxide; wool and other animal fibres are subjected to such acidic reducing agents as gaseous sulfur dioxide or to such mildly alkaline oxidizing agents as hydrogen peroxide. Synthetic fibres, when they require bleaching, may be treated with either oxidizing or reducing agents, depending upon their chemical composition. Cottons are frequently scoured and bleached by a continuous system.

Mercerization. Mercerization is a process applied to cotton and sometimes to cotton blends to increase lustre (thus also enhancing appearance), to improve strength, and to improve their affinity for dyes. The process, which may be applied at the yarn or fabric stage, involves immersion under tension in a caustic soda (sodium hydroxide) solution, which is later neutralized in acid. The treatment produces permanent swelling of the fibre.

Drying. Water, used in various phases of textile processing, accumulates in fabrics, and the excess moisture must eventually be removed. Because evaporative heating is costly, the first stage of drying uses mechanical methods to remove as much moisture as possible. Such methods include the use of centrifuges and a continuous method employing vacuum suction rolls. Any remaining moisture is then removed by evaporation in heated dryers. Various types of dryers operate by conveying the relaxed fabric through the chamber while festooned in loops, using a frame to hold the selvages taut while the fabric travels through the chamber, and passing the fabric over a series of hot cylinders. Because overdrying may produce a harsh hand, temperature, humidity, and drying time require careful control.

Finishes enhancing appearance. Treatments enhancing appearance include such processes as napping and shearing, brushing, singeing, beetling, decating, tentering, calendering or pressing, moiréing, embossing, creping, glazing, polishing, and optical brightening.

Napping and shearing. Napping is a process that may be applied to woollens, cottons, spun silks, and spun rayons, including both woven and knitted types, to raise a velvety, soft surface. The process involves passing the fabric over revolving cylinders covered with fine wires that lift the short, loose fibres, usually from the weft

yarns, to the surface, forming a nap. The process, which increases warmth, is frequently applied to woollens and worsteds and also to blankets.

Shearing cuts the raised nap to a uniform height and is used for the same purpose on pile fabrics. Shearing machines operate much like rotary lawn mowers, and the amount of shearing depends upon the desired height of the nap or pile, with such fabrics as gabardine receiving very close shearing. Shearing may also be applied to create stripes and other patterns by varying surface height.

Brushing. This process, applied to a wide variety of fabrics, is usually accomplished by bristle-covered rollers. The process is used to remove loose threads and short fibre ends from smooth-surfaced fabrics and is also used to raise a nap on knits and woven fabrics. Brushing is frequently applied to fabrics after shearing, removing the cut fibres that have fallen into the nap.

Singeing. Also called gassing, singeing is a process applied to both yarns and fabrics to produce an even surface by burning off projecting fibres, yarn ends, and fuzz. This is accomplished by passing the fibre or yarn over a gas flame or heated copper plates at a speed sufficient to burn away the protruding material without scorching or burning the yarn or fabric. Singeing is usually followed by passing the treated material over a wet surface to assure that any smoldering is halted.

Beetling. Beetling is a process applied to linen fabrics and to cotton fabrics made to resemble linen to produce a hard, flat surface with high lustre and also to make texture less porous. In this process, the fabric, dampened and wound around an iron cylinder, is passed through a machine in which it is pounded with heavy wooden mallets.

Decating. Decating is a process applied to woollens and worsteds, man-made and blended fibre fabrics, and various types of knits. It involves the application of heat and pressure to set or develop lustre and softer hand and to even the set and grain of certain fabrics. When applied to double knits it imparts crisp hand and reduces shrinkage. In wet decating, which gives a subtle lustre, or bloom, fabric under tension is steamed by passing it over perforated cylinders.

Tentering, crabbing, and heat-setting. These are final processes applied to set the warp and weft of woven fabrics at right angles to each other, and to stretch and set the fabric to its final dimensions. Tentering stretches width under tension by the use of a tenter frame, consisting of chains fitted with pins or clips to hold the selvages of the fabric, and travelling on tracks. As the fabric passes through the heated chamber, creases and wrinkles are removed, the weave is straightened, and the fabric is dried to its final size. When the process is applied to wet wools it is called crabbing; when applied to synthetic fibres it is sometimes called heat-setting, a term also applied to the permanent setting of pleats, creases, and special surface effects.

Calendering. Calendering is a final process in which heat and pressure are applied to a fabric by passing it between heated rollers, imparting a flat, glossy, smooth surface. Lustre increases when the degree of heat and pressure is increased. Calendering is applied to fabrics in which a smooth, flat surface is desirable, such as most cottons, many linens and silks, and various man-made fabrics. In such fabrics as velveteen, flat surface is not desirable, and the cloth is steamed while in tension, without pressing. When applied to wool, the process is called pressing, and employs heavy, heated metal plates to steam and press the fabric. Calendering is not usually a permanent process.

Moiréing, embossing, glazing and ciréing, and polishing. These are all variations of the calendering process. Moiré is a wavy or "watered" effect imparted by engraved rollers that press the design into the fabric. The process, applied to cotton, acetate, rayon, and some ribbed synthetic fabrics, is only permanent for acetates and resin-treated rayons. Embossing imparts a raised design that stands out from the background and is achieved by passing the fabric through heated rollers engraved with a design. Although embossing was formerly temporary, processes have now been developed to make this effect permanent.

Glazing imparts a smooth, stiff, highly polished surface to such fabrics as chintz. It is achieved by applying such stiffeners as starch, glue, shellac, or resin to the fabric and then passing it through smooth, hot rollers that generate friction. Resins are now widely employed to impart permanent glaze. Ciré (from the French word for waxed) is a similar process applied to rayons and silks by the application of wax followed by hot calendering, producing a high, metallic gloss. Ciré finishes can be achieved without a sizing substance in acetates, which are thermoplastic (*e.g.*, can be softened by heat), by the application of heat.

Polishing, used to impart sheen to cottons without making them as stiff as glazed types, is usually achieved by mercerizing the fabric and then passing it through friction rollers.

Creping. A crepe effect may be achieved by finishing. In one method, which is not permanent, the cloth is passed, in the presence of steam, between hot rollers filled with indentations producing waved and puckered areas. In the more permanent caustic soda method, a caustic soda paste is rolled onto the fabric in a patterned form; or a resist paste may be applied to areas to remain unpuckered and the entire fabric then immersed in caustic soda. The treated areas shrink, and the untreated areas pucker. If the pattern is applied in the form of stripes, the effect is called plissé; an allover design produces blister crepe.

Optical brightening. Optical brightening, or optical bleaches, are finishes giving the effect of great whiteness and brightness because of the way in which they reflect light. These compounds contain fluorescent colourless dyes, causing more blue light to be reflected. Changes in colour may occur as the fluorescent material loses energy, but new optical whiteners can be applied during the laundering process.

Finishes enhancing tactile qualities. Finishes enhancing the feel and drape of fabrics involve the addition of sizing, weighting, fulling, and softening agents, which may be either temporary or permanent.

Sizing. Sizing, or dressing, agents are compounds that form a film around the yarn or individual fibres, increasing weight, crispness, and lustre. Sizing substances, including starches, gelatin, glue, casein, and clay, are frequently applied to cottons and are not permanent.

Weighting. Weighting, in the processing of silk, involves the application of metallic salts to add body and weight. The process is not permanent but can be repeated.

Fulling. Also called felting or milling, fulling is a process that increases the thickness and compactness of wool by subjecting it to moisture, heat, friction, and pressure until shrinkage of 10 to 25 percent is achieved. Shrinkage occurs in both the warp and weft, producing a smooth, tightly finished fabric that may be so compact that it resembles felt.

Softening. Making fabrics softer and sometimes also increasing absorbency involves the addition of such agents as dextrin, glycerin, sulfonated oils, sulfated tallow, and sulfated alcohol.

Finishes improving performance. The performance of fabrics in use has been greatly improved by the development of processes to control shrinkage, new resin finishes, and new heat-sensitive synthetic fibres.

Shrinkage control. Shrinkage control processes are applied by compressive shrinkage, resin treatment, or heat-setting. Compressive, or relaxation, shrinkage is applied to cotton and to certain cotton blends to reduce the stretching they experience during weaving and other processing. The fabric is dampened and dried in a relaxed state, eliminating tensions and distortions. The number of warp and weft yarns per square inch is increased, contributing greater durability, and fabrics treated by this method are usually smooth and have soft lustre. The process involves spraying the fabric with water, then pressing the fabric against a steam heated cylinder covered with a thick blanket of woollen felt or rubber. The manufacturer is often required to specify the residual shrinkage, or percentage of shrinkage, that may still occur after the preshrinking process.

Residual shrinkage

Rayons and rayon blends may be stabilized by the use of resins, which impregnate the fibre. Such fabrics may also be stabilized by employing acetals to produce cross-linking, a chemical reaction. Such synthetics as polyesters and nylons, which are heat sensitive, are usually permanently stabilized by heat-setting during finishing.

Shrinkage of wools is frequently controlled by treatment with chlorine, partially destroying the scales that occur on wool fibres, thus increasing resistance to the natural tendency of wool to felt. Other methods employ coating with resins or with enzymes that attach to the scales in order to discourage felting shrinkage.

Durable press. Durable press fabrics have such characteristics as shape retention, permanent pleating and creasing, permanently smooth seams, and the ability to shed wrinkles, and thus retain a fresh appearance without ironing. Such fabrics may be safely washed and dried by machine. These useful characteristics are imparted by a curing process. Depending upon composition and desired results, fabrics may be precured, a process in which a chemical resin is added, the fabric is dried and cured (baked), and heat is applied by pressing after garment construction; or fabrics may be postcured, a process in which resin is added, the fabric is dried, made into a garment, pressed, and then cured.

Wash and wear fabrics

Wash and wear was an early durable press process employing chemical treatment and curing of fabrics; at least light ironing was required to restore appearance. Later, however, processes were developed that allowed such fabrics to regain smoothness after home machine washing at moderate temperature, followed by tumble drying.

Crease resistance. Crease, or wrinkle, resistance is frequently achieved by application of a synthetic resin, such as melamine or epoxy.

Soil release. Soil release finishes facilitate removal of waterborne and oil stains from fabrics such as polyester and cotton blends and fabrics treated for durable press, which usually show some resistance to stain removal by normal cleaning processes. Other finishes have been developed that give fabrics resistance to water and oil stains.

Antistatic finishes. The accumulation of static electricity in such synthetic fibres as nylon, polyesters, and acrylics produces clinging, which may be reduced by application of permanent antistatic agents during processing. Consumers can partially reduce static electricity by adding commercial fabric softeners during laundering.

Antibacterial and antifungus finishes. Antibacterial finishes are germicides applied to fabrics to prevent odours produced by bacterial decomposition, such as perspiration odours, and also to reduce the possibility of infection by contact with contaminated textiles. Fabrics may also be treated with germicides to prevent mildew, a parasitic fungus that may grow on fabrics that are not thoroughly dried. Both mildew and rot, another form of decay, may also be controlled by treatment with resins.

Moth-repellent treatments. Wool and silk are subject to attack by moths but may be made moth repellent by the application of appropriate chemicals either added in the dye bath or applied to the finished fabric.

Waterproofing and water-repellence. Waterproofing is a process applied to such items as raincoats and umbrellas, closing the pores of the fabric by application of such substances as insoluble metallic compounds, paraffin, bituminous materials, and drying oils. Water-repellent finishes are surface finishes imparting some degree of resistance to water but are more comfortable to wear because the fabric pores remain open. Such finishes include wax and resin mixtures, aluminum salts, silicones, and fluorochemicals.

Flameproof, fireproof, and fire-resistant finishes. Flameproof fabrics are able to withstand exposure to flame or high temperature. This is achieved by application of various finishes, depending upon the fabric treated, that cause burning to stop as soon as the source of heat is removed. Fireproofing is achieved by the application of a finish that will cut off the oxygen supply around the flame. Fire-resistant finishes cause fabrics to resist the spread of flame.

DYEING AND PRINTING

Dyeing and printing are processes employed in the conversion of raw textile fibres into finished goods that add much to the appearance of textile fabrics.

Dyeing. Most forms of textile materials can be dyed at almost any stage. Quality woollen goods are frequently dyed in the form of loose fibre, but top dyeing or cheese dyeing is favoured in treating worsteds. Manufacturers prefer piece dyeing, which allows stocking of white goods, reducing the risk of being overstocked with cloth dyed in colours that have not been ordered.

The dye used depends on the type of material and the specific requirements to be met. For some purposes, high lightfastness is essential; but for others it may be inconsequential. Factors considered in dye selection include fastness to light, reaction to washing and rubbing (crooking), and the cost of the dyeing process. Effective preparation of the material for dyeing is essential.

Types of dyes

Basic dyes include acid dyes, used mainly for dyeing wool, silk, and nylon; and direct or substantive dyes, which have a strong affinity for cellulose fibres. Mordant dyes require the addition of chemical substances, such as salts, to give them an affinity for the material being dyed. They are applied to cellulosic fibres, wool, or silk after such materials have been treated with metal salts. Sulfur dyes, used to dye cellulose, are inexpensive, but produce colours lacking brilliance. Azoic dyes are insoluble pigments formed within the fibre by padding, first with a soluble coupling compound and then with a diazotized base. Vat dyes, insoluble in water, are converted into soluble colourless compounds by means of alkaline sodium hydrosulfite. Cellulose absorbs these colourless compounds, which are subsequently oxidized to an insoluble pigment. Such dyes are colourfast. Disperse dyes are suspensions of finely divided insoluble, organic pigments used to dye such hydrophobic fibres as polyesters, nylon, and cellulose acetates.

Reactive dyes combine directly with the fibre, resulting in excellent colourfastness. The first ranges of reactive dyes for cellulose fibres were introduced in the mid 1950s. A wide variety is now available (see also DYES AND DYEING).

Printing. Printing is a process of decorating textile fabrics by application of pigments, dyes, or other related materials in the form of patterns. Although apparently developed from the hand painting of fabrics, such methods are also of great antiquity. There is evidence of printing being carried out in India during the 4th century BC, and a printing block dated at about AD 300 has been unearthed in the burial grounds of Akhmin in Upper Egypt. Pre-Columbian printed textiles have been found in Peru and Mexico. Textile printing has become highly sophisticated and has involved the skills of many artists and designers.

Principal methods of textile printing

The four main methods of textile printing are block, roller, screen, and sublistatic printing. In each of these methods, the application of the colour, usually as a thickened paste, is followed by fixation, usually by steaming or heating, and then removal of excess colour by washing. Printing styles are classified as direct, discharge, or resist. In direct printing, coloured pastes are printed directly on the cloth. For discharge printing, the cloth is first dyed with a background colour, which is destroyed by reagents, or reducing agents, carried in a print paste. This action may leave the discharged design white on a coloured background, although print pastes may also contain colouring matters not destroyed by the discharging agent, producing a coloured design. In the resist process, the cloth is first printed with a substance called a resist, protecting these printed areas from accepting colour. When the cloth is dyed or pigment padded only those parts not printed with the resist are dyed. A special application of this technique, imparting plissé effects, is the printing of the fabric with a resist, followed by treatment with caustic soda.

Block printing. Wooden blocks, carved with a design standing out in relief, are made from solid pieces of wood or by bonding closely grained woods with cheaper ones. When designs include large areas, these are

recessed and the space filled with hard wool felt. Fine lines are usually built up with copper strips, and other effects are obtained with copper strips interleaved with felt. To facilitate registration of successive prints, or lays, each block has several pitch pins arranged to coincide with well-defined points in the pattern. Cloth is printed on a table covered with several thicknesses of fabric or blanket, the whole covered with a thick sheet of tightly stretched synthetic rubber. The cloth to be printed is spread on the rubber, either gummed in position or pinned to a back cloth attached to the table. Colour is applied evenly to the block, and the pattern is stamped on the fabric to be printed, using the handle of a small heavy hammer, or maul, to aid penetration of the paste. More colour is then applied to the block and the process is repeated using the pitch pin to obtain true registration. After the fabric has been entirely printed with one colour, other colours are applied in the same way until the design is complete. Although block printing is becoming too laborious and costly for commercial use, some of the most beautiful prints have been made in this way.

Roller printing. This technique is used whenever long runs of fabric are to be printed with the same design. The modern machine, based on one originally devised in 1783, consists of a large central cast iron cylinder over which passes a thick endless blanket providing a resilient support for the fabric. Backing fabrics, called back grays, are placed between the blanket and the fabric to prevent undue staining of the blanket. Although formerly made of cotton fabric, most modern back grays are continuous belts of nylon. The blanket and back gray are appropriately tensioned, so that the fabric moves through the machine as the central cylinder rotates. Engraved printing rollers, one for each colour, press against the fabric and the central cylinder. The pattern on the roller is etched on the surface of a copper shell supported on a mandrel. High quality engraving is essential for good printing. Each printing roller is provided with a rotating colour-furnishing roller, partially immersed in a trough of printing paste. Finely ground blades (doctor blades) remove excess colour paste from the unengraved areas of these rollers, and each also has a lint blade. The printed fabric passes from the main cylinder and through a drying and steaming chamber to fix the colour. Although this machine prints only one side of the fabric, the Duplix roller machine, essentially a combination of two roller machines, prints both sides. Modern printing machines are smooth-running precision machines fitted with carefully designed roller bearings and hydraulic or pneumatic mechanisms to ensure uniform pressure and flexibility. Pressure is regulated from an instrument panel, and each roller is controlled independently. Automatic registration is effected by electromagnetic push-button control, and modern electric motors provide smooth-running, variable-speed drives. The washing of back grays and printer's blankets has also been automated.

Spray printing is the application of colour from spray guns through stencils and has limited but occasionally profitable use.

Screen printing. Screen printing may be a hand operation or an automatic machine process. The cloth is first laid on a printing table, gummed in position or pinned to a back gray, and then the design is applied through a screen made of silk or nylon gauze stretched over a wooden or metal frame, on which the design for one colour has been reproduced. This is usually a photographic process, although hand painting with a suitably resistant blocking paint is an alternative. A screen is placed over the fabric on the table against registration stops, ensuring accurate pattern fitting. Print paste is poured on to the screen edge nearest the operator and is spread with a squeegee over the surface of the screen so that colour is pushed through the open parts. The screen is moved until one colour has been applied to the cloth. For application of other colours, the process is repeated with different screens.

With the growing importance of screen printing, the hand operation has been largely replaced by mechanical methods. In some machines, the screens are flat, as in hand printing; others employ rotary screens.

Sublistatic printing. The popularity of polyester fabrics has led to the development of a completely new form of printing termed sublistatic printing, which prints the pattern on paper with carefully selected dyes. The paper is then applied to the fabric by passing the two together through a type of hot calender, and the pattern is transferred from one to the other. This method opens up new possibilities such as the production of half-tone effects.

Print paste viscosity

In all textile printing, the nature and, particularly, the viscosity of the print paste is important, and the thickeners employed must be compatible with all the other components. For conventional methods the thickeners are such reagents as starch, gum tragacanth, alginates, methyl cellulose ethers, and sodium carboxymethyl cellulose. Many types of dye can be applied, including direct cotton, vat, mordant, and reactive dyes, as well as pigment colours. Most dyes are fixed by steaming or ageing, by a batch or continuous method, and more rapid fixation is effected by flash ageing—*e.g.*, allowing a shorter steaming period by employing smaller machines. After steaming, the fabric must be thoroughly washed to remove loose dye and thickener, ensuring fastness to rubbing.

Most textile materials can be printed without special pretreatment, but wool cloths are generally chlorinated before printing. Tops (long, parallel wool fibres), printed in stripes, are used for mixed effects, and printed warps produce shadowy effects. Tufted carpets are printed by a process designed to ensure good penetration.

V. Textile consumption and trade

CHANGING USES OF FABRIC IN APPAREL

Textiles are commonly associated with clothing and soft furnishings, an association that accounts for the great emphasis on style and design in textiles. These consume a large portion of total industry production. Great changes have occurred in the fabrics used for clothing, with heavy woollen and worsted suitings being replaced by lighter materials, often made from blends of natural and man-made fibres, possibly due to improved indoor heating. Warp-knitted fabrics made from bulked yarns are replacing woven fabrics, and there is a trend away from formality in both day and evening dress to more casual wear, for which knitted garments are especially appropriate. The use of man-made fibre fabrics has established the easy-care concept and made formerly fragile light and diaphanous fabrics more durable. The introduction of elastomeric fibres has revolutionized the foundation-garment trade, and the use of stretch yarns of all types has produced outerwear that is closely fitting but comfortable.

Interlinings

Manufacturers of tailored garments formerly used interlinings made of horsehair, which was later replaced by goat hair, and then by resin-treated viscose rayon. Now fusible interlinings and various washable synthetics are widely used. The performance of a garment is greatly influenced by such factors as the interlining used and the sewing threads employed.

The care required by a textile fabric depends upon both fibre content and the application of various finishing processes. In 1972 the United States Federal Trade Commission passed regulations requiring fabric manufacturers to provide the consumer with care labels to be sewn into homemade garments, and requiring ready-to-wear manufacturers to sew permanent care information labels into clothing (see also CLOTHING AND FOOTWEAR INDUSTRY).

Soft furnishings. Household textiles, frequently referred to as soft furnishings, are fabrics used in the home. They include items frequently classified as linens, such as bath and dish towels, table linens, shower curtains, and bathroom ensembles. Related items include sheets, pillowcases, mattresses, blankets, comforters, and bedspreads. In addition, textile products contributing to the atmosphere and comfort of the home include rugs and carpeting, draperies, curtains, and upholstery fabrics.

Most of these items are also used in hotels and motels, and many are used in offices, showrooms, retail stores, restaurants, recreational facilities, and various other commercial establishments.

Industrial fabrics. This class of fabrics includes composition products, processing fabrics, and direct use types.

Composition products. In composition products, the fabrics are used as reinforcements in compositions with other materials, such as rubber and plastics. These products—prepared by such processes as coating, impregnating, and laminating—include tires, belting, hoses, inflatable items, and typewriter-ribbon fabrics.

Processing fabrics. Processing fabrics are used by various manufacturers for such purposes as filtration; for bolting cloths used for various types of sifting and screening; and in commercial laundering as press covers and as nets segregating lots during washing. In textile finishing back grays are used as backing for fabrics that are being printed.

Direct-use fabrics. Direct-use fabrics are manufactured or incorporated into finished products, such as awnings and canopies, tarpaulins, tents, outdoor furniture, luggage, and footwear.

Fabrics for protective clothing. Fabrics for military purposes must frequently withstand severe conditions. Among their uses are Arctic and cold-weather clothing, tropical wear, rot-resistant material, webbing, inflated life vests, tent fabrics, safety belts, and parachute cloth and harnesses. Parachute cloth, for example, must meet exacting specifications, air porosity being a vital factor. New fabrics are also being developed for garments used in space travel. In protective clothing a subtle balance between protection and comfort is required.

The many uses of textiles enter into almost every aspect of modern life. For some purposes, however, the role of textiles is being challenged by developments in plastic and paper products. Although many of these presently have certain limitations, it is likely that they will be improved, presenting a greater challenge to textile manufacturers, who must be concerned both with retaining present markets and expanding into completely new areas.

WORLD PRODUCTION AND TRADE

Table 1 shows the world's leading producers of woven fabrics, based on total yardage, for the year 1969. The statistics are fairly reliable, though by no means complete. Figures for handwoven fabrics are often excluded because of the difficulty of ascertaining them, although in some countries large amounts of such cloth are produced. In India, in particular, the annual production of handloomed cloth is roughly 2,000,000,000 square yards (1,700,000,000 square metres).

Table 1: Estimated Production of Woven Cloth, 1969*

Difficulties in reporting production

Another difficulty arises in attempting to analyze production in terms of type of fibre used, since a significant proportion may consist of cloths in which different fibres are combined, either in the component yarns or by using a different fibre in the weft from that in the warp. The Table, therefore, gives only a rough estimate of the world production for the main fibres and the main producing countries for one year. Mixture cloths are included under the heading of the dominant fibre, and a special category is included for woven carpets because at least three different kinds of fibres are normally used in their construction.

A summary table of this kind is necessarily incomplete, and some relatively large producers in a particular field (*e.g.*, Bangladesh in jute—a very large producer) are inevitably omitted. The Table also excludes wire, flax, silk, sisal, asbestos, and other miscellaneous fibres. It seems probable, therefore, that world production of all kinds of woven cloth in 1969 approached 90,000,000,000 square yards, equivalent to nearly 30 square yards (25 square metres) per person. These figures indicate the importance of weaving as an industrial process. Table 2 provides the same information for knitted fabrics.

International trade in textiles, as in other products, is subject to international agreements and restrictions. In the early 1970s many industrialized nations were members of the General Agreement on Tariffs and Trade (GATT) organization, concerned with regulating and promoting international trade. The Organization for Economic Cooperation and Development (OECD), under the sponsorship of the United Nations was mainly concerned with developing countries. Restrictive quotas, tariffs, and duties on textile raw materials, fabrics, and apparel, in effect or under consideration in various countries were the subject of much controversy.

Textual Criticism

Textual criticism distinguished from related fields

Textual criticism is the technique of restoring texts as nearly as possible to their original form. Texts in this connection are defined as writings other than formal documents, inscribed or printed on paper, parchment, papyrus, or similar materials. The study of formal documents such as deeds and charters belongs to the science known as "diplomatic"; the study of writings on stone is part of epigraphy; while inscriptions on coins and seals are the province of numismatics and sigillography. Textual criticism, properly speaking, is an ancillary academic discipline designed to lay the foundations for the so-called higher criticism, which deals with questions of authenticity and attribution, of interpretation, and of literary and historical evaluation. This distinction between the lower and the higher branches of criticism was first made explicitly by the German biblical scholar J.G. Eichhorn; the first use of the term "textual criticism" in English dates from the middle of the 19th century. In practice the operations of textual and "higher" criticism cannot be rigidly differentiated: at the very outset of his work a critic, faced with variant forms of a text, inevitably employs stylistic and other criteria belonging to the "higher" branch. The methods of textual criticism, insofar as they are not codified common sense, are the methods of historical inquiry. Texts have been transmitted in an almost limitless variety of ways, and the criteria employed by the textual critic—technical, philological, literary, or aesthetic—are valid only if applied in awareness of the particular set of historical circumstances governing each case.

The value of textual criticism

An acquaintance with the history of texts and the principles of textual criticism is indispensable for the student of history, literature, or philosophy. Written texts supply the main foundation for these disciplines, and some knowledge of the processes of their transmission is necessary for understanding and control of the scholar's basic materials. For the advanced student the criticism and editing of texts offers an unrivalled philological training and a uniquely instructive avenue to the history of scholarship; it is broadly true that all advances in philology have been made in connection with the problems of editing texts. To say this is to recognize that the equipment needed by the critic for his task includes a mastery of the whole field of study within which his text lies; for the editing of Homer (to take an extreme case), a period of some 3,000 years. For the general reader the benefits of textual criticism are less apparent but are nevertheless real. Most men are apt to take texts on trust, even to prefer a familiar version, however debased or unauthentic, to the true one. The reader who resists all change is exemplified by Erasmus' story of the priest who preferred his nonsensical *mumpsimus* to the correct *sumpsimus*. Such people are saved from themselves by the activities of the textual critic.

The law of diminishing returns operates in the textual field as in others: improvements in the texts of the great writers cannot be made indefinitely. Yet a surprisingly large number of texts have not yet been edited satisfactorily. This is particularly true of medieval literature, but also of many modern novels. Indeed the basic materials of most textual investigation, the manuscripts themselves, have as yet not all been identified and catalogued, much less systematically exploited. The first edition of the works of Dickens to be founded on critical study of the textual evidence did not begin to appear until 1966, when K. Tillotson's edition of *Oliver Twist* was published. Reliable principles of Shakespearean editing have begun to emerge only with modern developments in the techniques of analytical bibliography. The Revised Standard Version of the Bible (1952) and the New English Bible (1970) both incorporate readings of the Old Testament unknown before 1947, the year in which early biblical manuscripts—the so-called Dead Sea Scrolls—were discovered in the caves of Qumrān.

THE MATERIALS OF THE INVESTIGATION

The premise of the textual critic's work is that whenever a text is transmitted, variation occurs. This is because human beings are careless, fallible, and occasionally perverse. Variation can occur in several ways: through mechanical damage or accidental omission; through misunderstanding due to changes in fashions of writing; through ignorance of language or subject matter; through inattention or stupidity; and through deliberate efforts at correction. The task of the textual critic is to detect and, so far as possible, undo these effects. His concern is with the reconstruction of what no longer exists. A text is not a concrete artifact, like a pot or a statue, but an abstract concept or idea. The original text of Aeschylus' *Agamemnon* or Horace's *Odes* has perished; what survives is a number of derived forms or states of the text, approximations of varying reliability preserved by tradition. The critic must reduce these approximations as nearly as possible to the first or original state that they imperfectly represent; or if, as sometimes happens for reasons that will be explained below, no single original can be reconstructed or postulated, he must reduce their number to the lowest possible figure. His methods and the degree of his success will be determined by the nature of the individual problem; *i.e.*, the text itself and the circumstances of its transmission. The range of possible situations is vast, as the following survey indicates. The types of text with which the critic is concerned may be classified broadly under three heads.

Books transmitted in print. For practical purposes it is often assumed that the latest edition of a modern book published during the author's lifetime may be treated as the original. This is a simplification. The actual author's original may have been a manuscript or a typescript or a recording; in the process of publication it has passed through several stages of transmission, including possibly storage in a computer, at any one of which errors have necessarily occurred. Experience teaches that some errors will survive uncorrected in the published version. Further errors are likely to occur if a book is reprinted. Even an edition revised by the author is not to be regarded as textually definitive. Errors committed and overlooked by the author himself may be corrected by the critic in appropriate cases. Special problems are posed by an author's second thoughts, whether preserved in his books and papers or incorporated in editions revised by him; recent research has shown that authorial revision in modern printed books has been underestimated. The extent to which a critic is free to choose between authorial variants on aesthetic grounds is a matter of debate.

Books published before the 19th century pose essentially similar problems in a more intractable form, as may be seen in the case of Shakespeare. No manuscript of any of Shakespeare's plays survives, and there were substantial intervals between the dates of composition and the first printed versions, in which unauthorized variation clearly occurred. For Shakespeare's plays, indeed, the very concept of an author's original may be misleading. Elizabethan printers clearly had little regard for strict textual accuracy, so that allowance must be made not only for error but for deliberate alteration by compositors; thus the textual criticism of 16th- and 17th-century books must include a study of the practices of early printers.

Books transmitted in manuscript. Nearly all classical and patristic texts, and a great many medieval texts, fall into this category. Every handwritten copy of a book is textually unique, and to that extent represents a separate edition of the text. Whereas the characteristic grouping of printed texts is "monogenous" (*i.e.*, in a straight line of descent), that of manuscript texts is "polygenous" or branched and interlocking. The critic is in principle obliged to establish the relationship of every surviving manuscript copy of a text to every other. The difficulty and indeed the feasibility of this undertaking varies enormously from case to case. The following extremes embrace a wide range of intermediate possibilities. (1) The authority for a text may be a single surviving copy (*e.g.*, Menander, *Dyscolus*) or a copy that can be shown to be the source of all other copies (*e.g.*, Varro, *De Lingua Latina*) or an edition printed directly from a copy now lost (*e.g.*, the work of the Roman historian Velleius Paterculus); or a text may be transmitted in scores of copies whose interrelationships cannot be exactly determined (*e.g.*, Claudian, *De raptu Proserpinae*). (2) The interval between the original and the earliest surviving copies may be very short (*e.g.*, the French medieval poet Chrétien de Troyes) or very long (*e.g.*, the Attic tragedians). (3) A tradition may be "dynamic"—*i.e.*, the text may have been copied and recopied many times even in a short time (*e.g.*, Dante's *La divina commedia*); or it may be "static"—*i.e.*, the number of transmissional stages even over a long period may have been few (e.g., *Epigrammata Bobiensia*, a Latin translation of Greek epigrams). (4) A text may be a religious or literary work that was respectfully treated by copyists and protected by an exegetical tradition (*e.g.*, the Bible, the Latin poet Virgil); or a popular book that was exposed to correction, glossing, and amplification by readers (*e.g.*, the *Regula magistri* ["Rule of the Master," a Latin work related to the Rule of St. Benedict] and much medieval vernacular literature). (5) A text may have been written and transmitted after the establishment of a scholarly tradition, or it may show signs of "wild" and arbitrary variation dating from an age in which standards of exact verbal accuracy were low. To this extent all Greek books written before the establishment of the Alexandrian library (see below) were exposed to the hazards associated with oral transmission.

Books transmitted orally. Many texts have been orally transmitted, sometimes for long periods, before being committed to writing, and much textual variation may be attributable to this stage of transmission. Often in such cases the critic cannot attempt to construct an "original" but must stop short at some intermediate stage: thus the edited text of Homer means in practice the closest possible approximation to the text as established by the scholars of Alexandria. The length, complexity, and fidelity of oral traditions varies enormously. The text of the old Indian Ṛgveda was transmitted orally almost without variation from very ancient to modern times, whereas much old French epic and Provençal lyric has descended in variant redactions for which a common source may be postulated but cannot be reconstructed. Sometimes this is attributable not to spontaneous variation but to deliberate reworking, whether by the author, as appears to be the case with the three versions of the English poem *Piers Plowman*, or by later revisers, as with the four versions of *Digenis Akritas* (a Greek epic). The distinction, however, is not always easy to draw. These considerations apply to a wide range of texts from ancient Hebrew through Old Norse to modern Russian, but they are especially important for medieval literature. In this field perhaps more than in any other the critic's aims and methods will be dictated by the character of the oral tradition, the stage at which it attained a more or less fixed form in writing, and the attitude of copyists in a particular genre to precise verbal accuracy. A problem of particular difficulty and importance is posed by the Greek New Testament. Though the text appears to have been transmitted from the first in writing, the textual variations are in many ways analogous to those of an oral tradition, and it is commonly held that the essential task of the critic is not to try to reconstruct the "original" but to isolate those forms of the text that were current in particular centres in the ancient world.

CRITICAL METHODS

General principles. From the preceding discussion it is apparent that there is only one universally valid principle of textual criticism, the formulation of which can be traced back at least as far as the 18th-century German historian A.L. von Schlözer: that each case is special. The critic must begin by defining the problem presented by his particular material and the consequent limitations of his inquiry. Everything that is said below about "method" must be understood in the light of this general proviso. The celebrated dictum of the 18th-century English classical scholar Richard Bentley that "reason and the facts outweigh a hundred manuscripts" (*ratio et res ipsa centum codicibus potiores sunt*) is not a repudiation of science but a reminder that the critic is by definition one who discriminates (the word itself derives from the Greek word for "judge"), and that no amount of learning or mastery of method will compensate for a lack of common sense. To study the great critics in action is incomparably more instructive than to read theoretical manuals. As the English critic and poet A.E. Housman wrote,

> A man who possesses common sense and the use of reason must not expect to learn from treatises or lectures on textual criticism anything that he could not, with leisure and industry, find out for himself. What the lectures and treatises can do for him is to save him time and trouble by presenting to him immediately considerations which would in any case occur to him sooner or later.

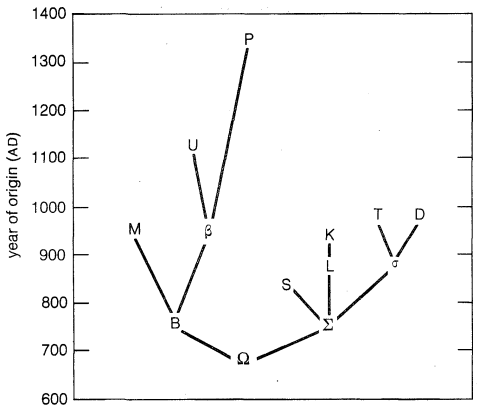
The importance of common sense

Admittedly, the technical advances in textual bibliography mentioned below are not such as would sooner or later occur to any reflective and intelligent person; but bibliography, like paleography, is ancillary to textual criticism proper, and Housman's words are strictly true. What they imply is that good critics are born, not made.

The critical process can be resolved into three stages: (1) recension, (2) examination, and (3) emendation. Though these stages are logically distinct, (2) and (3) are in practice performed simultaneously, and even (1) entails the application of criteria theoretically appropriate to (2) and (3).

Recension. The operation of recension is the reconstructing of the earliest form or forms of the text that can be inferred from the surviving evidence. Such evidence may be internal or external. Internal evidence consists of all extant copies or editions of the text, together with versions in other languages, citations in other authors, and other sources not belonging to the main textual tradition. These witnesses (as they may be called) must be identified, dated, and described, using the appropriate paleographical and bibliographical techniques. They must then be collated; *i.e.*, the variant readings that they contain must be registered by comparison with some selected form of the text, often a standard printed edition. Where the number of witnesses is large, collation may have to be of selected passages. If there is only one witness to a text, collation and recension are synonymous, and the critic passes straight to examination and emendation. Generally, however, he will be faced with two or more witnesses offering variant forms or states of the text.

The search for the earliest transmitted form of the text



Collateral evidence as to the transmission of a text may be supplied from sources external to the direct or indirect textual tradition. Thus the ancient biographers throw light on the circumstances in which Virgil's *Aeneid* was published. Inferred textual stages may be dated on the evidence of copying practices at different periods, or by association with a particular scholar, or from entries in medieval library catalogues. Generally speaking, information of this sort will contribute more to the history than to the criticism of the text, but the two fields are intimately connected; and the better the textual history is known, the more reliable the control of the critic over conjectural solutions to specific problems. In the case of printed books, such external evidence is as a rule more plentiful; it is often essential, since so much may turn on

the accurate dating of editions. Relevant information must be sought in the published and unpublished records of stationers, printers, booksellers, and publishers and in other archival material.

Having assembled his evidence, the critic may proceed, broadly speaking, in one of two different ways, according as he decides to handle the problem of interrelationships "genealogically" or "textually."

The "genealogical," or "stemmatic," approach. The attempt to reconstruct an original text here relies on the witnesses themselves regarded as physical objects related to each other chronologically and genealogically; the text and the textual vehicle (the book itself) are treated as a single entity. On the basis of shared variants, chiefly errors and omissions, a family tree of the witnesses (*stemma codicum*) is drawn up. Those witnesses that repeat the testimony of other surviving witnesses are discarded, and from the agreements of the remainder the text is reconstructed as it existed in the lost copy from which they descend, the "archetype." Thus in the tradition of the 6th-century monk Cassiodorus' *Institutiones* the relationships of the manuscripts of the authentic version of the text of Book II may be represented by the accompanying diagram. The Roman letters represent extant manuscripts,

Adapted from R.A.B. Mynors (ed.), *Cassiodori Senatoris Institutiones* (1961); the Clarendon Press, Oxford

Manuscript genealogy, with Greek letters representing sources upon which known manuscripts (Roman letters) must have been based.

and the Greek letters represent the lost manuscripts from which they derive, here arbitrarily dated. The text of the archetype Ω is established by the agreement of B and Σ. Since B survives, the readings of MUP, which are derived from it, would be of value only where B had suffered damage after M and β were copied from it. In such cases the text of β could be inferred from the agreement of UP and the text of B from the agreement of Mβ (or MU or MP. The text of Σ can be inferred from the agreement of SLσ or SL or Sσ (or ST or SD) or Lσ (or LT or LD). K, being copied from L, would be of value only where L had suffered damage after K was copied from it. An important distinction is here exemplified between "trifid" and "bifid" *stemmata.* Where there are three independent witnesses to a source, as with Σ, its reading is certified by the agreement of all three or of any two; where there are only two witnesses, as with Ω, and they disagree, the reading of the source cannot be certified. Even in the latter situation, however, the number of possible variants existing in the source would have been reduced to two. Thus in theory the genealogical, or stemmatic, method allows the critic to eliminate from consideration all variants that cannot be traced back to the archetype or earliest inferable textual state.

While in principle this method is unassailable, it depends for its practical validity on the assumption that each copyist followed only one model or exemplar and generated only variants peculiar to himself. This is called "vertical" transmission, and a tradition of this kind is called "closed." Once the possibility is admitted that a copyist used more than one exemplar or (the more probable supposition) copied an exemplar in which variants from another source or sources had been incorporated—*i.e.,* that more than one textual state may coexist in a single witness—the construction of a *stemma* becomes more complicated and may be impossible. This is called "horizontal" transmission, and a tradition of this kind is called "open" or "contaminated." The practice of critics faced with contamination tends to vary, for historical reasons, from field to field. Editors of classical texts generally adopt a controlled eclecticism, classifying the witnesses broadly by groups according to the general character of their texts and choosing between their readings largely on grounds of intrinsic excellence. Medievalists, following the French scholar Joseph Bédier (see below), sometimes revert to the traditional practice, to which their training may dispose, of selecting a single witness as the main basis of the text. For editors of printed books, contamination is not an important problem.

The "textual," or "distributional," approach. In the alternative method, the text and the textual vehicle are dissociated; the emphasis is on the analysis of the variants themselves and their distribution rather than on the character of the text as presented by individual witnesses. The techniques or models employed include those of statistics, symbolic logic, and biological taxonomy. Two theoretical advantages are suggested for this approach. First, objectivity: no judgments of value are entailed, whereas the genealogical method calls for decisions as to the correctness of readings or textual states. Second, the possibility of mechanization: long and elaborate calculations involving thousands of variants may be performed by a computer. This possibility is especially attractive to New Testament critics, who are confronted with about 5,000 manuscripts of the Greek text as well as versions in other languages and patristic citations. In practice, however, these advantages are to a large extent illusory. An "objective" (*i.e.,* undiscriminating) treatment of all variants in a literary text such as Ovid's *Metamorphoses* (of which more than 300 manuscripts exist) without regard to their metrical and stylistic quality would be a self-evident waste of time and produce merely confusion. The critic cannot abrogate his critical function, which implies discrimination, at the very beginning of the critical process. Moreover, the preparation or programming of a text for treatment in this way, whether mechanical aids are used or not, is long and laborious, and one must consider whether in a given case the results justify the expenditure of effort. Texts have been transmitted by a combination of purpose and accident that in any particular instance is both unique and unpredictable, and no machine or statistical model exhibits the versatility necessary to unravel the incomplete and tangled skein. Mechanical methods have been most successful in fields other than recension (see below).

Analysis of variants

Examination. The process of determining whether the transmitted text or any of the transmitted variants of it is "authentic"—*i.e.,* what the author intended—is known as examination. The prior process of recension has reduced the number of textual states having a claim to be considered "authoritative." Many different situations are possible. In a completely closed tradition it is theoretically feasible to reconstruct the archetype with such certainty that only a single form of the text without variants remains to be examined. In practice this is extremely unlikely to be the situation. Usually the critic is faced with pairs (sometimes triplets) of variants, all with a presumptive claim to be considered authoritative. In some traditions he will confront variant versions of the whole text. Where papyri or other early sources independent of the main tradition are available, he may have to reckon with "pretraditional" (*i.e.,* pre-archetypal) variants. The process of examination calls upon the critic's full range of knowledge as well as his innate powers of taste and discrimination. The criteria applied must be those appropriate to the particular author (supposing his identity to be known), the period, the genre, and the particular character of the work. The opposing demands of analogy and anomaly must be weighed according to the circumstances. Many of the older generation of critics based their decisions on aprioristic or rigidly analogical princi-

Authenticity of a text

ples of elegance and propriety, while the canons of modern criticism are based on historical studies of language and style. It is here that the circularity inherent in the whole operation is most evident, for the linguistic and stylistic criteria employed are themselves based on inductions from texts, probably including the one under examination. There is no escape from this difficulty; as the German philologist Karl Lachmann observed, it is precisely the task of the critic "to tread that circle deftly and warily."

Emendation. The attempt to restore the transmitted text to its authentic state is called emendation. There will usually be a chronological gap, sometimes of several centuries, between the archetype, or earliest inferable state of the text, and the original; nearly all manuscripts of classical authors date from the Middle Ages. The history of the text during the intervening period may be illustrated from external sources; but if examination has convinced the critic that the transmitted text (or its variants) are not authentic, he normally has no resource but to bridge the gap by conjecture. Conjectural emendation has been defined by the American scholar B.L. Gildersleeve as "the appeal from manuscripts we have to a manuscript that has been lost." Theoretically this definition is acceptable, if we interpret "manuscript" as "source," but in practice the making of conjectures, as distinct from testing them, is intelligent guesswork.

Conjectural emendation

No part of the theory of textual criticism has suffered more from misunderstanding than has conjectural emendation. Such conjectural, or divinatory, criticism has in the past enjoyed a traditional pre-eminence: Dr. Johnson observed that William Warburton's correction of "good" to "god" in the second act of *Hamlet* (scene 2, line 182) almost set the critic on a level with the author. That idea is as erroneous as the frame of mind in which the Italian scholar C. Pascal founded the Paravia series of editions in order to purge Latin texts of German conjectures. The best critic is he who discriminates best, whether between variants or between transmitted text and conjecture.

Conjectures as a rule occur to the mind spontaneously or not at all; diagnosis and prescription often present themselves at the same moment. This instinctive process is not under the critic's control, though he can sharpen and regulate it by constant study and observation. The outcome of the process, the emendation itself, can and must be controlled and tested by precisely the same criteria as are used in deciding between variants. This is essentially an exercise in balancing probabilities. These probabilities are historical. The conventional distinction between intrinsic and transcriptional (*i.e.,* paleographical or bibliographical) probability tends to obscure a fundamental historical point. If the transmitted form of the text lies at few removes or a short distance in time from the original, a conjectural solution which violates transcriptional probability is less likely to be correct than if the text has undergone a long and complex process of deterioration. In the latter case the critic may attach little or no importance to transcriptional probability. The critic cannot neglect the study of paleography or bibliography, but he must not give them more than their critical due. What that may be depends on the particular historical circumstances. He will study carefully the rationale of error in manuscripts and books themselves rather than in the schematic classifications of critical manuals; and he will learn from experience to distinguish between the types of error that may be called "psychological" (*i.e.,* those committed by a tired or inattentive copyist, whatever language or instruments he uses) and those contingent on the period and the medium of transmission, whether it be the mouth and the ear, the pen, the hand composing stick, the linotype or typewriter keyboard, the computer or photocopying machine, or the printing press. Two complementary principles originated by the New Testament critics of the 18th century are often cited as aids to decision: *utrum in alterum abiturum erat?* ("which reading would be more likely to have given rise to the other?") and *difficilior lectio potior* ("the more difficult reading is to be preferred"). These are no more than useful rules of thumb; it has been suggested that in practice these and other such principles reduce themselves to the truism *melior lectio potior,* "the better reading is to be preferred."

From this discussion it is apparent that the traditional opposition between "conservative" and "radical" styles of criticism that has haunted textual criticism since St. Jerome has no meaning. The critic does not attack or defend the transmitted text; he asks himself whether it is authentic. How radically he treats it, and how many conjectural readings he substitutes for transmitted readings, depends not on his temperament but on the nature of the problem. If he has studied the history of textual criticism he will know that as a matter of demonstrable fact nearly all conjectures are wrong, and he will accept that many of his solutions are in the nature of things provisional.

Editorial technique. Critical texts are edited according to conventions that vary with the type of text (classical, medieval, modern) but follow certain general principles. In some cases, as with newly edited papyri and with palimpsests (writing materials re-used after erasure), the edition will take the form of a diplomatic transcript; *i.e.,* the most accurate possible representation of a particular textual form. Generally, however, the editor constitutes his text in accordance with his own judgment on principles explained in his introduction; and he indicates his sources in critical notes (*apparatus criticus*), preferably at the foot of the page. These notes are usually couched in a special terminology that relies heavily on abbreviation and the use of conventional signs or letters (*sigla*) to identify the witnesses. In classical and patristic texts the language of the notes is usually Latin. Editorial judgment will be influenced by the presumed needs of readers: in an edition intended for scholars, very corrupt passages are often printed as transmitted and marked with a dagger (†), whereas in an edition for the student or general reader some compromise may be accepted in the interests of readability.

A much-discussed problem is the treatment of "accidentals"—variations in spelling, capitalization, punctuation, and the like. Few if any ancient text traditions preserve reliable evidence of authorial practice in these matters, so that the editor is concerned only with variants that affect the sense; in preparing his text for printing he will adopt modern conventions of presentation and punctuation and a normalized orthography. The same holds good for the majority of medieval texts. Printed texts, however, were generally corrected or seen through the press by the author, or at all events by a contemporary, so that the editor may be reasonably confident of reproducing at least a decent approximation to authorial usage. Whether, or to what extent, he should do so is much debated; opinions differ sharply as to the usefulness of "old-spelling" editions of Shakespeare and other early writers.

ORIGINS AND DEVELOPMENT

From antiquity to the Renaissance. Until the 20th century the development of textual criticism was inevitably dominated by classical and biblical studies. The systematic study and practice of the subject originated in the 3rd century BC with the Greek scholars of Alexandria. Literary culture had before that time been predominantly oral, though books were in common use by the 5th century, and many texts had suffered damage because the idea of precise textual accuracy and reproduction was unfamiliar. The aim of the librarians of Alexandria was to collect and catalogue every extant Greek book and to produce critical editions of the most important together with textual and interpretative commentaries. Many such editions and commentaries did in fact appear. Alexandrian editing was distinguished above all by respect for the tradition; the text was constituted from the oldest and best copies available, and conjectural emendation was rigidly confined to the commentary, which was contained in a separate volume. An elaborate battery of critical signs was used to refer from text to commentary. These techniques were applied, though on a less ambitious scale, by Roman scholars to Latin texts. Fidelity to tradition was the chief legacy of ancient textual scholarship to later ages; the copyist was expected to reproduce his exemplar as exactly

The librarians of Alexandria

as he could, and correction was based on comparison with other copies, not on the unaided conjectural sagacity of the scribe. Such was the practice of the best monastic scriptoria such as that of Tours, or of the best scholars, such as Lupus of Ferrières (fl. 850). From about 1350, however, a change in attitude is evident, particularly in the West. What is often called the revival of learning was in reality a practical movement to enlist the heritage of classical antiquity in the service of the new Christian humanism. In order to make them usable (*i.e.*, readable), texts were corrected freely and often arbitrarily by scholars, copyists, and readers (the three categories being in fact hardly distinguishable). At its best, as seen in the activities of a scholar like Demetrius Triclinius, later medieval and early Renaissance criticism verges on scientific scholarship, but such cases are exceptional. For the most part the correction of texts was a purely subjective display of taste, sometimes right but much more often wrong, and resting as a rule on nothing more solid than a superficial sense of elegance. In consequence, by the 1470s, when the first printed editions (*editiones principes*) of classical texts began to appear, most Greek and Latin authors were circulating in a textually debased condition, and it was manuscripts of this character that almost always served as copy for the early printers. Very little editing in any real sense of the word was done; the scholars who saw the *editiones principes* through the press generally confined themselves to superficial improvements.

Debasement of texts during the Renaissance

From Politian to Cobet. This state of affairs entailed that down to the 19th century most critics were engaged not in establishing and emending texts on scientific principles but in correcting, in a necessarily unsystematic fashion, a vulgate or received text (*lectio recepta*) that was itself the product of an almost entirely haphazard process of variation and conjecture. The situation was aggravated by the fact that the manuscripts themselves, the basic materials of the investigation, were largely inaccessible to scholars. The Italian poet and scholar Politian, unlike most of his contemporaries, was aware that only through the identification and comparison of the best manuscripts could texts be improved; his notes and collations show that he understood the problem correctly as essentially one of control of the sources. What might have been done in this field is shown by his work, cut short by his early death, on the Florentine codex of Justinian's Pandects. Many manuscripts were still privately owned, their very existence unknown to scholars; public libraries were few and published catalogues fewer; travel was difficult, expensive, and often dangerous. It was not until the twin disciplines of diplomatic and paleography were founded by the great Benedictine monks Mabillon and Montfaucon, and developed by their successors, that a critical use of the evidence became possible; and much of the evidence itself did not become available until after the Napoleonic Wars, when most of the private stock of manuscripts passed finally into public collections.

Some advances were taking place, slowly and unsystematically, in both the theory and practice of textual criticism. The history of critical method in this period is most profitably studied in the best editions of the best editors. The accepted method was to correct the text (*i.e.*, the text of the last printed edition) *codicum et ingenii ope; i.e.*, with the aid of the manuscript and printed sources and the critic's own ingenuity. Divination was subordinated to authority, and any reading found in a manuscript or printed text was accounted superior to any conjecture, whatever its intrinsic merits. The first important departure from this pattern is seen in the edition of Catullus by J.J. Scaliger (1577), in which the possibilities of the genealogical method, already understood in principle by Politian and other Renaissance scholars, were exemplified by the demonstration that all the extant copies derived from a lost manuscript, whose orthography and provenance Scaliger was prepared to reconstruct. Almost equally significant was Richard Bentley's edition of Horace (1711), in which for the first time the role of conjecture in the critical and editorial process was recognized and the tradition of producing a corrected version of the text of previous editors was decisively rejected. Bentley's scholarship was greatly admired in the Netherlands, and the editions of the great Dutch Latinists J.F. Gronovius and N. Heinsius were informed by Bentleian principles. Under his influence there grew up what may be called an Anglo-Dutch school of criticism, the two most typical representatives of which were Richard Porson and C.G. Cobet. Its strength lay in sound judgment and good taste rooted in minute linguistic and metrical study; its weaknesses were an excessive reliance on analogical criteria and an indifference for German science and method. Its influence may still be seen in the empiricism that characterizes much critical work by English scholars.

Richard Bentley's influence

From Bentley to Lachmann. The decisive influence on the editing of secular texts came from the New Testament critics of the 18th century. The printed text of the Greek New Testament in common use was still essentially that established in 1516 by Desiderius Erasmus. For his edition, produced in great haste, he had used such manuscripts, neither ancient nor good, as chanced to be accessible to him. Superficially revised, this was the text termed in the Elzevier edition of 1633 "now received by all," *nunc ab omnibus receptum*. Bentley proposed an edition on radical lines in which he engaged to give the text "exactly as it was in the best exemplars at the time of the Council of Nice. So that there shall not be twenty words, nor even particles, difference; . . ." This project never materialized, but editions of the Greek text that did not reproduce the *textus receptus* were published in England by Daniel Mace (1729), William Bowyer, the Younger (1763), and Edward Harwood (1776). On the Continent, meanwhile, New Testament criticism was being developed on scientific and historical lines by a succession of distinguished scholars, notably J.A. Bengel, J.J. Wettstein, J.S. Semler and J.J. Griesbach. They shaped the genealogical method that was later refined by editors of classical texts. Wettstein also deserves commemoration as the first New Testament critic to use *sigla* systematically. This was important, since some at least of the deficiencies of classical editions at this time are attributable to the lack of suitable conventions for the presentation of critical information, together with a conservative and belletristic attitude to technical jargon by publishers, scholars, and users of books in general. Though *sigla* occur sporadically in editions as early as the 16th century and were used by S. Haverkamp in his Lucretius (1725) in something like the modern style, they did not become normal until the second half of the 19th century.

The genealogical, or stemmatic, method of recension has already been described. It is usually associated with the name of the German Karl Lachmann, but it had its origins in the work of J.A. Bengel and his successors, and almost every essential feature of it was already present in the work of Lachmann's precursors such as J.A. Ernesti, F.A. Wolf, K.G. Zumpt, F.W. Ritschl, and J.N. Madvig. Nevertheless Lachmann occupies a central position in the development of textual criticism because of the unusual power and penetration of his scholarship, the range of textual material on which he worked, and his immense contemporary and posthumous influence. His edition of the Greek New Testament (1831; 2nd ed. 1842–50) was intended primarily as a vindication of the principles of Bentley and Bengel and a demonstration that the *textus receptus* must be finally rejected. Similarly his famous edition of Lucretius (1850) is important as an exemplification of the method in action, since the tradition of Lucretius is peculiarly suitable for the purpose. The demonstration fell short of completeness, for Lachmann had not fully grasped the problem and so failed to exploit the method fully. It has been suggested that Lachmann's best critical work was in his editions of medieval German texts; their influence will be considered below. The Lachmannian model of recension derived added authority from seemingly analogous models in other fields, especially that of comparative philology. As propagated by disciples, notably Moritz Haupt, it dominated textual studies for half a century.

The genealogical method of Karl Lachmann

Related developments in the late 19th century. *Photography.* Possibly the most important technical advance

in the latter part of the 19th century was the perfection of photography. Instead of travelling in search of his material, the paleographer or critic could now assemble and study it at relatively little expense and without leaving his desk.

Papyri. During the last quarter of the 19th century the tempo of archaeological discovery in classical and biblical lands was vastly increased, and many new texts were unearthed. Some of these were in previously unknown languages, setting new problems of decipherment. Specifically relevant to textual studies are the many Greek papyri recovered from Egypt. These have thrown much light on the history and techniques of ancient book production and scholarship and hence, indirectly, on critical problems. Where the texts they contain are already known, their evidence has tended to emphasize our ignorance of the textual history of classical literature in antiquity itself. Being usually far older than the manuscripts already known, they often illuminate the "pretraditional" state of the text; by sometimes offering readings that agree with those of late and "inferior" medieval copies they justify editors in a policy of cautious eclecticism. Papyrus discoveries have been of particular moment for the text of the New Testament.

English studies. Editors of printed texts, having invariably received a classical education (no other being available), had naturally followed, with minor modifications, the methods of classical editing. They would reprint the text of the last edition with such improvements as editorial taste and learning suggested but with no attempt to investigate the sources of the text. Since Lachmann's method was inapplicable to printed texts, this procedure continued until, by the end of the 19th century, the text of Shakespeare, for example, was in a state somewhat analogous to that of most classical writers at the time of the *editiones principes*. Much of the work of modern Shakespearean editors has consisted of undoing the damage inflicted by their predecessors. The early 20th century saw the rise of a new school of "biblio-textual" criticism, most notably represented by A.W. Pollard, R.B. McKerrow, and W.W. Greg. Its object was to devise a style of recension appropriate to the special circumstances under which early printed texts were produced and propagated, and its methods were those of analytical bibliography. These developments are of direct importance for the criticism and editing of a large range of texts of the 16th, 17th, and 18th centuries, particularly those of the Elizabethan and Jacobean dramatists. They have also engendered a discussion of general methodological interest on the role of bibliographical as opposed to historical and literary criteria in the editorial process. This debate continues.

Shakespeare texts

Medieval studies. Critics and editors of medieval texts had also inevitably been influenced by developments in the classical field. Before Lachmann it had been usual to choose a single manuscript as the main basis for an edition. Because of the circumstances in which much medieval literature was composed and transmitted this was not necessarily unscientific, and the surviving bulk of texts was so large as to dictate that approach in many cases if they were to be edited at all. This had been the style of editing followed by the Belgian Jesuits known as Bollandists, the French Benedictines called Maurists, and the Italian scholar L.A. Muratori, and perpetuated in the indispensable *Patrologiae Cursus Completus* (edition of the Church Fathers) of the French priest Jacques-Paul Migne. At its best it is seen in the editions of medieval Latin chronicles by the 18th-century Oxford antiquary Thomas Hearne, some of which are still standard works. A more scientific approach was adopted in the publications of the *Monumenta Germaniae Historica*, the later volumes of which (from about 1880) were produced by editors trained in the school of Lachmann. Similarly, editors of vernacular texts followed the lead that Lachmann had given in his editions of such early German poems as the *Nibelunge Not* (1826) and the *Iwein* (1827). An important development in the application of the method was due to the medievalists G. Gröber and G. Paris, who first emphasized the significance of common errors. But in the general uncritical enthusiasm for scientific method, the genealogical approach was too often used without regard for the special conditions under which medieval literature has been handed down.

Reaction against the genealogical method. Haupt had proclaimed in his lectures that his main object was to teach method. But confidence in method led to its misuse. The Lachmannian formula of recension was applied to texts, classical as well as medieval, for which it was unsuitable, often with grotesque results. Commonly this took the form of choosing on "scientific" (*i.e.*, stemmatic) grounds a "best manuscript" (*codex optimus*) and defending its readings as authoritative even where common sense showed that they could not be authentic. This was the type of editing satirized by A.E. Housman in the brilliant prefaces to his editions of Manilius (1903) and Juvenal (1905) and in many reviews and articles. It flourished chiefly between 1875 and 1900, but the dangers of excessive methodological rigidity had already been foreseen. In 1841 H. Sauppe in his *Epistola Critica ad G. Hermannum* had emphasized the diversity of transmissional situations and the difficulty or actual impossibility of classifying the manuscripts in all cases. In 1843 Lachmann's pupil O. Jahn, in his edition of Persius, had repudiated the strict application of the genealogical method as unsuitable to the tradition of that poet. The most extreme position was taken by E. Schwartz, who in his edition of Eusebius' *Historia ecclesiastica* (1909) denied that "vertically" transmitted texts of Greek books existed at all. The limitations of the stemmatic method have subsequently been stressed in a more temperate fashion by other writers. The modern tendency is to acknowledge the validity of the method in principle while recommending a cautious empiricism in its application. For the editor of a contaminated tradition—and most traditions are probably contaminated—the lesson of recent research is that authoritative evidence may survive even in late and generally corrupt or interpolated sources.

More radical criticism of the method has come from medievalists. In 1913 and again in 1928 the French scholar J. Bédier attacked the stemmatic method because the *stemmata* it produced for medieval texts almost invariably had only two branches. Subsequent investigation has shown that Bédier overrated the inherent improbability of this situation, and it is generally agreed that his criticisms had to do with improper application rather than with the method itself. The point taken by H. Quentin (1922) has already been mentioned: that the method entails argument in a circle, since it relies on the identification of errors at the beginning of a process designed to lead to that very end. This objection, more cogent in theory than in practice, applies with greater force to medieval than to classical texts. The linguistic and stylistic canons of classical Greek and Latin are relatively strict and well defined, whereas the vocabulary, grammar, and usage of many medieval authors (especially when an oral prehistory is in question) is often not certain enough to allow reliable discrimination between variant and error. Classical texts, moreover, have passed through a series of bottlenecks in their history, which have simplified editorial problems by eliminating a high proportion of the evidence (*cf.* the remarks on papyri above). With a few exceptions, such as the commentary of Servius, only one version of each text remains to be reconstructed, whereas many medieval texts are extant in several redactions that cannot be winnowed by the stemmatic method so as to leave only one. Quentin's own method, which depended on the comparison of variants in groups of three, without prejudice as to their correctness, has not been generally adopted. It is immensely laborious and does not in practice possess the objectivity that its inventor claimed for it. Bédier and Quentin have, however, done good service to textual criticism in enjoining caution. The best critics in all fields now agree in rejecting the "logical" (*i.e.*, the illogical) application of any method if the results conflict with common sense, and in stressing the necessity of judging variant readings and forms of a text on their intrinsic merits in the light of the information available.

Bédier and Quentin

Mechanical methods. Quentin also gave a lead to later investigators in calling attention to the possibility of bas-

ing recension on the variants themselves, and the more sophisticated methods of Greg (1927), Archibald Hill (1950), Vinton Dearing (1959), and J. Froger (1968) may be seen as a continuation of his work. It has already been suggested that methods of this type, so far as recension is concerned, have been of primarily theoretical interest. But the use of mechanical and computing techniques in this field is in its infancy, and assessment must be provisional. Certain practical applications seem to have proved themselves. Mechanical aids to collation have been successfully used in editing Shakespeare and Dryden. Computer storage and analysis of texts can provide information about authorial usage, such as stylistic and metrical patterns, and facilitate the production of concordances. These aids are more relevant to conjectural emendation (as shown by their application to the Dead Sea Scrolls) and the "higher" criticism (*e.g.*, determination of authenticity) than to the recension of texts. The formula or machine that will do the critic's essential work for him still awaits discovery; the best texts are produced by the best scholars, whatever their method or lack of method. Lachmann observed that the establishment of a text according to its tradition is a strictly historical undertaking. Twentieth-century research into the composition and transmission of ancient, medieval, and modern texts has confirmed the truth of his pronouncement.

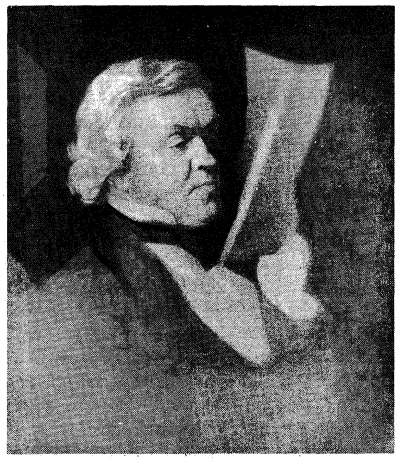
Use of the computer

BIBLIOGRAPHY

Transmission of texts: For oral transmission the fundamental work is H.M. and N.K. CHADWICK, *The Growth of Literature*, 3 vol. (1932–40, reprinted 1969). Classical, biblical, and medieval texts are all covered (but somewhat unevenly) by H. HUNGER *et al.*, *Geschichte der Textüberlieferung der antiken und mittelalterlichen Literatur*, 2 vol. (1961–64). For classical texts in general the best introduction is L.D. REYNOLDS and N.G. WILSON, *Scribes and Scholars* (1968); more specialized are A.C. CLARK, *The Descent of Manuscripts* (1918); and A. DAIN, *Les manuscrits*, 2nd rev. ed. (1964). For special areas, see B.A. VAN GRONINGEN, *Traité d'histoire et de critique des textes grecs* (1963); R.D. DAWE, *The Collation and Investigation of Manuscripts of Aeschylus* (1964); R. RENEHAN, *Greek Textual Criticism: A Reader* (1969); L. HAVET, *Manuel de critique verbale appliquée aux textes latins* (1911), an exhaustive catalogue raisonné of scribal error; E.G. TURNER, *Greek Papyri: An Introduction* (1968), important for the history of Greek texts in antiquity. For biblical texts, in addition to Hunger (*op. cit.*), the standard work on the New Testament is B.M. METZGER, *The Text of the New Testament*, 2nd ed. (1968). For patristic texts an excellent case study raising important general issues is M. BEVENOT, *The Tradition of Manuscripts: A Study in the Transmission of St. Cyprion's Treatises* (1961). For medieval texts a good exposition of typical problems may be found in D'A.S. AVALLE, "Die Liederhandschriften und die Textkritik," in Hunger (*op. cit.*), 2:273–290; see also J.A. ASHER, "Truth and Fiction: The Text of Medieval Manuscripts," *Aumla*, 25:6–16 (1966). For printed books the standard work is F. BOWERS, *Bibliography and Textual Criticism* (1964); while a useful collection of essays may be found in O.M. BRACK and W. BARNES (eds.), *Bibliography and Textual Criticism: English and American Literature, 1700 to the Present* (1969).

Method (the stemmatic method): For its history and the contribution of Lachmann, S. TIMPANARO, *La genesi del metodo del Lachmann* (1963), is definitive. For its application, P. MAAS, *Textual Criticism* (Eng. trans. 1958), an austere theoretical exposition; and G. PASQUALI, *Storia della tradizione e critica del testo*, 2nd ed. (1952), brilliant but discursive, are complementary and fundamental. The reaction to the stemmatic method may be studied in H. QUENTIN, *Mémoire sur l'établissement du texte de la Vulgate* (1922), *Essais de critique textuelle–ecdotique* (1926); J. BURKE SEVERS, "Quentin's Theory of Textual Criticism," *English Inst. Annual 1941*, pp. 65–93 (1942); J. BEDIER, "La tradition manuscrite du Lai de L'Ombre: Réflexions sur l'art d'éditer les anciens textes," *Romania*, 54:161–96, 321–56 (1928). A. CASTELLANI, *Bédier avait-il raison?* (1957); W.W. GREG, *The Calculus of Variants* (1927); A.A. HILL, "Some Postulates for Distributional Study of Texts," *Stud. in Biblphy.*, 3:63–95 (1950). For further discussion of these developments, see W.P. SHEPARD, "Recent Theories of Textual Criticism," *Mod. Philol.*, 28:129–141 (1930); J. ANDRIEU, "Principes et recherches en critique textuelle," in *Mémorial des études latines . . . J. Marouzeau*, pp. 458–74 (1943); E.B. HAM, "Textual Criticism and Common Sense," *Romance Philol.*, 12:198–215 (1959). For mechanized techniques, see V.A. DEARING, *A Manual of Textual Analysis* (1959); J. FROGER, *La critique des textes et son automatisation* (1968). For the taxonomic approach, see J.G. GRIFFITH, "A Taxonomic Study of the Manuscript Tradition of Juvenal," *Mus. Helv.*, 25:101–138 (1968); "Numerical Taxonomy and Some Primary Manuscripts of the Gospels," *J. Theol. Stud.*, 20:390–406 (1969).

Editorial technique: For classical texts the standard works are still: O. STAHLIN, *Editionstechnik*, 2nd ed. (1914); and A. DELATTE and A. SEVERYNS, *Emploi des signes critiques* (1938). For medieval texts, see A. DONDAINE, "Abbréviations latines et signes raccommandés pour l'apparat critique des éditions des textes médiévaux," *Bull. de la soc. int. pour l'étude de la philosophie méd.*, 2:142–149 (1960); and for papyri, see Turner (*op. cit.*); and H.C. YOUTIE, *The Textual Criticism of Documentary Papyri: Prolegomena* (1958).



General discussions: Many of the works cited above include discussion of general principles. In addition, the following works may be mentioned: H. KANTOROWICZ, *Einführung in die Textkritik* (1921), sound emphasis on the roles of probability and common sense; A.E. HOUSMAN, "The Application of Thought to Textual Criticism," *Proc. Class. Assoc.*, 18:67–84 (1922), a brilliant polemic against hard-and-fast "rules" of criticism; L. BIELER, "The Grammarian's Craft," *Folia*, 10:3–42 (1956), a useful summary discussion of modern developments; and A.H. MCDONALD, "Textual Criticism," in *Oxford Classical Dictionary*, 2nd ed. (1970), a sound and up-to-date exposition for classical students.

(E.J.Ke.)

Thackeray, William Makepeace

One of the great English Victorian novelists, William Makepeace Thackeray is chiefly celebrated as the author of *Vanity Fair* and *Henry Esmond*, though many critics also think highly of *Barry Lyndon* and *Pendennis*. His novels, teeming with innumerable personages (mostly of the upper and middle classes) and incidents, give the illusion of an actual world and reflect his belief in the conduct of the gentlemanly code of Victorian England. In the preface to the second edition (1848) of her novel, *Jane Eyre*, which she dedicated to Thackeray, Charlotte Brontë wrote that she regarded him as "the first social regenerator of the day." During his lifetime and for long afterward he was considered equal to or even superior to Charles Dickens, who was also his contemporary.

Thackeray, oil painting by S. Laurence (1812–84). In the National Portrait Gallery, London.

Early life and career. Thackeray was born on July 18, 1811, in Calcutta, India, the only child of Richmond and Anne Thackeray. His father, an official of the British East India Company, died in 1815, and two years later Thackeray was sent to live with relatives in England. After attending schools in Southampton and in Chiswick, a suburb of London, he went in 1822 to Charterhouse, the London public school, where he led a rather miserable existence. His mother and her second husband, Major Carmichael-Smyth, whom she had married in 1817, had moved to England in 1819. Thackeray was on affectionate terms with them, although occasionally he chafed at his mother's domineering personality and strict religious

views. In 1829 he entered Trinity College, Cambridge, but he left in the following year without taking a degree. He had already visited France, and now he went to Germany (July 1830–March 1831), staying for most of the time at Weimar, where he met Goethe, Germany's leading man of letters. Back in London, he studied law and engaged in bill discounting for brief periods. Although he led a desultory existence, he read widely and critically in English, French, and German, was an enthusiastic theatregoer, and cultivated stimulating friendships (with the poets Alfred Tennyson and Edward Fitzgerald at Cambridge, for example); he had a natural ability to write fluently and amusingly, and he was a skillful artist. Knowing that he was to inherit a considerable patrimony on his 21st birthday, he thought it unnecessary to apply himself seriously to a profession. Journalism, however, had long attracted him; and in May 1833 he became the owner of a weekly literary periodical, *The National Standard*. He was encouraged in this project by William Maginn, one of the leading journalists of the time. He wrote much for the periodical but was forced to close it in February 1834 for financial reasons. By that time, he had lost all his fortune, partly because it was invested in Indian banks that failed and partly because of his own improvidence. He took up the study of art in Paris, where he met Isabella Shawe, the daughter of an army officer. He married her on August 20, 1836, at the British Embassy in Paris; and in the following year they moved to London. Three daughters were born to them: Anne, Jane (who died in infancy), and Harriet.

Professional journalist

With a family to support and no private means, Thackeray began to work hard as a professional journalist, abandoning any thought of becoming a professional artist. In Paris, between September 1836 and February 1837, he had written articles on French politics for *The Constitutional*, a short-lived newspaper in which his stepfather, hoping to help Thackeray, had acquired a business interest. In London he wrote on a variety of topics for numerous periodicals. His work was unsigned, or written under such pen names as "Michael Angelo Titmarsh" and "George Fitz-Boodle." He contributed book reviews to *The Times*, *The Foreign Quarterly Review*, and *The Morning Chronicle*; but his most notable writing was done for *Fraser's Magazine* and *Punch*. His old friend Maginn, who was mainly responsible for editing *Fraser's Magazine* in the early 1830s, probably brought Thackeray on to its staff in 1834. Influenced by Maginn, the "Fraserians" were irreverent assailants of cant and pretension. Thackeray wrote scathing, witty articles about such subjects as Edward Bulwer-Lytton, a popular novelist (one of the magazine's chief butts), and the *Annuals*, elegantly produced volumes of insipid prose, verse, and pictures. Some of his best known contributions also arose from his scornful attitude to certain prevalent literary fashions: *The Yellowplush Correspondence* started as a review of a foolish book of etiquette; his short novel, *Catherine*, and his first full-length novel, *Barry Lyndon*, were intended as satires on the vogue for fiction with romanticized criminals as heroes. Other works serialized in *Fraser's Magazine* were *A Shabby Genteel Story* and *The History of Samuel Titmarsh and the Great Hoggarty Diamond*. He began writing and drawing for *Punch* in 1842, achieving his greatest success with *The Snobs of England*, later published as *The Book of Snobs*. His *Paris Sketch Book*, a collection of his writings about French matters, reprinted from various periodicals, appeared in 1840. *The Irish Sketch-Book* was a lively personal record of a stay in Ireland, and *Notes of a Journey from Cornhill to Grand Cairo* a similar account of a journey he took to the Mediterranean between August 1844 and February 1845.

This period was an unhappy one for him. He often found journalism irksome, had little money, and could not help feeling aggrieved that his great talents should go unrecognized for so long. He had, moreover, to bear a heavy personal sorrow, as his wife became insane in 1840; he was compelled to separate from her, and eventually to place her in the care of a friendly family living in the country. In 1846 Thackeray and his two daughters, to whom he was a devoted father, settled in Kensington, the district of West London where he was to live for the rest of his life. A tall, heavily built man of striking appearance, with prematurely white hair and a nose that had been flattened in a schoolboy fight at Charterhouse, he was a convivial clubman, affectionate and sentimental toward those close to him. He fell in love with Jane Brookfield, the wife of a friend from Cambridge days, the Rev. William Henry Brookfield, and this passionate but platonic affair tormented him until it ended in 1851. Thackeray had always known it could have no happy outcome, and Brookfield was determined that it should stop.

Personal characteristics

Mature writings. Under the influence of such anxieties and griefs, Thackeray's writing increasingly mellowed in the novels of his great period, which began with *Vanity Fair*. Although his early writing is amusing, acute, and full of vitality, it had remained unknown to the general public. *Vanity Fair*, however, first serialized in monthly shilling parts between 1847 and 1848, and illustrated by himself (as were many of his books), suddenly and belatedly brought Thackeray fame and prosperity. This "novel without a hero" (to use his own description), set in the second decade of the 19th century, the period of the Regency, deals mainly with the interwoven fortunes of two contrasting women, Amelia Sedley and Becky Sharp. The latter, an unprincipled adventuress, is the leading personage and is among the most memorable characters that Thackeray created. *Vanity Fair* was followed by *Pendennis*, which is partly fictionalized autobiography. In it, Thackeray traces the youthful career of Arthur Pendennis—his first love affair, his experiences at "Oxbridge University," his working as a London journalist, and so on—achieving a convincing portrait of a much-tempted young man. Thackeray was now a celebrated author, and in the summer of 1851 he set the seal on his fame by delivering a series of public lectures in London (subsequently repeated in other towns) on "The English Humourists of the 18th Century." He had always admired the authors of that time, and he chose the reign of Queen Anne for the period of his next novel, *Henry Esmond*. Some critics had thought that *Pendennis* was a formless, rambling book. Being highly sensitive to adverse criticism, Thackeray constructed *Henry Esmond* with great care, taking pains to get its historical detail correct. Unlike his other novels, it was published in book form without having been previously serialized. There is much of the author in its hero, Henry Esmond, a sensitive, brave, aristocratic soldier, whose love for two women, Beatrix and her mother, Lady Castlewood, is its main theme. Many admirers of Thackeray's work consider it to be his greatest novel. Throughout his works, he analyzed and deplored snobbery (but at the same time had some sympathy with it); he frequently gave his opinion on human behaviour and the shortcomings of society, though usually prompted by his narrative to do so. Subjects upon which he discoursed include hypocrisy, people's secret emotions, the sorrows sometimes attendant on love, remembrance of things past, and the vanity of much of life—such moralizing being, in his opinion, an important function of the novelist. He had little time for such favourite devices of Victorian novelists as exaggerated characterization and melodramatic plots, preferring in his own work to be more true to life, subtly depicting various moods and plunging the reader into a stream of entertaining narrative, description, dialogue, and comment, all flowing as one.

Lecturer in the United States

In October 1852, Thackeray went to the United States to deliver his lectures on the English humorists. After a highly successful tour, he travelled in Europe with his daughters, writing meanwhile *The Newcomes*. This novel is essentially a detailed study of prosperous middle class society, centred upon the family of the title; the love Clive Newcome and his cousin Ethel have for each other is unhappily thwarted for years because of worldly considerations. Like Dickens, Thackeray wrote "Christmas books," of which the best known, *The Rose and the Ring*, written mostly in Italy, appeared in 1854. He travelled to America again in October 1855, this time

to lecture on "The Four Georges" (the four Hanoverian kings of England of that name); he repeated the series of lectures in England and Scotland in 1856 and 1857. In July 1857, he unsuccessfully stood as an independent, reforming candidate for the city of Oxford constituency in a Parliamentary election. *The Virginians*, his next novel, is set partly in America and partly in England in the latter half of the 18th century and is concerned mostly with the vicissitudes in the lives of two brothers, George and Henry Warrington, the grandsons of Henry Esmond, the hero of his earlier novel. During its serialization, he became involved in a protracted quarrel with a young journalist and fellow member of the Garrick Club, Edmund Yates, who had written a satirical portrait of Thackeray in a periodical, *Town-Talk*, and who enlisted the support of Dickens in the dispute. Thackeray and Dickens were not reconciled until 1863.

The final years of Thackeray's life were dominated by *The Cornhill Magazine*, of which he became the first editor in January 1860. For this magazine he wrote two serial novels, the brief *Lovel the Widower* and the longer *Adventures of Philip*, and charming essays, *Roundabout Papers*, which, in the opinion of some critics, rank with the essays of Charles Lamb. He relinquished the editorship in March 1862, although he continued to write for the magazine. In May 1863 he began another historical novel set in the 18th century, *Denis Duval*, but did not live to complete it. He had been troubled by ill health for a number of years, suffering from digestive and urethral maladies, and died quite suddenly on December 24, 1863. He was buried in Kensal Green Cemetery in the suburbs of London, and a commemorative bust was placed in Westminster Abbey.

MAJOR WORKS

NOVELS: *Catherine* (serialized 1839–40; pub. 1869); *The Luck of Barry Lyndon* (serialized 1844; pub. 2 vol., 1852; rev. as *The Memoirs of Barry Lyndon, Esq.*, 1856); *Vanity Fair* (serialized 1847–48, pub. 1848); *The History of Pendennis* (serialized 1848–50; pub. 2 vol., 1849–50); *The History of Henry Esmond, Esq.*, 3 vol. (1852); *The Newcomes* (serialized 1853–55; pub. 2 vol., 1854–55); *The Virginians* (serialized 1857–59; pub. 2 vol., 1858–59); *Lovel the Widower* (serialized 1860, pub. 1861); *The Adventures of Philip on His Way Through the World* (serialized 1861–62; pub. 3 vol., 1862); *Denis Duval* (unfinished, serialized 1864; pub. 1864).

ESSAYS, SKETCHES, AND MISCELLANIES: *The Yellowplush Correspondence* (serialized 1837–38; pub. 1838, complete ed. 1852 as *The Yellowplush Papers*); *Some Passages in the Life of Major Gahagan* (serialized 1838–39, pub. in vol. 2 of *Comic Tales and Sketches*); *The Paris Sketch Book*, 2 vol. (1840); *Comic Tales and Sketches*, 2 vol. (1841); *The Irish Sketch-Book*, 2 vol. (1843); *Notes of a Journey from Cornhill to Grand Cairo* (1846); *The Snobs of England* (serialized 1846–47; pub. as *The Book of Snobs*, 1848); *The History of Samuel Titmarsh and the Great Hoggarty Diamond* (serialized 1841; pub. as *The Great Hoggarty Diamond*, 1848); *Miscellanies: Prose and Verse*, 2 vol. (1849–51); *The Kickleburys on the Rhine* (1850); *Rebecca and Rowena. A Romance upon Romance* (1850); *A Shabby Genteel Story, and Other Tales* (1852), includes "The Professor," "The Bedford Row Conspiracy," and "A Little Dinner at Timmins's"; *Men's Wives* (serialized 1843, pub. 1852); *Mr. Brown's Letters to a Young Man About Town; with The Proser, and Other Papers* (serialized 1845–50, pub. 1853); *Punch's Prize Novelists, The Fat Contributor, and Travels in London* (serialized 1844–50, pub. 1853); *The Confessions of Fitz-Boodle* (1852); *The Rose and the Ring* (1854, dated 1855); *Miscellanies: Prose and Verse*, 4 vol. (1855–57); *Christmas Books* (1857); *Roundabout Papers* (serialized 1860–63, pub. 1863); *Miscellanies*, 6 vol. (1864); *Early and Late Papers Hitherto Uncollected* (1867); *Miscellanies* (1870); *The Orphan of Pimlico, and Other Sketches, Fragments and Drawings* (1876); *Sultan Stork, and Other Stories and Sketches* (1829–44) (collected 1887).

LECTURES: *The English Humourists of the Eighteenth Century* (1853); *The Four Georges* (1860).

OTHER PROSE: *The Letters and Private Papers of William Makepeace Thackeray*, 4 vol. (1945–46); *Contributions to the Morning Chronicle* (1955).

BIBLIOGRAPHY. For a full description and assessment of writing on Thackeray, see LIONEL STEVENSON, "William Makepeace Thackeray," in *Victorian Fiction: A Guide to Research* (1964). The most comprehensive bibliography is HENRY S. VAN DUZER, *A Thackeray Library* (1919, reprinted 1971). Important manuscripts of letters and literary works are held by the Henry E. Huntington Library, San Marino, California; the Pierpont Morgan Library, New York; and the Berg Collection of the New York Public Library. The *Oxford Thackeray*, ed. by GEORGE SAINTSBURY, 17 vol. (1908), is the standard collected edition of the works. *The Letters and Private Papers of William Makepeace Thackeray*, ed. by GORDON N. RAY, 4 vol. (1945–46), provides much biographical information, and the letters are of absorbing interest in themselves. Ray's two-volume biography, *Thackeray: The Uses of Adversity, 1811–1846* (1955) and *Thackeray: The Age of Wisdom, 1847–1863* (1958), is definitive and indispensable. DUDLEY FLAMM, *Thackeray's Critics* (1967), is an annotated bibliography of 19th-century criticism, some of the most important items of which are reproduced in *Thackeray: The Critical Heritage*, ed. by GEOFFREY TILLOTSON and DONALD HAWES (1968). An interesting critical estimate by a friend and fellow novelist is provided by ANTHONY TROLLOPE, *Thackeray* (1879, reprinted 1968). Saintsbury's acute and enthusiastic introductions to the volumes in the *Oxford Thackeray* were collected as *A Consideration of Thackeray* (1931). GEOFFREY TILLOTSON, *Thackeray the Novelist* (1954), is a subtle, persuasive exploration of his art. A variety of 20th-century opinions is assembled in *Thackeray: A Collection of Critical Essays*, ed. by ALEXANDER WELSH (1968).

Thailand

A nation wedged like a keystone into the heart of Southeast Asia, Thailand in the last decades of the 20th century holds a critical position in the attempts of the countries of this area to achieve and maintain a political, economic, and social stability. Since 1932, when an absolutist monarchy was overthrown, the nation has been a constitutional monarchy with a representative legislature; in 1939 the official name was changed from Siam to Prathet Thai, or Thailand—literally, the "land of the free." The several ethnic and religious groups represented among Thailand's more than 34,000,000 people are characteristic of the cultural diversity that for centuries has spread across this portion of the continent, a mélange of influences from the two Asian giants, China and India.

Thailand's landscape is one of high mountains at the edge of the Himalayan chain, of fertile, alluvial plains dotted with rice paddies, and of sandy beaches and tropical forests set amid the latitudes of the Asian monsoons. The main body of the country is surrounded by Burma on the west and northwest, Laos on the northeast and east, Cambodia on the southeast, and the Gulf of Thailand (Gulf of Siam) on the south. From the southwest corner, part of Thailand stretches southward down the Malay Peninsula as far as Malaysia. This peninsula cuts off shipping using Thailand's capital and chief port, Bangkok, from points westward; Bangkok is, nevertheless, the international air hub of Southeast Asia.

Contacts of long standing between Thailand and the West have affected the forms if not the realities of Thailand's political and economic life. The relative political stability Thailand has maintained in the face of continual Communist guerrilla warfare inside its borders since World War II is largely the result of Western support. Thailand's free-enterprise economy participates vigorously in worldwide commerce yet remains based on primary products and relies on imports for manufactured goods. In addition, the nation's economic balance is maintained by aid from the United States and other nations. (For information on the nation's history, see the article SIAM AND THAILAND, HISTORY OF; for its linguistic background, TAI LANGUAGES; for its arts, SOUTHEAST ASIAN PEOPLES, ARTS OF; for an associated physical feature, MEKONG RIVER. See also the article BANGKOK.)

THE NATURAL AND HUMAN LANDSCAPE

The natural environment. Three main geological regions cover most of Thailand's 198,455 square miles (514,000 square kilometres)—the folded mountains in the north, the Khorat uplift in the east, and the Chao Phraya depression, comprising much of the central plains. In addition, the maritime southeast and the long, slender peninsula in the southwest constitute separate physical regions. The monsoon climate prevailing across most of the country has a distinct influence on the land-

scape, its vegetation and animal life, and its human uses.

Physiographic regions and drainage. The mountains, a continuation of the Himalayan system from India, Burma, and China, extend far southward in Thailand along the western border and the peninsula and into Malaysia. Long granitic ridges were formed when great masses of molten rock forced their way upward through the older sedimentary strata. Between the ridges lie relatively flat basins drained by the four principal tributaries of the Chao Phraya, Thailand's major river. Important provincial centres, or *changwats*, such as Chiang Mai, Lampang, Phrae, and Nan, grew up along these four streams. The alluvial soils of these intermontane basins provide fertile soil for the cultivation of rice, vegetables, tobacco, and fruit trees. Peaks average about 5,200 feet above sea level. Doi Inthanon, at 8,514 feet (2,595 metres) the highest in the kingdom, is southwest of the ancient city of Chiang Mai (Chiengmai), which is overshadowed by the peak of Doi Suthep, a tourist attraction and site of the royal resort palace, Phu Phing Ratchanivet. Many of the rugged limestone hills contain caves from which remains of prehistoric man have been excavated.

The mountains, the Khorat Plateau, and the southeast

The lower reaches of the mountains are rich in teak and other commercial timber, while the upper slopes are dotted with tea plantations. The rivers emptying through narrow valleys into the central plain are glutted by the monsoons, sweeping along in their steep descent great quantities of sediments that have produced vast, fan-shaped heaps of alluvial deposits along the flood plains at the foot of the mountainous regions.

The Khorat region, enfolded on three sides by Laos and Cambodia, consists of a two-sided geological fault that has been tilted rather than a uniform uplift of the underlying sedimentary rocks. At the western edge, the tilting produced north–south ranges whose escarpments look westward over the central plain. To the south, the tilting produced east–west ranges along the Cambodian border; these form steep escarpments that overlook the Cambodian plain. Surface elevations in the Khorat region are about 650 feet; the terrain is rolling, and the hilltops generally slope in conformity with the tilt of the land. Monsoon rains over the thin forest cover produce rapid runoff; flooding occurs almost yearly at Ubon Ratchathani at the junction of the Mun and Chi. These two major rivers have built up scattered alluvial lands that are used for rice growing.

Close to the Mekong River, which meanders across the north and east of the Khorat region and runs along most of the Laotian border, swampy land and lakes are common, in contrast to the aridity of much of the region. A high underground water table that can be tapped produces mostly unpalatable water, but the Thai government has done much to improve the freshwater situation in this part of the kingdom. The Mekong itself, from about 2,300 to 4,300 feet wide, is either studded with islands or broken up by impassable rapids. The governments of both Thailand and Laos, however, are planning for its use in agriculture and industry.

The generally rolling countryside of the southeast has high hills in the centre and along the eastern boundary with Cambodia. Notable peaks are Khao Khieo (2,614 feet [797 metres]), visible from the top of Phu Khao Thong (the Golden Mount) in Bangkok, and Khao Soi Dao ("Reaching for the stars"), which attains a height of 5,471 feet (1,668 metres). The mountains, reaching nearly to the sea, create a markedly indented coastline fringed with many islands, some of which are popular tourist resorts. The short, seaward-running streams have built up small alluvial basins and deltas along the coast, while the mouths of larger rivers consist of tidal flats and mangrove swamps. Long stretches of sandy beach make Chon Buri, Rayong, and some of the islands year-round resorts. On higher grounds plantations produce rubber, sugarcane, pineapples, and cassava.

The central plains and the peninsula

The central plains, which form the Thai heartland, consist of two regions—the heavily dissected rolling plains in the north and the Chao Phraya River Delta. A rolling plain in the north also is heavily dissected, principally by the three rivers—the combined Ping and Wang, the Yom, and the Nan—that merge to form the Chao Phraya and its delta. Like most deltas, that of the Chao Phraya, which stretches southward to the Gulf of Thailand, is braided into many small channels; it is joined by other rivers as it crosses the plains. The usual flooding of the flat delta in the wet season is an asset to the rice-growing activity, although higher ground on the extreme eastern and western edges of the delta requires irrigation. The entire delta was at one time covered by the Gulf of Thailand, but the water-borne sediments from the uplands to the north filled it in over many centuries. Such silting is a continuing obstruction to navigation channels of the Chao Phraya, but it also provides several feet of new land each year at the river's mouth—so much so that a temple once on an island now lies on the river's west bank.

The topography of the peninsula is rolling to mountainous, with little flat land. A gently sloping sandy coastline, the site of the famous beach Hua Hin, borders the Gulf of Thailand on the east. The Phet is one of several large rivers dammed for irrigation. Massive mountains on the west, reaching about 4,900 feet, contain difficult passes between Thailand and Burma. Toward Malaysia mountains look to the Andaman Sea to the west and to the South China Sea to the east. Off the rugged and much-indented west coast lie numerous major islands, including tin-rich Phuket and others rich in bird and fish life.

Climate. The major influences on Thailand's climate are its location on the Indochinese Peninsula within the sphere of the tropical monsoons and certain topographic features that modify the effects of the rains. Beginning in May, warm, humid air masses flow northeastward over the region from the Indian Ocean, depositing great quantities of rain that reach a maximum in September. Between October and February, the wind currents are reversed, and cold, dry air masses are driven in from the northeast. Stagnant air in March and April is associated with the hot, dry season.

Effects of the monsoons

Topographic effects are most noticeable on the peninsula, where Ranong on the west receives 188 inches (4,772 millimetres) of rain annually, and Hua Hin on the east receives only 40 inches (1,007 millimetres). Songkhla has its rainy season during the winter months, the result of moisture picked up from the Gulf of Thailand by the cold northeast air masses. In this area a true tropical rain-forest climate prevails.

Nationwide, temperatures are relatively steady throughout the year, averaging between 75° and 86° F (24° and

30° C). The greatest fluctuations are in the north, where frost may occur in December on higher elevations; maritime influences moderate the climate in the south. The cold, dry winter air produces frequent morning fogs that generally dissipate by midday.

Vegetation and animal life. About one-half of Thailand is forested, one-fifth covered by grass, shrub, and swamp, and the remainder under settlement or cultivation. Forests consist largely of such hardwoods as teak and members of the dipterocarp family of timber- and resin-producing trees. As elsewhere in Southeast Asia, bamboo, palms, rattan, and many kinds of fern are common. The southeastern forest is dense with undergrowth and aerial roots, while orchids climb the trunks of many trees. Grasses and shrubs have sprung up across many cutover areas, and lotuses and water lilies dot most ponds and swamps throughout the country.

Elephants, buffalo, cattle, horses, and mules are among the important domesticated animals for agriculture and transportation. Some elephants are still found wild in the west and the northeast. Although forestry is now done by machines, elephants remain helpful in difficult terrain. Agricultural machines are rapidly replacing draft animals, and horses and mules increasingly are used only as pack animals along the mountain trails of the north. Wild animals are decreasing in quantity and in number of species due to game hunting. The rhinoceros and tapir are almost extinct. Deer and antelope can still be found, but the big cats are becoming fewer in number. The Siamese cat is popular among foreigners.

Lizards live around houses and prey on insects. Frogs and toads (some of them edible) are numerous, and crocodiles are also found; a crocodile farm in Bangkok raises them for commercial and scientific purposes. Snakes abound, including the king cobra, numerous vipers, and dangerous water snakes. A snake farm in Bangkok raises many kinds for extracting venom. The green turtle of the sandy coast lays hundreds of eggs at a time, which are highly regarded as culinary delicacies.

Both freshwater and marine fish are abundant, as are edible crustaceans, such as shrimp, prawn, and sea crabs.

The most useful insect is the silkworm. Many species are wild, but some are raised for the prosperous silk industry. Mosquitoes still carry malaria, although incidence of the malady is decreasing. White ants and moths are a scourge to clothing and books.

Human uses of the land. *Traditional regions.* In the traditional or popular sense, the regions of Thailand are the Lanna Thai, or northern Thailand; the Isan, or northeastern Thailand; the central plain; the southeast; the Pak Tai, or south Thailand; and west and southwest Thailand.

The people of the mountainous Lanna Thai speak a dialect similar to that of neighbouring Burma. The women wear simple blouses and knee-length sarong; the men wear loose trousers and cotton jackets called *mohom*. Most of the people live on glutinous rather than common rice. The people have a complexion that is fairer than that of other Thai. The fertile valley plains grow rice and such other crops as peanuts, beans, garlic, onions, corn, and tobacco on the irrigated lands. Tea, widely cultivated as a permanent crop, is consumed in the north as both a pickled and a drinking tea. Besides rice, the outstanding export of the region consists of teak and other commercial timbers. The mountains of the north are also the home of the mountain Thai, who migrate from Burma, Laos, and sometimes from southern China.

Interactions of the natural and human ecologies

The Isan is situated on the undulating terrain bordered on the west and south by rather hilly topography. The people dress much like the northern Thai, except close to the Cambodian border, where the *pha chong kraben*—a side-rolled skirt for women, a broadly bloused and belted pantaloon-like garment for men—similar to the Hindu dress of India, is worn instead of trousers. The dialect is like that of Laos, although very similar to that of the central Thai. With some attention, however, the northerners and the northeasterners can understand one another. Agglutinous rice is consumed in most of the northeast, except near the Cambodian border. Besides rice, various kinds of timbers, jute, and cattle constitute important exports. In general, the people depend on agriculture, but the scanty rainfall and sandy soil make the living in the region difficult. As a result, migration from the northeast to other parts of the country is common. The highway to the northeast and thence to Laos makes the region a growing crossroads. It is probably the only part of the country to which the government is devoting both attention and money in an effort to raise the standard of living to that of the other regions.

The central plain, lying mostly on the undulating to flat delta region, is the major rice-producing area of the country, much of whose surplus is exported. Because of its central position, population and manpower are heavily concentrated, especially in Bangkok, and industrial and commercial enterprises have grown faster there than elsewhere. The eastern, western, and northern peripheries of the central plain, however, remain to be developed. The soil of the northern half of the plain is inferior. People from the northeast and other places have migrated to the central area in hope of a better living.

The southeast, lying close to the sea on an undulating to hilly region, is well watered. Close to the sea fishing predominates; plantations and gem mines are found on the inner hill and mountain slopes. Thai of Chinese descent live here in great numbers. Tapioca and sugarcane are the chief crops, and fish supply the Bangkok and the upper-country markets and are also exported. Chanthaburi and Trat are famous for their sapphires. The beaches are popular and attract foreign tourists.

The people of the Pak Tai region of the peninsula speak a dialect that has a different intonation from that of the central Thai. The extreme south consists of Thai who speak the Malay language, the majority of whom are Muslim. The southern economy depends on exports of tin and rubber. Fishing provides income for the people living close to the seas on both sides of the peninsula. Phuket and Songkhla are well-known for their fine beaches, which are lined with beautiful coconut groves.

The west and southwest, consisting mostly of hilly to mountainous terrain adjoining the Burmese border, is sparsely populated. The forest covers are chiefly mixed deciduous and bamboo. The soils are rich with minerals, such as tin, tungsten (wolfram), and fluorite. The Karen from Burma often migrate and live within the Thai border. They clear the land and cultivate the hill slopes in the same manner as the mountain Thai in northern Thailand. The region is also the chief supplier of the bamboo used in the curing of rubber.

Patterns of settlement. Hill settlements depend much on shifting cultivation of upland crops. Such mountain Thai as the Karen, Meo, Yao, Lahu, Lisu, and the lowland Thai who have migrated usually settle on the ridges and the slopes in groups ranging from two to three to 100 or more houses, depending on the resources of the area. The Meo are opium cultivators, preferring to live on high slopes where opium grows well in the cool climate. The Karen live along the stream valleys and grow rice on well-tended, terraced fields. The Thai who have migrated earn a living from their tea and coffee plantations.

Rural and urban Thailand

No true plains villages exist in Thailand, although in the northeast the villages are scattered on the higher grounds to escape the floods; the lower grounds are used for rice farming. In the north, where the villages are found on the alluvial basins of major rivers, increased population and transportation have tended to disperse the villages away from the river toward the main railroads and highways, reducing the amount of rice-growing land.

The delta is densely settled, but only on the high ground that is free from flooding. The irrigation canals modify the pattern of settlement; with increasing facility in transportation offered by small motorboats, the villages tend to become dispersed away from the rivers in an east–west direction. New highways also tend to modify the pattern of settlement, especially at the crossings of canals and rivers by highways, where new towns grow up rapidly.

The southern and southeastern plantations, especially the fruit and rubber plantations, are scattered along the fertile slopes, alternating with the low and narrow rice fields, and the villages are therefore arranged according-

ly. Most of them are joined by good roads and highways. Alluvial deposits containing tin, no matter how isolated, are accessible to all kinds of land and sea communications. Settlement is almost continuous along both sides of the peninsula. Most of the people live by fishing, except in areas in which bird's-nest collecting (the jelly-like adhesive of which is the basis of a popular soup or sweet dessert) brings a good income. The coastal villages are connected both by land and sea highways.

Urban settlement in Thailand is found mostly on the plains and in the coastal areas rather than on the hills. Bangkok, for example, grew from a small settlement on the east bank of the Chao Phraya. In other large towns, such as Chiang Mai, the old, square city walls are still apparent, with numerous Buddhist temples scattered inside and outside the walls. Thus, urbanization in Thailand can be said to centre around the original sites of the palaces and the temples. Other interesting patterns of settlement can be observed in certain urbanized areas. Phitsanulok, for example, has a number of floating houses along both banks of the rivers. Chon Buri, a seaside town, has a trellis pattern of houses on islands that are accessible by footbridges. Such patterns of settlement reflect the strong demand for living space in the urban areas.

THE PEOPLE OF THAILAND

The diversity of ethnic, linguistic, and religious groups in Thailand is characteristic of most nations of Southeast Asia, where shifting political boundaries have done little to impede the centuries-long migrations of people from one area to another.

Composition of the population. *Ethnic groups.* Thai people are found not only in Thailand but also in Laos, Burma, India, both Vietnams, and in southern China. These Thai speak the Thai language, but with different accents and a few different words. Little difference exists between the Thai in Laos, Burma, and even in China and those of northern Thailand, but there is a noticeable difference between them and the Thai living in the central plain and close to Cambodia. The peninsular Thai also are much influenced by the Malay.

Geographical dispersion of Thai peoples

Wars between Thailand and Burma in the past brought many refugees and prisoners of war into Thailand. The Mon, a Burmese people, settled in many parts of the north, the centre, and the west; their distinctiveness is evident in their festivals and religious rites. Even the original Thai are not completely free from ethnic intermixture, and the ethnic origin of the modern Thai is even more complex when the Chinese and the Indian descendants are considered. Bangkok is the chief melting pot of the Thai race. Tracing true Thai blood in Bangkok should not be attempted, as a famous Thai scholar (himself of Chinese descent) has said, for what makes the Thai is the institution.

Except the Karen, who mixed rather easily with the northern Thai, the hill tribes, or the mountain Thai, prefer to keep themselves isolated. They occasionally come down to the markets to trade with the lowlanders. They are probably of purer stock than the modern Thai. Two small hill tribes are of special interest, the Lawa and the Semang. The Lawa are believed by some historians to be the original dwellers of the delta plain, driven into the hills of the northwest by the Thai who conquered the area. The Semang of the southern mountains live by hunting with blowpipes and spears. Another ethnic group that often escapes attention is that of the Chao Nam, or sea dwellers. Rarely settling permanently, they live by fishing along the western coast and the adjacent islands of the peninsula.

Linguistic groups. The Thai, who live in almost all areas, comprise the majority linguistic group. The greatest concentration is in the Chao Phraya Delta. Burmese, Laotian, and Cambodian influences already have been noted. The people of Tak and Kanchanaburi, near the southwestern Burmese border, speak Karen and Mon. From Chumphon to the south, the Thai speak a southern dialect with much musical inflection. Most of the Thai have been in contact with one another, especially administrative officials and teachers, and the Thai living in remote areas can understand the central Thai.

The mix of tongues and faiths

Chinese is the second major language. In the commer-

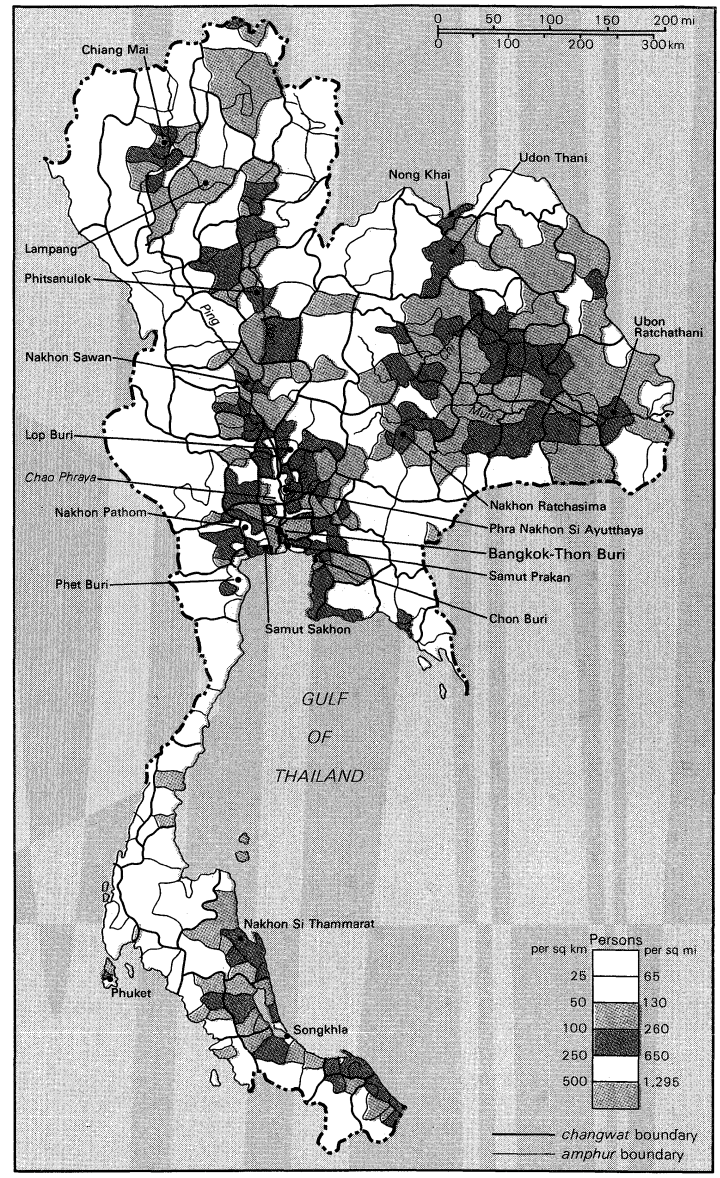
cial centres of Bangkok and other cities, Chinese or their descendants operate both large and small commercial enterprises. Those of Chinese descent also make a living as middlemen and storekeepers. Most of them speak Chinese, as do some of the northern hill tribes, such as the Meo and Ho.

Although no reliable statistics exist, English-speaking Thai probably make up the third major linguistic group. English is required in secondary schools and the university, and frequent contact with American military personnel also encourages the speaking of English. The prevalence of Indian dialects reflects the large number of Indian merchants and their descendants in the commercial centres. Other linguistic groups are found among the mountain Thai. Some of them can speak Chinese, although most of them understand the northern Thai dialect (see further TAI LANGUAGES).

Religious groups. The religious groups in Thailand, in order of size, are the Buddhists, the Muslims, the Confucians, the Christians, and the Sikhs. Buddhism, professed by more than 90% of the population, is considered the national religion, and Buddhists are scattered throughout the nation. Muslims live mostly in the south, whereas about one-half of the Christians live in the central region. Hindus and the Sikhs are concentrated in the central region, chiefly around Bangkok. Although several of the hill tribes have converted to Buddhism or Christianity, most remain animists. An interesting religious group in Thailand, although totalling only about 4,000 families, exerts much influence on the Thai religious life. These are the Brahmins. The royal and the official ceremonies are almost always directed or performed by the Brahmins, whose rites are blended harmoniously with those of the Buddhists. Brahmins are famous for their astrological experiences. The plowing ceremony, carried out in the presence of the king and queen by Brahmins and other officials, is believed to bring a good rice harvest. The Brahmins and the royal astrologers are also responsible for the preparation of the national calendar.



Brahmin religious influence

Contemporary demography. *Birthrates and mortality rates.* By the early 1970s, Thailand's population had more than doubled since World War II. Trends suggest that comparable growth will continue, since the government's attempts at family planning run counter to much social and religious tradition. The very high birthrate of about 33 per year per 1,000 people is about twice that of many Western nations, but, since Thailand is an agricultural country, the population pressure on the land is not as serious as it would be in an industrial country. The World Health Organization has helped to suppress such endemic diseases as malaria and tuberculosis. The death rate has been reduced from about 16 persons per 1,000 to about 7.0 per 1,000 since World War II.

Distribution of population. Productivity and location make the delta plain of the Chao Phraya the most densely populated area. The municipality of Bangkok-Thonburi alone had a population of about 3,200,000 persons in 1970. Population centres in the north and northeast generally follow the rivers. The southern population is concentrated along the eastern coast, where there are some wide strips of agricultural lands. Tin mining and smelting and shipping on the west coast make Phuket Island the most densely populated province of the south. The southeast coast is also another heavily populated area. Areas of forest, rugged topography, dry and infertile soils, or swampy vegetation are thinly populated.

Migratory patterns. Immigration, especially from China, is more significant than emigration. The government has felt that overpopulation by the Chinese in Bangkok and other commercial centres must be controlled. Although the quota has been brought down to 200 a year, the number of Chinese nationals in Thailand at present is about 400,000, not including Chinese who are Thai citizens. Of the Europeans, Americans, and Indians who take up residence for commercial purposes, only some of the Indians make Thailand their permanent home.

The northern hill tribes, of course, have immigrated from neighbouring countries. This influx continues, and in the early 1970s they numbered between 300,000 and 500,000 persons. Their immigration can be traced to their need for more land to grow opium and other crops, to the demand for labour in the forest industry, and to political unrest in their original homeland.

Population density of Thailand.
By courtesy of the Royal Thai Survey Department

Emigration of Thai doctors and nurses to other countries, especially to the United States, has resulted in serious shortages of medical personnel in Thailand.

THE NATIONAL ECONOMY

Thailand's economy is still based on the production of basic agricultural, mineral, forest, and other raw materials. Its gold and other foreign-exchange reserves increased by about 15% annually after 1957, and the Thai unit of currency, the baht, is among the world's most stable currencies.

The economic milieu. *Areas of economic activity.* Growing demands have encouraged a stronger and more diversified Thai agriculture. Rice is likely to remain as the major crop, unless radical dietary changes occur in Asia. Sweet corn, cassava, and plants yielding fibres are other major crops. Fine breeds of cattle and pigs have been introduced from the West. Hardwoods, such as teak and yang (a source of gurjun balsam), are major forest products; rubber trees—introduced into the country during the 19th century—are important. Fishery includes both marine species and freshwater fish caught in the rivers or in cultivation ponds.

Primary and fabricated products

There are more than 650 tin mines, most of them in the peninsula, making Thailand the world's third-largest producer of tin. Construction of a smelter has made possible domestic smelting of most of the ore. Iron-ore production rose manyfold during the 1960s. Other important mining and quarrying operations produce gypsum, fluorite, tungsten, limestone, and marble.

The share of the gross national product (GNP) contributed by manufacturing is only about 15 percent, with the major part of it involved in processing agricultural, forest, and mineral products. The main centres for large industry is the Bangkok-Thonburi metropolis, while numerous cottage industries in the north produce textiles, teak carvings, lacquer ware, and similar products. In the southeast, in addition to food processing, oil refining and gem cutting are carried on.

Thailand has several hydroelectric plants, but most electrical power is produced by generating plants using gas and solid fuels, such as lignite, which is mined in Thailand. A nuclear-power plant is under construction at Chon Buri. Small amounts of petroleum are produced domestically, and the government has granted concessions for offshore explorations in the Gulf of Thailand.

The Bank of Thailand, established in 1942, issues currency, acts as central banker to the government and to the 16 commercial banks, and serves as fiscal agent in dealing with international monetary organizations. Nearly one-half of the nation's retailing and other distribution businesses are located in Bangkok-Thonburi. Middlemen handle most farm commodities. Retail stores are small, except in Bangkok, which has several large department and cut-rate stores. In these, as well as in most food markets, prices are fixed; bargaining occurs mostly in the souvenir and gift shops of larger cities.

With agricultural and raw materials the basic exports, manufactured goods, such as machinery and transportation equipment, account for the highest value among imports. Thailand's major trading partner, both for exports and imports, is Japan; most other exports are sent to other Asian nations, whereas most other imports are from Europe and the United States.

Management of the economy. A huge public debt, incurred since World War II, is componded by the situation created by the rapidly increasing population that leaves less agricultural surplus for export. During the 1960s, however, the volume output of the Thai economy doubled, rising about 8% annually. Under government development plans, gross national products increased at a slightly lower figure annually. Private and governmental investment rose consistently in this period. Aiming at diversification, the government has supported a greater number of small industries since 1964. To encourage exports, duties are low, except on rice, to which a premium is attached to prevent domestic shortages.

Government and economic planning

Unions are prohibited, but the Labour Disputes Act of 1966 guarantees good working conditions and fair wages. Strikes are not allowed, unless management representatives fail to agree with employees and Labour Department mediators.

Transportation and communications. Bangkok is the centre of Thailand's water, land, and air transport. The rivers of the delta have been used for transport since antiquity, and modern irrigation canals have added to the inland-waterway mileage. Because of the rains, it is difficult to keep some highways open all year, especially in the peninsula. Mountain trails are often the only means of travel in remote areas. Where roads are inadequate, airplane and helicopter services often compensate. Rail lines radiate from Bangkok in several directions, one linking up with the Cambodian rail system.

The port of Bangkok, at Khlong Toei, is the largest and busiest of the 22 in the kingdom, handling 95% of imports and 85% of exports. It is congested, however, and expansion is planned. Don Muang Airport, north of Bangkok, is served by 28 international airlines, including Thai Airways International, a state-owned line. Over 20 smaller airports are located throughout the country.

There are some 8,000 post offices, performing both regular and ancillary services. Domestic and foreign telegraphic facilities are also available. The Telephone Organization of Thailand services well over 150,000 (a figure constantly rising) telephones and links 25 provinces with telephone and radio-relay cable.

ADMINISTRATION AND SOCIAL CONDITIONS

Structure of government. Following the revolution of 1932, a provisional constitution was promulgated, stating that supreme power lay in the hands of the people. The monarch, the National Assembly, the Commissariat of the People (later, the State Council), and the law courts were to exercise power on their behalf. Since then, several constitutions have been created because of changes of government, but the provisions are similar.

Under the present constitution, the king is head of state and of the armed forces. He is held to be sacred and inviolable, and in the name of the people he exercises legislative power, with the advice and consent of the Assembly. He also appoints the prime minister. Executive powers are vested in a Council of Ministers, judicial powers in the courts; both operate in the name of the king. The royal family is very much at the core of modern Thai society, being regarded as the symbol of national unity and the protector of national welfare and traditions.

Constitutional framework and legal system

In form, the Thai government resembles those of Western nations; various ministries are responsible for such matters as finances, agriculture, education, public health, communications, and justice.

The province, or *changwat*, of which there are 70, is the major unit of local government. Beneath these are districts, subdistricts, and communes and villages. The 120 municipalities in the kingdom are classified as cities, towns, or communes, according to their populations; they are run by an elected mayor and councillors.

Thai law has been influenced heavily by the Hindu code of Manu, which probably was transmitted through the ancient Mon kingdom located in central Thailand. Reform in the late 19th century introduced concepts of Western jurisprudence. All judges sitting in the 110 courts across the country are professionals, appointed without political consideration; they are bolstered by a system of judge trainees.

Under the king as commander in chief, the army, navy, and air forces are assisted by the Military Assistance Program, and by the Southeast Asia Treaty Organization (SEATO), of which Thailand is a member. Thai soldiers have fought in Korea and Vietnam, but in the early 1970s they were fully occupied in containing Communist infiltration from neighbouring countries.

The political process. Thailand has had only nine elections since 1932, and in those years 13 attempts have been made to overthrow the 16 cabinets, of which six were successful. The military has been involved in most of these attempts to influence the course of government. Dissatisfaction with the pace of Thailand's progress toward achieving standards of living comparable with those in most Western nations has been at the bottom of many of these coups, some originating from within the parliament. The successful coup of November 1971 was directed also at slowing the Communist insurgency within the country and at a rapidly rising crime rate.

The social milieu. The average per capita income in Thailand is about 3,400 baht (21 baht = $1 U.S.; 50.4 baht = £1 sterling, on December 1, 1970), with regional averages ranging from 4,800 in the central region to only 1,300 in the northeast. In the early 1970s almost half of the population was under 15 years of age, creating an enormous dependency rate. The cost-of-living index was also rising dramatically.

Thailand's health and welfare services remain far from adequate. The emigration of potential medical practitioners to more lucrative practices in the West has tended to undermine governmental attempts to upgrade services within the country. Mobile medical centres and helicopters attempt to alleviate the lack of widespread facilities. The doctor-patient ratio in the early 1970s was 15 per 100,000, and medical practice on the midwife level was common. Infant mortality and diseases of childbirth are leading causes of death, whereas malaria has been widely

Health, welfare, housing, and education

reduced through the use of DDT, which has hastened the devastation of forest areas as a side effect.

Only Bangkok-Thonburi, and a few other large municipalities have housing shortages. The construction of government-financed housing cannot keep pace with demand, and slum areas have proliferated in some parts of the city.

A National Scheme of Education was introduced in 1960, requiring children under 15 to complete seven years of elementary education. Secondary education generally lasts five years, but when it is vocational it lasts six. Only a small minority of students go on to secondary training, however. The entrance without examination of some 60,000 students into newly opened Ramkhamhaeng University in 1971 nearly trebled the nation's university and teacher-training population. Eight other institutions, not including military academies, offer degrees in undergraduate and postgraduate fields.

CULTURAL LIFE AND INSTITUTIONS

According to many historians, the Thai's original home was in China, perhaps as far north as Mongolia. The Thai brought with them many cultural institutions of the Chinese. They began settlement in the Indochinese Peninsula about 800 years ago, at which time some Indian colonies already were established. Indian culture has been continuously absorbed into Thai life. Modifications were affected by the cultures of the Mon people, the Javanese, and the Khmer and Burmese people.

Traditional arts and customs

Thai arts are reflected in religion, architecture, porcelain and pottery, painting, music, drama, and literature. In religion artistic expression can be found in the sculpture of Buddha images. Thai architectural style is to be seen in the temples. Wood is usually the basic construction material. The ornamental parts are generally gilded and enriched with glass mosaic, gold leaf, porcelain, stucco, lacquer, and inlaid mother-of-pearl. The multiple-structured temple ground is a paradise for architects. Porcelain and pottery, although at first put to utilitarian uses, were later regarded as objects of art. Thai painting probably derived from India and Ceylon and is mostly religious; the artists are anonymous monks or dedicated laymen. The paintings are usually drawn on the temple walls, which are constructed with bricks and plaster.

Thai music is based on a unique system. It is not derived from the Chinese or Javanese systems, although the instruments used for playing may look the same.

The royal palace plays an important role in leading and preserving Thai culture through frequent royal functions and state ceremonies. Among these is the Kathin ceremony, a colourful pageant marking the end of the Buddhist Lent. It takes place with a procession of royal barges on the Chao Phraya, reconstructing a tradition dating from the earliest days of Buddhism. Thai temples hold ceremonies to mark the special events of Buddha's life. These are often accompanied by fun fairs to attract large crowds to the temples.

The University of Fine Arts teaches all Thai fine arts, including drama and music. It also designs architectural structures for the government as well as the religious institutions in a style that will preserve Thai forms. The Royal Institute of Thailand and the Siam Society are responsible for research and publication concerning the Thai way of life. The National Museum acts as an educational and information centre for the evolution of culture in the country.

The first type for printing Thai letters was devised by a British captain in 1828, and the first printing press was brought to Thailand by an American missionary in 1836. The Thai government made use of the printing press for the first time in 1839, when a royal proclamation banning opium smoking and trade was printed.

The communications media

The number of newspapers in the early 1970s—more than 15 in Bangkok printed in Thai, Chinese, and English, and some 50 in the provinces—was growing rapidly. Similarly, the number of radio and television sets was soaring: farmers often carried radios in the fields, and the roofline of many small towns sprouted a forest of antennas. About 30 radio transmitters, which cover most of Thailand, are operated by the government's Public Relations Department. In 1955 Thailand became the first nation of mainland Asia to have regular television programming, and in the early 1970s Bangkok had eight channels; three provincial stations reach over 30 provinces. Two Earth satellite stations were built at Si Racha in 1970 to facilitate overseas television links.

BIBLIOGRAPHY. The annual *Thailand Official Year Book* is the best source for current information. An excellent, well-illustrated pamphlet of the TRIBAL RESEARCH CENTER OF THAILAND, "Tribesmen and Peasants in North Thailand, 1967" (1969), briefly describes all the tribesmen in Thailand. The ROYAL THAI SURVEY DEPARTMENT, *Thailand National Resources Atlas* (1969), is the only atlas that can be used authoritatively as a reference. MASASHICHI NISHIO, "Public Health in Thailand," *Southeast Asian Studies*, vol. 11, no. 1 (1964; Eng. trans. JPRS 32217, 1965), based on scholarly research, gives a true picture of health conditions in Thailand. On physical geography, see ROBERT L. PENDLETON, *Report to Accompany the Provisional Map of the Soils and Surface Rocks of the Kingdom of Siam* (1953); and the SIAM, MINISTRY OF COMMERCE AND COMMUNICATIONS, *Nature and Industry* (1930).

(P.P.A.)

Thames River

The Thames, the principal river of England and the stream on the banks of which London was built, winds through six of the country's southern counties for 210 miles (338 kilometres), of which 92 miles are tidal, to the North Sea. Rising in the southwest in the Cotswolds of Gloucestershire at Thameshead, three miles from Cirencester, it broadens to 125 feet at Oxford and 250 feet at Teddington, the tidal head. At London Bridge it has widened to 750 feet, and 16 miles downstream, at Gravesend, it is 2,100 feet wide; and nearer the sea, between Sheerness and Shoeburyness, the estuary expands rapidly to 5½ miles. The average gradient from source to tidal water is 30 inches per mile (for related information see LONDON).

The first of its tributaries enters the stream 154 miles above London Bridge; this is the Churn, whose source at Seven Springs, four miles south of Cheltenham, has some claim to be the source of the Thames. Descending a broad vale, it accepts the waters of the Coln, the Windrush, the Evenlode, the Cherwell, the Ock, and the Thame before its valley becomes steep-sided as it divides the Chiltern Hills from the Berkshire Downs. At Pangbourne the river turns abruptly eastward and flows beneath beautifully wooded slopes, taking in the Kennet and the Loddon. Below Maidenhead the landscape flattens, save for Windsor's lone knoll, after which it is joined by the Colne, the Wey, and the Mole. Below Teddington Lock, 19 miles upstream from London Bridge, the river is tidal. Through Greater London it is embanked and spanned by 18 roads and six railway bridges. After the Tower Bridge and the Pool of London down the ten miles to Greenwich, the banks are given over to quays and docks, and tunnels replace bridges: Rotherhithe, Blackwall, Greenwich, and Woolwich, the latter two for pedestrians only. Along the next stretch to Tilbury and Gravesend, estuarine marshes alternate with factories and chalk bluffs; the Purfleet–Dartford Tunnel, connecting Essex and Kent, permits bypassing of London. Below Tilbury, the main outport, the wide estuary is coastal in nature.

Drainage pattern of the river basin

The Thames Basin divides distinctly in two, above and below the Goring Gap. The upper portion, on Jurassic strata of which older Lias and oolitic (round-grained limestone) series form the higher rim, is itself divided by a line of hills breached by the river at Oxford, where drainage converges. The lower basin consists of chalk downfolded into a syncline or depression, with a west–east axis and a covering of Eocene sands and clays.

The thick series of Mesozoic clays and limestones, of varying resistances to erosion, were subject at a later period to folding that created a downwarp along the line of the present Kennet-Thames. Individual streams flowing east toward the proto-Kennet-Thames were later captured by its more effective westward flow. The upper Thames itself developed as a west–east subsequent stream and captured southward-flowing Cotswold streams (see RIVERS AND RIVER SYSTEMS).

Eventually, the whole of this intricate pattern was profoundly influenced by the Ice Age with its climatic changes. Ice invaded the north and northeast of the basin, and in periods of melt and of heavy rain great floods poured down the valleys, which were successively deepened and finally left encumbered with gravel and alluvium upon which the present relatively small rivers meander. In addition, the lower Thames was pushed southward from the vale of St. Albans to a position near the southern chalk rim. Throughout the Thames system, tiers of river terraces were formed, often of sand and gravel of economic value. In the Middle Gravels of the Boyn Hill terrace at Swanscombe, a fragmentary skull was found, dating from the interglacial period and closely related to *Homo sapiens*.

A permeable basin and year-round rainfall ensure a regular flow. The monthly averages of the daily mean natural discharge at Teddington from a drainage basin of 3,812 square miles (9,873 square kilometres) vary from 4,900 cusecs (cubic feet per second) in January to 1,074 cusecs in August, with an annual mean of 2,703 cusecs (1 cusec = 0.0283 cubic metre per second). When the river runs full to its banks (with a flow of 9,114 cusecs), it temporarily floods the nontidal lowlands; during heavy floods the flow may exceed 19,000 cusecs. Floods occasionally threaten the embanked stretches in the centre of London when high-river spates pour toward the estuary at the same time that strong spring tides are running from the sea. Fears that the city may be inundated by rare "surge tides" thrust up the estuary by North Sea gales have led the London authorities to consider the erection of downstream barriers. Because the Thames is the chief water supply for London and its western suburbs (and also for districts around Oxford and Faringdon), drought, when the flow can drop below 300 cusecs, is also a matter for serious concern. The freshwater Thames has been controlled by the Thames Conservancy Board since 1857 and the tidal Thames below Teddington by the Port of London Authority since 1908.

Called the Tamesis by Julius Caesar and, by early English chroniclers, variously the Tamis, Tamisa, or Tamensim, the river has been sweetly sung of by bards throughout history. But in London after the mid-19th century it became more of an open sewer than a poetic stream. Starting in 1963 the freshwater and tidal authorities, aided by new regulations, began a battle against pollution that is visibly restoring the purity of the Thames.

Poetry and pollution of the Thames

The river became navigable by barges to Oxford and beyond by 1624 but with difficulty until locks were constructed above Staines in 1771. Locks between Staines and Teddington were added in 1810–15 by the London Corporation. Later improvements allowed boats drawing three feet to reach Lechlade. Some barge traffic uses the river above Teddington, especially to Kingston. Passenger steamers ply daily in summer between Oxford and Kingston, also from Westminster in London County upstream to Kew, Richmond, and Hampton Court, and downstream from Tower Pier to Tilbury, Southend-on-Sea, and Margate. Water-buses run between Greenwich and Putney. Ferries cross the Thames at Woolwich–North Woolwich and Gravesend–Tilbury. Pleasure boating is popular, especially on the freshwater Thames.

Some of the derelict canals that connect with the freshwater Thames were restored for pleasure boating in the 1960s; those off the tidal stretches are used commercially, including the Grand Union Canal to the Midlands. The Thames below Tower Bridge is one of the world's most important commercial waterways, its traffic supervised by the Thames Navigational Service.

BIBLIOGRAPHY. *The Thames Book* (1971), is a useful general guide, supplemented by K. FIDLER, *The Thames in Story* (1971) and ROY CURTIS, *Thames Passport* (1970). See also *The Thames Book* (annual), and the ASSOCIATION OF THAMES YACHT CLUBS, *Thames Handbook* (1956–60). *The River Thames: The Highway of the Port of London* (1970) covers the river's economic importance; while *The Oarsman's and Angler's Map of the River Thames . . . with Notes on Punting* (1927) deals with a recreational side.

(B.E.)

Thar Desert

The Thar Desert, or Great Indian Desert, consists of a tract of rolling sand hills lying partly in the Indian state of Rājasthān and partly in Pakistan. Covering 77,000 square miles (200,000 square kilometres) of territory, it is bordered by the irrigated Indus Plain to the west, the Arāvalli Range to the southeast, the Rann of Kutch to the south, and the Punjab Plain to the north and northeast. The desert results from the dryness of the prevailing monsoon winds, which do not bring sufficient rain to keep the region moist. The name Thar is derived from *t'hul*, the general term for the region's sand ridges. The Thar is inhabited by about 7,000,000 people, most of whom eke out a modest existence through subsistence agriculture.

Since the India-Pakistan waters agreement in 1960, both countries have undertaken major irrigation schemes in the region. Mineral deposits remain largely unexploited, however, and the economic emphasis remains on agriculture (for a related physical feature, see INDUS RIVER; see also DESERTS).

The landscape. *Geology.* The desert sands cover early Precambrian gneiss (granite-like metamorphic rocks formed in the oldest geological era, which began 4,600,000,000 years ago), sedimentary rocks from 570,000,000 to 2,500,000 years old, and more recent material deposited by rivers (alluvium). The surface sand is aeolian (wind-deposited) sand of the Quaternary Period (the most recent geological period, which began 7,000,000 years ago).

Relief. The desert presents an undulating surface, with high and low sand dunes separated by sandy plains and low, barren hills, or *bhakars*, which rise abruptly from the surrounding plains. The dunes are in continual motion and take on varying shapes and sizes. Older dunes, however, are in a semistabilized or stabilized condition, and many rise to a height of almost 500 feet. Several playas (saline lakes), locally known as *dhands*, are scattered throughout the region.

Drainage and soils. The drainage is mainly interior, except for the Indus River in the west and the Lūni River, which drains the southeast. Short, seasonal streams (wadis) are formed in the uplands only during the rains, but they soon die out in the sand.

The soils consist of seven main groups—desert soils; red desertic soils; sierozems (brownish-gray soils); the red and yellow soils of the foothills; the saline soils of the depressions; and the lithosols (shallow, weathered soils); and regosols (soft, loose soils) found in the hills. All these soils are predominantly coarse-textured, well-drained, and calcareous (calcium-bearing). A thick accumulation of lime often occurs at varying depths. The soils are generally infertile and, because of severe wind erosion, are overblown with sand.

The seven groups of soils

Climate. The amount of annual rainfall in the desert tract is generally low, ranging from about 4 inches or less in the west to about 20 inches in the east. Precipitation is highly erratic, and there are wide fluctuations in the amount from year to year. About 90% of the total annual rain occurs during the season of the southwest monsoon, from July to September. At other seasons the wind blows from the northeast. May and June are the hottest months of the year, with temperatures rising to 122° F (50° C). During January, the coldest month, the mean minimum temperature ranges between 41° and 50° F (5° and 10° C), and frost is frequent. Dust storms and dust-raising winds, often blowing with velocities of 140 to 150 kilometres per hour (87 to 93 miles per hour), are common in May and June.

Vegetation and animal life. The desert vegetation is mostly herbaceous, or of stunted scrub; trees occasionally dot the landscape. On the hills, gum arabic acacia and euphorbia may be found. The *khajri* (*Prosopis cineraria*) tree grows throughout the plains; several other trees and shrubs, including the jujube, also occur. The stable sand dunes support a scanty vegetation of grasses, shrubs, and trees; a wild gourd, the *Citrullus colocynthis* (colocynth), is widespread.

Game animals

The thinly populated grasslands support the black buck, the chikara, and some feathered game, notably the francolin and quail. Among the migratory birds, sand grouse, ducks, and geese are common. The desert is also the home of the vanishing great bustard.

There are five major breeds of cattle in the Thar tract. Among these, the Tharparkar breed is the highest milk yielder, while the Kankre breed is good both as a beast of burden and as a milk producer. Sheep are bred for both medium-fine and rough wool. The camel is commonly used for transport, as well as for ploughing the land and other agricultural purposes.

The inhabitants. About 80% of the population of 7,000,000 are rural, and they are distributed in densities that vary from ten persons per square mile in Jaisalmer District in the south to 104 persons per square mile in Churu district in the east. Customs, rituals, and modes of dress are manifold. Both Islām and Hinduism are practiced, and the population is divided into complex economic and social groups. Many nomads are engaged in animal husbandry, crafts, or trade. They do not belong to a specific ethnic group, nor are they associated with a separate area; in general they are symbiotically related to the sedentary population and its economy.

Natural resources and their exploitation. *Grasses.* The grasses form the main natural resources of the desert. They provide nutritive and palatable pasturage, as well as medicines used locally by the inhabitants. Alkaloids, used for making medicine, and oils for making soap are also extracted.

Water. Water is very scarce. Whatever seasonal rain falls is collected in tanks and reservoirs and is used for drinking and domestic purposes throughout the year. Most groundwater cannot be utilized because it lies deep underground and is often saline. Recently, however, good aquifers (geological formations containing water) have been detected in the central part of the desert.

Minerals. Lignite (brown coal) is mined at Palana near Bīkaner, and natural gas has been located at Kamli Tal, northwest of the town of Jaisalmer. Deposits of gypsum now being exploited—located in Nāgaur, Jaisalmer, Bīkaner, and Barmer districts—are estimated at about 100,000,000 tons. Other minerals found in the region are limestone, bentonite (a clay formed from the decomposition of volcanic ash), glass sands, and minerals suitable for making ceramics. Salt is harvested from the saline lakes.

Irrigation. Apart from wells and tanks, canals are the main sources of water throughout the desert. When water is available, crops such as wheat, cotton, sugarcane, millet, sesame, castor beans, and chili peppers are grown. The Sukkur (Lloyd) Barrage on the Indus River, completed in 1932, irrigates the southern Thar region in Pakistan by means of canals, while the Gang Canal brings water from the Sutlej River to part of the northern region. The Rājasthān Canal, when completed in 1980, will irrigate 2,470,000 acres, mainly in the Bīkaner and Jaisalmer districts of India. The canal begins at the Harike Barrage—at the confluence of the Sutlej and Bēas rivers in the Indian Punjab—and continues in a southwesterly direction for 292 miles. It is hoped that it will provide agricultural land in the project area that will support about 2,000,000 people in place of the present (1970) 100,000 and will turn a substantial part of the dreary desert into a rich granary.

Power. Thermal power-generating plants, fuelled by coal and oil, are located only in the large towns and supply power only locally. Hydroelectric power is supplied by the Nangal power plant located on the Sutlej River in Punjab. When the Rājasthān Canal is completed it will generate about 22,000 kilowatts of hydroelectric power generated at big falls situated along its length.

Transport. Roads and railways are few. One railway line serves the southern part of the region from Lūni Junction, India, to Hyderābād, Pakistan. In the Indian part of the desert, a second line goes from Merta Road to Sūratgarh via Bīkaner, while another connects the towns of Jodhpur and Jaisalmer. In the Pakistani part of the desert, another railway line runs between Bahāwalpur and Hyderābād. There are few paved roads in the region.

The India-Pakistan waters agreement. The partition of India and Pakistan in 1947 left most of the irrigation canals fed by the rivers of the Indus System in Pakistani territory, while a large desert region remained unirrigated on the Indian side of the border. The Indus Water Treaty of 1960 fixed and delimited the rights and obligations of both countries concerning the use of waters of the Indus River system. Under the agreement, waters of the Rāvi, Bēas, and Sutlej rivers are to be made available to the Rājasthān Canal to irrigate mainly the desertic tract covering the Bīkaner and Jaisalmer districts in India.

Future prospects. Future economic development in the desert depends to some extent upon the harnessing of the sun's rays and the wind. Such possibilities as developing high-temperature solar furnaces for the production of electricity, and constructing windmills for lifting deep groundwater and powering flour mills, were investigated in the late 1960s with promising results. It has also been indicated that solar electricity can be generated from saline water contained in "solar ponds." Such developmental projects when completed would do much to enhance the living standards of the inhabitants of the region. (B.B.R./S.Pa.)

Theales

Theales constitutes one of the larger orders of the flowering plants, consisting of 21 families, with approximately 155 genera and 2,550 species. Theales plants vary in form, structure, and range of habitats and are related to many other plant orders. Some authorities suggest that at least a few of the related orders evolved from an ancestor that, if still extant, would be included within the Theales. From this viewpoint, therefore, the order is of considerable interest.

Another feature of interest is the distribution of the species within the families. Four families contain 400 or more species; one has about 120 species; and the other 16 are of somewhat equivocal status. None contains more than 40 species. Many authorities merge the 16 small families with one or another of the larger families or place them in other orders.

GENERAL FEATURES

Distribution and abundance. The order Theales is predominantly tropical in distribution, occurring in rain forests or in upland evergreen broad-leaved forests; few species occur in temperate regions. Members of the order are found almost worldwide; however, the centre of distribution is in Southeast Asia.

Importance. Members of one family, Dipterocarpaceae, are characteristic of the Malaysian rain forest, where species form the upper canopy at heights up to 250 feet (about 80 metres). Many species of this family are of economic importance for their timber; others produce valuable resins. *Camellia* (*Thea*) *sinensis*, the tea plant, is the most important economic species in the order. It has been cultivated for a long period of time in eastern India (Assam), Tibet, and China, the area to which it is probably native. Tea is also grown in several other areas (*e.g.*, Ceylon, Turkey, and the U.S.S.R.).

The tea plant

Other species of *Camellia* (*e.g.*, *C. japonica*) are widely cultivated as ornamentals in gardens in the temperate zone. *Gordonia*, *Stuartia* (both of the family Theaceae), *Hypericum* (Hypericaceae), *Ochna* (Ochnaceae), and many other genera are used as horticultural ornamentals.

Edible fruits include the souari nut (*Caryocar nuciferum*, family Caryocaraceae), the mammee apple (*Mammea americana*, Clusiaceae), and the mangosteen (*Garcinia mangostana*, Clusiaceae).

NATURAL HISTORY

Pollination. Not much is known about the pollination mechanisms in the order, but a number of notable structural developments seem to be related to pollination.

The most simple is the uniting of the stamens (male parts) either in a ring, as in the cultivated camellias, or in

bundles, as in the common Saint-John's-wort (*Hypericum*) and in many tropical members of the order. In some members of the family Clusiaceae the stamens are united into very condensed groups known as phalanxes. A further adaptation, presumably effective in pollination, is the extreme elongation of the stamens of the family Caryocaraceae; these project considerably beyond the petals and are also united at the base.

The most remarkable pollination adaptations are found in members of the Marcgraviaceae, in which the floral bracts, small leaflike structures located just below the flowers, are transformed into nectar-secreting organs of various shapes, but always hollow and somewhat pitcher-like. In the simplest case (found in three genera), a bract subtends each flower. In the genus *Marcgravia*, however, the flower cluster is pendulous and umbellate —the flowers are on stalks that radiate from a common point, umbrella fashion. The central flowers of the umbel are sterile, and their bracts are enlarged to form erect, pitcher-like structures, superficially very like the insectivorous pitchers of *Nepenthes*, which hang below the outer ring of fertile flowers. These nectar-filled pitchers attract hummingbirds, which were once thought to pollinate the fertile flowers as they hovered, drinking the nectar. In at least two Guyanese species, the hummingbirds approach the pitchers from above the fertile flowers and do not come into contact with the stamens or the stigmata (female parts). In these two species, the stamens open in the late bud stage, and the flowers are actually self-fertilized.

Hummingbird flowers

Seed dispersal. Various dispersal mechanisms occur in the order, but only two are noteworthy. In most families, the aging sepals persist around the ripening fruit, and in various groups, notably the families Dipterocarpaceae and Lophiraceae, two or more of them enlarge above the fruit, producing a two-winged structure that is distributed by the wind.

The most remarkable development connected with the seeds occurs in the family Dioncophyllaceae. In this group the fruits open before ripening, and the developing seeds are pushed out from the fruit by the lengthened and hardened funiculi—the stalks on which the ovules grow within the ovary. The seeds continue to develop in this exposed position until ripe, when they fall, leaving the remains of the fruit and the funiculi. The function of this strange process, which is unique among flowering plants, is unknown.

Ecology. The order is extremely diverse in its habitat requirements. There are trees of the tropical rain forests (the family Dipterocarpaceae and others), climbers in the same forests (Marcgraviaceae), mangrove growth forms in coastal tidewaters (Pellicieraceae), trees and shrubs of the mountain evergreen broad-leaved forests (Theaceae and others), herbs and shrubs of various temperate habitats (Theaceae, Hypericaceae), and aquatics of tropical and temperate freshwaters (Elatinaceae). The morphological variability of the order is thus reflected in its ecology.

FORM AND FUNCTION

Vegetative characters. The order Theales is not well distinguished from other plant orders, and there are no conclusive diagnostic characters that will consistently serve to distinguish it. The following features occur frequently in the order, however, and, in combination, serve to characterize it in a general way.

The plants are usually woody, often with evergreen foliage. The leaves are usually simple, and resins are often present in the tissues. The bisexual flowers are mostly hypogynous; *i.e.*, the sepals, petals, and male parts (stamens) arise at the base of the ovary, a condition in which the ovary is described as "superior." The calyx consists of free sepals and the corolla of free petals, and the flower is radially symmetrical. The stamens are usually numerous, with a tendency to be united, either in a ring or in a number of separate bundles. The ovary is composed of two to many usually united segments called carpels, or simple ovaries, that each bear ovules—developing seeds—that attach along the central axis.

Resins are found in many members of the order, and some are of economic importance. In the family Hypericaceae, the resins occur in distinct, often globular glands, which may be yellow, orange, red, or black; similar glands occur in some of the smaller families (*e.g.*, Diegodendraceae and Tetrameristaceae). In the family Dipterocarpaceae, the resins are more generally distributed throughout the tissues.

Although most species of the order are evergreen trees or shrubs, the family Marcgraviaceae, found in the forests of tropical South America, is composed of climbers. These have a number of structural modifications, particularly in the genus *Marcgravia*, which shows shoot dimorphism, a condition that consists of two distinct types of vegetative growth patterns. The climbing shoots bear small leaves without stalks that are arranged in two rows (distichous) on the branches. Short adventitious (aerial) roots develop along these shoots and enable them to climb. The upper shoots, which bear pendulous flower clusters at their ends, have much larger, stalked, spirally arranged leaves, and lack the adventitious roots of the climbing stems. The transition between one shoot type and the other is often quite abrupt. The cause is unknown, but it is thought that the increase in the amount of light received by the shoots as they climb higher may be involved.

Variable plant organs

The family Dioncophyllaceae also shows remarkable vegetative modifications. In two of its genera, the leaves have two forms, one being "normal," the other terminating in two leathery hooks that presumably enable the plant to scramble over other vegetation. In the third genus, the leaves are of three forms, two as just described plus a third type with an elongation of the midrib, projecting beyond the blade and bearing glandular hairs. The function of the elongated part, which is called a rhabdode, is unknown, but the glandular hairs borne on it are very similar in structure to the "tentacles" of the insectivorous genus *Drosophyllum* of the order Nepenthales. The leaves of the Dioncophyllaceae have been compared both to the leaves of the Droseraceae and to the pitcher-bearing leaves of the family Nepenthaceae, but botanists agree that they are not insectivorous.

Floral characters. The flowers are exceptionally variable, and a wide range of structures occurs. There are usually distinct sepals and petals, though in some cases (family Dipterocarpaceae) the petals may be rather leathery and not brightly coloured. The sepals are usually four or five in number, free, and overlapping. In some groups, however, there is no sharp distinction between the sepals and the floral bracts and bracteoles—small green appendages just below the flowers—and the calyx appears to consist of a compressed spiral of several segments. This condition of the flower buds is called perulate. The flower petals vary from two to many, though four or five occur most commonly. They are normally free but may be fused to the ring formed by the united bases of the stamens.

The stamens are usually numerous (more rarely five to ten) and are centrifugally arranged (*i.e.*, they ripen from the centre of the flower toward the circumference). They are usually united, either into a ring, to which the petals are sometimes joined, or into distinct bundles. The anthers (pollen sacs) usually open by slits, but terminal pores occur in some groups (*e.g.*, Ochnaceae). The connective between the anthers is sometimes prolonged into an appendage (as in Dipterocarpaceae and Oncothecaceae).

The ovary consists of two or more (frequently five) carpels that are united, or, if apparently free, have a united style—the narrow upper portion. The ovules have two integuments, or coverings, and endosperm, a starchy nutrient tissue for the developing embryo, may be present or absent in the seed.

EVOLUTION

Fossil record. As with most flowering plant groups, the fossil record of the Theales order is both scanty and of little value in deducing the evolutionary history of the group. Noteworthy features include the occurrence of

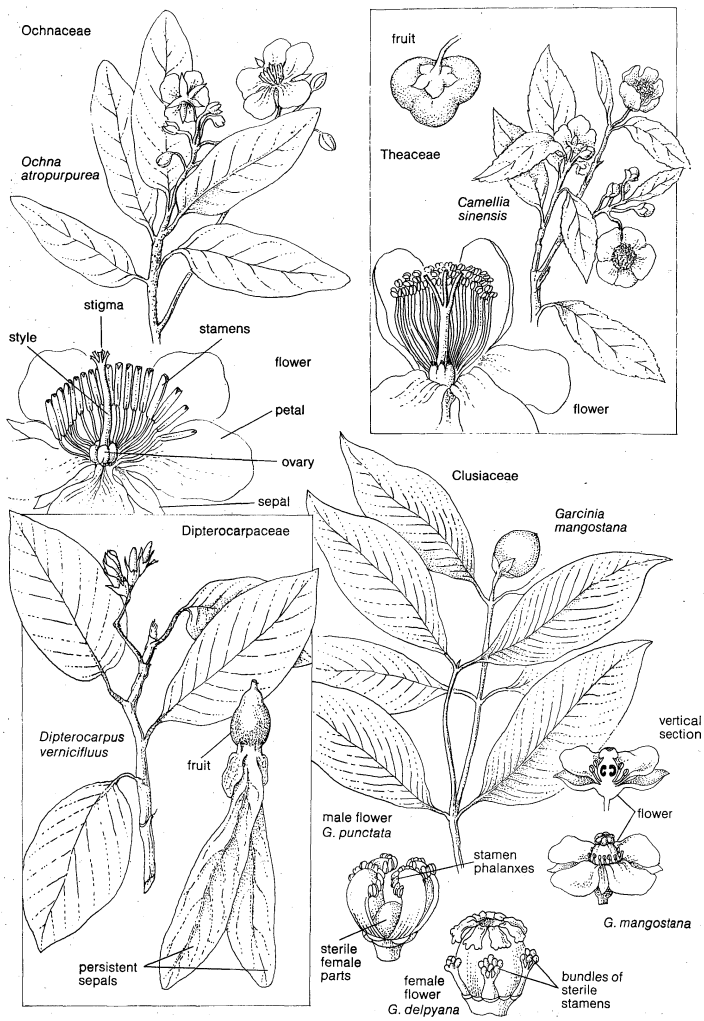


Figure 1: Vegetative, floral, and fruiting structures of four of the larger families of the order Theales.

Drawing by M. Pahl; *G. punctata and G. delpyana* based on A. Engler, *Syllabus der Pflanzen familien;* floral details of *G. mangostana* based on L.H. Bailey, *Manual of Cultivated Plants* (1949); the Macmillan Company

fossils from families that are at present entirely tropical (Dipterocarpaceae and Clusiaceae) in deposits of Tertiary age (beginning about 65,000,000 years ago) in Europe and in the Mediterranean area.

Phylogeny. The difficulty of deducing evolutionary relationships of such a variable group is revealed by extreme affinities that have been suggested for it. It has been suggested by some authorities, for example, that the order is derived from early members of the family Dilleniaceae (order Dilleniales). Others stress this relationship by merging the Theales and Dilleniales, either completely or in part. Again, the similarity between the orders Theales and the Ericales leads to the view that the order Ericales was derived from the Theales. Some authorities, in fact, place the order Theales in a crucial position in their systems, suggesting that the origins of several other plant groups are to be found in a "thealaceous" ancestor. These groups are the orders Capparales, Primulales, Diapensiales, Salicales, Violales, Sarraceniales, and Malvales, and the family Lecythidaceae of the order Myrtales, as well as the Ericales already mentioned.

Central evolutionary position of the Theales

The problem of the precise meaning of phylogenetic origins occurs with this group. It cannot be denied that similarities exist among the orders mentioned, but many botanists are skeptical that all or even most of them arose from the Theales.

Within the order the problems of phylogeny are similar. A few indications as to the evolutionary relationships of the families emerge, however, even though they do not give a clear picture of evolution within the order.

The family Ochnaceae, for instance, appears to be linked to the Dipterocarpaceae through the family Lophiraceae. Similarly, the families Theaceae and Clusiaceae are linked by the Bonnetiaceae. Many of the smaller families included in the order are sufficiently similar to various of the larger families for them to be merged by various workers. Thus, the family Lophiraceae is usually included in the Ochnaceae; Bonnetiaceae, Asteropeiaceae, Tetrameristaceae, and Pellicieraceae in the Theaceae; and Hypericaceae in the Clusiaceae (the resulting large family, in the last instance, is often called Guttiferae). The remaining smaller families—Strasburgeriaceae, Ancistrocladaceae, Dioncophyllaceae, Diegodendraceae, Marcgraviaceae, Pentaphylacaceae, Caryocaraceae, Quiinaceae, Medusagynaceae, and Oncothecaceae—form a mixed group. Some of them are clearly allied to the large families within the order, whereas others are of more controversial status.

Drawing by M. Pahl based on (Dioncophyllaceae) Nach Airy Shaw in A. Engler, *Syllabus der Pflanzen familien*, Gebruder Borntraeger Verlag, Berlin, Stuttgart

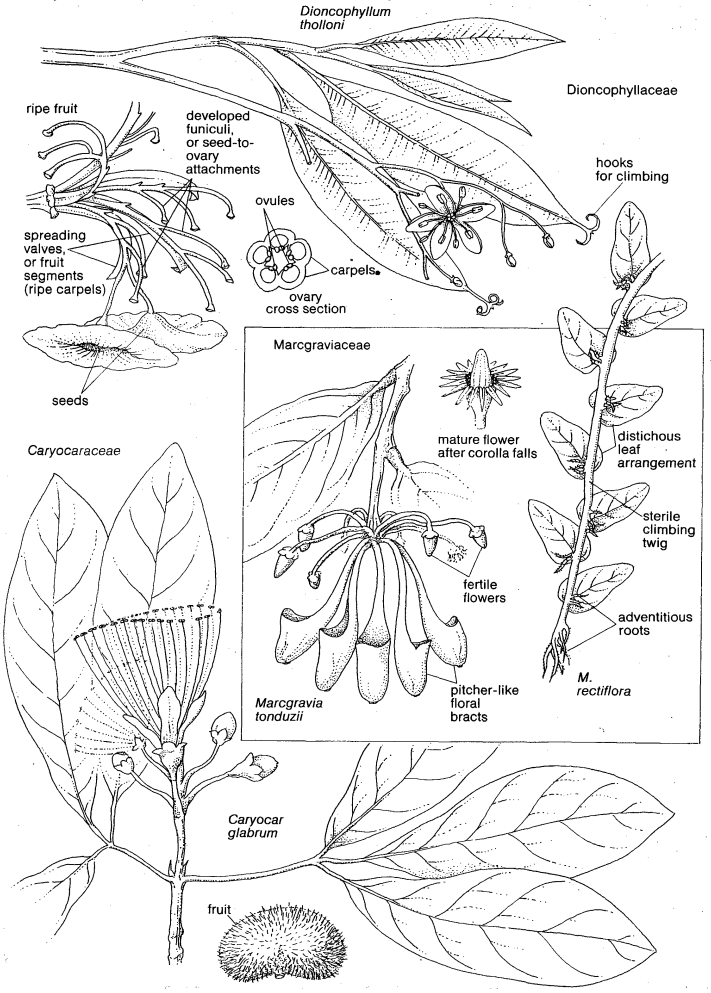

Figure 2: Vegetative, floral, and fruiting structures of three of the smaller families in the order Theales.

CLASSIFICATION

Distinguishing taxonomic features. Some of the characteristics used in distinguishing the families have been mentioned. The curious bracts of the Marcgraviaceae and the enlarged and persistant calyx of Lophiraceae and Dipterocarpaceae, for instance, serve to diagnose these families. Because the group is so variable, many other characters are used in its classification; these include variations in habitat, leaf position and form, presence or absence of stipules, and floral characters.

Annotated classification. The following classification treats as separate families groups that have traditionally been considered as subfamilies or tribes of the larger families. Also included here are a few small families (Medusagynaceae, Oncothecaceae, and Elatinaceae) whose relationship to the rest of the order is somewhat

doubtful. The affinities of these families have not yet been settled, and their inclusion here is based, to some extent, on taxonomic intuition.

ORDER THEALES

Trees, shrubs, or woody climbers, rarely herbs. Leaves alternate or opposite, usually simple and evergreen, with or without stipules. Flowers solitary or in inflorescences (clusters) of varying degrees of complexity and usually radially symmetrical and bisexual. Sepals sometimes 4 but usually 5 to many, usually free and overlapping, sometimes not distinguishable from the bracts and bracteoles. Petals usually 5, free or rarely united at the base (sometimes to the tube formed by the stamens) or the apex. Stamens usually numerous, maturing from the centre of the flower outward, often united in bundles or in a ring. Carpels usually 5, more rarely fewer or more numerous, usually united; when free they are still joined by means of the united styles. Placentation (ovule attachment) usually axile—to the central axis of the ovary. Seeds with or without endosperm. Twenty-one families with approximately 155 genera and 2,550 species. Distribution throughout the tropics, with extensions into subtropical and temperate regions of both hemispheres.

Family Ochnaceae

Trees, shrubs, or very rarely herbs. Leaves alternate, usually simple, with many pinnately arranged (*i.e.*, branching from a midrib), parallel, lateral secondary veins. Stipules are present but inclined to fall early and are sometimes deeply cut into narrow lobes. Flowers in racemes or panicles (simple- and complex-branched flower clusters, respectively), bisexual, usually radially symmetrical (rarely bilaterally symmetrical, at least with regard to the stamens). Sepals 4 or 5, or sometimes up to 10, free, usually overlapping. Petals sometimes 4, usually 5, but occasionally up to 10, free, contorted, or overlapping, falling early. Stamens usually numerous, in 3 to 5 whorls, free; in some genera sterile stamens (staminodia) are present. Filaments short, anthers (pollen sacs) usually opening by terminal pores, more rarely by longitudinal slits. Ovary variable, of 1 to 15 carpels. Two main types of ovary structure occur: (1) carpels united into a compound ovary with terminal style; (2) carpels free, borne on the fleshy receptacle (the expanded tip of the flower stalk bearing the flower parts), united by means of the single style. Ovules 1 to several in each carpel, placentation along the central axis of the ovary or on the inner walls. Fruit a capsule, usually splitting between the carpel segments in ovaries of type (1) or, in ovaries of type (2), a group of fleshy drupes (stone-seeded fruits) borne on a fleshy receptacle that enlarges with age. Seeds 1 to many, with or without endosperm, usually with a straight embryo. Twenty-seven genera and about 400 species widely distributed in the tropics of the world, with a few species in subtropical areas, notably in southern Africa. The largest genera are *Ouratea* (about 210 species) and *Ochna* (95 species).

Family Lophiraceae

Trees, with alternate, simple leaves with venation like that of the Ochnaceae. Flowers large, showy, in panicles. Sepals 5; petals 5; stamens numerous, anthers opening by short slits near the apex only. Ovary of 2 carpels, incompletely 2-chambered; styles 2, terminal, ovules 10 to 12 per chamber, placentation basal. Fruit a woody capsule, surrounded by the persistent calyx, of which the outermost segment is much enlarged and the next somewhat enlarged, producing an unequally 2-winged reproductive structure reminiscent of that of the family Dipterocarpaceae. One genus with 2 species, distributed in tropical Africa.

Family Dipterocarpaceae

Trees with resin. Leaves alternate, simple, with a covering of stellate (branched in star shapes) hairs or peltate (shield-like) scales. Stipules present, falling early. Flowers bisexual, radially symmetric, often fragrant, arranged in panicles. Calyx of 5 overlapping or valvate (touching along the edges) sepals, free or united; may be joined to the ovary at the base. Petals 5, twisted, often leathery. Stamens numerous, anthers opening by slits, the connective (the apex of the filament between the anther sacs) prolonged, usually to a point. Ovary of 3 carpels, with 3 chambers; ovules 2 in each chamber, placentation axile. Style entire or 3-lobed. Fruit indehiscent (*i.e.*, it does not split open along definite seams), usually 1-seeded, surrounded by the persistent calyx, of which 2 or more lobes are much enlarged, forming a winged reproductive structure. Seeds without endosperm. Twenty-two genera and about 400 species distributed mainly in the Asian tropics but also with 2 genera (about 24 species) in tropical Africa.

Family Strasburgeriaceae

Trees with large, alternate, simple, remotely toothed leaves. Stipules present, each pair fused into a simple or 2-parted scale borne in the axil (upper angle between leaf stalk and shoot) of the leaf. Flowers bisexual, radially symmetrical, solitary, axillary. Calyx of up to 10 closely overlapping, free segments, not sharply distinct from the bracts and bracteoles, persistent in fruit. Petals 5, free, overlapping, fleshy. Stamens 10, with versatile (movable) anthers. A thick, lobed, nectar-producing disk is present, its 10 lobes alternating with the 10 stamens. Ovary 10-ribbed, of 5 united carpels; ovules 2 in each carpel, placentation axile. Fruit berrylike, pulpy throughout, indehiscent, more or less corky when ripe. Seeds 2 or 1 in each ovary chamber, winged, with endosperm. One genus and species (*Strasburgeria calliantha*), distributed in New Caledonia.

Family Ancistrocladaceae

Climbing shrubs with the ends of the branches forming hooks. Leaves alternate, simple, with small, early-falling stipules. Flowers small, borne in panicles with recurved branches, bisexual, radially symmetrical. Calyx of 5 segments, united below to form a tube, which at maturity becomes fused to the ovary. Sepals persistent and unequally enlarged and winglike in fruit. Petals 5, contorted, slightly fused at the base. Stamens 5 or 10. Ovary of 3 carpels, with one chamber containing a solitary ovule. Fruit a nut. Seed with remarkably folded cotyledons ("seed leaves"), the seed coat intruding between the folds. One genus with about 16 species, distributed in southern India, Ceylon, Southeast Asia, and tropical West Africa.

Family Dioncophyllaceae

Scrambling shrubs. Leaves alternate, simple, with many parallel lateral veins, dimorphic (2 forms), or, in one genus trimorphic; *i.e.*, the leaf forms are (1) "normal," (2) with hooks at the apex, or (3) bearing an elongate extension of the midrib covered with capitate (swollen-headed) glands (a rhabdode). Stipules absent. Flowers in cymose inflorescences (flower clusters that mature from the top downward), bisexual, radially symmetrical. Sepals 5, free or somewhat united at the base, persistent in fruit. Petals 5, free. Stamens 10 or many, free. Disk absent. Ovary of 2 to 5 carpels, 1-chambered, ovules numerous, placentation parietal. Fruit at first closed, later opening by 2 to 5 valves, from which the seeds project as they ripen, borne on elongate, thickened and woody funiculi (stalks). Seeds peltately borne (shieldlike, the stalk into the centre of the disk), disklike, broadly winged, hanging from the funiculi. Endosperm present. Three genera with 1 species each or 1 genus with 3 species, depending on the authority consulted. Distribution in the forests of west tropical Africa.

Family Diegodendraceae

Trees or shrubs (2 growth forms of the single species found in this family) with alternate, simple, entire, pinnately veined, leaves dotted with transparent depressions. Stipules present, very long, wrapped around the bud and falling early, leaving an annular (ring-shaped) scar. Flowers bisexual, radially symmetrical, in a cymose-paniculate terminal inflorescence (many-branched flower clusters maturing from the top downward). Sepals 5 or 6, unequal, overlapping, free, persistent. Petals 5, free, equal, deciduous (falling). Stamens many, free. Carpels 2 or 3, free, on a small receptacle, covered with peltate scales, united by the style, which divides above into 2 or 3 separate stigmata (pollen-receiving surfaces). Ovules 2 in each carpel, basal. Fruit unknown. This family, which was first described in the early 1960s, contains a single genus and species (*Diegodendron humbertii*), distributed in Madagascar.

Family Theaceae (Ternstroemiaceae)

Trees or shrubs with alternate, simple, mostly evergreen leaves without stipules. Flowers usually showy, solitary, or more rarely in racemes or panicles, radially symmetrical, mostly bisexual. Calyx of 5 or more sepals (when more than 5 these not distinguishable from bracts and bracteoles), overlapping, usually free. Stamens usually numerous, free, or shortly united in a ring, sometimes fused to the petal bases. Anthers usually opening by slits, rarely by terminal pores. Ovary 3- to 5-carpellate. Ovules 2 or more in each chamber, placentation axile; styles free or united. Fruit dehiscent or indehiscent. Seeds with folded or twisted embryo and scanty endosperm. Twenty-eight genera and about 575 species, distributed in tropical and temperate regions of the world.

Family Marcgraviaceae

Climbing or epiphytic (*i.e.*, not rooted in soil but living upon aerial surfaces) shrubs. Leaves alternate, simple, without stipules, sometimes dimorphic. Flowers bisexual, radially or bilaterally symmetrical, borne in racemes or pseudo-umbels, the bracts variously modified into nectar-producing, pitcher-like bodies that are sometimes winged. Sepals 5, overlapping. Petals 5, free or completely fused

into a cap or head, which is shed as a whole when the flower opens. Stamens 5 to many, free or slightly united. Ovary of 2 or more united carpels, 2- to many-chambered, ovules numerous, in several rows in each chamber, placentation at first parietal, later appearing axile. Stigmata sessile ("perched"—no stalk or style) on top of the ovary. Fruit fleshy, more or less indehiscent. Seeds numerous, with or without endosperm. Five genera with about 120 species, distributed in the tropics of South America.

Family Pentaphylacaceae

Shrubs or trees. Leaves simple, alternate, entire, evergreen, without stipules. Flowers bisexual, radially symmetrical, borne in racemes or spikelike inflorescences. Sepals 5, free, overlapping, persistent. Petals 5, free, overlapping. Stamens 5, free, flexed inward in the bud, anthers opening by valves. Ovary 5-chambered, with 2 ovules in each chamber attached near the apex of the ovary along the central axis. Style 1, stigmas 5, small. Fruit a capsule that opens by means of a dorsal suture. Seeds winged, with scanty endosperm. One genus, with four species distributed in Malaysia and western China.

Family Tetrameristaceae

Trees with alternate, simple, leathery leaves without stipules and which are dotted beneath with black glands. Flowers bisexual, radially symmetrical, in axillary, umbel-like racemes. Sepals 4, overlapping in 2 series, persistent, the outer pair larger. Petals 4, overlapping, persistent. Stamens 4. Ovary 4-chambered, each chamber containing 1 ovule, placentation basal. Style single, with 4 stigmatic teeth. Fruit a berry, surrounded by the persistent perianth (sepals and petals). One genus with three species, distributed in Malaysia, Borneo, and Sumatra.

Family Caryocaraceae

Trees or shrubs. Leaves evergreen, opposite or alternate, with 3 fingerlike lobes. Flowers bisexual, radially symmetrical, in terminal racemes. Sepals 5 or 6, united below, the lobes overlapping. Petals 5 or 6, free, overlapping. Stamens many, in 5 or 6 series, sometimes shortly united at the base, much exceeding the perianth. The inner stamens are sometimes sterile (staminodia). Ovary 4- to 20-chambered, each chamber with 1 ovule, placentation axile. Fruit fleshy or splitting into woody sections. Seeds with scanty endosperm. Two genera with 25 species, distributed in tropical South America.

Family Asteropeiaceae

Similar to Theaceae, differing in having 10 to 15 stamens united at the base and an indehiscent fruit surrounded by the accrescent (enlarging with age), winglike calyx. One genus with 5 species, confined to Madagascar.

Family Pellicieraceae

Completely glabrous (smooth, no plant hairs or scales) trees. Leaves alternate, toothed, leathery, without stipules. Flowers axillary, solitary, sessile, included for a time in the 2 long bracteoles. Sepals 5, free, overlapping. Petals 5, free, overlapping. Stamens 5, the filaments free, the anthers elongate and adherent to the style. Ovary 10-grooved, 2- or 5- chambered, with 1 ovule in each chamber, placentation axile. Fruit 10-grooved, indehiscent, leathery. Seed 1 (by abortion of the other ovules), with no endosperm, and a long plumule (growing point of the embryo). One genus and species distributed in Panama and Colombia.

Family Quiinaceae

Trees, shrubs, or climbers. Leaves opposite or whorled, pinnately lobed or simple, with numerous lateral nerves and pinnately arranged tertiary nerves. Stipules present. Flowers bisexual or unisexual, in racemes or panicles, radially symmetrical or sometimes very slightly bilaterally symmetrical. Sepals 4 or 5, overlapping, free, unequal. Petals 4 to 8, free, overlapping. Stamens 15 to 150. Ovary of 2, 3, or 7 to 13 carpels; chambers as many as carpels, each with 2 almost basal ovules. Styles free, as many as carpels. Fruit berrylike, fleshy, but dehiscent at maturity. Seeds covered with silky hairs, without endosperm. Three genera and 37 species, distributed in the forests of tropical South America.

Family Medusagynaceae

Shrubs. Leaves opposite, simple, leathery, without stipules. Flowers in terminal panicles, bisexual, radially symmetrical. Sepals 5, overlapping, deciduous. Petals 5, overlapping, free. Stamens very many, anthers opening by slits. Ovary of 20 to 25 almost free carpels, each bearing a style on the upper, outer angle of the carpel, the styles of the whole ovary thus forming a ring. Ovules 2 in each carpel, 1 ascending, 1 descending, placentation axile. Fruit a capsule opening between the segments, the valves diverging from the base upward, and remaining attached to the top of the central column, the whole umbrella-like. Seeds winged. One genus and species (*Medusagyne oppositifolia*), occurring in the Seychelles.

Family Oncothecaceae

Small, glabrous trees. Leaves alternate, entire, evergreen. Flowers bisexual, radially symmetrical, in terminal paniculate inflorescences. Sepals 5, overlapping. Petals 5, fused at the base, with a rotate (circular in outline) limb of 5 overlapping lobes. Stamens 5, borne on the corolla (collection of petals) tube, anthers opening by slits, the connective prolonged into a hooked appendage. Ovary of 5 carpels, each carpel containing 2 ovules, placentation axile. Styles 5, recurved. Fruits not well-known but drupelike, with 5 to 10 seeds. One genus and species (*Oncotheca balansae*), distributed in New Caledonia.

Family Bonnetiaceae

Trees or shrubs. Leaves alternate, entire, without stipules. Flowers in terminal panicles or racemes, bisexual, radially symmetrical. Sepals 5, unequal, overlapping. Petals 5, contorted. Stamens numerous, free or united at the base or united into 5 bundles. Ovary of 3 to 5 united carpels, ovules numerous in each chamber, placentation axile. Style usually entire. Seeds with or without endosperm, sometimes winged. Five genera with about 20 species, distributed in South America and Southeast Asia.

Family Clusiaceae

Trees or shrubs. Leaves opposite, simple, without stipules. Inflorescence various, flowers radially symmetrical, unisexual or polygamous (unisexual and bisexual flowers on the same plant), rarely bisexual. Sepals occasionally 2, usually 4 or 5 or sometimes 6, overlapping, free. Petals as many as sepals, contorted or overlapping, free. Stamens numerous, mostly fused, at least in the lower part, into bundles (phalanxes) in the same number as and opposite to the petals. Staminodia frequently present in the female flowers. Ovary 1- to many-chambered, ovules 1 to many, placentation axile or parietal. Fruit various, dehiscent or indehiscent. Seeds without endosperm, often with arils (fleshy appendages). A large family of 41 genera and 460 species, with worldwide tropical distribution.

Family Hypericaceae

Trees, shrubs, subshrubs, or herbs, rarely climbers. Leaves opposite or in whorls, usually gland-dotted, without stipules. Plant hairs (when present) often stellate. Flowers bisexual, radially symmetrical, and mostly solitary or in panicles. Sepals usually 5, imbricate. Petals usually 5, overlapping, or contorted. Stamens many, often united into 3 or 5 bundles. Sepals, petals, and stamens often with black or amber glands. Ovary of 3 to 5 carpels, with 1 chamber or 3 to 5 chambers. Ovules numerous, placentation axile or parietal. Styles usually more or less free. Fruit a capsule or berry. Seeds numerous, without endosperm. Eight genera and about 440 species centred in the tropics, but with 1 genus (*Hypericum*) widely distributed in temperate regions.

Family Elatinaceae

Herbs or rarely low shrubs. Leaves opposite or in whorls, simple; stipules present. Flowers small, axillary, solitary or in cymes. Sepals 3 to 5, free, overlapping. Petals 3 to 5, free, overlapping, persistent. Stamens 3 to 5 or 6 to 10, free. Ovary 3- to 5-chambered; ovules numerous, with axile placentation. Fruit a capsule opening between the segments. Seeds horseshoe-shaped, without endosperm. Two genera with 45 species, mostly confined to aquatic or at least wet habitats throughout the world.

Critical appraisal. The order Theales is a variable group with a large number of unusual modifications. Thus, it is not surprising that taxonomic treatments of the 21 families included here vary.

Comparisons reveal a wide diversity of opinion as to which families the order Theales should contain, which groups should be regarded as families, and which orders are related to the Theales. The main conclusion arising from this lack of agreement is that the order Theales, as presented here, is variable and shows multiple relationships in many directions; for example, more than 60 plant families have been placed in the order Theales or have belonged to other orders that include genera at some time placed in the Theales as defined here. This represents about 13 percent of all flowering plant-families, an impressive number to be related to the 21 families. This large group is understandably difficult to divide so that all assumed relationships take their proper place.

The problem of determining relationships

Certain groups, however, show more or less clear affini-

ties with the Theales; these are the orders Dilleniales, Ericales, and Violales, with which the Theales are closely associated in all of the most authoritative classification systems.

When the content of the group is considered, it is clear that it may be viewed as one order, as is done here, or divided into a number of separate orders. Because there are no objective standards for satisfactorily defining orders, no final decision can be made. It seems, however, that within the large and variable Theales as presented here, some eventual subdividing is likely and would be useful.

Some of the authors of the various taxonomic systems dealing with the Theales recognize a large number of relatively small families, while others recognize a smaller number of relatively larger families. In view of the extreme variability of the group and its multiple relationships, the former treatment—the one followed here—seems to be a more accurate reflection of the natural situation, and it seems likely to gain wider acceptance.

Further study of the group, however, from many points of view, is likely to result in modifications. Many of the families comprising the Theales are small, tropical, and not well-known. Detailed studies of them may reveal unsuspected similarities or differences that will result in altered viewpoints. The habitats of many species in the group are in danger of extinction as a result of man's activities, and it is extremely important that they be preserved for study.

Theatre, Art of

Although a wide range of entertainment is presented in arenas called theatres, the art of theatre is concerned almost exclusively with live performances in which the action is precisely planned to create a coherent and significant sense of drama. Though the word theatre is derived from the Greek *theaomai*, "to see," the performance itself may be directed either to the ear or to the eye, as is suggested by the interchangeability of the terms spectator (which derives from words meaning "to view") and audience (which derives from words meaning "to hear"). Sometimes the appeal is strongly intellectual, as in Shakespeare's *Hamlet*, but the intellectual element in itself is no assurance of good theatre. A good performance of *Hamlet*, for example, is extremely difficult to achieve, and a poor one is much less rewarding than a brilliant presentation of a farce. Moreover, a good *Hamlet* makes demands on the spectator that may be greater than he is prepared to put forward, while the farce may be enjoyed in a condition of comparative relaxation. The full participation of the spectator is a vital element in theatre.

There is a widespread misconception that the art of theatre can be discussed solely in terms of the intellectual content of the script. Theatre is not essentially a literary art, though it has been so taught in some universities and schools. The literary side of a theatrical production should be subordinate to the histrionic. The strongest impact on the audience is made by acting, singing, and dancing, followed by spectacle—the background against which those activities take place. Later, on reflection, the spectator may find that the meaning of the text has made the more enduring impression, but more often the literary merit of the script, or its "message," is a comparatively minor element. This is even more apparent in opera than in drama; the composer, the singers, and the conductor nearly always contribute more to the success of the event than the librettist.

The literary element of theatre

Yet it is often assumed that the theatrical experience can be assimilated by reading the text of a play. In part, this is a result of the influence of theatrical critics, who, as writers, tend to have a literary orientation. Their influence is magnified by the fact that serious theatre cannot be made widely available—for each person who sees an important production, thousands of others will know it only through the notices of critics. Those who write the most widely read notices usually are most interested in textual and thematic values, and they underestimate or even ignore elements that are nearer to the heart of theatre. If great paintings were not available in reproduction, and if it were thus necessary to rely on descriptions of them by critics, the literary bias of those critics would have a profound effect on the art, as indeed it had through the writings of John Ruskin, for example, in 19th-century England. Theatre critics have had just this sort of influence on the taste of audiences.

This is not to say that the contribution of the author to the theatrical experience is unimportant. The script of a play is the basic element of theatrical performance. In the case of many masterpieces it is the most important element. But even these dramatic masterpieces demand the creative cooperation of artists other than the author. The dramatic script, like an operatic score or the scenario of a ballet, is no more than the raw material from which the performance is created. The actors, rather than merely reflecting a creation that has already been fully expressed in the script, give body, voice, and imagination to what was only a shadowy indication in the text. The text of a play is as vague and incomplete in relation to a fully realized performance as is a musical score to a concert. The Hamlets of two great actors probably differ more than two virtuoso renditions of Bach's *Goldberg Variations* possibly can.

This article contains a treatment of the art of theatre in the most general terms, an attempt to illuminate what it is and why it has been regarded as a fundamental human activity throughout man's history. It makes no attempt to provide a systematic treatment of either the history of theatre or its constituent elements. The theatrical traditions of the various cultures of the world are considered at length in articles such as THEATRE, WESTERN; and DANCE AND THEATRE, EAST ASIAN; and in the theatre sections of articles such as SOUTH ASIAN PEOPLES, ARTS OF; and AFRICAN PEOPLES, ARTS OF. Much more extensive treatment of the elements of theatre will be found in articles such as STAGING AND STAGE DESIGN; THEATRES AND STAGES; ACTING; and DIRECTING. Genres of dramatic literature are discussed in TRAGEDY; COMEDY; and SATIRE, as well as in DRAMATIC LITERATURE.

ORIGINS

The Dionysiac festival

Exactly how the theatre came into being is not known. The earliest known theatrical works of major significance are the tragedies that were performed in Athens in the 6th century BC. They were presented as part of a festival in honour of the god Dionysus, a deity concerned with intoxication, with sex, with art. The Dionysiac festival was a spring festival, devoted to the thoughts and emotions evoked by the ending of winter and the return of fertility to the earth.

The festival had religious origins, although by the time

of the three great tragedians of ancient Athens, Aeschylus, Sophocles and Euripides, of the 5th century BC, it had become considerably secularized. The earlier religious character of the festival may have made it analogous to the rites of very primitive people, still to be observed in some parts of the world. Such primitive rites are at least in part dramatic: war dances, for instance, which are intended to frighten the enemy and to put courage into the hearts of the participants, imitate the battle itself, or at least the way in which the participants hope to see the battle develop. Other rites also have a practical purpose and a mimetic form; in rain dances, for example, the dancers imitate rain.

In the Orient, too, the theatre is closely tied to religion in its origins. Ritual dance-drama is traceable to about AD 100 in India, where the transition to theatre coincided with the advent of Buddhism in India in the 2nd century AD. A similar transition from dance-drama to theatre is discernible in China with the advent of Buddhism by the 6th century and in Japan by the 14th.

The art of theatre achieved its first full flowering in Athens in the 5th century BC. It is assumed that the classical drama of this period was a sophisticated elaboration of more primitive rites. At one time the performers were priests; from the form of the plays it is reasonable to assume that the principal feature of the stage was an altar and that the principal feature of the occasion was a sacrifice.

The ultimate sacrifice is the human being, and the original form of the drama may have been the ritual slaying of an important victim—a king's son, for example, or a young virgin. As the Athenian community became more civilized, however, the idea of human sacrifice, along with the idea of the savage kind of deity who would demand it, became unacceptable. Gradually, doubtless after many generations, even the sacrifice of an animal became abhorrent. In its place a symbolic sacrifice was offered—a story of sacrifice, in which the protagonist suffered on behalf of the community and died for the people. This idea is at the heart of the Greek tragedy, such as Sophocles' *Oedipus Rex*, in which King Oedipus must extirpate his own wrongs to redeem his people from the catastrophes that plague them.

Comedy, as well as tragedy, has roots in Athens of the 5th century BC. Along with deeply serious attempts of tragedians to discern a moral order at work in the universe, comic dramatists such as Aristophanes ridiculed the notion of any enduring significance in the acts of either gods or men. In addition to the genres of tragedy and comedy, classical Greece left to posterity a measure of specialization among the performers—between the actors, each of whom impersonated several characters of the play, and the chorus, who stood back from the action, commented upon it, and interpreted its significance for the audience.

Drama as an expression of its cultural milieu

Beyond these formal elements, however, classical drama offers a pattern of development that is re-enacted continually in other cultures throughout history. The rapid rise and decline of drama in ancient Athens parallels the rise and decline of the Athenian civilization itself. Great periods of achievement in theatre have tended to coincide with periods of national achievement, when man's breadth of vision expands to encompass the cosmos, as in Elizabethan England. Conversely, periods of excessive materialism, such as those of the decay of ancient Greece or ancient Rome, tend to produce theatre in which ostentation, spectacle, and vulgarity predominate.

When a great culture declines, its theatrical tradition need not die with it. Ancient Athenian tragedy experienced a rebirth in 17th-century France in the works of Racine and Corneille and, in the 20th century, in the plays of Jean Anouilh and Jean Cocteau. Similarly, there was a vogue for Shakespeare in 19th-century Germany. This cross-fertilization of theatrical tradition is a salient aspect of theatrical history. Probably more than in other arts, each theatrical style represents an amalgamation of diverse heritages.

The course of drama in the centuries since the Athenian drama reached its peak in the 5th century BC has added little that is fundamental to the art of theatre. That the heights achieved by ancient Greek drama have never been equalled stands as a powerful argument against an easy belief in the constant progress of mankind.

THEATRE AS EXPRESSION

Mimesis in theatre. The art of the theatre is essentially one of make-believe, or mimesis. In this respect it differs from music, which seldom attempts to imitate "real" sounds, except in so-called program music, such as Tchaikovsky's *1812 Overture*, which suggests the sounds of a battle. In this respect, the art of narrative in literature is much closer to that of the theatre. In a story, considerable attention must be paid to plausibility. Even if the story is not intended to be believed as having actually happened (*e.g.*, *Don Quixote* or *Pilgrim's Progress*), plausibility is essential if the story is to hold the auditor's attention. The principal factor in plausibility is not precise correspondence with known facts but inner consistency in the story itself.

Factors in dramatic plausibility

Drama also requires plausibility, but in drama it must be conveyed not by a narrator but by the actors' ability to make the audience "believe in" their speech, movement, thoughts, and feelings. This plausibility is based on the connection between the impression made by the actors and the preconceptions of the auditors. If the character Hamlet is to be plausible, the actor must make his audience believe that Hamlet could conceivably be as he is presented. This does not mean that the actor must make his audience believe that he literally is Hamlet; merely that he is plausibly and consistently making-believe to be Hamlet. The aim of a performance is not to persuade spectators that a palpable fiction is fact, that they are "really" there, out on those bitterly cold battlements of Hamlet's castle at Elsinore. Indeed, they are far more free to appreciate the play and to think about it if they are not "really" present. Knowing all the time that it is a figment, they are willing to enter into the make-believe, to be transported, if it is sufficiently convincing. Yet they know that, however thrilling or pleasurable the rapture, it may be shattered at any moment by some ineptitude or mistake on the stage or by a coughing neighbour in the audience.

The rapture is sustained by an inner consistency in the performance, as long as the rules of the game are kept. The actor must not behave, even for a second, in such a way as to betray the audience's belief; for it is this sympathetic concentration by the audience that makes his performance possible.

That is the basic rule, or convention, of the make-believe of the theatre. The actor breaks the basic rule of the game if he forgets his words, or laughs at private jokes, or is simply incompetent, or is unsuited to his part. No audience can accept a vulgar, lumpish, elderly Hamlet, because Hamlet is a young prince whose lines are consistently thoughtful and witty. Yet it is not necessary that the actor playing Hamlet should "really" be all these things; he need only give the impression of being princely, witty, elegant, and young enough to sustain the credulity of the people sharing the make-believe.

Degrees of realism in performance

Thus, in every performance there must be realism in some degree. At certain epochs and in certain kinds of play the aim has been to be as realistic as possible. In the early years of the 20th century, productions of the Moscow Art Theatre and of the Abbey Theatre in Dublin exemplified this aim to a high degree. But even the most realistic production, *e.g.*, Anton Chekhov's play *The Cherry Orchard* in Konstantin Stanislavsky's production at Moscow, made immense concessions to theatrical artifice. Conversation in real life often leads nowhere; it is full of vaguely inconclusive, meaningless, boring passages. It does not necessarily attempt, as every word in Chekhov's play must, to fit into a story, to be part of the expression of a theme, or to introduce and reveal a group of characters.

Extreme realism continued to be a goal in theatre until the advent of motion pictures. Just as realistic painting declined when photographs achieved similar effects mechanically, so did staging that attempted to reproduce the

actual world in every detail decline when such effects became commonplace in films.

Though most commercial, light comedies continue to be written and acted as realistically as possible, realistic theatre fell out of fashion in the first half of the 20th century as much as realistic painting. The most extravagantly unrealistic productions, however, inevitably retained certain quite realistic features; the actors still must be recognizably human, no matter how fantastic the script and settings may be.

Theatre as social expression. In different contexts, different aspects of humanity have seemed important and have therefore been stressed in theatrical representation. Renaissance drama, for instance, emphasized the individuality of each character, while in 17th-century theatre, which was much more restricted in its philosophy and in its setting, man was presented not as a creature proclaiming his unique importance in the universe but rather as one adapted to the quite limited environment of 17th-century society. The greatness of the Elizabethan theatre was the universality of its outlook and the breadth of its appeal; these have never been regained. Since the latter part of the 17th century the art of the theatre has been concerned with smaller themes and has aimed at a smaller section of society.

Upper-class characters of 17th–19th-century drama

From the 17th to the 19th centuries, the theatre's principal leading characters were persons of breeding and position; the "lower classes" only appeared as servants and dependents, mostly presented in terms of low comedy. Rustics were almost automatically ridiculous, although sometimes their simplicity might be shown as endearing or pathetic. The 17th-century plays of Molière are a good deal more egalitarian than English plays of similar date, or even of a century later; but even Molière never allowed the audience to forget that his plays were about, and for, persons of high station. A very clear line is drawn between employers and employed, and the latter, though often more intelligent, never seem to belong to quite the same species.

By the early 19th century the theatre had become more democratic, or at all events, more middle class. As far back as Oliver Goldsmith's *The Good-Natured Man* (first performed 1768) and *She Stoops to Conquer* (1773), the principal characters were persons of upper middle class rather than aristocrats. By the middle of the 19th century the whole European theatre had become at least as much a middle class as an aristocratic entertainment. Nevertheless, it was still thought important, especially in London, that the actors should suggest gentility. George Bernard Shaw in *Our Theatres in the Nineties* remarked that to be employed in a good production it was far less important that a young actor be talented than that he speak "well" and be beautifully dressed. The plays that succeeded throughout Europe were plays about men and women of good social position and the plots were concerned with some infringement, usually sexual, of the genteel code of behaviour: *The Second Mrs. Tanqueray* (1893) by Arthur Wing Pinero is an example.

After the Russian Revolution of 1917 the Soviet theatre made a clean break with gentility. The heroes and heroines of Soviet theatre were the splendid, muscular, idealistic workers; elegance, wit, and good tailoring were considered symptoms of decadence. In western Europe, however, gentility continued between the two world wars, the 1920s and the 1930s, to be the dominant aim of the fashionable theatre. In New York it received a setback at the time of the economic Depression of the 1930s. At a famous series of productions at the New York Group Theatre, a director, Harold Clurman, was in conscious revolt against the oppressive bourgeois gentility of the day. The theatre was not spectacularly successful, however, and stayed in existence for no more than a few years.

In Europe it was not until after World War II ended in 1945 that deep changes in social structure became apparent. By the 1950s the theatre everywhere was making efforts to reflect and to interest a wider section of society. By that time, however, audiences at all levels had lost the habit of theatregoing and were fast losing the habit of moviegoing, as television was becoming the popular medium of drama—indeed, of all entertainment. Theatre began to be directed not to any one class in society or to any one income group, but rather toward anyone who was prepared for the energetic collaboration in the creative act that the art demands.

ELEMENTS OF THEATRE

The theatrical hierarchy. Theatrical art demands the collaboration of the actors with one another, with a director, with the various technical workers upon whom they depend for costumes, scenery and lighting, and with the business people who finance, organize, advertise, and sell the product.

Collaboration among so many types of personnel presupposes a hierarchy. In the commercial theatre the most powerful person is usually the producer (American parlance), or manager (British parlance). He is responsible for acquiring the investment that finances the production. The rehearsal of the play is conducted by the director (American parlance), or producer (British parlance), who is responsible for interpreting the script, for casting, and for scenery and costumes. Under his general direction a stage manager, possibly with several assistants, looks after the organization of rehearsal and the technical side of the performance—light and curtain cues, properties, sound effects, and so on.

Producers, managers, and directors

Naturally, the hierarchy varies somewhat in different circumstances. In the National Theatre of Great Britain, for example, the apex of the pyramid is an artistic director, who is more concerned with guiding the policy of the theatre than with details of administration or the preparation of any single production—though he may, of course, also assume responsibility for the preparation of a number of productions.

An art that involves the close cooperation of so many people can scarcely express the views of all participants. A novel or a painting may bear the unmistakable hallmark of its authorship, but no work of theatrical art can be other than a compromise.

The dominant expression so far as the audience can tell is nearly always that of the actor with the most important part. It may, therefore, be wondered why theatres are no longer dominated by actor-managers, as they were in 19th-century London, where Sir Henry Irving managed the Lyceum for 21 years (1878–99) as its artistic director, administrator, producer-director, and leading actor. Since Irving's day theatrical business has become infinitely more costly and complicated. Budgets in Irving's time were only one-tenth as large; and he had no aggressive trade unions to deal with; and taxes were very much lower and less complex than in the 1970s.

Also, although the leading actor seems completely to dominate the performance, he is often only a mouthpiece; the words he speaks so splendidly were written by somebody else; the tailor and wigmaker must take some credit for his appearance; that he should play the part at all was usually not his own idea but that of a producer or director.

Even before the actors assemble for the first rehearsal, the producer, director, and designer, and—if he is available—the author, have conferred on many important decisions, such as the casting and the design of scenery and clothes. The capacity of the theatre that is selected determines the budget and therefore the scale of the production. Certainly the most lively part of the work still lies in the period of rehearsal, but much of it has been predetermined before it begins.

Role of the playwright

Although it might be supposed that the author would be the best person to direct a play, he usually is not, for several reasons. First, authors are apt to love their brainchildren not wisely but too well; and, like most parents, are not usually the most impartial judges of their character and quality. Also, authors rarely combine a knowledge of their own craft with a good working knowledge of the quite different craft of direction. Finally, the authors of many plays are dead or unavailable.

The role of the audience. It is partly because it is a collaborative art, involving so much compromise, that the

theatre seems often to lag behind other arts, expressing dated views in a dated manner. There is another reason too: the theatre depends more than most arts upon audience response. If the house is not full, not only does the performance lose money, it loses force. It is unusual for new ideas, even for new ways of expressing old ideas, to be popular. With few exceptions, people apparently do not go to the theatre to receive new ideas; they want the thrilling, amusing, or moving expression of old ones.

If a performance is going well, the members of its audience tend to subordinate their separate identities to that of the crowd. This phenomenon can be observed not only at the theatre, but at concerts, bullfights, and prizefights. The crowd personality is never as intelligent as the sum of its members' intelligence, and it is much more emotional. Intelligent members of an audience lose, to an extraordinary degree, their powers of independent, rational thought; instead, unexpected reserves of passion come into play. Laughter becomes infectious; grave and solid citizens, as members of an audience, can be rendered helpless with mirth by jests that would leave them unmoved if they were alone.

This being the case, theatre audiences are virtually incapable of an intellectual consideration of the ideas presented to them unless those ideas are already familiar. Familiar ideas can be received effortlessly while the emotional or thrilling or amusing aspects of the presentation are enjoyed. This is why the effectiveness of a theatrical performance never depends solely upon the excellence of a text. It is also why the excellence of theatre is so difficult to convey in cold prose after the event. Irving's most thrilling performance was not in any of the many great plays in which he appeared but in *The Bells*, a script of negligible literary quality. Similarly, Laurence Olivier's performance as Shakespeare's *Richard III* was more exciting than his performances in many superior works of Shakespeare. Theatrical art succeeds to the degree that excitement is engendered in the audience, a factor that is unrelated to the intellectual merits of the text.

The effect of theatre structure. From the 17th century to the 20th century, few dreamed of building a theatre in other than the now traditional, proscenium style. This style consists of a horseshoe auditorium in several tiers facing the stage, from which it is divided by an arch—the proscenium—which supports the curtain. Behind the closed curtain, the backstage machinery facilitates quick changes of illusionistic scenery. This type of theatre was developed for Italian opera in the 17th century. It is ironic that opera, the least naturalistic of theatrical forms, should have given birth to the proscenium theatre, the stronghold of theatrical illusion. From its introduction, productions of plays of all themes have tended to exploit the audience's pleasure in its dollhouse realism.

The dominance of the proscenium

The proscenium theatre separates the audience from the performers, not only by the proscenium arch but also by the footlights and by the pit holding the orchestra. In the theatres of Elizabethan England, the actors performed in the very midst of their audience. Their theatre had evolved from the courtyards of inns, in which a raised platform was erected for a stage. Some members of the audience stood around it while others watched from windows and galleries surrounding the inn yard.

In the early years of the 20th century, the English actor-manager William Poel suggested that Shakespeare should be staged so as to relate the performers and the audience as they had been on the Elizabethan stage. His ideas slowly gained in influence and, in 1953, the Shakespearean Festival Theatre at Stratford, Ontario, was built with just such an "open" stage, with no curtain, and with the audience sitting on three sides of it. A considerable success, it had a strong influence on subsequent theatre design.

Advantages of the "open" stage

It could no longer be taken for granted that the opera house with a proscenium was the right way to build a theatre. The open stage proved suitable not only for Elizabethan plays but for a wide repertoire. Probably it will never completely replace the proscenium, which remains more suitable for the countless plays that were written with such a stage in mind, such as the comedies of Molière or the highly artificial comedies of Richard Brinsley Sheridan and Oscar Wilde. On the other hand, the more realistic plays of Ibsen, Shaw, and Chekhov, all written for the proscenium theatre, lend themselves very well to the open stage.

There are three solid reasons for preferring the open stage. First, more people can be accommodated in a given cubic space if arranged around the stage instead of just in front of it. This is important not merely for the economic advantage of a larger capacity but also for artistic reasons —the closely packed audience generates more concentration and excitement.

A second reason for preferring the open stage is that the actors are nearer to more of their audience and can therefore be better heard and seen. This point is contested by adherents of the proscenium stage, who claim that the actor at any given moment must have his back turned to a large part of the house and, as a result, must be more difficult to see and hear. If the open stage is used efficiently, however, the actor's back will never be turned to anyone for more than a few seconds at a time.

The third reason is that members of an audience seated all around the stage are far more aware of the presence of the others than is the case in an opera house. The performance thereby is appreciated more as an event jointly shared and created by the audience and the actors.

The proscenium has come to be associated so closely with creating "illusion" that it has led to a misconception about the function of drama, and a misdirection of the energies of dramatists, players, and audiences. The single-minded attempt by the actors to create, or by the audience to undergo, illusion, reduces drama to a form of deception.

The art of the theatre is concerned with something more significant than creating the illusion that a series of quite obviously contrived events are "really" happening. *King Lear* is far more complex and interesting than that. Art is concerned not with deception but with enlightenment. The painter's art helps its audience to see and the musician's art helps it to hear in a more enlightened way: Rembrandt and Bach are trying not to deceive their audiences but to express and to share their deepest thoughts and feelings. Similarly, the art of the theatre is concerned with expressing the most profound thoughts and feelings of the performers about the story they are enacting, so that the audience may partake in this ritual event.

The influence of writing and scholarship. Like the other arts, the theatre has been the subject of a great deal of theoretical and philosophical writing, as well as criticism, both of a journalistic and of a less ephemeral character. Members of the theatrical profession have probably been influenced by the work of scholars and theorists more than they realize. Scholarship has made Shakespeare's work, for example, far more intelligible and coherent. On the other hand, many of the scholarly debates over small points seem irrelevant in the theatre.

A commendable example of scholarship is the emendation of Mrs. Quickly's description of Falstaff's death in Shakespeare's *Henry V* (Act II, Scene 3), from "a table of green fields," which, in the context, seems unintelligible, to "a [*i.e.*, he] babbled of green fields," which is not only comprehensible but touching. But it scarcely alters the way in which an actress will speak this phrase. It is one descriptive phrase among five or six others relating his fumbling with the sheets, playing with flowers, and smiling at his fingers' ends. It may be the greatest description of the moment of death in all literature; in the course of performance, however, an audience does not follow even so great a passage as this word by word.

A compelling actor playing Hamlet can ask whether 'tis nobler in the mind to suffer the "eggs and bacon" of outrageous fortune and few will be aware that he has not said "slings and arrows." And if Mrs. Quickly says "a table of green fields" with good accent and discretion, the musical flow and emotional effect of this marvellous speech will hardly be diminished.

Similarly, the highly respected English scholar Dover Wilson speculates whether Hamlet's too, too "solid" flesh ought rather to be read "sullied." The arguments have

little force in theatre because audiences can scarcely distinguish whether the actor has, in fact, said "solid" or "sullied."

Interaction between scholars and actors

The scholars and the theatre professionals live almost completely segregated from each other. Dover Wilson went to his first professional rehearsal when he was well over 70 and professed himself surprised at the illumination the actors seemed intuitively to bring to points that were obscure when regarded as solely literary conundrums. Conversely, the actors found he could give extremely useful advice and information about the meaning of certain passages and other matters relevant to their work.

Much journalistic criticism is marred by the difficulties imposed upon a writer who wants to be just without being dull. Justice demands reason and moderation, but such qualities are often less interesting to read than high-coloured opinion.

George Bernard Shaw was perhaps the greatest theatrical and musical critic in the English language, but he is again and again betrayed, in the pursuit of readership, into exaggeration, prejudiced partisanship, and facile jokes at the expense of actors' deficiencies, as in his *Our Theatres in the Nineties* (1931).

THE PLACE OF THEATRE IN CONTEMPORARY LIFE

Work, leisure, and theatre. There have been widely different opinions as to what the aim of the theatre should be. Some have insisted that it have a serious purpose; others regard it merely as a medium of entertainment; and still others see no reason why it should not be simultaneously entertaining and serious.

In general, mankind has regarded as serious the activities that help him to survive and to propagate his species —feeding and sheltering himself and his family. At all levels of sophistication, however, mankind's serious pursuits offer opportunities for entertainment. All of man's tools—whether made of bone, stone, iron, or bronze in the early stages of his development, or the ox, horse, steam engine, and atomic power in later stages—not only make his work easier or more efficient but also afford a means of self-expression. The ablest members of the human species have never made a clear-cut distinction between work and play. The best workers enjoy their work, be it surgery, carpentry, housework, or fieldwork. They engage themselves in work that permits, even demands, an expression of their invention and ingenuity. Indeed, the most valuable workers are not the most strenuous but the most ingenious and resourceful; and as their tasks increase in complexity and responsibility, the need for intelligence and imagination increases. These qualities will also be expressed in the play of such people.

In the times and places in which theatre has become frivolous or vulgar or merely dull, intelligent and imaginative people have stayed away from it. This was the case in London during the first half of the 19th century. There was very little significant writing for the theatre; Charles Dickens and William Makepeace Thackeray, whose talents were to a considerable degree histrionic, chose to write novels rather than plays. A similar movement away from the theatre by the intelligentsia occurred in New York City in the middle of the 20th century, as fewer and fewer serious productions were undertaken.

Of the many theories and philosophies propounded about the purposes of theatrical art, from the *Poetics* of Aristotle onward, most presuppose that the theatre is directed towards an elite consisting of the wealthier, more leisured, and better educated members of a community. In these theories, popular theatre is assumed to be noisily cheerful and egregiously sentimental, with very easy tunes, obvious jokes, and plenty of knockabout "business." In the 20th century, however, the distinctions between social classes have become progressively more blurred.

Egalitarian manners became fashionable, indeed obligatory; and the theories that gave serious art a role exclusively for the upper classes lost much of their force.

Thus, the theatre has come to face a dilemma: it has become necessary for it to re-examine the purposes of its existence. Paradoxically, while more people are enjoying more leisure than ever before, there has not been a proportional increase in theatrical attendance. Those engaged in the professions or employed in a managerial capacity, unlike the aristocrats of earlier times, generally allow themselves little leisure time. Of those engaged in industry, whose leisure time has increased, the enormous majority are engaged in dull and repetitive tasks that leave them tired and apathetic at the end of the day. Comparatively few make imaginative, intelligent, and decisive use of their leisure.

The dilemma of the contemporary theatre

The theatre's efforts to appeal to the whole community generally have been futile. There exists an ever-widening gulf: on one side, a small, enthusiastic, and highly vocal minority clamours for art galleries, symphony concerts, and drama; on the other, the vast majority is apathetic to such serious art.

The necessity for subsidies. A serious theatre, with or without massive public attendance, must be sustained by other financial support. Public funds have been used for this purpose throughout Europe and in much of Asia. The assumption behind such a subsidy is the realistic one that a serious theatre is now too costly to pay its way.

In Great Britain in 1940, under the threat of imminent invasion in World War II, the government took the first steps toward subsidizing theatre by guaranteeing a tour of the Old Vic Theatre against loss. Subsequently, its support of theatre increased continually, to the sum of millions of pounds annually.

In governmental support of the arts, the United States lagged considerably behind most of the civilized world. Until the middle of the 20th century, private patronage was still the sole support of legitimate theatre. With few exceptions, however, professional theatrical management in the United States has been strictly a commercial business. Its record has been blotted by numerous instances of greed and irresponsibility and an absence of a longer view than immediate personal advantage. Unions have sometimes pressed demands that have made professional theatrical production economically difficult.

Academic theatre. A significant new factor on the contemporary scene is the theatrical activity conducted by the universities with departments of drama. Their theatres, often handsomer and better equipped than professional houses, present plays of all sorts. Millions of people attend performances in university theatres each year, and the academic theatre is beginning to compete with the professional theatre for audiences. In serious planning and choice of programs its standards are far superior to professional theatre, since the aim is educational. The standard of performance is more debatable. Unfortunately, many leading parts, whether in classics or in potboilers, call for assured and authoritative actors, between 35 and 50 years of age. Academic theatre, therefore, is handicapped at the outset by the immaturity of most of its student-actors, though professional actors are sometimes hired for special productions or to become actors-in-residence.

Problems of academic theatre

A more serious drawback is that the direction of drama departments and of university theatres is often entrusted not to theatre men but to academics, chosen in most instances for scholarly rather than theatrical distinction. Furthermore, most college theatres operate on extremely low budgets, and, while money without taste and intelligence cannot create good theatre, taste and intelligence without money can seldom do so either. The highest standards can, in certain instances, be achieved by sheer ingenuity, but, in general, shoestring budgets result in that desperate air of "making do"—almost a trademark of academic theatre.

It is a common error in universities to suppose that the mere production of a masterpiece must amount to an educational experience for players and audience alike. It is not so. Incompetent acting and direction can reduce the greatest masterpiece to suffocating, excruciating tedium. Moreover, in many schools, the theatre must be economically self-supporting, and each season one of the successful Broadway musicals of yesteryear is put on to redeem the losses incurred by Shakespeare, Molière, and O'Neill.

In Britain, the universities still, with few exceptions, take the view that theatrical art has no place in a university curriculum. If university students want to act, they must join a club and act in their spare time. The universities that do have theatre departments, such as Manchester and Bristol, aim to teach not professional skills but theatrical history, criticism, and theory.

The diminishing audience. In Great Britain, government subsidy has been made available to the National Theatre of Great Britain and the Royal Shakespeare Company, two institutions offering a predominantly classical program; to the Royal Court Theatre in London, producing new and experimental work; and to resident companies in most of the principal cities outside London. These companies present serious programs and play to excellent houses. In the short time since their establishment (mostly in the 1960s) they have created a revolution in the quality both of theatregoing and of theatrical organization. Still, there is a gulf between theatre audiences and the masses, and, more and more, theatre becomes a "mandarin" activity, designed for the edification of a select few.

In the communist world there is far less contrast between mandarin and popular art. In the Soviet Union the statistics of popular interest in art and literature are very impressive, but the level of creative work is kept low by censorship. Artistic creation is compelled to conform to party policy; and the political machinery often manipulates popular opinion. In the theatre, success can sometimes be assured to productions that are politically acceptable, denied to those that are not.

In both the East and the West tremendous efforts are being made towards more fruitful use of the leisure time that technology has made available. By the second half of the 20th century, theatre had become a regular leisure-time activity only to a small minority. Although the civilized world generally regarded a serious theatre as an essential activity, deserving of public support, the mere existence of an intelligent and imaginative theatre does not ensure such support. This can probably be achieved only by profound changes of belief concerning the purpose not merely of theatre but of human existence.

Prospects. It is not unreasonable to suppose that, by the end of the 20th century, the live theatre could cease to exist, in which case movies and television or possibly television alone would hold the dramatic field. In television, it is possible to anticipate not only many technical improvements—larger, less wobbly and distorted pictures, more subtle and credible colour—but, more important, an improvement in the method of distribution and the material that is distributed, including the widespread use of video cassettes. There may even be a demand for something more intellectually ambitious and spiritually nourishing than currently popular programs.

Another negative factor is the declining number of people with professional theatrical experience. Most of those who have furthered the art of theatre—actors, directors, managers, technicians—grew up in the theatre; even many of those who now devote most of their time and earn most of their money in movies and television spent their most impressionable years on the stage. Among the generations arising since World War II, however, there has been very much less theatrical experience and little interest in whether the theatre survives or not. As the years pass, fewer and fewer people, not just among the professionals but lay people as well, will have seen a play acted by live actors at a level higher than school or college theatricals.

Two factors, however, contribute to the perpetuation of theatre. First, there are the theatrical classics themselves, the classic dramas of different epochs and different cultures such as Racine's *Phèdre* (1677), Molière's *Le Tartuffe* (1664), Congreve's *Love for Love* (1695), Ibsen's *Peer Gynt* (published 1867), Shaw's *Saint Joan* (1923)—the instances could be multiplied countless times without exhausting the great works of the human spirit. Such works were written for the stage and can only be given full expression by stage representation.

Adaptations for the screen or television of material that was conceived in terms of the stage remain merely adaptations. If the original is a work of genius, the adaptation must seem presumptuously inadequate. It is possible that the adaptation of some stage pieces may excel the original: Puccini's opera *Madama Butterfly* is a more important work than the play by David Belasco from which it was adapted. But it can hardly be argued that Laurence Olivier's film adaptations of Shakespeare's *Henry V, Hamlet, Richard III,* or *Othello* were equal to the original stage productions. These films were justified in that thousands of people, who would not otherwise have had the opportunity, saw the adapted plays magnificently performed. The texts were necessarily garbled and hashed, however, and the acting and direction were adapted to suit a medium for which the originals were not conceived. Some part of the public will always believe that it is as important to see fine performances of theatrical masterworks as to see the originals of great achievements in painting, sculpture, and architecture, rather than mere photographic reproductions. As long as this is the case, there is a good reason for the continued existence of a live theatre.

Adaptations for the screen or television

The second reason for believing in the survival of theatre is that the live theatre can achieve a sense of occasion impossible for canned events. This sense of occasion is a heightening of everyday people and occurrences into a new vividness and significance: not just the heightening of characters and events of the drama but also a heightening of the people who take part, spectators as much as performers.

This can occur more effectively if the occasion is a great one, if the house is large and full, if the audience appears to be distinguished, and if celebrated performers are taking part. But the sense of occasion can be achieved more simply, more subtly, and less expensively. What matters is that, when the performance begins, the audience should be excited, receptive, and ready.

A live theatrical performance has a built-in sense of occasion. A first night at the Comèdie Française, the Bolshoi, the National Theatre in London, the Metropolitan Opera in New York, draws some hundreds of national figures, pacesetters in different fields. This is one of the things that the motion pictures aimed at but failed to achieve in any lasting way with their gala premieres. Yet the heart of the occasion lies not in the auditorium, however bedizened with celebrity, but on the stage. There, a troupe is about to create either a new work or a new interpretation of a classic. The sense of occasion is at its strongest when the cast is distinguished; but even unknown players in obscure performances can create it.

Activity is required of the theatre audience if the performance is to succeed; the audience is required to share with the performer, to assist him in the act of creation.

The participating audience

In films and in television, mistakes can be eliminated, unsuccessful scenes can be reshot, even rewritten, the whole work can be manipulated, edited, titivated, and set before the public with every detail in its proper place. The product has been prefabricated without the cooperation of its ultimate audience, which is therefore reduced to the status of a mere consumer.

In the theatre, on the other hand, every audience helps to create or to destroy the performance. To some extent, audiences get the performance they deserve.

Moreover, in every live performance is the imminence of disaster. An actor must be skilful and an audience must be imaginative if Macbeth, seeing a phantom dagger in the air, or Othello, falling down in an epileptic fit, is to be moving and impressive instead of merely ludicrous. Yet it is precisely this hairbreadth division between the sublime and the ridiculous that creates the sense of occasion.

Some dozens of immortally great expressions of the human spirit have been written for performance by live actors for live audiences and cannot be adequately experienced in any other medium. This is why, in spite of economic difficulties, in spite of far smaller technical resources and far greater distributive problems, the live theatre must survive. (T.G.)

BIBLIOGRAPHY. Few works have dealt extensively with the aesthetics of theatre as a body of knowledge or theory

unrelated to particular productions, schools of playwriting, or historical periods. Most philosophical writings or manifestoes—those of Aristotle, Castelvetro, and Victor Hugo, for example—deal almost entirely with the form and content of dramatic literature, though they have had great impact on all aspects of theatre over long periods of time. Notable modern exceptions are ANTONIN ARTAUD, *Le Théâtre et son double* (1938; Eng. trans., *The Theatre and Its Double*, 1958), which considers theatre in its broadest implications and has had enormous influence on avant-garde theatre since World War II; and JERZY GROTOWSKI, *Towards a Poor Theatre* (1968), an elucidation of personal artistic values by a director-teacher whose Polish Laboratory Theatre has been among the most controversial and innovative theatrical phenomena of the century. The ideas of one of this century's most important playwrights and directors emerge in *Brecht on Theatre: The Development of an Aesthetic*, ed. and trans. by JOHN WILLETT (1964). Perceptive analyses of aesthetic points of view represented in theatrical production include: MORDECAI GORELIK, *New Theatres for Old* (1940, reprinted 1962), a classic work on staging and design that covers the late 19th century and first four decades of the 20th; G.B. SHAW, *Our Theatre in the Nineties*, 3 vol. (1932), an incisive contemporary view of drama in the 1890s; and the writings of such major 20th-century critics as Harley Granville-Barker, Stark Young, and George Jean Nathan. Personal histories by leading theoreticians and practitioners, including KONSTANTIN STANISLAVSKY, *My Life in Art*, trans. from the Russian (1924, reprinted 1956); and HAROLD CLURMAN, *The Fervent Years* (1957), carry implicit commentaries on the art of theatre. Stanislavsky's *An Actor Prepares*, trans. from the Russian (1936, reprinted 1956); and T. COLE (comp.), *Acting: A Handbook of the Stanislavski Method*, rev. ed. (1957), though specialized, develop aesthetic points of view that have underlain much of the theatrical production in the West during the 20th century. A classic study of theatre in terms of its aesthetic intentions is contained in FRANCIS FERGUSSON, *The Idea of a Theatre* (1949), while PETER BROOK, *The Empty Space* (1968), is a brilliant analysis of theatrical values as they are manifested in such diverse areas as commercialized drama, the popular or "rough" theatre, and the dedicated avant-garde or "holy" theatre. An overview—outdated but still singular—of the many different forms and aesthetic conditions of Oriental theatre is contained in FAUBION BOWERS, *Theatre in the East* (1956). Discussions of the conditions under which theatrical forms have emerged appear in many anthropological works, including SIR JAMES FRAZER, *The Golden Bough*, 3rd ed., 12 vol. (1907–15), and those of Margaret Mead and others. Finally, such periodicals as *The Drama Review* (formerly, *Tulane Drama Review)* and the defunct *Theatre Arts* contain important reportorial, critical, and philosophical writing on theatre both as an artistic and a social expression. The entertainment sections of *The New York Times* and other journals often contain important analytical commentary or deliberately arranged clashes of aesthetic points of view toward theatre.

Theatre, Western

This article is divided into the following sections:

I. The origins of Western theatre
  Preclassical antiquity
    Religious ritual
    Solemn and grotesque rites
  Ancient Near Eastern and Egyptian civilizations
    Mesopotamia
    Egypt
  Greece
    Dramatic genres
    The theatre
  Rome
    Native theatrical tradition
    Imitation of Greek models
    Seeds of decay
    Mimic tradition

I. The origins of Western theatre

PRECLASSICAL ANTIQUITY

Religious ritual. *Imitation.* Drama as an art form emerged at a comparatively late stage in man's cultural evolution, but it is generally believed to have had its roots in primitive religious ritual, and there are patterns in the behaviour of primitive societies that can justifiably be called pre-theatrical. These patterns indicate something of the psychology of peoples standing face to face with what was mysterious and unknown in their environment, and they reveal an attempt to establish some sort of contact with those sources of power in nature that seemed most hurtful and destructive—violent phenomena such as excessive heat, cold, drought, fire, and flood. Backed up by ceremonies of propitiation, involving first human and later animal sacrifices, the rituals such peoples undertook were an appeal, made to deities supposed to control the various elements, for assistance or protection. Ritual activity was at first confined to simple imitation, either of the phenomena themselves or of objects observed to be associated with them: the consuming power of fire, for example, was sought through the ashes and the secret of fertility through evergreens. The rhythms of nature, as seen in the movement of the wind or of the sea, were simulated in the dance.

Transfiguration. Of special interest is the early use of masks and other ritual disguises to aid imitation, to fortify pretense. The imagination that could give rise to such a notion was already active by the Lower Paleolithic Period, because ancient cave paintings that date from this time (such as those that are to be seen at Lascaux in southern France) depict dancers who are half human, half beast. Persons involved directly in the celebration of the rite wore the forms of nature or emblems associated with the god to whom appeal was being made. A state of heightened emotional awareness was achieved by the frenzy of the dance, and in many of the primary rites it was supposed that the god took possession of the dancer at the height of his ecstasy. This was transfiguration rather than simple imitation. Among many tribes and peoples the priest, magician, or medicine man would employ special effects—smokes, smells, incantations, and the like—to achieve the desired trancelike state. Meanwhile, others would participate in the rite by forming processions, by executing certain steps and rhythms, or by clapping and perhaps by chanting. They thus assisted in the transformation, though they themselves were not transformed.

The role of the dance

Solemn and grotesque rites. Two basically different types of rite were celebrated: the solemn and the grotesque. Both had the effect of evoking terror, prompting the fear that arises when facing the inconceivable or utterly unknown. The solemn rites were part of a rigid tradition that had been evolved and handed down from generation to generation, and young members of the people or tribe were initiated into the rites step by step. A cultural system thus found coherence and protection by institutionalizing itself: not to observe the tradition was thought to bring about misfortune. The solemn rites were mainly an embodiment of death—the fear that is commonest among all individuals—and were attempts to ward off its evil. They chiefly concerned those elements of nature in which rebirth noticeably follows upon death—that is, on the solstices and seasons—and this fact accounts for the most persistent of all early theatrical imitations, the ritual slaying of the god of fertility (winter) and his subsequent resurrection (spring). Solemn rites were further concerned with propitiation for past misdemeanours or for assistance in future struggles.

The grotesque rites, on the other hand, were in the main evolved to give thanks for assistance received. Their celebration called for spontaneous reactions, and they were to a great extent impromptu. They were not marked by a coherent narrative pattern but were expressions of joy, and their most remarkable characteristic was, simply, excess. Whereas the solemn rites can be said to be the forerunner of Western tragedy, which has always tended to preserve some links with its religious origins, the grotesque rites led to secularized farces and, eventually, to the other two major dramatic genres in Western theatre, comedy and satire play.

ANCIENT NEAR EASTERN AND EGYPTIAN CIVILIZATIONS

The transition (which is still taking place in parts of the world in the 20th century) from tribal communities toward a society organized by the division of labour has imposed enormous strains, both physical and psychological, on man. It has, however, challenged all of the arts to serve not merely as a means of man's self-expression but also to become an integral part of his cultures as they evolve.

In ancient cultures, the gods were still thought of as more or less concrete, real authorities—a conception of their deity reflected in the various social and political structures that were set up, at first by a system in which the king was regarded as "chosen" by the god, and afterward by a system in which he was regarded (in Egypt) as the god himself. Only much later was there a "twilight of the gods" to rob them of their legislative power. Even then, other authorities had to be evoked, since something approaching a godlike supremacy was thought necessary to uphold a civilization. Extreme alternatives were dictatorship and anarchy, but there was also the possibility of the individual's being encouraged to participate in the evolution of society and being given the political means to do so. At all times theatre, as a community celebration and activity, has played an important part in this evolution, sometimes directly, sometimes simply by reflecting political change and development.

Mesopotamia. There is evidence of a Sumerian civilization dating from at least 3000 BC. The Sumerians, who were originally from the Caucasus, occupied Mesopotamia (the land lying between the rivers Tigris and Euphrates) and established city states there, with palaces and temples. Each city had its own god, whose priests were of great importance and influence in the community. The Sumerians' chief religious festival was that of the New Year, celebrated in the autumn and the spring with rituals symbolizing the peoples' hope that winter (when the god of fertility was dead) would not last forever and that the coming year would be prosperous. During the 1st Ur dynasty (*c.* 2650–2500 BC) a new custom was introduced at the spring festival, and it might well be a reflection of a constitutional change: a popular king ruled the city for a day, a lord of misrule—the custom later reappeared in Christian times, when the usual power structures were turned upside down for one day on the Feast of the Holy Innocents—and on this occasion the high priest would also ritually slap the real king's face.

Sumerians' New Year festival

The Babylonian civilization borrowed wholesale the culture of the Sumerians and elaborated upon it, so that by the time of Nebuchadrezzar I (1124–1103 BC) the New Year was being celebrated in Babylon by most splendid processions, by a recitation of the myth of creation, and by pantomimic performances. Here, clearly, are signs of a germinating theatrical activity.

Egypt. There is much similarity between Egyptian and Mesopotamian mythologies and between the ways their civilizations developed. Because of the necessity of controlling the waters of the Nile, the two regions eventually became one kingdom, and Egyptian myths retained many characteristics that had belonged to the earlier Mesopotamian civilizations. To the early peoples inhabiting the region, a "god" was the spirit of the tribe, and for each there was a different god, taking an animal form—for one the falcon, for another the pig, and so on. This primitive belief later found expression in the animal-headed gods of Egypt: Horus the falcon headed, Thoth the ibis headed. The Egyptian pharaohs were not regarded as chosen by the god, they were thought to be the god himself. While alive, the pharaoh was the god Horus; after his death he was transformed into the god Osiris. Thus the myths relating to Osiris and Horus came to be especially important.

Since the end of the 18th century Egyptologists have sought to interpret the significance of what are known as the Pyramid Texts. These were found written on the inside walls of the pyramids, and the earliest dates from the 5th dynasty (*c.* 2494–*c.* 2345 BC). In 1882 it was suggested for the first time that these texts should be called dramas. Some scholars further suggested that priests, wearing animal masks, had given performances of the texts in the tombs and buildings attached to the pyramids. These views were much disputed, but there is more general agreement that one of them, known as the Abydos passion play, really was performed, though many prefer to regard it as expanded ritual rather than as drama. Its subject is the death and dismemberment of the god Osiris and the reassembling of his scattered limbs by his wife, the goddess Isis, and their son, Horus. No text survives, but there is an account left by a court official that describes a presentation of the play for which he was responsible between 1887 and 1849 BC.

The Pyramid Texts

GREECE

Greek drama originated in the festivals of the nature god Dionysus (who was particularly associated with the vine, the bull, and the goat), whose cult originally had gone to Greece from Egypt by such paths as trade routes. The great Dionysia festival at Athens, where the important theatrical events took place, was very much a religious festival. It is generally accepted that drama emerged from the ritual celebrations of religious festivals, but the steps by which it did so are not fully understood.

Dramatic genres. The classical Greek theatre divided drama into tragedy, comedy, and satyr play; there were dramatic masterpieces in each of the genres. The size and shape of theatre buildings were also a new concept largely influenced by Greek developments, while actors in character roles were separated from actors who commented, as a chorus, on the unfolding story, the latter being intermediaries, as it were, between audience and protagonist. Another feature was the use of strongly characterized masks worn by the actors. Early tragedy (originating at Athens in 534–531 BC and named after a connection with Greek *tragos*, "goat": that is, tragedy either originated as a song with a goat as prize or as a song connected with a goat's sacrifice) had a single actor–chorus–audience pattern like religious ritual's priest–initiates–congregation one. The parallel is reinforced by themes and structures of the earliest surviving plays, for tragedy dealt with the universe's moral regulation in a serious, formal way. The tragic poet was required to submit three tragedies on the same myth, along with a satyr play (a burlesque of the myth) to the festival competition. The only complete satyr play to sur-

Chorus in Greek drama

vive is Euripides' *Cyclops*. Comedy (from Greek *kōmos:* revel) developed later, its origins in spontaneous thanks to Dionysus for the fertility that aided agriculture.

Drama as a whole developed a tendency to occupy itself with more human, immediate concerns as time went on, and it has been argued that tragedy was formed, ennobled itself, and then lost its vigour while Athens was doing the same thing in its political life. Comedy began as broad political satire (old comedy), developed into social satire (middle comedy), and then developed into a comedy of manners with stereotyped characters in plots dependent on intrigue and situation. The only extant Greek tragedies are the collective 35 plays of Aeschylus, Sophocles, and Euripides. Aeschylus, the oldest of the three great tragedians, introduced a second actor to drama (both actors doubled in more than one part, however), marking a move away from convention patterned on religious ritual as new scope was opened up. Sophocles introduced a third actor, and in his and Euripides' hands the number of characters to a play further increased. Euripides went further, and the chorus was whittled away, in prominence as much as in numbers. Aeschylus started with a 50-strong chorus who, in addition to a purely dramatic task, sung a hymn to Dionysus at his festival; by Euripides' day the chorus was half the size and merely filled breaks in the action with lyrical odes.

In comedy, Aristophanes, the greatest old comedy playwright, used his chorus as formally as Sophocles, but Menander, the new comedy's chief exponent, had choruses introduce songs for their own sake. The realistic direction the theatre took changed both stage language and setting correspondingly, for early works consisted of choral odes interrupted by "episodes" of speech for individual actors but, with Sophocles' dialogue and chorus, achieved parity. The metrical rhythms were significant.

The theatre. The original setting for performances was a large dancing floor (or *orchēstra* in Greek), to which a dressing room (or *skēnē* in Greek, whence scene) was later added, then extended, permitting the use of revolving panels (*periaktoi*) bearing pictures announcing the place of action. The late-5th-century-BC theatre was an open-air one, with the now-customary three actors taking perhaps some ten parts among them, while a chorus of 15 (24 in comedy) was in attendance. Theatrical devices were sparse, and the actors' sumptuous dresses were a change from simple, everyday Greek clothes. Everybody on stage wore a mask, and a crane (or *mēchanē* in Greek, whence mechanical) was used to introduce flying gods. A movable platform (*ekkylēma*) suggested an indoor setting, but on the stage actors chiefly talked and did not use properties to any great degree. Action, sometimes gruesomely violent, was recounted by messengers, rather than staged.

Equipment and techniques of Greek theatre

Songs and dancing provided by the chorus divided the plays, short by modern standards, into "scenes," of which there might be four to a play. The actor would often remain while the chorus provided the interlude, so that though a greater amount of time could be thought to have elapsed dramatically than in actual fact, there was nothing like the modern curtain's power of speeding the action on by years. At suitable dramatic peaks, songs might replace spoken dialogue; Euripides, for instance, wrote long solos.

The Greek theatre was symbolic, with men impersonating women and with place identified by some token. In any case, the auditorium held 10,000 to 20,000 people, ranged steeply so as to appreciate the geometric configurations of the chorus dances by looking down on them, while the landscape beyond the *skēnē* compensated for any austerity of the orchestra.

ROME

Of the plays written and performed in Roman times, only a few have survived. But the Romans make little claim to originality in their drama, and on the whole their literary production was heavily dependent upon Greek models. Indeed, the Roman period is of interest in the history of Western theatre not so much for the way it flourished as for the way it declined—resulting in 400 years of seeming death for organized theatre. Many factors must be taken into account in explaining why this happened, but perhaps the dominant reason lay in the political cynicism with which the Roman authorities used public games, at which theatrical performances took place, to divert the populace from economic and political dissatisfaction. The number of official festivals proliferated. They had little or no basis in religious tradition, and theatre lost its close ties with religious ritual, degenerating into theatricality and spectacle for its own sake.

Native theatrical tradition. There was at least the germ of a native theatrical tradition in Italy from early times, in what were known as the Fescennine verses, crude exchanges of ribaldry sung in a rough and improvised rhythm at harvest celebrations and other times of country merriment. Livy, the historian, says that in 364 BC Etruscan players were summoned to Rome at a time of pestilence to avert the wrath of the gods by their dancing and music. This tradition of early Etruscan influence is given some substance by the similarity of the Etruscan word for player, which was *ister*, to the Latin *histrio*. From the combination of Fescennine verse and Etruscan dance to the music of pipes, there apparently grew what Livy calls a "medley" (*satura*). This seems to have been a plotless entertainment, consisting of jests, horseplay, and songs. The Oscan inhabitants of Campania, in the Neapolitan region of Italy, also had a long established tradition of burlesque which was afterward carried to Rome and known under the title of *fabula Atellana* ("Atellan play," Atella being the name of a Campanian town). It has been suggested that the playwright Plautus (2nd century BC) was associated with this tradition before moving to Rome and presenting his plays at the state festivals there.

Imitation of Greek models. It was, however, the introduction of Greek plays that characterized the literary development of Roman theatre. In 240 BC Livius Andronicus, a Greek from Tarentum, who made his living at Rome as a teacher, first translated a Greek play for performance at the Roman games. Though the literary merit of his translations was slight, he himself is of some importance as a pioneer. The first signs of native genius shone in the comedies (and to a much lesser extent in the tragedies) of Gnaeus Naevius, whose first play was produced in 235 BC. The fragments of his work that survive reveal that they were Italian in spirit and dealt with low life, but that they retained a Greek setting. The kind of play so set was to be called *fabula palliata* ("play in Greek dress"). Naevius also showed striking evidence of his originiality by inventing the Roman historical play, dealing with legendary Roman heroes and events, afterward to be known as *fabula praetexta*. Naevius incorporated with his work sharp and outspoken attacks on the Roman nobility. As a result, it appears that he was punished with imprisonment or exile. Perhaps in view of this fate, the great poet Quintus Ennius, who followed him as a dramatist, adapted his talent to the social conditions of the time and tried, by his translations of Greek tragedies (his version of Euripides' *Medea* became especially famous), to satisfy the Hellenistic tastes of the contemporary nobility. Plautus and Terence, Rome's outstanding playwrights of the 2nd century BC, modelled their comedies upon the work of such Greek playwrights as Menander. More obviously Roman in theme and allusion, they nevertheless retained the Greek setting and dress. Native Latin comedy, dealing with Roman themes and set in Italy, seems to have come into being toward the end of the 2nd century BC, and the genre was distinguished as *fabula togata* ("play in Roman dress").

The works of Gnaeus Naevius

Seeds of decay. Plays were given as part of the free entertainment offered at public festivals. From the start, however, Roman theatre was dependent upon popular taste in a way that had never been known in Greece. If a play failed to please, the manager of the festival was obliged to return part of the subsidy from public funds. Thus, even in Republican times, there was some anxiety to give the public what it wanted—and this proved to be the sensational, the spectacular, and the crude. During imperial times, Roman emperors made even more cynical use of this knowledge, providing

"bread and circuses" (the withering phrase of the 1st-century-AD satirist Juvenal) to divert the people from their miserable and, therefore, politically dangerous lot. Buildings such as the Colosseum in Rome and amphitheatres erected throughout the empire were evidence of the power and grandeur of Rome but not of its artistic life and energy; there is little reason to believe that they were intended for anything but trivial and degrading display. At least in Republican days there had been a written text and a genuine attempt to expose vice and ridicule folly in as amusing a way as possible. But as the people's taste for spectacle came more and more to indicate what was put on in the arenas—gladiatorial combats to the death, water spectaculars with mock sea battles, wild beasts exhibited and encouraged to tear one another to pieces, Christians covered with pitch and used as human torches—it is not surprising that serious people avoided the theatre as demeaning and undignified and that writers were alienated from it. During the imperial age there was a fashion for tragedies to be written as closet drama or for recitation rather than for stage performance. Plays of this kind included the tragedies of Seneca, a Stoic philosopher and leading statesman under the emperor Nero, and they were to exercise enormous influence during the Renaissance, especially in England.

Closet drama in the imperial age

Mimic tradition. The most popular form of acted entertainment came to be the mime and pantomime, which relied upon the actors' improvisations and physical agility and offered ample opportunity for the audacious presentation of immorality and open obscenity. These entertainments had replaced Plautine comedy and Atellan farce in public favour even by Cicero's day, in the dying years of the Republic. By the time of the Christian persecutions under the emperors Nero and Domitian, mimes and pantomimes were used to ridicule the Christian faith on stage. In *Centunculus*, for example, a clown is baptized and martyred, being grotesquely crucified in a way calculated to burlesque his faith. It is not entirely surprising that, after the triumph of Christianity, theatrical performances were stopped in the 5th century, and the theatre was abominated by the Church Fathers as an art so debased through commercial exploitation as to have lost any relevance to the general good of society.

Christian Byzantium. The theatre of the ancient world thus survived only in fragments, like some river that has temporarily split itself into several channels. There were a few texts; a variety of theatre buildings, useful as quarries; some theoretical treatises; and groups of itinerant mimics, singers, and dancers who exercised their talents illicitly wherever a patron or passer-by could be found to look or listen.

The old Roman Empire was Christianized and split into two sectors, one based at Rome and the other at Constantinople (Istanbul). The Byzantine Church, centred at Constantinople, took on something of the stylistic refinement attached to court ceremonials of the Byzantine Empire. Public worship was marked by magnificent processions, some of them directed by the emperor's master of ceremonies. Homilies (sermons of edification) were often characterized by dialogue, revealing the influence of Oriental poetry. In 968, Bishop Liudprand of Cremona, who had been sent to Constantinople on a diplomatic mission from the German emperor, Otto I, left a description of theatrical performances at the Hagia Sophia. But almost all the detailed evidence of organized religious and secular drama that certainly developed within the Christian Church of Byzantium—long preceding the emergence of dramatic forms from the liturgy of the Western Church—has been lost and the subject is still a matter of some controversy.

II. The Middle Ages and the Renaissance

THEATRICAL REVIVAL IN THE MIDDLE AGES

Secular theatrical activity. Although the principal kinds of drama that flourished in the West during the Middle Ages were religious, inspired by the Christian's liturgy, there were other kinds of theatrical activity that existed side by side with the church, though not connected with it. Eventually they merged to create a theatre, religious in inception but recreational in its later development, that by the 16th century was healthy, full of initiative, and equipped to reanimate the newly discovered classical heritage of Greece and Rome.

Long before any organized theatre began to emerge in the 10th century, there were survivors of the Roman mimic tradition—singers, acrobats, dancers, jugglers—who seem to have formed themselves into a wandering fraternity. They would appear at festivals and other occasions when their presence was desirable, afterward to vanish again into the obscurity that has always characterized the wandering player's life. Their performances were not encouraged by the church, but neither do they seem effectively to have been banned. During the late Middle Ages these burlesque entertainers were to find a more secure place at princely courts and in the households of lords both spiritual and temporal, where they performed as actors or minstrels and musicians at their masters' festivities. The written texts that they evolved for performance were, especially in France, literate and often sharply satirical.

Survival of the Roman mimic tradition

Old traditions and customs, too, flourished locally throughout the countries of Europe. While zealous monks and missionaries Christianized the West, often making use of former places of pagan worship to build their churches and adapting pagan rites to Christian use, it seems they did not Christianize existing theatrical traditions. It is difficult, today, to say just how far the people who took part in sword dances, masked carnival processions, May dances, spring festivals, wedding rites of sexual initiation, and the like were aware that these stemmed from pagan rites practiced by their forefathers. The subject is of primary interest to folklorists. In the clowning, jugglery, singing, dancing, mimicry, and burlesque that took place there would, however, sometimes come together the three basic components of drama: impersonation, dialogue, and action. The results were farces—called *soties* in France, *Fastnachtsspiele* in Germany, *kluchtspelen* in the Netherlands—usually dealing with such themes as foolish or cunning peasants, disgruntlement about work, the relationship between master and servant, husband and wife. Eventually these farcical scenes were included as interludes in the religious-inspired drama (which had by this time moved out of the churches into the villages and was no longer performed exclusively by the clergy), making the latter infinitely more vigorous, more effective as entertainment, and providing scope for dramatic irony and counterpoint.

Liturgical drama. During the 9th century there was a new impulse to increase the musical effect of the church's plainsong. Musical embellishments were added, for example, to the final syllable of the Alleluia, and whole texts eventually were elaborated as sequences to be sung during the mass. Antiphonal singing, in which the choir divides into two parts, is a form of choral drama and proved to be most important in the rebirth of organized drama. A text contained in a 10th-century manuscript from the monastery of St. Gall in Switzerland dramatizes antiphonally the visit of the three Marys to the tomb where Christ's body had been buried. They find the sepulchre empty and an angel (here angels) guarding it. The angels ask them, "*Quem quaeritis?*" ("Whom do ye seek?"), and a short dialogue follows. The part of the angel was sung by one division of the choir, the part of the women by another. This simple vocal dramatization of one event mentioned in the Easter liturgy led to much of the rest being presented in a more elaborate dramatic form, involving movement and "soloists." The aim seems always to have been to convey, in as vivid a way as possible and for the benefit of an uneducated laity, the deep significance of events ritually celebrated in liturgical worship. Gradually rules were drawn up in various dioceses through Europe governing gesture, vestments to be worn, and ways of suggesting locale. By the end of the 13th century not only the Easter liturgy but also that of the Passion and the Nativity (and also the messianic prophecies that form the liturgy of Advent, leading up to Christmas) had been so dramatized. The little religious plays that resulted were performed at different places

Pedagogical aim of liturgical drama

within the church, then in the church grounds, finally in village and town itself. The vernacular was used alongside the Latin, again with the intention of making events as clear as possible, spoken scenes replaced chanted antiphons, and by the early 14th century the religious drama had in most places passed from the hands of the clergy into the hands of the laity.

Miracle plays. It is thought that trade guilds, which were also religious guilds, were the main avenue of transition. The plays became entirely vernacular, were much expanded from the original liturgical elaborations, and became known in Italy as *sacre rappresentazioni*, in Spain as *autos sacramentales*, in France as *mystères* (borrowed in England after 1800 as mysteries, this word derives from the Latin *ministerium*, meaning "service"), and in England as miracle plays. Performances were directed sometimes by one of the clergy, by a teacher, by the master of a craftsmen's guild. Each guild, indeed, would assume responsibility for one play of the "cycle" into which, by their final development in the 16th century, the individual plays had grown. Cycles covered the entire story of the redemption, from the fall of man up to the Last Judgment, but centring on the Passion and designed to stress the humanity as much as the divinity of Christ. Church vestments were replaced or supplemented by contemporary costumes suitable to the character being portrayed, scenery became more elaborate and ingenious (especially in Spain, Italy, and France; it remained fairly sparse in the northern countries of Europe). Most important of all, however, that use of the vernacular and the consequent relaxation of the strictly ritualized presentation which had characterized liturgical drama allowed comic interludes to be incorporated with the central religious theme. These interludes were the farces that had evolved from folklore customs; in the religious drama they were particularly (though not exclusively) associated with scenes in which devils or peasant characters appeared.

The theatre thus became as secular as that of classical antiquity, though it was consistently Christian in ethos. The kinds of play that evolved throughout Europe were distinct, national, and independent. Yet all reflected a common spirit of Christian man. Performances were closely linked to the feasts of the Christian calendar, themselves adapted from the earlier folk festivals of the agricultural year: Christmas (winter solstice); Shrovetide, Easter, and May Day (advent of spring); Ascension Day, Whitsunday, and Corpus Christi (summer solstice); St. Michael's Day and All Saints' Day (harvest thanksgiving and autumn). Modern observers may be surprised at the endurance of audiences willing to sit or stand all day for several days to watch simple but surprisingly dignified and profound plays. They had a rarity value, however, augmented by long months of preparation in which the entire community had been involved, and they were heightened by a sense of occasion.

Involvement of entire communities in miracle plays

Morality plays. The miracle plays reveal a faith and hope for salvation that does not appear in a later kind of medieval drama known as the morality play. Morality plays, which were commonly produced during the 15th century, reflect something of the sociological turmoil of an age in which the existing social framework was turned upside down. They are dramatized allegories, and their characters are abstractions such as mankind, good, evil, death, chastity, and lust. Vivid sermons focussing on the seductive power of evil to which Christian man is exposed, they show how he may nonetheless arrive at the day of judgment with an army of virtues rather than vices to settle his fate. In the plays scholarly theological learning, Christian allegory, and Old Testament themes predominate. Meant to provide moral education, they were performed by and for the new middle classes of the fast expanding towns.

This theatrical development is interesting in relation to other changes that took place in the age of the merchants' revolution, including a switch from payment in kind to the use of money (which alone had a tremendous effect on people, involving them in risks and investments with the great banking concerns that had begun to emerge). There had also been a rise in trading, which paved the way for speculation and stemmed from the new financial profit system and the newly opened sea routes. The conflict between virtue and luxury became the principal theme of literature: man was urged to lead his life in accordance with Christian faith (plays about Lazarus); to endure suffering with patience (plays about Job); to be honest in his dealings with fellowmen (*Cenodoxus*); not to become the slave of luxury (*Everyman*); above all, to avoid committing the seven deadly sins. The morality plays present the dilemma of man faced with the reorganization of educational and economic systems and the breakdown of old political structures who was at the same time striving to hold fast to his soul.

CLASSICAL REVIVAL OF THE RENAISSANCE

Full of disgust and disdain for the decadence of life and society in 15th-century Italy, men began to desire a new kind of life in the manner of classical Roman times. The old ideals of Roman morality and humanity were sought for their elegance, wit, and knowledge of the world. Learning had traditionally been sought in the seclusion of the monasteries, but the "new learning" of the Renaissance was more dynamic. Scholars wished not only to understand the ideals of antiquity but to re-create them. They regarded this world not as something to be overcome in order to have life in the next but as something created to be enjoyed by man. They began to hunt for classical manuscripts and to study the other remains of antiquity. Even the papacy promoted these new humanistic aims. The Vatican Library amassed works embodying classical culture from all over the Christian world. The worldly popes of this period encouraged both artists and scientists of the highest renown to gather at their courts, even though their liberal ideas often clashed with Christian doctrines.

Italian Neoclassicism. During the 10th and 11th centuries, especially in Germany, Roman culture had enjoyed a mild renaissance, in the course of which a nun, Hrosvitha, had studied the comedies of Terence in her convent at Gandersheim (now Bad Gandersheim) in Germany, copied his style (which might have caused many a nun to blush with embarrassment), and produced her own Christian comedies. She substituted chaste Christian women, honest men, and constant Christian martyrs for Terence's bawds, slaves, and foolish old men. Although interesting in her own right, Hrosvitha did not have any practical influence on theatrical developments. During the true Renaissance, however, classical literature and drama—first that of Rome, especially the works of Plautus, Terence, and Seneca, later that of Greece—were discovered and not only became an object of research and reading but a starting point from which to recreate theatrical traditions of the past. In Rome itself, classical works of Roman antiquity were performed by Pomponius Laetus and his company; in 1486 Sulpitius Verulamus edited Vitruvius' *De architectura libri decem* (Marcus Vitruvius Pollio had dedicated this remarkable treatise on the architectural arts of the classical world, which included a description of ancient Greek and Roman theatres, to the Roman emperor Augustus). The whole educational system was meanwhile revolutionized by the invention of printing. Up to this time scholars had passed on their theological and scientific knowledge to succeeding generations either orally or via handwritten manuscripts. New works of learning could be made accessible to a rapidly growing number of educated men. The printed Latin texts of Vitruvius, Terence, Plautus, and Seneca were widely read and exerted a striking influence on further developments in the theatre. Throughout Europe, theatrical performances were given in learned and aristocratic society, in academies, private institutions, and religious societies. For many of these revivals, careful reconstructions of classical stages were erected. The printings of Vitruvius' work, by now published all over Europe and often appearing in translation, were provided with woodcuts showing ground plans and front elevations of classical stages. Not many "classical" theatres were actually built, however, but of these few the Teatro Olimpico at

The chaste Christian comedies of Hrosvitha

Vicenza (1585), designed and started by the Venetian architect Andrea Palladio and completed by Vincenzo Scamozzi, is one of the most beautiful. Early revivals of comedies by Plautus and Terence relied on the rather modest descriptions of the classical stage supplied by the scholar Aelius Donatus in his annotated edition of Terence.

It was not a great step from reviving Latin comedy to imitating it in the vernacular. The early Humanists, led by Ludovico Ariosto, were the first to do so, treating contemporary themes in a critical, sarcastic, yet humorous manner.

In this period, dramatists (and Humanist poets in general) had a political role to play, feared and at the same time courted. Sovereigns preferred to win their affection rather than take issue with them; in their comedies they could either belittle a man or praise him to the skies, merely by their words. Consequently, the most important personalities were invited to live at the courts, which thus became centres of the arts of the theatre and of poetry.

The Renaissance stage

The stages used in the Renaissance for performance of these works of the Italian classical period were based on the principles found in Vitruvius' work on classical architecture. In the matter of painted backdrop scenery, however, a new element was now introduced because Renaissance painters had mastered the rules of perspective. A facsimile of "nature" was the aim, but "nature" was to be more perfect on stage than in reality, for it could be freed from all the accidentals and impurities of real life. For the staging of pastoral plays (artificial evocations of the shepherd's sensitive life set in a pristine and wholly delightful landscape) a setting that depicted fields and woods was provided. The Renaissance tragedy setting was characterized by temples and palaces. For comedies, perspective settings depicted the houses of the "little" man of the middle and lower classes.

Opera. The birth of opera in the late 16th century stemmed from new information about the important part played by music in the classical theatre. It was realized that in their theatrical performances the Greeks had adopted a special declamatory vocal style (*recitativo*), different from the more solemn monologue (*aria*) and choruses. A group of Florentine patricians known as the Camerata (*c.* 1580) undertook a revival of Greek theatre as they imagined it to have been, and it is from their endeavours that the European opera arose. It is not entirely surprising that the first operatic compositions should have dealt with Greek myths (such as the stories of Orpheus and Eurydice, Daphnis and Chloë). Great scenic artists were engaged to create suitable settings, which took full advantage of the 16th-century mastery of perspective. Voices were to ravish the audience's ears, the beauty of the setting to please their eyes: the opera was a field in which artists—composers, singers, poets, technicians, and painters alike—surpassed nature and proved their creative abilities. Opera was given on sumptuous occasions, intended to make manifest the patron's power and wealth, and thus it was politically important. Indeed, while enjoying the artistic and aesthetic experience of a theatrical performance, patrons were at all times keenly aware of the political implications of such activities. Ambassadors' reports from the time show that an overall political climate was reflected in theatrical performance, even though the works might not deal specifically with a political subject (see OPERA).

Commedia dell'arte. Another kind of dramatic skill was also becoming appreciated at court: this was the delightful commedia dell'arte, a tradition of playing highly developed at this time and thought to be in direct descent from the Atellan plays of Roman antiquity—a link which cannot, however, be established by research. Commedia dell'arte ("comedy of art") is also known as *commedia all'improviso* ("improvised comedy"), so called to distinguish it from the *commedia erudita* ("comedy of learning") of the earlier Italian Renaissance period. It flourished during the 16th century and later. At first it was performed chiefly at the courts and only in the 18th century was it primarily associated with country fairs (*théâtre de la foire*) and suburban theatres in Italy and Austria. The artistic demands made of actors in commedia dell'arte were considerable. As well as physical dexterity they had to be of a high educational standard, command several languages, be quick witted, and be able to react fast in improvised situations. On top of this, players were expected to have at their disposal a number of *lazzi* (short sketches, brought to a pitch of perfection, which could be inserted anywhere in the performance). Originally the main characters were supposed satirically to portray "types" of Italian citizen: there was Pantalone, an old lustful Venetian merchant; the Dottor, a learned doctor (*dottore*) of Bologna; a servant, Arlecchino, of Bergamo; the boastful Neapolitan Capitano, of Spanish origin (Naples having been conquered by the Spaniards). These "type" characters were masked, as in the pantomime of Roman times; the actors playing the lovers, however, were not (see COMMEDIA DELL'ARTE).

High demands made on actors of commedia dell'arte

Professional troupes. Only professional players were able to reach the high playing standards of commedia dell'arte, and so permanent troupes were formed, playing perfectly in ensemble. These troupes were paid to perform in Italian courts and in those abroad. The tradition flourished for nearly two centuries throughout Europe, inspiring such dramatists as Molière in France during the 17th century and Carlo Goldoni in Italy during the 18th century. Even the 20th-century theatre was stimulated by the example of commedia dell'arte in its efforts to revive a "theatrical theatre."

By the mid-16th century professional players had made organized theatre their own province, were in commercial competition with one another, and had thus made the theatre part of the general competitive profit system. This fact meant that the audience was able to exert great influence on further theatrical developments through its likes and dislikes. At this time, too, the first measures to achieve publicity were taken in order to win the public's attention and favour: heralds announced details of performances, playbills carried them. Licenses to play were dependent on magistrates' findings with regard to the moral standards of their repertoire—were they offensive to public morality, religion, or the state?—and thus the early workings of a public magisterial censorship were established.

Ruzzante's troupe

Angelo Beolco of Padua, called Ruzzante, organized one of the earliest professional troupes in Italy. Already, since 1520, they had travelled throughout northern Italy, performing at the courts and in the markets. Keeping their Paduan dialect, they played rustic comedy, themes based on the social tensions between urban and rural life, and love farces or tragicomedies, usually with a pastoral background. After experimenting with Plautine comedy, Ruzzante's main achievement was to develop certain character "types" which may be considered the forerunners of the commedia dell'arte characters. He also introduced a more natural style of acting, drawn from life and observation of people—an approach that in this period was adopted in the other arts as well (François Rabelais in literature, Orlando di Lasso in music, Pieter Bruegel the Elder in painting).

Courtly entertainments. During the 15th and 16th centuries the courts did not at first employ theatre specialists. Courtiers, noblemen holding a court appointment, court painters, musicians, and masters of ceremonies—all were involved in the organization and performance of courtly entertainment. Leonardo da Vinci (who ranks among the most famous theatre technicians, having designed by 1490 the first revolving stage, incorporating a movable planetary system) arranged the setting, masks, and costumes of *Festa del Paradiso,* an entertainment given during the wedding celebrations for Lodovico Sforza, duke of Milan. Raphael also painted much admired stage settings. The court poets were naturally expected to devise the texts, the master of ceremonies to organize the production. Equestrian ballets (to specially composed music by the court musician) and triumphal processions were a spectacular feature, needing careful preparation, and became the highlight of these displays of power and glory. Princes, dukes, and monarchs were invited to these festivals. They came with their suites, riding on horse-

back or else in ornate carriages, and even their arrival processions were sometimes choreographed, especially in France, where the *entrées solennelles*, entrance processions of great pomposity, were developed to a peak of elaboration and ceremonial. In England the masque, a short allegorical drama, became the favourite court diversion, reaching its climax under the reign of the Stuarts, when the designer Inigo Jones and the poet Ben Jonson joined forces.

Members of the court all had a thorough training in dancing, fencing, singing, instrumental music, and courtly ceremonial. They were therefore well equipped to perform in these masques and ballets, even to take the solo parts as well as appear in the choruses.

Jesuit drama. The continuous development of religious theatre was interrupted by the Reformation and Counter-Reformation which separated the Protestant north of Europe from the Catholic countries of the south. In the south it was the Society of Jesus (the Jesuits) that took particular interest in the theatre, being fully aware of the persuasive power inherent in performed action. It was also a means of teaching their pupils how to behave and express themselves in accordance with the requirements of the upper classes of society. Finally, theatre was considered an effective way of fulfilling the Jesuit order's professed missionary task. Thus it was that the Jesuits encouraged colourful theatrical activities in such Latin American countries as Brazil (*Auto de Santiago*, 1564), Venezuela (1566), Peru (1569; building upon traditions of Spanish religious and secular drama, established there since 1548), Bolivia (1578), Paraguay (1596; following up Corpus Christi plays and *autos sacramentales*, which had been introduced there *c.* 1544), and in Argentina, Ecuador, and Chile (1646).

The Jesuit theatre

During the 17th and 18th centuries—when the order was suppressed in many countries—the Jesuit theatre flourished, standing fast to its didactic intentions. Many of the most important theorists of Baroque theatre, moreover, were Jesuits or their pupils, especially in the field of scenic design. The Jesuit theatre made full use of the elaborate operatic stage, of its towering architecture and luxurious settings, and of its flying machinery and stage trapdoors. The Jesuits had their own composers and librettists of high rank, and Jesuit schools gave special training in grammar and rhetoric. Princes often took part in close of term performances at Jesuit colleges, and the Catholic emperors attended them.

Spain's Golden Age. During the second half of the 16th century professional troupes had been established in Spain and England. These troupes did not perform for one particular social class; members of high society attended professional performances in the Spanish *corrales* (courtyards), and in the English public playhouses the upper classes attended as well as the groundlings. Professional troupes were specially hired to act at court on certain occasions.

Since the process of Reformation had not affected Spain, the *autos sacramentales* continued to preserve the long tradition of religious drama. The prudent Spanish clergy had successfully purged religious drama of those elements that had laid it open to ridicule in other European countries. *Autos* were written by the most famous poets of the Spanish Golden Age. Early professional troups, such as that of Lope de Rueda, were of strolling players, and they introduced Italian culture and Humanist-inspired comedy to Spain. They were so poor that they were said to keep all their belongings "in a single sack." The traditional theatre of the strolling players also proved to be the father of Cervantes' *drama a noticia* (tragedies based on his own experiences in Algerian prison) and of his *entreméses* (comic interludes), which were performed by the professional troupes. The establishment of *corrales* meant a more secure livelihood for the actors and a better chance of control over theatrical entertainment on the part of church and town authorities. Naïve religious faith plus national pride, relish for an elegant way of life, and incomparable creativeness and versatility—these all distinguished the work of Lope de Vega, who wrote both secular comedies for the *corrales* and *autos sacramentales* for Corpus Christi celebrations. The *gracioso*, a comic servant character, appeared in many of his dramatic works, originating from the Spanish tradition of strolling players and virtuoso actors. He is contrasted with the hero, and the relationship has much in common with that between Sancho Panza and Don Quixote in Cervantes' novel.

Not until the late Baroque period was Italian perspective setting introduced to the Spanish theatre. Thereafter, however, it played an equally important part in theatrical production as it had done in other European countries. During this Golden period, the Spanish theatre was distinguished by the work of poets of highest rank, including Calderón de la Barca, and that is one of the reasons why dramatic literature reached a height of perfection and refinement, able to integrate man with the "great theatre of the world," a hierarchical concept in which every man played his part before God, who held each class of society as equally important: the poor, the rich, the servant, his master, the sick, the healthy man, the ugly, and the good-looking; to each God gave life and each must prove himself worthy of it.

This world picture had already been accepted by progressive Spanish Jesuits and was even expressed in their motto *vox populi, vox dei* ("the voice of the people is the voice of God"). It meant that the Spanish (and also the Austrian) Baroque theatre differed widely from contemporary theatrical activities in other absolutist states. This divergence of attitude is also revealed in the fact that in Spain (and again, also Austria) comic characters, presented as an analogy to the hero, continued to play an important part on the stage: the servant is confronted with an experience equivalent to that of the master but reduced to an apt intellectual horizon and is, thus, a reflection of the hero's image. This conception of a corporate state, in which each class bears its appropriate responsibilities, was most clearly expressed in Calderón's *El gran teatro del mundo* (*The Great Theatre of the World*) and *La vida es sueño* (*Life Is a Dream*).

Continuing importance of comic characters as reflections of their masters

The Elizabethan playhouse. In England during the Reformation, the theatre was active in disseminating Protestant propaganda, and several interludes mocking the traditions of the former religious stage made their appearance. Adapted from traditional miracle and morality plays, their performance frequently led to riots and disorders. Tudor governments, both Protestant and Catholic, were at various times forced to take legislative action against the theatre. Actors were placed under strict supervision and control; an increasingly vigorous censorship was imposed on play texts, in manuscript and in print; places of performance were made subject to license.

The influence of the Neoclassical drama of Italy was a long time reaching Protestant England, partly because of its association with Rome and the Latin language, partly because its plots of intrigue were less interesting to English audiences than topical debate, partly because a people tends to rely more on native resources at times when it is faced with the threat of foreign invasion. There was, however, a relaxation of this tension in 1587 after the execution of the Catholic Mary, Queen of Scots, and the defeat of the Spanish Armada the following year opened the door for new ideas in the arts and education. But by that time a distinctly English style had already grown out of the ashes of the old religious theatre. It was distinguished by a reliance on the symbolism derived from liturgical plays and from heraldry; it owed its narrative scheme and structure (of plot–subplot) to the miracle cycles and saint's plays; its emphasis on debate and parable to the moralities; and its professional character to the players of interludes who had been employed to perform at court since the end of the 15th century. Professionally organized and relying on the support of commercial speculators and the protection of sovereign and court officials, the theatre of Christopher Marlowe, Shakespeare, Jonson, and John Webster retained its links with the popular theatre and with its medieval heritage and was self-confident enough to draw what it wanted and no more from Neoclassical precepts.

During the reign of Elizabeth I (1558–1603) the first

Elizabethan playhouses

regular playhouses were built in London, including the Globe, Swan, Fortune, Hope, and Red Bull. All of these were open to the air. The licenses to run them were usually granted to an entrepreneur belonging to the players' company, whose management aimed at making a profit. The spectators came from all walks of life. During the winter the company of actors would perhaps stay at the castle of one or more noblemen and perform for him. They were also engaged for court performances. Private theatres were opened in some of the old monasteries, suppressed under Henry VIII and now abandoned, including the Blackfriars (from 1576) and Whitefriars (after 1605). Later on, under the first Stuart kings, James I and Charles I, roofed theatres were built along Italian lines. But in 1642, the theatres were closed by the Puritans at the outbreak of the Civil War and remained closed during the Commonwealth period until 1660, when England took up once again her theatrical traditions at the Restoration of the monarchy. The theatre flourished but along lines quite different from those established in the age of Shakespeare.

Shakespeare and most of his famous colleagues were truly professionals of the theatre, usually being attached to a particular professional company. Their characters were written for particular actors, whose abilities and personalities were well-known to them. Their plays were efficiently designed to appeal to their audiences but did not merely present a tragic or comic "mirror of the world." They argued highly explosive political topics. In Shakespeare's histories, for instance, the subject of kingship is thoroughly examined in all its implications: both the rightful but incompetent sovereign and the usurping but strong monarch are scrutinized—a most daring undertaking in the days of Elizabeth.

Rough theatre in Germany. Monopolies, suppression, and withdrawal of playing licenses were some of the reasons why many troupes of actors left Tudor England and went to the European mainland. Unlike the commedia dell'arte troupes, who were mainly engaged by the courts, these English strolling players usually travelled from one fair to another, playing to an audience of rural folk. (Only very rarely did they perform at court, although there is a record of Christopher Marlowe's *Doctor Faustus* being given in 1608 at Graz, in Austria.) At first they adopted a rough style of acting, having to express themselves chiefly through mime because of language problems. They played in innyards, on primitive wooden platforms constructed on the spot, in market squares, or before the church. The German-speaking countries benefitted most from the importation of Elizabethan plays and stage conventions. By and by these troupes were reshaped and their repertoires extended to include plays given in the vernacular, though with an intermingling of many English words and phrases. Shakespearean drama included *Der bestrafte Brudermord* ("Fratricide Punished," based on *Hamlet*) and *Hieronimo, Marschalk in Spanien* (based on Thomas Kyd's *Spanish Tragedie*). There was also Italian pastoral comedy, French tragedies, and Spanish cloak-and-dagger drama. Favourite themes included tested virtue, human nobility, the courageous suffering of ill fortune or pain; the sudden change of man's fortune, the power of fate; pride, jealousy, lust for power, and malice of every kind. The style was bloody, bold, and melodramatic. From the mid-17th century, Dutch strolling players also visited Germany: though their playing was of a very high standard, they could not earn their living in their native country, and so they roamed throughout northern Germany and Scandinavia, performing *vertoonige* ("living tableaux") and contemporary comedies and tragedies, Spanish drama being much favoured. Italian travelling players in the main presented their marionette and puppet theatre in Austria and southern Germany. These "Pulcinella" players influenced Austrian popular theatre a good deal, much more so than the commedia dell'arte (called *wällische*) troupes who played in Austria from the end of the 17th century. Commedia dell'arte, however, had an enormous success at the Austrian courts, and their style of acting was much imitated (as, for example, in productions of the *Edelknabenkomödien*, or "Comedies of the Pages," that were given at the court of Holy Roman emperor Leopold I, an ardent admirer and connoisseur of the theatre).

Travelling troupes in Austria and Germany

There were, of course, many who derided the strolling troupes and who contemptuously dismissed their repertoire as "debased cultural property." They considered the play *Der bestrafte Brudermord* as only a crude travesty of *Hamlet*. Such critics, however, did not appreciate the valuable results of the troupes' activities. Links were established between one country and another, and audiences were confronted with new outlooks on life and experience, on man and the world. And thus—in an age when compulsory education was still unknown, when few could read and write, when scientific knowledge and experience of the world were limited to a very few privileged people—the strolling players opened doors to the future and the past, to other peoples, and to other cultures. They conveyed new knowledge that enlarged the range of experience. This was the real achievement of the strolling players.

French Neoclassicism. In France sacred drama was forbidden by decree in 1548 to prevent its being used by the Protestants to bring Roman Catholicism into contempt. Continuity of theatrical tradition was thus lost, and French dramatists, deprived of their great heritage of religious plays and popular farces, began to ape Italian "academic" drama. The sterility of the results is one of the reasons why a taste for dancing and spectacle developed among court amateurs in France. New "rules" for the new drama were invented, the most notorious being that of the "unities" (of action, time, and place) that were to be observed in both tragedy and comedy. According to this rule, the play should consist of one central action, occurring at one time (not to exceed the time it takes to perform the play), and in one place. Plays that followed the rule were performed mainly in colleges and universities; at court, the queen Catherine de Médicis much preferred Italian poets and actors. But a permanent home for these was not established until 1598 at the Hôtel de Bourgogne.

In the 17th century under Cardinal Richelieu, French statesman and minister to Louis XIII, a special board was set up to bring new life to the theatre, and one of its tasks was to make the "regular" tragedy and comedy flourish. Another professional theatre was opened in the Marais district of Paris, keen competition ensued between it and the Bourgogne, by 1650 Italian stage machinery had been imported, and the playwrights Pierre Corneille, Molière, and Jean Racine had brought the French theatre to an eminence that many students believe eclipsed that of England and Spain. These masters brought to the theatre a degree of observation of both human foibles and human passion and suffering that sufficed to give a genuine vitality to the revived classical forms not attained before or since. Their influence was felt throughout Europe and was synthesized in the French poet and literary critic Nicolas Boileau-Despréaux's *L'Art poétique* (1674). The theatre once again assumed an educative role: people were to behave in a "courtly" manner, to master passion by means of reason, or to transform violent feelings into "noble passions."

Influence of Corneille, Molière, and Racine

Rise of the national theatres. French national pride being invoked, poets and theatrical artists were called upon to develop French styles of artistic expression. After a period of training in Italian art, the stage-struck kings now demanded French styles in opera, drama, and ballet. The Académie Royale de Musique (opera) was founded in 1669; the Comédie-Française, which may be considered the first national theatre, was established in 1680 with a mandate to pursue the cultural aims of France that has continued to the present day.

In the course of the succeeding centuries, national theatres were also established in many other European countries but not necessarily for the same reasons. German national theatres fought to shake off the infiltration of French culture and to develop a native theatre. It was the aim of Emperor Joseph II to institute national theatres for all the peoples of his empire so as to open up the

possibility of becoming acquainted with the works of world literature in their own tongue. After establishing a German national theatre for the German-speaking population of Austria, Joseph II then supported the Czechoslovakians' efforts toward their own national theatre; later, a national theatre was founded in Budapest for the Hungarians. Gustav III created the Swedish national theatre. Catherine II the Great of Russia, like Joseph II, wished to educate her people by confronting them with the dramatic works of world literature performed in their own language. During the 19th and 20th centuries, however, as individual countries strove for autonomy, endeavours toward establishing national theatres became a political target. England managed to found a subsidized national theatre only in the second half of the 20th century—and then without a permanent home—a fact explained largely by the profit-system upon which the English theatre has traditionally operated.

The ballet. The triumphant progress of opera and the ballet during the 17th century is a major chapter in the history of theatrical development during the age of Baroque. At the beginning of the 17th century, ballets were often given as an interlude and curtain piece during the performance of an opera. Eventually they were integrated with the plots of the operas, though they were usually placed at the end of the acts. The "star" opera was inaugurated in Venice, giving pre-eminence to aria or a solo vocal part (as opposed to the Florentine tradition of chorus-dominated works). Composers made new demands on singers, who had to study for many years in order to meet them successfully. After the mid-17th century, singers exerted considerable influence on the structure of new works because they demanded showpiece arias at certain places in the text. The dramatic technique of Baroque opera adopted followed set rules: arias were to be sung front stage facing the audiences; the chorus was directed as a static body; the ornate setting was an elaborate decoration to please the eye rather than a functional definition of the acting area (see BALLET).

Decline of classicism. The influence of Molière and Racine, together with that of Corneille, was felt everywhere in Europe. Nowhere else, however, was their genius matched. Only in England was anything written that has survived the test of time in terms of frequent adaptation and revival and then only in comedy. English tragedy attempted to provide an equivalent of the French classical play in a genre known as rhymed heroic drama. Nevertheless, the English heroic play as written by John Dryden, Sir Robert Howard, and Nathaniel Lee was unclassical in its bombast and general lack of restraint, concentrating upon expressing the marvellous as well as exaggerating the passions in a quite unnatural manner. There were one or two exceptions—Joseph Addison's *Cato*, the early success of which was partly due to its relevance to current political crises, is thoroughly classical and held the stage for over a century. Comedy, on the other hand, classified as "comedy of manners," thrived for some decades in the hands of William Wycherley, William Congreve, and George Farquhar and at its best was elegant, witty, cynical, and sharply critical of contemporary society. In the rest of Europe, including France itself, nothing of much note was produced apart from lifeless imitations of French classical tragedy and comedy. This decay of the Neoclassic drama continued throughout the 18th century, flickered to life with the tragedies of Voltaire in France and Vittorio Alfieri in Italy, and finally gave way to a new spirit in both comedy and tragedy.

Restoration drama

III. The rise of a middle class theatre

THE 18TH CENTURY

The history of Western theatre in the 18th century is dominated by personalities. Everywhere it was actors and designers whose names counted with audiences rather than writers. The costume designs of Lodovico Burnacini, the perspective settings of the Bibiena family, whose members between 1680 and 1780 were unchallenged for originality and activity, define the Baroque spirit and its Rococo sequel that spread outward from dramatic representations to enhance the whole of aristocratic life. Theatre worthy of the name became a courtly or at least a metropolitan toy designed to kill time in a manner as costly as befitted its aristocratic patrons. Popular theatre dwindled into fairground improvisations and the meagre, eviscerated repertoires of strolling players.

Middle class drama. Reaction came neither from right nor left but from the centre—from the middle classes who had been denied a theatre for so long: by Puritan sentiment in England, by aristocratic privilege in France, by war and social unrest in the Low Countries and middle Europe, by stagnation in Spain, and by feudalism in Russia and Scandinavia. The new drama took the problems of middle class life as seriously as the old drama had treated the aristocracy.

In England, the cynical comedy of manners was displaced by the sentimental comedy of such dramatists as Colley Cibber and Richard Steele, in which middle class social and domestic problems were treated in moralizing scenes of pathos leading to a happy ending. Sincerely moral, if artistically inept, the sentimental comedy in England is related to the *comédie larmoyante* ("tearful comedy") in France, whose best representative is the playwright Pierre-Claude Nivelle de La Chausée. George Lillo in England extended the accepted range of tragedy by making persons of the middle class the protagonists of his *The London Merchant, or the History of George Barnwell* (1731), something that had only been done previously by Thomas Heywood in *A Woman kilde with Kindnesse* (1603). Lillo's play inspired G-E Lessing in Germany to write *Miss Sara Sampson* (1755), in a deliberate attempt to free German drama from the dead hand of French Neoclassicism, and to create *bürgerliches Trauerspiel* ("middle class tragedy"). In France, the same extension of the tragic genre led to the *drame bourgeois* of Denis Diderot. All of the middle class plays were seriously written to enunciate moral truths, to preach against the crimes of civilization and conventional society, to advocate the strength and purity of the natural virtues, to express pity for the oppressed, and admiration for the solid, serious, virtuous middle class merchant.

Sentimental comedy

There was some opposition to the sentimental spirit in the drama, notably in England and Italy. Oliver Goldsmith tried to provide an alternative in the shape of what he called laughing comedy, with plays like *The Good-Natur'd Man* (1786) and *She Stoops to Conquer* (1773). The work of Richard Brinsley Sheridan was also fundamentally opposed to the lachrymose comedy, which is mocked (in the character of Lydia Languish) in his most famous play, *The Rivals* (1775).

In Italy, Carlo Goldoni and Carlo Gozzi both made use of the old commedia dell'arte traditions in their plays. Commedia dell'arte still survived in the fairs and suburban theatres of Italy and Austria but only as a shadow of its former vigorous self.

Nevertheless, despite this literate opposition, it was exploitation of the sentimental drama and of the new audiences' penchant for it that brought the tear-drenched successes of David Garrick, England's foremost actor, and first in the long line of actor-managers who were to dominate the establishment theatre in the 19th century. The feeling for spectacle and display which it engendered also fostered in that century the extravagant historico-realistic productions of Edmund Kean and John Philip and Charles Kemble (*i.e.*, the Kemble brothers) and supported the later development of pantomime, music hall, and extravaganza which flourished throughout the Victorian age.

Romantic movement. The Romantic reaction against Neoclassical insistence on cool reason was, in Germany, ushered in by the *Sturm und Drang* ("Storm and Stress") movement—headed by Johann Wolfgang von Goethe's *Götz von Berlichingen* (1773), a celebration of natural man, and closed by Friedrich Schiller's *Kabale und Liebe* (1784). Both these dramatists were involved in the court theatre established at Weimar, one of the many principalities of which Germany was made up at that period, where Goethe established a recognizable, if rather stiff,

company style that was copied in other parts of Germany and was of great influence on young actors during the first part of the 19th century.

Beginnings of an American theatre. The spirit and form of the English theatre in the Restoration and Georgian periods dominated the start of professional theatre in North America. Actors, scenery, and repertory were imported to the American colonies around 1750, and early performances were given in existing halls or else in hastily erected quarters. For a long time, however, Puritan prejudice against the theatre proved difficult to overcome—one touring company announced their presentation of Shakespeare's *Othello* as "a moral dialogue in 5 acts."

THE 19TH CENTURY

Nineteenth-century interest in specialty entertainment

This was a century, above all, of progress in the theatre. There were especially significant advances in the field of stage lighting. More and more theatres were built. A quickening interest in specialty entertainment saw the rise of music hall and vaudeville; the actor-manager enjoyed his heyday. Toward the end of the century Western theatre was revolutionized by a number of "free" theatres that were seeking escape from the established systems of theatre management, production, and acting styles and were looking to promote a new kind of play.

A sharp increase in the number of theatre buildings matched a rapid growth in urban development. During the London winter season of 1807, for example, only ten theatres were operating; by 1870 there were 30. Most of the new theatres were smaller than hitherto. None rivalled the new Drury Lane in London, opened in 1794 to seat 3,600 people, about whose size the actress Mrs. Siddons had bitterly complained when her London debut there failed badly. England (1843) and France (1864) removed state censorship over who might and might not present plays, acts that encouraged the opening of new theatres.

In 1803 gas replaced candles as the source of illumination at London's Lyceum Theatre, and other theatres quickly followed suit. The advantages included control and brightness, to a degree never before known, while the obvious disadvantages were an appalling smell and an increased danger of fire from the naked jets of flame (between the introduction of gas illumination and the introduction of electric lighting systems toward the end of the century, some 400 theatres in Europe and North America were burned down). Experiments with electricity at first permitted certain "special" effects (lightning, sunrise, rainbows) and finally resulted in fully electric lighting systems. The first such was installed at the Paris Opéra in 1880–81.

Plays and players. Much of the drama performed during the 19th century derived from the movement initiated by the *Sturm und Drang* dramatists of the late 18th century in Germany. The works of Schiller and Goethe, for instance, gave rise to a spate of "fate dramas" between 1800 and 1825; in 1830 the performance of Victor Hugo's *Hernani* caused riots when it was presented in Paris at the conservative Comédie-Française playhouse, but it at last saw the rout of Neoclassical drama 50 years after the German dramatist Lessing had called for a return to the inward dramatic truthfulness of Shakespeare. Elsewhere in France, some good Romantic plays were written by dramatists such as Alfred de Musset. In England, almost nothing that repays serious attention was written for the theatre between the time of Sheridan and that of Oscar Wilde and George Bernard Shaw; in 1879, the poet and critic Matthew Arnold was able to observe with some justification that "In England we have no modern drama at all." It is not a far step from the Romantic imagination and its attitudes to romantic agony and attitudinizing—to crude, barnstorming melodrama, which reached its nadir in 19th-century England and the United States, where the popular section of audiences derived great pleasure from spectacular effects within plays that mixed sentimentality, villainy, and violence. Parodies of the classical theatre were also popular (*extravaganza*; *burletta*).

Melodrama

Some individuals began to capitalize on their special talents as singers, dancers, mimics, jugglers, and to give solo performances in ale houses and taverns. These entertainments became so popular and so financially successful that, from the "music room" annex of the public saloon, a great chain of provincial and metropolitan theatres sprang up during the 19th century to be known in England as music hall and in the United States and elsewhere in Europe as vaudeville.

The actor-manager. Personalities also triumphed in the more orthodox dramatic genres, just as they had a century earlier. The 19th century, however, was the heyday of the actor-manager—star, licensee of the theatre (or theatres), and arranger of the performance. He dominated the forestage while his fellow actors were relegated to the background as a sort of mobile set dressing, but after the invention of gas lighting he was forced into retreat behind the proscenium arch to become part of the stage picture as a whole. Because of the technical difficulty in manipulating complicated special effects—storms, forest fires, earthquakes—the star was eventually obliged to hand over artistic control of the production to a neutral observer; thus the stage manager, who had not been of any special importance hitherto, was elevated to the status of *régisseur*, or director, and eventually became a theatre giant in his own right. Finally, the actor-manager's control over the business side of his productions was gradually replaced by that of financial speculators whose interest was in theatre real estate rather than in artistic triumphs.

Movement toward realism. After the actor retired from his forestage and the picture-frame stage had won the day, realism of an almost photographic kind became a main object of production. The Romantic movement had stimulated an interest in historical plays, and strenuous efforts to ensure total accuracy of costume and setting had been made since the early years of the century culminating in the extravagant and costly productions of Sir Henry Irving (died 1905) and Sir Herbert Beerbohm Tree in England. This development, however, meant that the gulf between realistic appearance and rhetorically overblown texts and their delivery was ludicrously apparent. Sacrifices that had to be made included the language of poetry in drama by the playwrights and extravagance of diction and determined bravura performances by the actor.

A move toward ensemble acting and away from virtuoso displays of talent was perhaps the logical continuation of efforts to establish realistic stage presentation in settings and costume. In England, Madame Vestris, an actress and stage singer whose real name was Lucia Elizabeth Mathews, had opened the intimate Olympic Theatre in 1831 and demanded natural movements and gestures from her players. Charles Kean was well-known for his handling of crowd scenes (the extras were split into groups and led by a competent actor). The leading company of German-speaking Europe, the Burgtheater in Vienna, was famous for its company spirit and style. But it was George II, the ruler of the tiny duchy of Saxe-Meiningen, who was the most significant individual in the modern development of ensemble acting. He assumed direct control of his state theatre company in 1866 and achieved a harmony and discipline of playing never before known. The company's extensive European tours between 1874 and 1890 influenced not only the actor-managers of the established theatre but also André Antoine (in Paris) and Konstantin Stanislavsky (in Moscow), both of whom were to be champions of the school of realism in acting and direction later in the century.

The new playwrights. In the established theatre, revivals of the classics were the order of the day, along with the undemanding "well-made plays" of such banal French playwrights as Eugène Scribe, Eugène Labiche, and Victorien Sardou. The new dramatists of the movement known as realism include Henrik Ibsen, Bjørnstjerne Bjørnson, and August Strindberg in Scandinavia; Anton Chekhov and Maksim Gorky in Russia; Gerhart Hauptmann and Frank Wedekind in Germany; Henry Becque in France. Their plays dealt with themes belong-

The "well-made play"

ing to a real, contemporary society, treated in action and dialogue that looked and sounded like everyday behaviour and speech. In one form or another they influenced the mainstream of Western drama up to the present day. In 1867 the French novelist Émile Zola called for a rejection of all artifice in the theatre arts as in the novel, demanding that plays be faithful records of behaviour, scientific analyses of life. This "slice of life" technique, an extreme form of realism, characterizes some of Strindberg's plays (such as *Miss Julie*) as well as those of Becque. The new generation of writers found their audience, small but sympathetic, in a number of "free" theatres that now began to appear throughout Europe.

The work of André Antoine

Théâtre Libre. In 1887, André Antoine, an enthusiastic amateur actor, who worked as a clerk for a Paris gas company, formed a small company that he called Théâtre-Libre (Free Theatre). His intention was to provide a showcase theatre for the young playwrights, both from France and abroad, who could find no other opportunity of bringing their work before the public. Antoine's first bill was a group of one-act plays, and it attracted the attention of leading avant-garde theatre intellectuals including Zola and Becque. In 1888 Leo Tolstoy's *The Power of Darkness* was presented, and Théâtre-Libre took on an international significance. Apart from the work of French writers such as Becque, Eugène Brieux, François de Curel, and Georges de Porto-Riche, the Théâtre-Libre also presented the plays of Ibsen, Strindberg, Bjørnson, and Hauptmann. Théâtre-Libre was an artistic triumph but a financial disaster, piling up debts until in 1894 Antoine gave up its direction. Although best known for his efforts to promote realistic drama and realistic production—he was famous for hanging real carcasses of meat in the stage setting of a butcher's shop—and although his production methods best suited the realistic plays of Ibsen and Strindberg, Antoine also presented many poetic dramas that were Romantic or semi-Romantic in approach. But to these, by presenting them without bombast, he gave a new humanity and dignity. All this was his primary achievement, but he also influenced theatre production elsewhere. In Paris, the Théâtre de l'Oeuvre was opened in 1893 by one of his former actors, Lugné-Poe, who had broadly the same aims as Antoine but who combined artistic sensibility with good business sense, so that his theatre prospered. The Vieux-Columbier, founded by Jacques Copeau in 1913, whose history belongs to 20th-century theatre, can also be considered in direct line of descent from Théâtre-Libre. But it was in Germany that Antoine's influence was most immediately evident.

Freie Bühne. Berlin had emerged as a leading centre of dramatic activity during the 1880s, with the foundation of two important theatres, the Deutsches Theatre and the Lessing Theatre. Neither at first presented the new drama of the realistic school. Antoine's work in Paris, however, was noted and admired and in 1889 a group of men headed by the theatre critic Otto Brahm formed a stage company, called Freie Bühne (Free Theatre) after its Paris counterpart. First productions were of Ibsen's *Ghosts* and Hauptmann's *Before Dawn*. Plays by other avant-garde dramatists followed, but the Freie Bühne effectively ceased to function in 1894—largely because of its own success, for the new drama was quickly accepted by theatres throughout Germany: in Berlin itself there were the Deutsche Bühne and the Freie Volksbühne (Free People's Theatre); others were established in Munich, Leipzig, Breslau (now Wrocław, Poland), Hamburg, and Vienna. Brahm's productions were marked by outstanding ensemble work, and his direction of realistic drama was widely acclaimed. But his range was not so wide as that of Antoine, and his revivals of the German classics were not successful when presented in the modern style. Freie Bühne avoided possible conflict with state and police censorship by presenting private, or club, performances to members only, again following Antoine's earlier example in Paris.

The independent theatre. Dissatisfaction with established systems of theatre, including the all-powerful actor-manager, also existed in England. Critics since Matthew Arnold had further deplored the lack of worthwhile modern English drama. Experimental theatre in Paris and Berlin was watched with approval and interest. William Archer and George Moore were two of many writers who called for an English equivalent of the Théâtre-Libre. A Dutchman living in England, Jacob Grein, organized a group known as the Independent Theatre and in the spring of 1891 produced Archer's translation of Ibsen's *Ghosts*, provoking a storm of moral fury. One champion of the new group and its policies was the theatre critic George Bernard Shaw, whose play *Widowers' Houses* (on the subject of slum landlordism) was produced by the Independent Theatre in 1892. The theatre was supported by a small group of subscribers, many of them distinguished writers, and it ceased activity in 1897. But it prepared the way for the Stage Society, founded in 1899, which played chiefly at the Court Theatre in London, whose work is an important episode in the history of 20th-century British theatre.

The influence of Stanislavsky

Moscow Art Theatre. Probably more has been written about the Moscow Art Theatre than about any other stage company, while its director, Konstantin Stanislavsky, has perhaps had more widespread influence on 20th-century acting than any other theorist. Russian theatre during the early 19th century was one of the most backward in Europe, content to play a repertoire of stock theatrical pieces, mainly French comedies and farces or Russian imitations of them. Little time was spent in rehearsal; the plays were so similar that the same performances (and sets) could be used time and again. During a lengthy conversation in a Moscow restaurant, Stanislavsky, deeply interested in theatre from boyhood and with considerable amateur experience of the stage, and Vladimir Nemirovich-Danchenko, a playwright, teacher, and dramatic critic, talked over their vision of an ideal theatre group, its artistic policy, and its production methods. On the basis of their discussion they formed a theatre group, which they called the Moscow Art Theatre Company, going into rehearsal of a play by Tolstoy in summer of 1898. No great stir was made until, on December 17, 1898, they revived Anton Chekhov's play *The Seagull* (which had failed badly in an earlier production). It established the reputation of the theatre, as well as that of Chekhov and Stanislavsky. The intimacy and naturalness of the acting were something entirely new, and Stanislavsky developed his method of infinitely detailed production until he achieved a perfect surface naturalism. He then became dissatisfied with the narrow confines thus imposed and aimed instead for what he called the inner truth, or "realism of the spirit." This aim, whose achievement was to be sought in a variety of ways, is perhaps the only acceptable description of all 20th-century theatrical endeavour.

The American theatre. The first American plays, as has been said, were modelled on English drama. A native type, the shrewd, rural Yankee, first appeared in Royall Tyler's *The Contrast* (1787) which introduced also a favourite theme of an early American drama: the triumph of native honesty and worth over foreign sham and affectation. In 1798, William Dunlap, America's first professional playwright, dramatized recent American history in a blank-verse tragedy, *André*, in which George Washington is a principal character. The heroic Indian was added in John Augustus Stone's *Metamora* (1829), the tough city lad in Benjamin Baker's *Glance at New York in 1848* (1848), and the stout-hearted frontiersman in Frank Murdoch's *Davy Crockett* (1872). Native-born actors early performed in minor roles, and the native star, able to hold his own with the best on the London stage, appeared with Edwin Forrest in the 1820s and with Charlotte Cushman in the 1830s. Forrest's "American" style was characterized by muscular strength and vocal power. Theatre, first confined to the Eastern Seaboard, in 1815 expanded into the Ohio Valley and then to the Mississippi Valley.

To begin with, settings including all except a few pieces of furniture actually used by the actors were painted on wings shutters. The use of real instead of painted rugs and draperies and a full complement of furniture appeared in

the production of Dion Boucicault's *London Assurance* (1841). Detailed historical accuracy in setting and costume first attracted attention in Charles Kean's production of *King John* (1846). In Edwin Booth's theatre in 1869 the box setting began to be used. In the next 30 years the detailed realistic setting was perfected by such producer-directors as Augustin Daly, Steele MacKaye, and David Belasco. Realistic production was stimulated by the introduction of gas lighting about 1825 and of electricity about 1885.

Realism in acting appeared in some of the characterizations of Yankee specialists such as George H. Hill in the 1830s and 1840s; in Francis S. Chanfrau's tough city boy in the '40s; in Matilda Heron's unconventional *Camille* in the '50s; in Edwin Booth's quieter acting of Shakespeare and Joseph Jefferson's "natural" Rip Van Winkle in the '60s; and was fully developed by William Gillette and Mr. and Mrs. James A. Herne in the '80s. James A. Herne's *Margaret Fleming* (1890) was the first realistic problem play in the manner of Ibsen. Herne could not, however, secure production of this "new" drama in a regular theatre.

Growth of civic companies

At the beginning of the 19th century each major city had a resident repertory company. As population grew and spread westward, so did the number of resident companies, and a leading actor found it profitable to set himself up as a star, playing brief guest engagements with one resident company after another. The proliferation of such stars and the rise of the long run, which was necessitated by increasingly expensive staging, eventually destroyed the resident company, which was replaced in the 1860s and 1870s, except in a few of the largest cities, by the travelling "combination." Originating usually in New York City, which since 1825 had been the leading theatre centre, hundreds of these combination companies, presenting either a smaller repertory or a single play, were providing entertainment the length and breadth of the land. Booking agencies were formed as liaison between companies and theatres. Several theatre owners, producers, and agents, of whom Charles Frohman was the best known, formed the Theatrical Syndicate in 1896, which by controlling booking in key cities gained a virtual monopoly of theatre throughout the country. The syndicate was not interested in plays with limited audience appeal. The theatre on all levels, from serious drama to burlesque, was the country's chief medium of entertainment. It was a big and prosperous business, and it was beginning to be attacked for "commercialism." The change from repertory to the single play and the rise of realistic production also shifted artistic control from the actor to the manager, who became the producer-director, or *régisseur*. In the last decades of the 19th century Augustin Daly, Steele MacKaye, and David Belasco not only selected and cast their plays and directed the rehearsals but also personally supervised all other aspects of production.

IV. 20th-century theatre

The late-19th-century movement toward realism had involved dramatists, designers, directors, and actors. But the term "realism" only approximately describes the work produced by the playwrights. Ibsen, for example, who had begun his career with poetic, visionary work such as *Brand* (published 1866; Eng. trans. 1891), turned to "realistic" plays such as *The Pillars of Society* (1877) and *Ghosts* (1881), which occupied him for some 15 years. Even these, however, were not dispassionate "slices of life" but artfully constructed, psychologically probing, and profound dramas. His later work from *The Master Builder* (1892) to *When We Dead Awaken* (1899) is invested more and more with symbolism. Strindberg did not allow himself to be restricted by naturalistic limitations: his later work, especially *A Dream Play* (1929), presents life strangely distorted in a way that is akin to the Expressionism of the German playwrights Georg Kaiser and Ernest Toller in the second decade of the 20th century, which strives to penetrate beyond the appearances of reality to approach emotional truth. The plays of Frank Wedekind defy classification. *Spring's Awakening* (1891) used the scientific analysis of behaviour (the slice-of-life technique) in a "real" study of adolescence, yet its ending moves toward expressionism: one of two boy heroes returns to urge the other to commit suicide, while a man in a mask, representing life, urges him to live.

The quest for a new theatre toward the end of the 19th century, in fact, only seemed to go hand in hand with realism. For almost immediately, designers, playwrights, and directors were seeking ways of escape. There was a common desire that contemporary truth should be a keystone of contemporary theatre and that the world should be brought onto the stage. But there was little agreement over the means of achieving these aims. Western theatre in the early 20th century was eclectic, using a variety of means to escape from realism, though not reality.

ESCAPES FROM REALISM

The new stagecraft. Technological advances made in the late 19th century, which brought a variety of new stage machinery and opened up new possibilities in the art of stage lighting by electricity, gave rise to new theories of stagecraft. Leading theoreticians included two designers. In Switzerland, Adolphe Appia turned from opera to drama to expound his theory of design, which demanded a fully three-dimensional setting, with various stage levels, and the use of "living" light. All were to strengthen the dramatic action of the play and were to change and evolve as a counterpoint to it.

An Englishman, Edward Gordon Craig, the illegitimate son of the actress Ellen Terry, thought of the theatre as a place where "the inner beauty and the meaning of life" is revealed. Recognizing that the experience of theatre is a combination of many arts—acting, directing, music, movement, mime, design, makeup, lighting—his aim was "total theatre," with one man being responsible for harmonizing every aspect of the play produced so that it might achieve its fullest effect. He felt that a suggestion of reality could create in the imagination of the audience a physical reality: the one Gothic pillar, for instance, designed to stand alone and carefully lit, can suggest a church more effectively than can a cardboard and canvas replica faithful to the last detail.

The work of Max Reinhardt

The young Max Reinhardt was an actor in Otto Brahm's Freie Bühne company and had been allowed to direct there a number of experimental productions (of Strindberg, Oscar Wilde, Wedekind, Gorky, and others). In 1903 he left the company and opened his own at the Neues Theater, winning acclaim for his staging of *A Midsummer Night's Dream* (1905). Reinhardt brought his love of colour and gaiety, richness and display to his productions and was attacked by both the old school of directors and the realists. All disliked the "theatricality" of his work, a quality scrupulously avoided in their own low-key work. It was his great service to the European theatre, however, that he restored its vital theatricality without reinstating its old staginess. In so doing, he also revolutionized theories of acting: rejecting the idea of "one style," he demanded for modern plays a style realistic in feeling but avoiding the drab exactness of realism. In productions of the classics he demanded lively, supple speaking in place of the slow, ponderous delivery of the traditionalists. He made his actors think afresh about their characters instead of assuming ready-made characterizations.

In 1902 he opened his Kleines Theater in Berlin and initiated a movement that aimed to break down the separation of stage and auditorium and to restore intimacy between actor and audience. In his endeavours to rescue the players from their isolation behind the proscenium arch, he often took them out of the theatre to play in places that seemed eccentric settings for a theatrical entertainment—a square in Venice, a palace ballroom in Vienna, the Boboli Gardens in Florence, and the Domplatz (cathedral square), where every year he directed *Jedermann* (*Everyman*), by his contemporary Hugo von Hofmannsthal, at the Salzburg Festival. He produced *Oedipus Rex* (1910, Vienna) in a circus arena, using one end for gigantic architectural settings unframed by any

proscenium. For his production of the mimed religious play, *The Miracle* (1911), he transformed the huge Olympia exhibition building in London into a cathedral so that the audience became part of the congregation. But although he was a master of spectacle, his versatility was such that he directed subtle and intimate plays in small theatres with equal skill. Until World War I his personality dominated the German stage; nearly all the young directors and actors had either worked in one of his companies or been trained in one of his schools.

Revolt in Russia. In Russia, the general European reaction against over-attention to the externals of realism in theatre production came at more or less the same time that Stanislavsky himself was beginning to feel he must seek new paths. In 1905 he founded a small studio theatre for experiment and research, appointing Vsevolod Meyerhold director. A member of the Moscow Art Theatre Company, Meyerhold had left in 1902 when he became a convert to the Symbolist movement. After months of preparation, Meyerhold staged two productions, but Stanislavsky disliked them so intensely that he closed the studio. He thought the actors had been used as puppets to illustrate Meyerhold's theories. Yet these productions had an important effect on him as a demonstration of the slavish obedience to which the dictatorial producer could reduce his actors. He determined that the actor should in future be his collaborator not his subordinate, and he began to develop a method of "inner realism" that became known as the Stanislavsky method (and remains the basic training of Russian actors).

After the Revolution in 1917 Stanislavsky refused to allow his theatre to become a platform for spreading propaganda. He believed that its mission was to maintain a standard of acting that other theatres might emulate when the first excesses of the Revolution had abated.

Effect of governmental influence on Stanislavsky

The official edict decreed that characterization, ideas, and emotions should be reduced to the simplest possible terms for the new audiences, many of them illiterate. This amounted to a command to actors to overact, abandoning all subtleties and returning to a crude, melodramatic style. Some of Stanislavsky's company were much taken by the enthusiasm with which the new audiences acclaimed their overacting, so he decided to take his company abroad and in 1922 left on a tour of Europe and the U.S. On returning (1924), deciding that the Moscow Art Theatre must adapt itself to the new audiences, he began to produce in bold, sweeping strokes, stressing the dramatic elements and enlivening comic scenes with tricks borrowed from vaudeville. Although far from subtle, this new style did not stoop to the crude exaggerations of the contemporary Soviet propaganda theatre.

Meyerhold had meanwhile become one of the most powerful influences in the Russian theatre. He declared that the principles of propagandist theatre conformed with those of Marxism because they attempted to underline "the elements which make prominent what is common to all men, the unindividual." Detailed portrayal of emotion was described as "worthless soul junk," and the actor was ordered to "forget his little rickety ego" and become "an instrument for social manifestos." Many other producers, educated to despise an individualistic society, exercised ingenuity to deprive actors of individuality. Aleksandr Tairov, founder of the Kamerny Theatre (1914), made his actors wear fantastically exaggerated makeup so that they would not resemble anyone in real life and thus become individuals to the audience. Tairov invented the "constructivist" setting, a gaunt scaffolding supporting bare platforms on different levels, with every strut and bolt exposed to view. The aggressive functionalism of this kind of setting was regarded as having considerable propaganda value when the Russians were being taught to revere the machine as part of their training to become a great industrial nation.

A more moderate director was Yevgeny Vakhtangov, a pupil of Stanislavsky. In 1914 he was in charge of one of the studios attached to the Art Theatre and in 1920 was appointed director of this subsidiary, renamed the Third Studio (or Workshop). But Vakhtangov was not altogether in accord with the quiet naturalness of the Art Theatre. His natural exuberance impelled him toward a style of production that, while avoiding the extreme stylization and unrealism of Meyerhold and Tairov, nevertheless enlarged, heightened, and sharpened character, emotion, and gesture. He wanted to work in vivid colours instead of halftones. In place of Stanislavsky's inner realism he wanted what he called "outer-technique." He found the ideal actors for his purpose when Stanislavsky put him in charge of a group of Jewish players who in 1917 had formed a company for production of plays in Hebrew, calling themselves the Habima Players. In 1918 they became affiliated with the Art Theatre. Vakhtangov's masterpiece was his production of Rappoport Ansky's *The Dybbuk* (1922).

Revolt in Germany. The German theatre had been revitalized by the work of Max Reinhardt, and soon after World War I two former members of his company, Leopold Jessner and Erwin Piscator, became the leading directors. Their productions employed actors on a bare, darkened stage picked out by shafts of light against a black background; scenery was limited to one or two small pieces, symbolic rather than realistic. Stylized staging inevitably led to stylized acting, which in turn demanded stylized writing. Thus was created the German school of Expressionist drama, which was regarded not as a movement in art but as a reform of life. Its leading dramatists were Georg Kaiser and Ernst Toller. Characters became symbols instead of people, their lines stripped of all but key words and phrases. In the age of technology technical devices were used openly on stage. The actor was reduced to a puppet, into which he poured his life, to become a ritualized, priestly figure, celebrating not the unindividual but the super-individual. Marxist economic theory eventually replaced this theology, and the people who secularized the German theatre were all involved in politics. Later in the 1920s, when steel, timber, and other materials became more plentiful, Piscator directed a series of productions using elaborate and expensive machinery. The front of his stage was constructed on the conveyor-belt principle; in the centre a cantilever bridge moved up and down; lantern slides and motion-picture films were projected onto the back wall; above the proscenium slogans blazed in lights; the gigantic shadows of pulsating machines were thrown onto gauzes. Jessner, too, made free with building materials once postwar restrictions on their use had been lifted. His favourite setting was a vast flight of steps extending the entire width of the stage, rising steeply to a high platform at the back. He was greatly influenced by the new stagecraft of Craig and by the work of the Soviet directors of the immediate post-revolutionary period, whom he copied in oversimplifying characters and their motives, abandoning subtlety for elementary Symbolism. The political theatre to which Expressionist drama gave way was described by one of its leading personalities, Bertolt Brecht, as Epic Theatre. Brecht's theorizing was to be of enormous influence during the middle decades of the 20th-century Western theatre.

Contributions of Jessner and Piscator

Revolt in France. The reaction against realism was slower to reach France. The founding of the Théâtre du Vieux-Colombier by Jacques Copeau in 1913 initiated the reaction. Copeau was a literary critic who set up his own company. Like Reinhardt, he sought to break down the barrier between actor and audience. His stage was unframed; there were no wings and no line of demarcation between stage and auditorium. Decor was used sparingly; the atmosphere for each play was created almost entirely by lighting.

The work of Jacques Copeau

Before opening the Vieux-Colombier, Copeau took his company to Le Limon, where they improvised scenes and practiced exercises. They learned much from Charles Dullin, a singer in the Montmartre cafes and an exponent of traditional *comédie improvisée*, still popular in Parisian cabarets and provincial fairs. The acting at the Vieux-Colombier in a modern play was at first sight realistic, although the detail was minimized; but closer watching showed that gesture was being used selectively to give each gesture unusual significance. Copeau's productions of Molière and Shakespeare were notable for their light-

ness, grace, and gaiety. In 1924 he took a group of young actors to Burgundy, where, besides studying acting, they worked in the fields and in a carpenter's shop and took part in the local wine festival. The peasants called them "Les Copiaux," under which name they first appeared at Basel, Switzerland, in 1926. Their characteristic production was *La Danse de la ville et des champs*, written and produced by Michel Saint-Denis, who in 1930 took over the company, renamed the Compagnie des Quinze. It was disbanded in 1936 but had become internationally famous. The company had its own playwright, André Obey, who wrote to suit its methods and talents.

Revolt in Italy. The new technology of the 20th century is clearly reflected in theatrical activity in Italy during the early decades, especially in the Futurism of Filippo Tommaso Marinetti. Inspired by Bergson's philosophy of an élan vital, by Nietzche's philosophy of a superman, and by the new ecstacy of speed—with automobiles and airplanes as the symbols of speed and progress—his work was a celebration of man the machine and involved the use of inanimate objects as vital actors in his productions.

Anton Giulio Bragaglia initiated an experimental theatre in 1921, which borrowed from the Futurists but subordinated mechanics and technology to the play. He aimed to restore theatricality to the drama, using light, multidimensional space, intricate masks, and costume to surrealistic effect. He also wished his actors to master the acrobatic art of the commedia dell'arte as an antidote to cerebral acting. The dramatist Luigi Pirandello also challenged realism, with its stress on social environment shaping the individual, for he believed that the individual was capable of shaping his environment. His own Theatre of Art, opened in Rome in 1925 at the Odeschalchi Theatre, was an attempt to make the theatre something more than a place where an ironic tolerance of the human condition was developed, but one where people became aware of man himself.

The Irish national theatre

Ireland. The establishment of an Irish national theatre during the early years of the 20th century was not a reaction against existing forms in theatre but the result of a nationalist political movement and a desire to displace the cheaply sentimental plays in which the Irish had previously been presented to the world. The first step was taken in 1899, when the poet William Butler Yeats and the playwright Lady Augusta Gregory founded the Irish Literary Theatre, a society encouraging poetic drama. During the early years of the 20th century they and their associates achieved a recognizable company style in play and production. After a London appearance in 1903, Miss A.E.F. Horniman (pioneer of the British repertory movement) provided a permanent home for them in Dublin at the rebuilt Abbey Theatre. Their brilliant work there became world famous, with fine native actors and outstanding dramatists, including J.M. Synge and Sean O'Casey.

Britain. British theatre paid very little attention to the anti-realistic movements that characterized experimental theatre in the rest of Europe. Outstanding during the first decade was the work of Harley Granville-Baker and J.E. Vedrenne at the Court Theatre in Chelsea, who encouraged new writers uninterested in writing for an artificial theatre (they included George Bernard Shaw and John Galsworthy). An acting style evolved whereby characters "seem to live and move by the laws of their own being." Later, Granville-Barker's Shakespearean productions at the Savoy Theatre revolutionized the approach to directing and acting Shakespeare's plays, which he presented with simplicity, continuity, and speed. His method of production work was developed after his retirement by directors such as Basil Bean and Gerald du Maurier.

Equally significant for the British theatre was the pioneer work done by Miss Horniman when she founded the first provincial repertory theatre at the Gaiety, Manchester, in 1908. It introduced to England the work of a number of important continental dramatists and gave opportunities to promising British playwrights. The Playhouse, Liverpool, was founded in 1911 and developed a great number of talented actors. The most adventurous and distinguished repertory theatre, however, was founded at Birmingham by Sir Barry Jackson in 1913, where notable first performances were given of plays by Shaw, the Scottish dramatist James Bridie, J.B. Priestley, John Drinkwater, and others, as well as revivals of classic plays. The repertory movement continued with distinction but after World War II was regarded largely as a ground where actors gained experience before making an assault on the capital—an attitude that was not rectified until the late 1950s and 1960s.

United States. In the first decade of the 20th century realism dominated the American theatre; in the plays of Clyde Fitch, William Vaughn Moody, and Edward Sheldon; in the acting of Mrs. Fiske, Richard Mansfield, and Ethel Barrymore; and in the productions of David Belasco and Harrison Grey Fiske. At the same time, however, the pretty operettas of Victor Herbert and the brash musical comedies of George M. Cohan were popular. The first *Ziegfeld Follies* appeared in 1907. The New Theatre in New York City, with a resident company dedicated to art rather than business, was established in 1909 but collapsed after two seasons.

Visits of the Abbey Theatre in 1911, Reinhardt's *Sumurūn* in 1912, Granville-Barker's company in 1915, and Copeau's group from the Vieux-Colombier in Paris in 1917 provided exciting glimpses of the work of Europe's art theatres and of the "new stagecraft," thus adding to a growing dissatisfaction with the United States theatre.

The modern period on Broadway may be said to have begun in 1918 with the establishment of the Theatre Guild, the first commercially successful U.S. art theatre, and in the next decade there occurred a flowering that placed U.S. theatre for the first time on a par with the best theatre of Europe. Eugene O'Neill emerged from the Provincetown Players in 1920 with *Beyond the Horizon* to win worldwide fame. He was quickly followed by other playwrights including Robert Sherwood, Maxwell Anderson, Elmer Rice. Their plays provided an expression of American life that was unprecedented in its richness and variety. Besides the Theatre Guild, independent producers also staged the new American drama, as well as interesting new plays from abroad and some classics in the new style. Designers such as Lee Simonson, Norman Bel Geddes, and Jo Mielziner provided distinguished settings that were realistic, symbolistic, or expressionistic as required by the new drama. The Moscow Art Theatre company visited New York in 1923, and, impressed with the quality of ensemble acting they found there (which only a permanent organization could achieve), some of its members remained in New York to teach the Stanislavsky system. In 1926 Eva Le Galliene established a permanent repertory company that presented classics old and new. *Show Boat* appeared in 1927 and became a classic of the musical stage. Outside New York City, competition from motion pictures reduced the number of theatres open to travelling companies from 1,500 in the early 1900s to 500, but on Broadway the number of productions grew from 150 in 1920-21 to 280 in 1927-28.

Distinguished U.S. designers

MID-20TH-CENTURY THEATRE

The most exciting place in Europe during the 1920s was, arguably, Berlin. Countless stories and anecdotes celebrate the city in this decade. The stage had earlier been flooded by the despair and disillusion of postwar Europe, but during the 1920s an overtly political theatre emerged.

Bertolt Brecht. One of the dramatist-directors working at this time was Bertolt Brecht, whose theories of stage presentation perhaps exerted more influence upon the course of mid-century drama in the West than did those of any other individual. His theory of Epic Theatre was evolved in an attempt to appeal to his audience's mind instead of to its emotions—the theatre of argument instead of the theatre of empathy—and he derived inspiration from the popular theatre with its blatant theatricality rather than from the "realistic" theatre of illusion. His own early plays have something in common with the German Expressionist drama; he then embarked upon a number of jazz ballad-operas in collaboration with the composer Kurt Weill. His greatest original work was written during the late 1930s and early 1940s, while in

exile from the Nazi regime, first in Norway, then in the United States. Like the Russian director Meyerhold, Brecht was vehemently opposed to illusive stage presentation. He did not wish his audience to appreciate his plays like gourmets enjoying a meal; he wanted to stir their critical faculties in such a way that they would be forced to think about their own lives. In illusive stage productions, such as those of Stanislavsky, there is a danger that the audience will identify emotionally with the play's characters as characters—that they will witness not their own real life but somebody else's real life. In an effort to free the audience from "the spell cast upon them by the witchcraft of realistic producers who make a dream world of reality," Brecht evolved what he called the "alienation effect" (*Verfremdungs-effekt*). This does not mean that he wished to alienate the audience; it refers to his constant use of anti-illusive techniques in order to remind the audience they were in a theatre and to emphasize his dictum that "the actual world exists and is our subject; but this play and this stage are not it." He flooded his stage with hard white light during the play, regardless of when the action might take place; he projected captions, slogans, and comments onto a gauze screen between scenes; important points raised during the action were driven home by songs that were otherwise unrelated to the play; Stanislavsky's doctrine that the actor must identify himself subjectively with the character he is playing was reversed, and Brecht demanded instead an objective style of acting in which the actor remains always aware of himself.

Devices of Brechtian stagecraft

The influence of Brecht's frontal attack on the illusive theatre has since been evident, directly or indirectly, in the theatre of every Western country. But traditions and conditions vary so much from one country to another that, though it is possible to trace here this influence and there another, playwrights, designers, and directors have become sufficiently aware of one another's work to borrow whatever they want for a given purpose. The theatre in the Western world is vigorous, but it is a cross-fertilization of many styles that makes it so. Brecht's attack on illusive theatre by no means universally triumphed. Many fine new plays of today belong to the school of realism. By the 1950s, moreover, at least three other approaches to the staged presentation of life were commonly to be found.

The "Cruel" approach. In France during the early 1930s, Antonin Artaud elaborated a theory of a Theatre of Cruelty. A surreal theatre based on ritual and fantasy, it launches an attack on the audience's subconscious in an attempt to release deep-rooted fears and anxieties that are normally suppressed, forcing people to view themselves and their natures without the shield of civilization. In order to shock the audience and thus win the necessary response, the extremes of human nature (often madness, or perversion) are graphically portrayed on stage. The style of physical playing is here more important than the texts performed. Artaud's influence is apparent in the work of such French directors as Jean-Louis Barrault, Jean Vilar, and Roger Blin. It was obvious also in Peter Brook's direction for London's Royal Shakespeare Company of the *Marat/Sade* by a German dramatist, Peter Weiss. The one major playwright associated with the Theatre of Cruelty is Jean Genet. Many others, however, make use of "Cruel" elements in their plays, including the British playwrights Edward Bond and David Rudkin.

The "Absurd" approach. The plays of a number of dramatists, especially in France during the 1950s, offered a vision of humanity struggling vainly and therefore absurdly to control its fate in a world that seemed in any case bent on destruction. Although no two playwrights were much alike in style, certain recurring themes, especially of futility and hopelessness, caused them to be labelled the "Absurd" school. Theatre of the Absurd has been traced directly from the work of the French dramatist Alfred Jarry, whose play *Ubu roi* caused a sensation when it was produced in Paris in 1896. Texts are of much more importance than they are in Theatre of Cruelty, even though many of them seek to convey the total inadequacy of words as a means of communication. Distinguished writers whose names have been linked with the Absurd school include Samuel Beckett, Eugène Ionesco (both writing in Paris), Harold Pinter (in Britain), and Fernando Arrabal (a Spanish refugee writing in the French language). Each of these, however, has developed his own distinctive approach to the theatre and defies a common classification. Inverted logic and verbal humour (puns, non sequiturs) were a feature of "Absurd" plays and have been absorbed—much diluted—into mainstream light entertainment.

Jarry's *Ubu roi*

The "Factual" approach. Another method of presenting contemporary truth on the stage has been called Theatre of Fact, or Documentary Theatre. During the social protest movement that arose during the years of depression in the 1930s, groups such as the Federal Theatre in the United States adopted what are called Living Newspaper techniques, borrowing inspiration from the cinema (especially in the use of short, succinct scenes fast cutting one to the next), to present a highlighted version of contemporary problems. The technique has had a long, if intermittent, life. Surprisingly effective in the theatre, real events are reconstructed and interpreted, either through fictional revisions so arranged that they carry the unemotional weight of genuine official documents or else through the use of authentic documentary material (transcripts of trials, official reports, lists of statistics). Well-known works of this sort include the plays of Rolf Hochhuth (*The Representative, Soldiers*), of Reinar Kipphardt (*In the Matter of J. Robert Oppenheimer*), of Michael Hastings (*The Silence of Lee Harvey Oswald*), and the Royal Shakespeare Company's *US*.

It is clear that the Brecht approach to stage presentation has something in common with the Theatre of Fact, and that the Theatre of the Absurd has elements in common with the Theatre of Cruelty. But "schools" of drama are more usually constructed by critics than by playwrights, and many individual theatrical presentations borrow techniques from more than one approach.

Germany. The exciting German theatre of the 1920s was swept away when the Nazis came to power in 1933. After World War II, a few people were able to return. Bertolt Brecht formed the Berliner Ensemble company in East Berlin, creating a brilliant company style for the presentation of his plays. After his death in 1956 his widow, the actress Helene Weigel, continued to train actors and to present her husband's work. The influence of this company on theatre throughout the West can hardly be overemphasized, but even before Brecht's death it had begun to lose its dynamic power and seemed more concerned to preserve its established, albeit brilliant, style than to tread new paths. In West Germany Fritz Kortner, who had worked as a young actor with Reinhardt and was a leading player with Jessner, returned to Germany in 1947 to direct a series of brilliant productions. His interpretations of classical plays and of modern drama can be regarded as the culmination of the German tradition begun by Otto Brahm in the 1890s.

Otherwise, in spite of the number of theatres and the money lavished upon them in government and municipal grants, there were few signs in the 1950s of any strongly progressive theatrical movement. Much of the best creative work was done in the opera houses. But, after a revival of German drama, mainly by Swiss-German playwrights (including Max Frisch and Friedrich Dürrenmatt) and Peter Weiss, the theatre throughout Germany began to revive. Later, the work of such dramatists as Günter Grass, Siegfried Lenz, Reinar Kipphardt, and Rolf Hochhuth provided more opportunity for original direction and staging.

Swiss-German dramatists

U.S.S.R. The youngest post-revolutionary director of importance was Nikolay Okhlopkov. His earliest productions were entertainments given during World War I on an improvised platform in the square of his home town to entertain the troops, who encircled the stage. As a result of this experience of the open stage, he found the proscenium theatre cramping and in Moscow experimented with ways of breaking down the barrier between actor and audience.

In 1932 he became director of the Realistic Theatre, where for his production of Aleksandr Serafimovich's *The Iron Flood* he converted the auditorium into a mountainous terrain, seating the audience among the rocks so that actors, playing in every part of the auditorium, mingled with audience. He made other experiments in staging, but in 1938 the Realistic Theatre was closed on the grounds that his work appealed too exclusively to intellectuals. In 1934 Meyerhold, censured for his "obsession with the vague abstractions of decadent art," and for being "the father of formalism," was deprived of his position. Tairov, rebuked for being out of touch with his audiences, had been relieved of the direction of the Kamerny Theatre and forced to work under a committee. It is true that their work was too cold and abstract to please audiences who wanted warmth, humanity, and reality. But under Stalinism the theatre virtually ceased to progress, since any originality was condemned as decadent. Scenery became more and more laboriously realistic, as a setting in any way impressionistic was condemned as belonging to "abstract art." Only the magnificent standard of acting remained unchanged.

After Stalin's death in 1953 the theatre was relieved of many shackles and there was a cautious return to experiment, particularly at the Satire Theatre. Okhlopkov, only survivor of the experimentalist producers of the 1920s, remained the most original and stimulating director, though at times under Stalinism his originality had displeased the authorities, and he had been criticized for too unruly an imagination.

Soviet theatre in the 1960s

In the 1960s the Soviet theatre was perhaps at its best in productions of the classic Russian authors, directed with meticulous care. Its unique feature was its gigantic scale —the vast number of theatres, the fact that there were companies playing in more than 50 languages, the size of the companies (100 actors was not unusual), the size of the repertoire of each theatre, the huge and superbly equipped stages showing a succession of elaborate scenes, the size of the theatregoing audience, and the vast state subsidies to theatres, so that they need not even attempt to pay their way and thereby could keep their prices low.

The professional theatre could not satisfy the demand for dramatic entertainment, and every encouragement was given to the amateur. Most theatres accepted responsibility for at least one amateur group, the members of the company giving much time to training and advising it. Amateur companies of outstanding merit were given the title "people's theatre." Most of these companies toured neighbouring towns, as well as playing in factories and collective farms. The close relations between professional and amateur were mutually beneficial, for professionals found that contact with the personnel of the amateur groups infused freshness and reality into their own performances. By the late 1960s there was an even greater loosening up; satire, even political, became increasingly dominant and methods and techniques increasingly experimental and symbolic.

France. The influence of Jacques Copeau was extended through the productions of Louis Jouvet and Dullin, who left his company in 1922 to start their own theatres. Jouvet's productions of Molière were his most important contribution. He freed the plays from the weight of tradition that was stifling them. His *L'École des femmes* (1936) was hailed as a return to the spirit of Molière. While Jouvet was careful to subjugate himself to his author, Dullin's productions were strongly coloured by his own personality and tastes. He loved bright colours, music, movements, and his productions were in sharp contrast to the asceticism of Georges Pitoëff, who believed that the director's primary aim should be to focus attention on a play's central idea, and eliminate all details of decor and acting that might obscure it. His great contribution to the French theatre was the number of foreign dramatists whom he introduced to the Parisian public.

Jouvet, Dullin, and Pitoëff, with Gaston Baty, were known as Les Quatre ("The Four"). Baty had served his apprenticeship under Reinhardt. His pictorial sense was superb, and his groupings and movement were beautifully composed, but they existed for themselves rather than for the play. He was often accused of over-elaborating the classics to display his own inventiveness.

Dullin's use of mime was elaborated in the productions of his pupil Jean-Louis Barrault, who left the Comédie-Française in 1946 to form, with his wife, the actress Madeleine Renaud, the Compagnie Renaud–Barrault, which played in the provinces and abroad and, in Paris, at the Théâtre Marigny. In 1959 he became director of the Théâtre de France, to which in 1966 the annual Théâtre des Nations was transferred. Much of his work is symbolistic—a combination of pantomime, rhythmic movement, and shadowgraph.

He became the chief exponent of "total theatre," a theory evolved by Gordon Craig. Another pupil of Dullin, Jean Vilar, in 1951 founded the Théâtre Nationale Populaire (TNP). His style was governed by the size of the Palais de Chaillot, a theatre seating nearly 3,000 with a stage 70 feet (about 20 metres) deep and a proscenium opening 80 feet (about 25 metres) wide. Vilar made no attempt to fill the stage with scenery. He did no more than suggest the background of the play and filled his stage with big, swirling movement. He trained his actors to use bold, simplified gestures and delineate character in powerful outline.

Until the 1950s theatrical activity was almost entirely concentrated in Paris but with government help theatrical centres were established at Strasbourg, Aix-en-Provence, Saint-Étienne, Toulouse, and Reims.

Great Britain. A director who refreshed English acting and direction in the 1930s was Theodore (Fyodor) Komisarjevsky, who in 1919 went to England from Russia, where he had been director of the Imperial and State theatres. His direction of plays by Chekhov and other Russian authors set a new standard in the English theatre. His Shakespearean productions at Stratford-on-Avon often infuriated audiences accustomed to conventional presentation. They were full of invention, sometimes brilliant, amusing, and illuminating, sometimes merely wayward. In the same tradition was Tyrone Guthrie; a director with a superb theatrical imagination, who began in the 1930s at the Old Vic, London. Sometimes his inventiveness was used merely to surprise and shock the audience or to satisfy his own sense of humour. Other fine Shakespearean producers include Peter Brook, whose productions in the 1950s and early 1960s gave early evidence of rare talent, and Peter Hall. In the late 1950s the most influential British director was Joan Littlewood. In 1945 she had founded the Theatre Workshop company at Manchester for working class audiences. In 1953 it moved to the Theatre Royal, Stratford, in the East End of London. She encouraged audience participation; allowed actors to improvise—all her later productions were "collective" in that the actors shared in planning the presentation and often took liberties with the text—and borrowed techniques from music hall, such as impromptu asides to the audience and the introduction of topical songs and jokes. Her productions also owed much to Bertolt Brecht. George Devine set up the English Stage Company at the Royal Court Theatre in 1956 to allow novelists to try their hand as playwrights and to introduce new writers and modern foreign drama. Its club, the English Stage Society, gave Sunday performances without decor, so allowing experimental plays to be tried out. Most of the new English playwrights of the 1950s and 1960s had their works first produced by the English Stage Company, which has also given many directors, designers, and actors later outstanding in the West End their first chance.

The work of Joan Littlewood

There was no permanent dramatic company in London until 1960. To remedy this lack Peter Hall engaged a company (called from 1961 the Royal Shakespeare Company), on long-term contract to play at Stratford-on-Avon and at the Aldwych Theatre, London, presenting modern plays as well as Shakespeare and other classics, both often produced in experimental styles. Michel Saint-Denis became a co-director (with Brook and Hall) in 1962. The Aldwych is the summer home of a World Theatre Season, established in 1964 by Peter Daubeny.

Provincial and repertory theatre. In the provinces the theatre divides into touring, repertory, and amateur. The

touring theatres are visited by London companies either before or after they play in London and by companies engaged to tour a London success. At Christmas nearly all these theatres stage an elaborate pantomime, so popular that the run often extends for three or four months. In the early 1920s there were more than 250 touring theatres in England and Scotland. By 1966 the number had dwindled to little more than 20. Many had failed to survive the competition of motion pictures; others were destroyed during World War II; and after the war television proved a deadly rival. "Repertory" theatres in the provinces withstood competition more successfully. These repertory theatres had at first no right to the title, because they did not keep a repertoire of plays ready for production as do continental "repertoire" theatres, which give performances of several plays from their repertoire each week. But by the mid-1960s, the nature of provincial repertory had changed considerably, as a result of increased government grants and bigger audiences. Most theatres had replaced the giving of a play for a short run (after which the production was scrapped) by a limited form of continental repertoire. By the early 1970s it was evident that the efforts to promote the repertories as basic to the life of their local community had often brilliantly succeeded.

The "little theatre"

The third branch of the provincial theatre, the amateur "little theatre," also makes a valuable contribution to theatrical experiment in Great Britain. Actors, designers, and stagehands are amateur and often anonymous. One of the leading provincial little theatres is the Maddermarket, Norwich, built in 1921 as the only theatre in England with an Elizabethan stage. Several other amateur dramatic societies flourish throughout Britain, many of them associated with the British Drama League. In the 1930s, a number of experimental "club theatres" were opened. The first was the Gate (1925). Its policy of producing unlicensed or uncommercial plays and witty reviews made it one of the most important of the prewar club theatres. Also influential were the Mercury, Notting Hill Gate (1933), famous for producing poetic plays by T.S. Eliot, Christopher Fry, Ronald Duncan, and others; the Hampstead Theatre Club; the Arts and New Arts Theatre Clubs; the Unity, St. Pancras, which in 1936 declared its intention of replacing the "escapism and false ideology of the conventional theatre" with a left-wing "agitational theatre," carried out with first English productions of plays by Clifford Odets, Sean O'Casey, and Soviet dramatists.

The national theatre. In 1949 Parliament passed the National Theatre Act, empowering the Treasury to make a grant of £1,000,000 to build a national theatre. Successive governments put off building the theatre until, in 1963, the government decided to finance a National Theatre, which opened under the directorship of Sir Laurence Olivier, with the Old Vic as its temporary home. In 1966 the government agreed to contribute half the cost of a building containing two auditoriums, the Greater London Council contributing the rest.

Other European countries. In northern Europe in the 1960s the largest audience was in Finland, where more than a quarter of the population were regular theatregoers. The number of plays by native authors was unusually high. Few have been performed abroad because of lack of good translations. In Denmark, production of a Danish play was comparatively rare, but a variety of foreign plays was produced. In Sweden, where the number of native playwrights was increasing, good theatre spread over the country. Göteborg rivalled Stockholm, and both were challenged by Malmö, Uppsala, Norrköping, and Hälsingborg. The Norwegian theatre has spent most of its life in financial crisis, partly because audiences have been scanty. It had to rely on private enterprise—even the National Theatre was founded in 1899 without state or municipal aid—until in 1961 the government took over financial responsibility for the whole theatre. To take the theatre to the people it founded the State Traveling Theatre, which played even in small villages beyond the Arctic Circle.

In eastern Europe the most advanced theatres were in Poland and Yugoslavia. Both were molded by great producers whose work has been continued by their pupils. In Yugoslavia, Branko Gavella was for nearly 50 years a free-lance producer, striving to improve standards and encourage originality. In Poland the work of Leon Schiller, a disciple of Gordon Craig, was continued by his most brilliant pupil, Erwin Axer. In Bulgaria, Romania, and Czechoslovakia development was hampered by subservience to socialist realism, but by the 1960s playwrights were beginning to write with more freedom and sophistication, and Josef Svoboda, chief designer at the National Theatre, Prague, after 1950, was widely regarded as the world's leading scenic designer. After World War II the number of Romanian theatre companies increased from 18 to 32, and Czechoslovakian theatres more than trebled. The Hungarian theatre, perhaps because of its situation, was the most cosmopolitan in its choice of plays. Never respectful of the dictates of socialist realism, it was a gay and sardonic theatre, excelling in satirical topical revues.

United States. The stock-market crash of 1929 heralded the end of the unparalleled prosperity in the theatre and in the nation. The nation recovered from the ensuing economic depression, but the theatre, under increasing competition from motion pictures, radio, and television, did not. In the next 30 years travelling companies all but disappeared, and productions on Broadway shrank to 60 in 1949–50 and thereafter averaged between 60 and 70 a year. No new theatres were constructed. Nevertheless, live theatre continued to attract talented writers: from the social protest movement of the 1930s came Clifford Odets, Sidney Kingsley, Lillian Hellman, Thornton Wilder, and William Saroyan; Tennessee Williams, Arthur Miller, and William Inge emerged in the 1940s, Edward Albee in the 1960s.

Effects of the Great Depression on U.S. theatre

Rising costs and shrinking audiences necessitated longer runs of plays. Enterprises outside the standard pattern, however, enjoyed some success. The Group Theatre for ten years maintained a permanent company, developed new playwrights, and evolved a new acting style based on the Stanislavsky system. From 1935 to 1939 the Federal Theatre Project presented hundreds of productions of all sorts and showed that a large untapped audience existed for live theatre at low prices. From 1937 to 1939 Orson Welles and John Houseman maintained a permanent company and gave limited runs of plays at the Mercury Theatre. From 1947 the Actors Studio cultivated the "method," derived from Stanislavsky's system and practiced by many outstanding U.S. actors. In 1955 the first U.S. Shakespeare festival was held at Stratford, Connecticut, and it became more popular each summer. The American National Theatre and Academy (ANTA), chartered by Congress in 1935 and activated in 1946, encouraged theatre, professional and nonprofessional, throughout the country. As bulk theatre activity decreased, the producer declined in importance and the stage director rose. Among the important directors in the 1940–60 period were Elia Kazan, Robert Lewis, Harold Clurman, Joshua Logan, and José Quintero.

Rise of the musical

The musical show after 1930 gained in polish and sophistication. In 1935 George and Ira Gershwin turned the play *Porgy*, by DuBose and Dorothy Heyward, into America's first successful folk opera, *Porgy and Bess.* Later examples were: *Pal Joey* (1940), *Lady in the Dark* (1941), *Oklahoma!* (1943), *South Pacific* (1949), *My Fair Lady* (1956), and the star-vehicle productions *Hello, Dolly!* (Carol Channing), *Funny Girl* (Barbra Streisand), and *Fiddler on the Roof* (Zero Mostel), all in 1964.

Off-Broadway theatre. Plays have always been produced in small theatres outside as well as in the main theatrical district in New York. In 1915–18 the Washington Square Players, in the 1920s the Provincetown Players, and in the 1930s the New Playwrights drew audiences and critics off-Broadway. A new era began in 1952 with the successful revival of Tennessee Williams' *Summer and Smoke* at the Circle in the Square and gained momentum with productions at the Phoenix, the Theatre de Lys, and the Fourth Street Theatre. In 1961–62, *The New York Times* counted 100 off-Broad-

way productions, 34 more than on Broadway. From 1962–63 the number of off-Broadway productions declined. Revivals of classics and of recent plays that had failed on Broadway predominated at first, but the proportion of new plays increased. Since production often took place in improvised quarters under makeshift conditions, it showed styles and forms seldom seen on Broadway. Many productions were stages without a proscenium arch and with the audience on two or three sides of the playing area. Actors, directors, designers, and producers who achieved success off-Broadway were soon active on Broadway. And Broadway successes began to appear off-Broadway, attracted by the greater artistic freedom.

Summer theatre. Declining production on Broadway was accompanied by a growth of theatre in resort areas during the vacation season. In 1940, 80 summer theatres were open for a ten-week season, performing a different play or musical each week in tents, barns, and sometimes in regular theatre buildings. By the 1960s more than 200 "straw-hat" theatres were in operation. Resident companies, frequently augmented by visiting stars, usually performed recent Broadway successes. Occasionally, these summer theatres were used to test new plays for possible Broadway production.

The Negro in the U.S. theatre. In native plays, the Negro appeared first as a plantation hand, a minor comic character. Later he was frequently seen as a comic domestic servant. The slavery plays like *Uncle Tom's Cabin* (1852) and the Civil War plays like *The Reverend Griffith Davenport* (1899) were the first to treat the Negro seriously. Edward Sheldon's *The Nigger* (1909) was the first play to deal with Negro problems in modern society. After the Civil War, Negroes became popular in minstrel shows and in all-Negro musicals.

From 1910 on, individuals like Bert Williams were featured in musicals like the *Ziegfeld Follies;* the integrated musical appeared in the 1940s. Negroes gained recognition in serious drama somewhat later; Charles Gilpin in *The Emperor Jones* (1920), Richard Harrison in *The Green Pastures* (1930), Canada Lee in *Native Son* (1941), and Paul Robeson in *Othello* (1943). Playwrights who contributed to the drama of Negro life include Ridgely Torrence, DuBose and Dorothy Heyward, and Paul Green. Negro playwrights had little success on Broadway until Lorraine Hansberry's *Raisin in the Sun* became a hit in 1959. The racial ferment of the 1960s created an audience for accusatory melodramas such as *Dutchman* (1964), by the poet LeRoi Jones (Imamu Amiri Baraka) and *Blues for Mister Charlie* (1964) and *The Amen Corner* (1965), by the novelist James Baldwin. *In White America* (1964), a documentary of 300 years of Negro grievances, by Martin Duberman, became a propaganda piece of the civil rights movement.

Community theatre. Community theatre grew out of the little theatre movement and its art theatres that sprang up (*c.* 1900–25), inspired by the "free" theatres of Europe, in protest against the commercial theatre. The little theatres presented noncommercial plays, European and American, with the "new stagecraft," in small theatres for small audiences.

Changing function of community theatre

As road companies disappeared, most of these organizations became substitutes for professional theatre, presenting popular plays in larger theatres to larger audiences with more paid personnel. By the late 1960s three types of community theatre existed: (1) a growing number with paid actors and staff, like the Arena Stage, Washington, D.C., and the Minnesota Theater Company in Minneapolis, of which Tyrone Guthrie was artistic director; (2) a few more paid staff and a few paid actors, like the Cleveland Play House; and (3) the great majority with some paid staff only. A new form of subsidy in the 1960s was exemplified by Ford Foundation grants in the Alley Theater in Houston and the Actor's Workshop in San Francisco.

University theatre. Dramatic performances by students go back to the colonial period, but instruction in theatre subjects did not enter the curriculum until about 1900, largely in colleges of liberal arts and as part of the reaction against commercial theatre. After World War I there was a tremendous expansion of courses, departments, and degrees in theatre studies. The National Theatre Conference of leading university and community theatres was founded in 1932. The American Educational Theatre Association (AETA) was established in 1936 and after 1949 published the *Educational Theatre Journal.* By 1964–65 nearly 600 college theatres were producing annually about 3,000 plays for an audience of more than 7,000,000. Much of this growth was because of the disappearance of professional theatre outside New York City. Although the aims of university theatre have been primarily cultural, it has affected the professional theatre, especially off-Broadway. Its unique contributions have been the development of theatre for children and the popularization of arena and other forms of open staging.

BIBLIOGRAPHY

Reference works: B.M. BAKER, *Theatre and Allied Arts* (1952, reprinted 1967), a bibliography containing more than 6,000 items published between 1885 and 1945, with cross-references and indexes; D.F. CHESHIRE, *Theatre: History, Criticism, and Reference* (1967), a comprehensive bibliographical guide to the main branches of theatrical endeavour, excluding opera and ballet; F.M. LITTO, *American Dissertations on the Drama and the Theatre* (1969), a bibliography that covers the period from 1865–1965; *Theatre Documentation* (semi-annual), an annotated bibliography of current publications; *Enciclopedia dello spettacolo,* 9 vol., 3 vol. appendixes (1954–68), the only work of reference that treats all fields of the theatre and the film (opera and ballet included) exhaustively; PHYLLIS HARTNOLL (ed.), *The Oxford Companion to the Theatre,* 3rd ed. (1967), a single-volume standard work with bibliography and illustrations; SIEGFRIED MELCHINGER, *The Concise Encyclopedia of Modern Drama* (1966), four main sections, chronology of first performances, illustrations, and bibliography; J. GASSNER and E. QUINN (eds.), *The Reader's Encyclopedia of World Drama* (1969), covers the drama of five continents from the origins to the present; ANATOLE CHUJOY and P.W. MANCHESTER (eds.), *The Dance Encyclopedia,* rev. ed. (1967), a comprehensive, single-volume reference; A. LOEWENBERG, *Annals of Opera, 1597–1940,* 2nd rev. ed., 2 vol. (1955).

Theatre history—general: KENNETH MACGOWAN and WILLIAM MELNITZ, *The Living State: A History of the World Theater* (1955), an exemplary, concise introduction to theatre history providing time-charts, many excellent illustrations, bibliography, and an index; GEORGE FREEDLEY and J.A. REEVES, *A History of the Theatre,* 3rd rev. ed. (1968), a new edition especially important for its additional sections on the theatre in South America, Canada, and Germany under Hitler; RICHARD SOUTHERN, *The Seven Ages of the Theatre,* 2nd ed. (1964), an imaginative but none the less cogent and precise introductory book accompanied by an excellent booklist; MORDECAI GORELIK, *New Theatres for Old* (1940), an original and stimulating introductory work that contains a valuable glossary of stage terms, bibliography, and a wealth of excellent photographs; GEORGE ALTMAN *et al., Theater Pictorial: A History of World Theater As Recorded in Drawings, Paintings, Engravings, and Photographs* (1953); S. D'AMICO, *Storia del teatro drammatico,* 4th rev. ed., 4 vol. (1958), contains a wealth of illustrations, both monochrome and colour; H. KINDERMANN, *Theatergeschichte Europas* (1957–), vol. 3 and 4 provide a comparative survey of the Baroque theatre in Europe—the chapters on the court theatres and festivals in Austria and Germany are of particular interest (extensive bibliography, indexes, and chronology of opera and ballet included).

Theatre history—national and special studies: ALLARDYCE NICOLL, *Masks, Mimes and Miracles: Studies in the Popular Theatre* (1931, reprinted 1963), a well-documented account of the unliterary drama from classical mime to the commedia dell'arte with illustrations, footnotes, and appendix; MARGARETE BIEBER, *The History of the Greek and Roman Theater,* 2nd ed. rev. (1961), a detailed, indispensable account of the rise and development of all streams of theatrical endeavour in the ancient world with many illustrations, chronology, and an extensive bibliography; GLYNNE WICKHAM, *Early English Stages, 1300–1660,* 3 vol. (1959–72), the standard work on the English theatre from 1300 to 1660; ALLARDYCE NICOLL, *Stuart Masques and the Renaissance Stage* (1937); and A.M. NAGLER, *The Theatre Festivals of the Medici, 1539–1637* (1964), two detailed studies of the theatre festivals of the Renaissance in England and Italy, respectively, providing copious illustra-

tions; E.K. CHAMBERS, *The Elizabethan Stage*, 4 vol. (1923, reprinted 1951), still a standard work on the history of the British theatre from the beginning of Elizabeth's reign to the death of Shakespeare, with appendixes of documents, statistics, and lists of plays; G.E. BENTLEY, *The Jacobean and Caroline Stage*, 7 vol. (1941–68), a sequel to Chambers though even more detailed covering the period from 1616 to 1642; *The London Stage, 1660–1800* (1960–), a reference book with critical introductions to each volume recording all known performances of plays (with dates and cast lists); N.D. SHERGOLD, *A History of the Spanish Stage* (1967), a detailed account of the Golden Age in Spanish drama and its medieval heritage; JOSEPH S. KENNARD, *The Italian Theatre*, 2 vol. (1932, reprinted 1964), a history of the Italian theatre from its beginnings to 1930; D.C. MULLIN, *The Development of the Playhouse* (1970), a survey of theatre architecture from the Renaissance to the present; FREDERICK W. HAWKINS, *Annals of the French Stage from Its Origins to the Death of Racine*, 2 vol. (1884, reprinted 1968); and *The French Stage in the Eighteenth Century*, 2 vol. (1888, reprinted 1968), still the best history of the French theatre in chronological sequence available in English (vol. 2 provides a chronology of the French stage, 1699–1799); JOHN LOUGH, *Paris Theatre Audiences in the Seventeenth and Eighteenth Centuries* (1957), a succinct survey of the other side of the theatre and a complementary work to Hawkins; W.H. BRUFORD, *Theatre, Drama, and Audience in Goethe's Germany* (1950), a thorough account of the interaction between life and drama, dramatic performance, and its reception; M.H. WINTER, *Le Théâtre du merveilleux* (1962; Eng. trans., *The Theatre of Marvels*, 1964), a lavishly illustrated book mainly concerned with French melodrama and romantic ballets; GEORGE ROWELL, *The Victorian Theatre* (1956), a thorough study of the English theatre from 1792 to 1914; MARK SLONIM, *Russian Theater, from the Empire to the Soviets* (1961), the fullest and most objective history of the Russian theatre yet produced; BARNARD W. HEWITT, *Theatre U.S.A., 1668–1957* (1959), contemporary documents in chronological order linked by lucid commentary; *History of the Theatre from 1800 to the Present* (1970).

Theatres and Stages

The English word theatre derives from the Greek *theatron*, literally, "a place for seeing," and, in its most common usage, it has come to signify a building or place so arranged that people can see and hear a performance given by others. The part of such a building in which these others perform is usually called the stage. This article deals with the art of the theatre from the viewpoint of the structures in which it has traditionally been presented. Although stage design is often a factor in determining the structure of the theatre, that subject is treated more fully in the article STAGING AND STAGE DESIGN. Aspects of theatre design are also discussed in THEATRE, ART OF and are treated in articles such as THEATRE, WESTERN; DANCE; and THEATRE, EAST ASIAN.

In this article there are three major sections. In the first, the development of theatre as place and its implications through the centuries is described; the second section is given over to a description of theatre in Asia; the final section contains an outline of the historical development of Western theatre.

Theatre as place

Forerunners of formal theatre

The civilizations of the Mediterranean basin in general, of the Far East, of northern Europe, and of the Western Hemisphere before the voyages of Christopher Columbus in the second half of the 15th century have all left evidence of constructions whose association with religious ritual activity relates them to the theatre. Studies in anthropology suggest that their forerunners were the campfire circles about which members of a primitive people's community would gather to participate in tribal rites. Karnak in ancient Egypt, Persepolis in Persia, Knossos in Crete, Stonehenge in Britain all offer examples of architectural structures, purposely ceremonial in design, so arranged and of a size to accommodate large audiences. They were used as places of assembly at which a priestly caste would invoke communication with supernatural forces. The transition from primitive ritual, in which there was mass participation, to something approaching drama, in which a clear distinction is made between active participants and passive onlookers, did not take place in societies that failed to mature. Where the distinction was made, however, the priestly caste and, eventually, the performer were in time physically set apart from the spectators. Thus, theatre as place emerged.

A development such as this not only was a vital element in the process of formalizing ritual, it also brought with it the possibility of intense and empathetic response to the performance on the part of a now statically positioned audience. An interplay of the communicative senses, particularly sight and sound, therefore assumed the major roles they have continued to play. (From time to time, the sense of smell has also been involved, as in the burning of incense.) Consideration of audience requirements, such as sight and sound, have, in fact, determined the essential physical requirements of theatre as place and have also influenced the aesthetic of theatre design. Spectators are able to see a static performer's facial expression clearly without artificial aid if they are within a distance of about 100 feet (30 metres) of him and if they are set within a viewing angle of 150°–180°. Unaided, the performer's natural speaking voice can be heard over a distance of approximately 80 feet (25 metres). Consciously projected, it is audible for up to approximately 120 feet (37 metres). The chanted or singing voice can be heard over distances of up to 240 feet (73 metres). But in every case the sound effectively travels in one direction, sustained only within a cone of 150°–160° in front of the vocalizing source.

VARIED USE OF THEATRE BUILDINGS

Even a cursory survey of world civilizations would reveal that Western theatre, beginning in Greece *c.* 600 BC, is rich and varied in terms of theatre building. The art of theatre in the West also became socially sophisticated and varied. The first fact stems from the second. Broadly speaking, changes in theatre building have kept a sometimes laggardly pace with the theatre's evolution from something religious in inspiration to something of wider social significance. The Greek dramatists of the Classical period (5th century BC), especially the tragedians, whose plays were performed at time-hallowed religious festivals, celebrated gods and heroes in work that was also an eloquent statement of Greek theology. The comic playwrights, on the other hand, began to explore the drama's potentiality for expressing biting social comment and political satire, thereby changing the significance and the direction of the ancient festivals. Aristophanes, for instance, made use of the existing form of Greek theatre building that had been devised for the presentation of tragedy, but there is reason to believe that his comedies demanded effects more overtly theatrical than had the older tragedies. The change in emphasis from a drama that was dominated by the chorus (as in the early tragedies) to one in which the speaking actor played an increasingly important part (as in the comedies) was one reason why, during the Hellenistic Age, the performers were physically set apart: the chorus remained in the circular arena (orchestra), while the actors were elevated to a high, narrow platform immediately in front of the stage (*skēnē*), which, at that time, was a high wall backing the orchestra and giving access to it by three doors. Drama itself became increasingly secular as it was exposed to "corrupting" social influences, and changes in the physical theatre reflected this. In particular, the Roman comedy of the playwrights Plautus and Terence, which appealed to an experience far more sensual than spiritual, demanded an intimate contact between performers and audience that the older theatre form of Greece could not provide. As a result, the height of the stage was lowered and the full circle of the orchestra reduced to a semicircle. A pattern thus established during Classical times has been continued throughout the history of Western theatre: the playhouse adapts, however unwillingly, whenever a new kind of work becomes sufficiently established to demand it.

Change in dramatic emphasis during the Hellenistic Age

Once theatre buildings became established in major cities of Greece and Rome, they began to be used not only for dramatic performances but also as the principal place

of public assembly. Orators and politicians quickly appreciated the fact that theatre facilities enabled them to be properly seen and heard; the Acts of the Apostles records that St. Paul addressed the Ephesians in their theatre; there is every reason to believe that theatres became the accepted place of confrontation between ruler and ruled.

Extra significance of theatres. Theatre buildings in Greece were always sited with regard to religious significance, but, from Roman times onward, convenience was the only factor in choosing the location for a new theatre. Theatres have long been regarded as symbols of glory, at first of the gods. In Greece, many theatres were associated with precincts sacred to the gods Apollo and Dionysus. One of the most popular theatres of the ancient Mediterranean world stood at Delphi, the great oracle of Apollo, located on the flank of Mt. Parnassus, birthplace of the muses; and it remained in use from the time of Pericles almost until the fall of Rome. The great theatre of Dionysus in Athens, though much remodelled by both Greeks and Romans (and revered above all others in the Classical world as the birthplace of public drama), was located along with a small cult temple in the precinct sacred to Dionysus. During the Roman Empire, theatres were often dedicated to the emperors as physical symbols glorifying the reigning deity. The first Roman remodelling of the theatre of Dionysus in Athens, for example, was dedicated to the emperor Nero, who is believed to have appeared there as actor and musician in the 1st century AD. During the following century, the emperor Hadrian was especially renowned for building and restoring theatres in all parts of his empire. In the grounds of his private villa at Tivoli, a few miles east of Rome, he caused three theatres to be built: one for Greek tragedy, one for comedy, and a small roofed odeum for intimate poetry readings and concerts. Even the austere emperor Augustus, who had established the empire in 27 BC, had both a small open-air theatre and a covered odeum at his private villa at Posillipus (modern Posilipo) on the Bay of Naples. Private philanthropy was as important in the ancient world, where theatre building is concerned, as it is in modern times. Herodes Atticus, for example, a famous Greek orator who was the tutor of the Roman emperor Marcus Aurelius in the 2nd century, built a theatre in Athens dedicated to his wife, and others in Corinth and Patras; there were countless royal patrons of the performing arts from the Renaissance onward; the Rockefeller family today is associated with foundations such as the Lincoln Center arts complex in New York City.

Importance of private philanthropy

Audience comfort. The Greek theatre, essentially a religious festival building, was principally concerned with what was to be presented on the stage. There is no record or archaeological evidence of a lobby, courtyard, or other enclosure being provided as an amenity for the audience—in which, for example, people might pass the interval between the separate plays of a long trilogy. The Romans, however, once the social side of theatre was stressed rather than the religious, were always careful to make provision for the audience, and most of their theatres were built close by a public courtyard; if this was not done, then a new one was built specifically for the theatre, usually immediately behind the stagehouse and giving easy access to the seating. Baroque theatres of the 18th century and the Neoclassical buildings of the 19th century paid particularly lavish attention to the design of lobby amenities for the audience, in general, and for important royal visitors, in particular.

"Theatrical" theatres. The very location of a theatre can itself be "theatrical." One of the great vistas of the Classical world is at Pergamum, where King Attalus, during the Hellenistic period of the 2nd century BC, before the ascendancy of Rome in that part of the world, built a magnificent Greco-Hellenistic theatre on a hillside facing a great ceremonial way that led to the temple of Dionysus. The stage was built of wood, so that all or part of it was portable and could be moved out of the way for ceremonial state processions, which could then be viewed by the entire free population of the town who seated themselves in the auditorium of the theatre. There is evidence that those Roman theatres lying along the marching route of victorious generals and emperors, returning in triumph with their armies from foreign wars, were used in a somewhat similar way. The spectacular pageantry attendant on "royal entries" during the Renaissance and Baroque periods, for which the main square became an outdoor theatre with triumphal arches and portable seating along the line of march, was akin to the processional ceremonial of Classical Rome.

The Renaissance and Baroque periods in western Europe in many ways surpassed even the Roman in the ostentatious theatricality of their buildings. From the Medici court of 16th-century Italy until the fall of the Romanov royal family in Russia during World War I, the public and private theatres of one court vied with those of another in efforts to outshine their rivals. More recently, this sort of grandiose scheme has been on the decline, though in Germany and Italy dictators Adolf Hitler and Benito Mussolini found theatres and similar constructions an excuse for autocratic indulgence in ceremonial architecture. The performing arts themselves tended to get crushed in the embrace of the heavy stone masonry.

Rejection of formal buildings. Recent tendencies in theatre building—and also in the form and content of the drama itself—indicate a movement, especially on the part of the younger generation, to break away from the traditional relationships that have developed over the centuries between performer and audience. The abolition of formal playwriting is advocated, along with the conception of formal theatre as a high art. Instead, impromptu happenings are favoured, in which rigorous artistic training and discipline give way to orgiastic, spur-of-the-moment improvisation involving the active participation of all those in attendance. For such proceedings there is little need of a theatre building in any formal sense. Indeed, a structure of any kind is not an essential requirement. This approach to theatre has been adopted by many young revolutionaries, who show a zeal that is almost medieval in its fervour. It has manifested itself in recent years as a street theatre and is sometimes called guerrilla theatre. Often its devotees, intensely political, are seeking to overthrow established government as well as theatre. But, in fact, their methods are not of themselves new and do not necessarily result in a new definition of the actor–audience relationship. In all probability, such methods will, if they develop true vigour, create their own form of theatre building, as has happened in the past. Essentially, the only difference between modern guerrilla theatre and commedia dell'arte, the popular, rough theatre of the late Renaissance and early Baroque periods, is that the modern version does not seek primarily to entertain. Both are of the streets, but the modern version can, by means of electronic sound amplification or the klaxon "bull horn," force its message into the consciousness of the most unwilling and disinterested urban passerby.

Radical break with tradition in modern buildings

OUTDOOR AND INDOOR THEATRES

Theatres logically divide between those designed for outdoor performance and those for indoor use. In ancient times an outdoor theatre, for reasons of visibility and structure, was the only practical kind. The ancient Chinese, Japanese, Indian, Greek, and Roman theatres were all outdoor, except for the small roofed odeums of the Greco-Roman period, and these had to be small because the architectural problem of spanning a very large enclosed space had not then been solved. The problem of lighting in odeums was variously overcome by windows in the sidewalls or even by omission of an entire wall, usually in the southern exposure, which was instead provided either with piers or columns to support the roof structure.

Outdoor acoustics. The problem of acoustics is always more difficult to overcome out of doors, because there are no surrounding surfaces to reflect and redirect the acoustical energy field toward the audience. Audibility also depends on quiet surroundings because many distractions can easily top the vocal power of the performers. Out-

Problems of large outdoor facilities

door theatres are also prey to adverse weather—too hot, too cold, or too wet—and this limits the time of year when any given facility may comfortably be used.

Outdoor theatre activity today is even more vulnerable, for modern society is noisy. To compensate, there is electro-acoustical amplification, but inferior equipment results in an artificial and unlifelike reproduction of speech and music. Outdoor theatre today very often aims at great size, as it has in all ages and all civilizations. As modern examples there are the Hollywood Bowl in California, the Red Rocks Park in Colorado, and the many outdoor music- and drama-festival theatres associated with national parks and rural developments, such as Tanglewood in Massachusetts and Blossom Center in Ohio. Here, symphony orchestras, opera, ballet companies, and, sometimes, drama companies can perform before large audiences, but it is generally recognized that such places are no substitute for good theatre buildings in an urban setting. Historically, the outdoor theatre has not been long-lived—even that of Shakespeare in England and that of Lope de Vega in Spain soon found their way into permanent buildings.

Indoor lighting and acoustics. It was not until the theatre moved indoors during the late Renaissance that the stage began to resemble that with which most audiences today are familiar, with provision for elaborate scenery, backstage machinery, lighting, and other trappings familiar in the modern theatre. Efficient lighting, however, did not arrive until the late 19th century, when electricity at last provided a safe as well as an artistically expressive means of illumination. Prior to that, there had been an ever-present danger of fire from the use of open-flame illuminants in close proximity to highly combustible scenery and, indeed, to the wooden constructions used in the buildings themselves. Between the early 17th and late 19th centuries, thousands of theatres were destroyed by fire.

The move indoors also helped to isolate theatres from distracting outside noises. It created a host of new acoustical problems, however, such as excessive volume, room shaping that caused unexpected reverberations and echoes, and other dislocations of sound that were not fully understood until the 20th century. Instrumentation and scientific method were then employed to measure, sort out, and identify these phenomena, so that steps could be taken to ensure there would be no repetition of previous errors in theatre design. For, whereas architects from the Renaissance onward had contributed many aesthetic innovations to theatre design—the horseshoe-shaped auditorium, for example—most of these did not contribute to the understanding and improvement of the relationship between audience and performer. Instead of concentrating on problems related to sight and sound, they had been preoccupied with surface detailing—Classic, Baroque, Neoclassical, Neo-Baroque, and a host of other inessentials. It was not until the late 1880s that theatres began to be designed in consultation with engineers and scientists, who devised the means by which interior spaces for performance could be built with some degree of assurance as to their efficiency in terms of sight lines and acoustics. The first theatre building to be so planned was at Bayreuth in Germany, built to house the composer Richard Wagner's music dramas. The project's technical consultant was Carl Brandt.

VERSATILITY OF THEATRE AS PLACE

There is nothing new in today's rejection of traditional relationships between spectator and performer. The history of Western theatre is one of constant improvisation with whatever methods and materials were to hand. Indeed, such improvising often resulted in a golden age of theatre—the Elizabethan theatre in England, for instance, which was the culmination of improvised performances in innyard and animal-baiting pit; or commedia dell'arte of the late Renaissance in Italy, which was spontaneous and skillfully improvised; or the miracle play cycles of the Middle Ages, which evolved from the simple enactment of events in the church's liturgical worship. The satyr plays of Greece and the improvised farces that were performed in the Naples district of Italy from early Roman times were acted in marketplaces and in the streets for the delight of a popular audience; today, a radical element in society is exploiting the potentialities of street theatre as a kind of impromptu happening with political overtones. Experimental theatres are a striking feature of college and university theatres, the members of which work from, as it were, an architecturally uncommitted or empty space; this they arrange in whatever way the playwright, director, or designer requires.

Fixed forms arising from improvisation

In the past, however, what began as an improvisation from necessity usually resulted in an "established" form of theatre: the open stage eventually developed into the "confrontational" relationship between stage and auditorium; the pageant wagon stage of the Middle Ages developed into the fixed thrust stage, eventually surrounded on three sides by spectators. In the 20th century the confrontational proscenium stage has shown signs of giving way to the open and thrust stage. In all this flux, it has always been the basic requirement of an audience to see and to hear that has established some more or less static form of theatre and that has determined whether or not such a form works efficiently.

Another reason for the theatre's tendency to mobility has been the limited availability of talented performers and the lack of widespread, adequate performance facilities. These factors depend on geography, the state of a given culture, and its relative wealth. A primitive country cannot support expensive theatre centres, and so performers have to become adaptable, ready to perform anywhere—on the flat part of a truck, a wagon, an easily erected and dismantled portable platform—with an audience gathered round in a more or less informal manner (a feature still characteristic of the theatre of Southeast Asia, where the steps of a temple or other public building become a stage for the performers). Ingenuity such as this can inspire the quality of performance, which inevitably becomes the focal point. Elaborate architectural buildings, on the other hand, have sometimes swamped what goes on in them, emphasizing instead the theatrical effect of vulgar ornament and ostentation of every kind. Manifestations of this phenomenon include the monumental architecture of Nazi Germany, the 19th century opera houses, the architectural display of ancient Rome, and the fantastic movie palaces of the 1920s and 1930s.

Theatre building today is in the midst of a dilemma. In the wealthy nations, large sums of money are spent on such cultural bodies as symphony orchestras, opera, dance, and theatre companies, and facilities for their use must likewise be provided. Thus, a long tradition of philanthropy and support for the arts is being continued—imperial, bourgeois, or state in origin. But a subculture is developing that wants no part of the tradition maintained by this vast amount of money, preferring to go back to the "primitive" approach in order to rediscover the roots of Eastern as well as Western cultural genius. And so the cycle renews itself. The means are available, with the hand trumpet and megaphone giving way to the electric guitar and the klaxon bull horn, and the performers are ready; but, in addition, an audience must be attracted, for without an audience no dramatic message has any meaning. No one, however, can say whether a genuinely new definition of encounter between performer and audience is possible—or even desirable.

Theatre of Asia

The ancient, rich, and varied cultures of Asia produced three distinct types of theatre: (1) the religious dance drama of the south, of which Vietnam, Cambodia, Java, Bali, and India are representative; (2) the music drama or opera of China; and (3) the classical and popular drama of Japan. Collectively and generally, they contrast with Western drama in form, substance, and style of presentation. None, however, exhibits the range, variety, and continuity of development that characterizes Western theatre. This is not to belittle either the cultural or the ethnic values of Eastern theatre as an art. It simply reflects the fact that, in many instances, public art in Asia took to other forms of expression. Of the three types of

Lack of range and variety in Eastern theatre

theatre mentioned, that of Japan is the most varied and shows the most sustained development.

Theatre of Japan

The theatre of Japan is of two kinds: Nō, the classical or court theatre of the aristocracy, and Kabuki, the public theatre of the people. Nō drama originated in about 1350 and Kabuki around 1600. The literal meaning of Nō is Talent. Kabuki takes its name from a slang word of the day roughly meaning gaudy. Each has roots in a much older puppet theatre, in which most of the dramatic literature dealt with ancient legends. The acting styles of Nō and Kabuki theatre are in sharp contrast: whereas the principal characteristic of Nō is an uncompromising restraint, bordering on the austere, Kabuki employs deliberately exaggerated emotional posturing, broad playing, and bombastic declamation. Scenically, they are also a contrast. Nō, in the restrained manner of the Japanese print and wall screen, uses a few simple, formal, stylized elements; it is restrained and much given to understatement to achieve its effect. Kabuki delights in spectacle and trick effects, sometimes startling and bizarre. Nō invariably employs a static background, simply painted to suggest land, sky, and pine. Kabuki, however, strives for mobility, plasticity, and variety, employing trick effects achieved by mechanical lifts, trapdoors, and revolving stages (a Japanese invention). Both, as in the theatre of Shakespeare in the West, are essentially actors' theatres, achieving great intimacy and rapport with the audience despite their quite different artistic frameworks. Both, again as in the Shakespearean theatre, began in the open air but moved indoors with time. The smaller in size and the more formal is the open stage of Nō, with an attached left stage bridge extension. Kabuki favours an actor–audience confrontational approach, such as the Western proscenium stage permits, but also employs long runway extensions right and left of the stage at the point where it joins and bisects the main-floor audience seating area. The Nō auditorium is small and intimate, designed for a connoisseur audience of between 200–300; contemporary Kabuki auditoriums, however, often seat more than 2,000. Almost up to the end of the 19th century, Kabuki auditoriums provided only for the traditional cross-legged Japanese seating posture, on a flat floor covered with mats and split up into square boxes. There were no aisles, as such, providing access to and from the seating system. But, as the form developed, side and rear balconies were added to the auditorium; and the Western type of seating, ranged on a gently sloping floor, was eventually provided in most parts of the theatre. Newly built Kabuki theatres, notably the national theatre in Tokyo (which was built after World War II), have all the most up-to-date stage machinery and lighting, and theatre design takes into account maximum acoustical efficiency.

Nō theatre, on the other hand, remains virtually untouched by 20th-century mechanical innovations, still depending, to a great extent, on exquisite detailing of costumes and hand props for theatrical effect. Kabuki actors wear heavily stylized makeup, whereas the Nō actors use finely detailed and traditional masks of intricate design. In this respect, it is somewhat similar to the Classical theatre of Greece, but no formal connection between the two has ever been established nor is likely to be (see DANCE AND THEATRE, EAST ASIAN; KABUKI THEATRE; and NO THEATRE).

Historical development of Western theatres

In the Western world, theatre building, like theatre art, separates into two main divisions. The first, beginning with the theatrical activity of primitive peoples *c.* 1st millennium BC, lasted until the fall of Rome in the Christian Era. There followed a long hiatus during the Byzantine period and the Dark Ages, when no theatres were built at all. Although drama revived in the Middle Ages, no theatres in a formal architectural sense were built. The second period of theatre building began with the Renaissance, when there was a widespread interest in the Classical heritage of Greece and Rome, and it was at first sponsored by the academies and ducal courts of northern Italy. Theatre building has continued unabated since that time.

Revival of drama in the Middle Ages

It is, however, notable and significant that periods of particularly intense theatre building in the West have, at all times, followed periods in which dramatic activity had already reached new heights. This clearly indicates that theatres are built to satisfy an existing demand; excellence creates theatres, not the other way about. The vigour of the Elizabethan theatre, for example, was developed in improvised performing facilities—animal-baiting pits, innyards. The familiar thrust stage of the permanent playhouses built in later Elizabethan and Jacobean times was the outcome of that existing vigour. Theatre building has also tended to flourish during periods of economic surplus, which has encouraged both private and public philanthropy: such philanthropy has not, however,

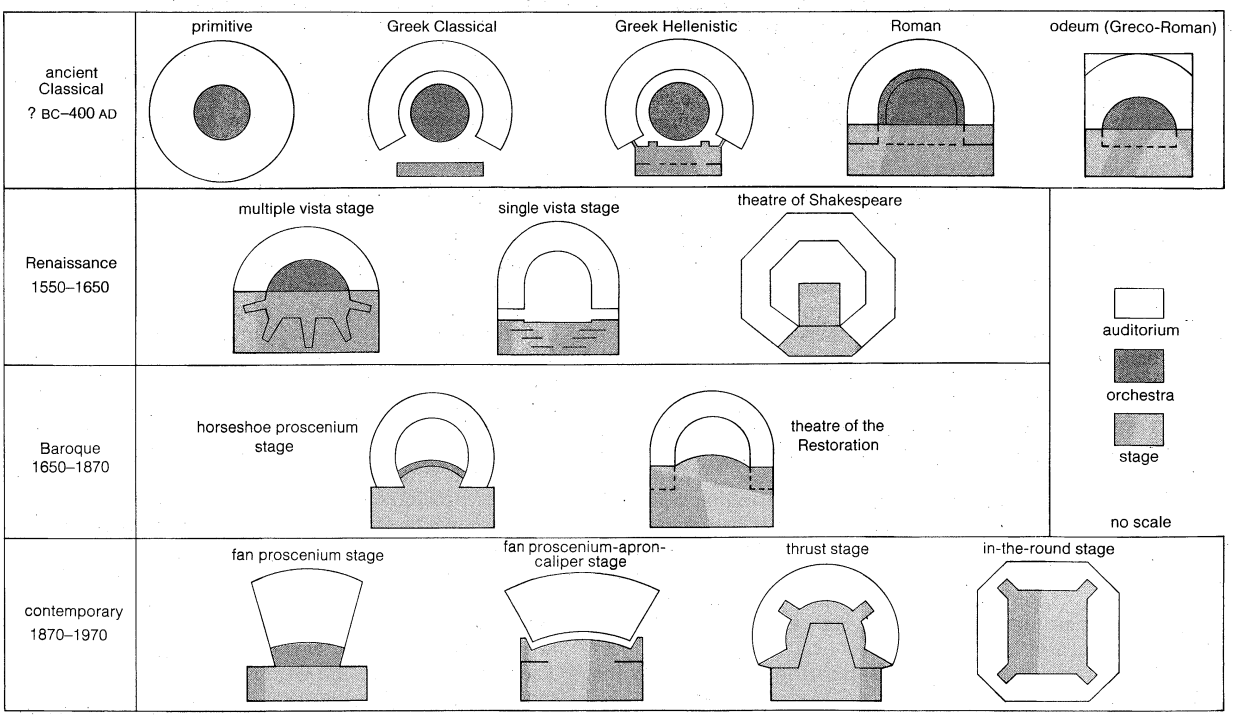

Figure 1: Form outline plans of Western theatres.

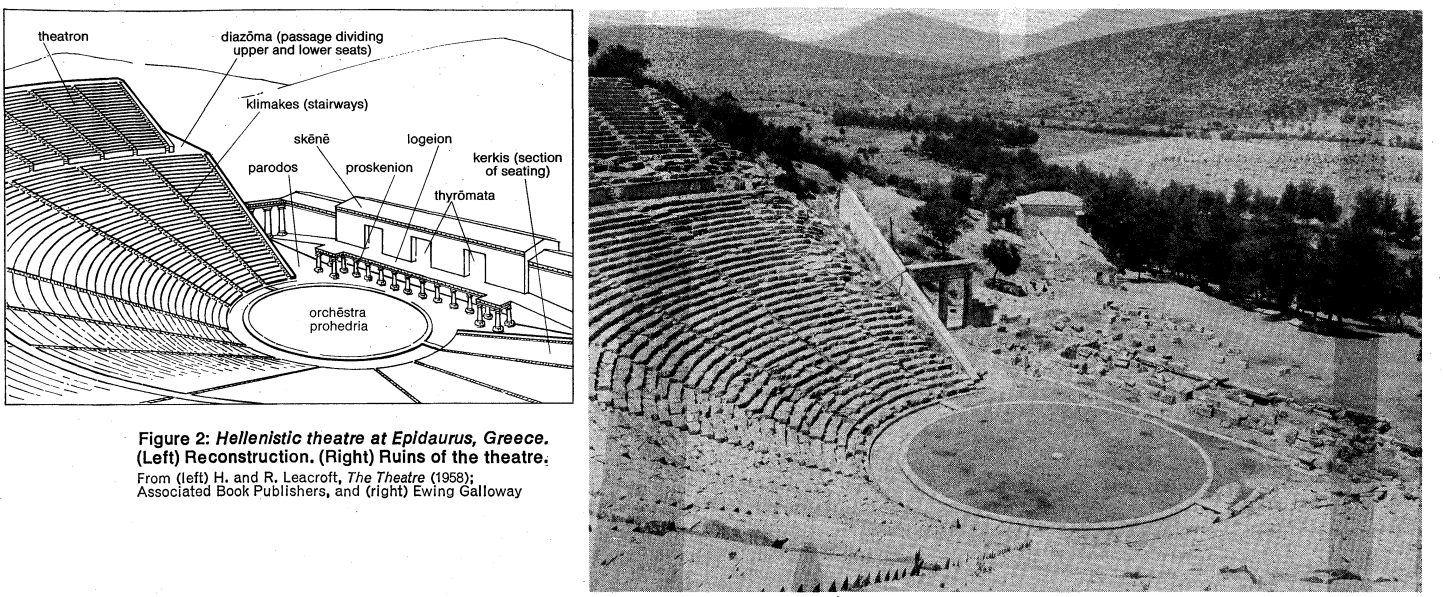

Figure 2: *Hellenistic theatre at Epidaurus, Greece.* (Left) Reconstruction. (Right) Ruins of the theatre.
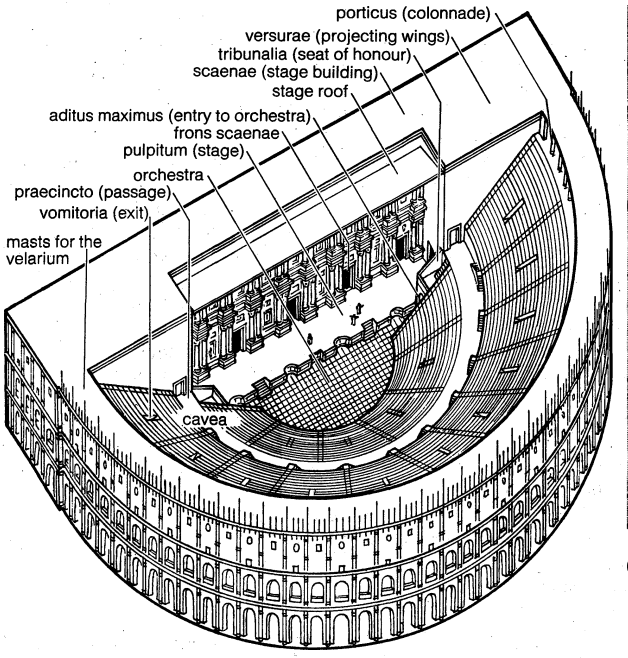
From (left) H. and R. Leacroft, *The Theatre* (1958); Associated Book Publishers, and (right) Ewing Galloway

always been altruistic, the chief incentive often being profit, prestige, or political advantage.

The form of theatre building, particularly of the auditorium in relation to the stage, has undergone change and mutation, thus reflecting the progress of the drama itself. The changes have occasionally been due to some other factor, such as etiquette: during the Baroque period, for example, a system of stratified seating in the auditorium was dictated by the prevailing rigid class structure of society. Less often, change has been due to some startling innovation, notably, the introduction of electric light, that has changed the course of development more abruptly. Indeed, the development of buildings in which the Western world has housed its drama presents a sometimes contradictory, baffling, and occasionally obscure reflection of the cultural mainstream itself (Figure 1).

THEATRES OF ANCIENT GREECE AND ROME

Greek theatre. The temples of the ancient Egyptians may indeed have provided the setting for their dramas, and the theatral area adjoining the palaces at Knossos and Phaestus (in Crete) served as a place for ritual dances and ceremonies of a dramatic nature. But it was in ancient Greece that Western theatre can be said to have begun, emerging from rites sacred to the nature and fertility god Dionysus and reaching its first flowering in the Classical period of the 5th century BC. Those not taking active part in performance were grouped about the designated participants in such a way as to retain an empathetic yet vicarious sensual contact with them. This separation between actors and audience meant that the latter needed to be in direct line of sight and sound with the place of dramatic action, and it was almost certainly the repeated conjunction of these circumstances that led to the first theatre constructions. In a land blessed with a benign climate and a hilly terrain, the Greeks could utilize a hillside, a hollow between two hills, or some other natural bowl-shaped formation as a site for their theatres, positioning the spectators around and above the performers. During the Classical age in Athens, temporary wooden scaffoldings were used as audience seating. These seem to have been rectilinear in arrangement, rather than curvilinear—the latter plan being commonly associated with the later, Hellenistic period. Scholars have determined that these temporary constructions were placed in the agora (marketplace), and they thus constitute the first attempt at urban theatre design. The first permanent stone theatre in the world, the theatre of Dionysus, was built in Athens on the south slope of the Acropolis by the politician Lycurgus in about 330 BC. It consisted of an irregular, circular bank of seating, built of local stone placed on impacted earth, about a circular orchestra, and, from the start, it could probably accommodate from 6,000 to 12,000 spectators.



Primary importance of sight and sound in Greek theatre

The stage. Most authorities agree that during the Classical period, in the 5th century BC, when the great tragedians Aeschylus, Sophocles, and Euripides flourished, all action performed by chorus and actors took place within the orchestra circle, with a beaten-earth surface like the threshing floors then to be found in countries of the Aegean. The stage (*skēnē*) was at that time not a raised platform but a low wooden barrier closing the back of the orchestra, behind which the actors and chorus removed for changes of mask and costume. Although archaeological evidence gives a clear picture of the auditoriums of Greek theatres after that built by Lycurgus, knowledge of the stage itself and of its subsequent development is less certain. The evidence suggests that all dramatic action continued to take place in the orchestra until the Hellenistic period, when a platform was raised in front of the permanent *skēnē*—by this time, a high wall that gave access to the orchestra by three doors. The speaking actors performed on the platform, while the chorus remained in the orchestra. It was in this period that the great theatre in Epidaurus (Figure 2) was built, with what is believed to have been a high, two-level stagehouse replacing the simpler wall structure of the *skēnē*.

Acoustics. Much recent study has centred on the problem of acoustics in the ancient theatre. The difficulty in achieving audibility to an audience of thousands, disposed around three-fifths to two-thirds of a full circular orchestra in the open air, seems to have been insoluble so long as the performer remained in the orchestra. A more direct, horizontal path between speaker and audience was therefore essential if unaided voice power was to reach a majority of spectators in the auditorium. Some contend that the acoustical problems were to a degree alleviated when the actor was moved behind and above the orchestra onto the raised platform, with a greater proportion of the audience being thus placed in direct line of sight and sound with him. By this time, the actors' masks had reached considerable dimensions, and there are grounds for believing that their mouth orifices were of help in concentrating vocal power—much as cupped hands or a rudimentary megaphone produce a simple sound-wave guide.

Sophistication of the Hellenistic Age

Increased architectural and engineering sophistication in the Hellenistic Age encouraged further innovations. The theatres of mainland Greece, the Aegean islands, and southern Italy (generally speaking, all older than those in Asia Minor) had been constructed on hillsides wherever

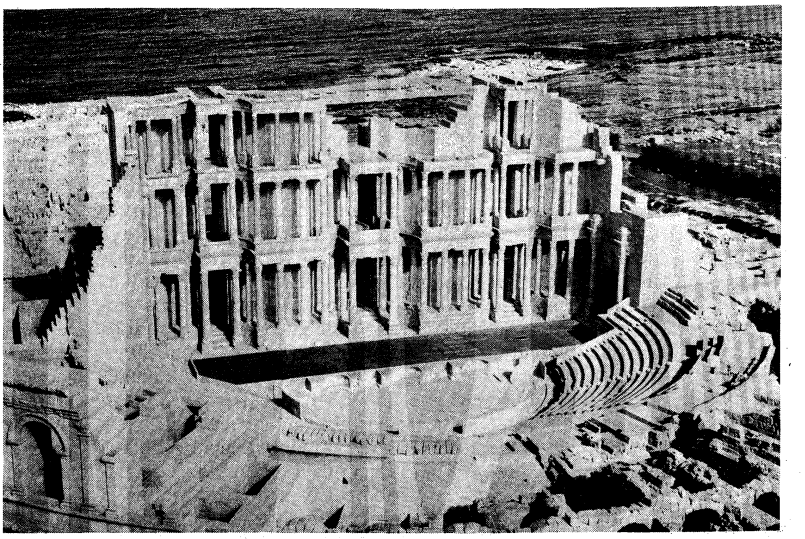


Figure 3: *Roman theatre.*

possible, so that excavation and filling were kept to a minimum; or, lacking a suitable slope, earth was dug out and piled up to form an embankment upon which stone seats were placed. By contrast, the cities of Asia Minor, which flourished during the Hellenistic Age, did not rely on a convenient hillside or other slope on which to locate their theatres. The principles of arch construction were understood, and theatres were built using vaulting as the structural support for banked seating. Archaeological remains and recent restoration of theatres at Perga, Side, Miletus, and other sites in modern Turkey exhibit this type of construction. By a third method of construction, auditoriums were hewn out of living rock. Of some six such Greek theatres extant, two excellent examples (both extensively remodelled in Roman times) are the great theatre at Syracuse in Sicily and that at Argos in the Peloponnese on the Greek mainland. The best preserved of all Greek theatres, also in the Peloponnese and now partially restored, is the magnificent theatre at Epidaurus, sacred city of Asclepius, the god of healing. It provided seats for some 12,000 people, and its circular orchestra is backed by a stagehouse and surrounded on three sides by a stone, hillside-supported bank of seats. Both chorus and actors performed in the orchestra, but only the actors used the two levels of the stagehouse. Theatre building flourished during the Hellenistic Age as never before in Classical times, and no city of any size or reputation was without its theatre.

Roman theatre. *Stage and auditorium.* The Romans inherited Greek tradition and technique in building generally and were the first to make theatres into true buildings. Their knowledge of engineering, moreover, and their supreme confidence in execution gave them an unlimited choice of sites when locating their theatres. Beginning by remodelling Greek and Hellenistic theatres, they eventually succeeded in giving architectural unity to auditorium and a single-level, raised stage. This they did by limiting the orchestra to a half circle and joining it to the auditorium, thereby improving acoustics over the Greek and Hellenistic theatres. They also brought to perfection the principles of barrel and cross vaulting, penetrating the seat bank at regular intervals with *vomitoria* (exit corridors) to provide a more convenient system of ingress and egress for the audience as well as to give sound structural support for the seating. The raised stage was at a single, much lower level than in the Hellenistic theatre. It was roofed, and entrances to it were increased to five: three, as before, in the wall at the rear of the stage and one at each side (Figure 3). The Romans' love of ostentatious architecture led them to adorn the permanent background with profuse sculptures, a development that characterized all Roman stages built in imperial times. In some theatres a drop curtain, fixed in a trough across the front of the stage, was used to signal the beginning and end of performance. In some cases, a canvas roof was hoisted onto rope rigging in order that the audience be shaded from the sun. The best preserved Roman theatre, dating from about AD 170, is at Aspendus on the Mediterranean coast of modern Turkey.

Incorporation of the orchestra into the auditorium

In Roman theatres the stage alone was used by the actors. The orchestra became part of the auditorium in Rome, reserved by statute for those of privileged rank, who seated themselves there on a variety of portable chairs and litters. The orchestra was no longer needed as part of the performance area because the chorus had long since ceased to be an integral part of drama. The tragedies of Seneca, in the 1st century, of course included a chorus since they followed the example of their Greek models. But they never achieved the popularity of earlier comedies, especially those of Plautus and Terence. These had at first been performed on temporary wooden stages set up on a convenient slope and sometimes surrounded by temporary wooden seating.

Until the first triumvirate ("rule of three men," 60 BC), a puritanical Senate had banned all permanent theatre building within the city of Rome itself as decadent, not befitting a virile Roman society. Thus, theatre constructions there were temporary affairs, set up in the Campus Martius and taken down at the conclusion of the games at which they had been used. In 52 BC, however, the triumvir Pompey the Great built Rome's first permanent stone theatre. Another public theatre was built in Rome in 13 BC and named after Marcellus, son-in-law of the emperor Augustus. Like that of Pompey, it was a stone-vaulted structure. Both were used for the *scaenae ludi* ("scenic games"), which were part of religious festivities or celebrations of victory in war and which were paid for by triumphant generals and emperors. Archaeological remains of these two theatres are meagre. Only foundations remain of the theatre of Pompey, while the theatre of Marcellus was converted into a multiple dwelling during the late Middle Ages and survives in that form. During the empire, however, civic pride demanded that all important cities have theatres, amphitheatres, and, in many instances, a small, permanently roofed theatre (*theatrum tectum,* an odeum, or music hall). In fact, it is from outlying cities of the empire such as Arausio (Orange), Thamagadi (Timgad),

Leptis Magna, Ṣabrāth, and Aspendus that archaeological evidence provides most firsthand knowledge of Roman theatre building.

Vitruvius' treatise on architecture. Literary documentation complements and enhances archaeological knowledge of theatre building by the ancients. *De architectura libri decem* ("Ten Books on Architecture"), by the Roman architect Vitruvius (1st century BC), devotes three books to Greek and Roman theatre design and construction. The author gives general rules for siting an open-air theatre and for designing the stage, orchestra, and auditorium. These rules are based on principles of Euclidian geometry in matters of layout and proportion. His dictums on the provision of good sight lines from auditorium to stage are generally sound. Apart from that, however, his treatise is not very helpful. He mentions changeable scenery but is vague about what was involved. On this and on other subjects, notably acoustics, there has been much conjecture, but no archaeological remains provide sufficiently convincing proof of any interpretation. Vitruvius' notion of acoustics, which he claims is based on theory as well as practice, is vaguely associated with Greek ideas of musical theory but has since been proved to have no scientific or mathematical basis. Indeed, his views on this important matter were to cause problems for almost 2,000 years.

Vitruvius' principles of acoustics

The odeum. Vitruvius has nothing to say about the odeum, which, according to some authorities, represents the final refinement of theatre building in the ancient world. Modern studies in Classical archaeology have suggested that the roofed odeum was the high point of design and perfection of structure in ancient theatre building. Theatre history has, unfortunately, largely overlooked these buildings. Excavation work has revealed more than 30 of them, in a wide range of building materials. One of the most imposing, which also boasts the greatest span for a wooden trussed roof in the ancient world, was the Odeon of Agrippa, named after the emperor Augustus' civil administrator. A Roman building located in the Athenian agora, dating from about 15 BC, it is a beautifully detailed building, with an open southern exposure to light a stage surrounded by a truncated curvilinear bank of seating. It achieves an atmosphere of great dignity and repose, despite the vast size of the room. Odeums were apparently first built in Athens under Pericles (5th century BC). They continued to be built throughout the Hellenistic Age and also in the Roman Empire right up to the time of Emperor Severus Alexander (3rd century AD). They range in size from a minimum seating capacity of 300–400 to a maximum of 1,200–1,400. Experts who have studied these buildings in any detail disagree as to their specific purpose and use but claim they exhibited a refinement of detail and architectural sophistication found in no other Greco-Roman buildings devoted to the performing arts. They are usually found in Greek cities dating from Hellenistic times, on the grounds of private villas built by Roman emperors from Augustus to Hadrian, and in major cities of the empire usually dedicated to the emperors. In the dying years of the Roman Empire they were, it is claimed, the last remaining home of the performing arts, since by this time open-air theatres had long been given over to satisfying debased and perverted popular taste with sensational, crude, and, at times, bloody entertainments.

Greek and Roman theatre building is the basis of all later theatre design in the Western world. The theatres of the golden age of Spanish drama and of the English Elizabethan theatre in the 16th century—and the 20th century's avant-garde experiments with primitive theatre-in-the-round techniques—are, however, the exceptions.

THEATRE IN THE MIDDLE AGES

After the fall of Rome and the triumph of Christianity, organized theatre was suppressed during the 5th century as an art so debased as to serve no useful social or moral purpose. There were survivors of the Roman mimic tradition who formed a wandering fraternity of players. But, naturally enough, under such conditions there was no theatre building in a formal, architectural sense. Drama, at length, emerged in the Middle Ages from centuries of seeming death, finding its inspiration in the liturgy of the church. At the same time, interest in tournament and secular pageantry developed. (Such forms of entertainment, though theatrical, are not strictly dramatic.)

Church theatre. Medieval drama itself arose from a desire to educate. The task of conveying moral truths and a rudimentary understanding of Christian doctrine and dogma to a laity unable to read and write was considerable. The clergy began to dramatize events from the New Testament because this was a more dynamic teaching method than the static sculptures, stained-glass windows, and mosaics that for centuries had been the chief means of bringing home the meaning of these stories to their congregations and with which Byzantine, early Christian, and Gothic church buildings abound. It is doubtful whether there is any connection between the drama of Classical times and the new, rudimentary dramatizations that slowly grew into the miracle and mystery cycles of plays in the Middle Ages. As early as the 10th century in Switzerland, France, England, and Germany, short and simple dramatic renderings of parts of the Easter and Christmas liturgy of the mass were being performed. As the short scenes so dramatized grew in number, small stages—called mansions—were placed at the sides of the church nave. At these, stories of the Nativity, Passion, and Resurrection, depending upon the particular season of the Christian calendar, were acted out. The mansions were at first simply marked-off areas of the floor, but eventually small raised platforms, backed by curtains and simple scenery, came into use. At the conclusion of each scene, the congregation turned its attention to the next mansion, so following a succession of scenes set out at intervals around the nave, in much the same way as the 14 Stations of the Cross are placed for devotional purposes in the side aisles of churches today. Gradually, the performance of liturgical drama passed out of the hands of the clergy and into those of the laity, probably via the trade guilds of craftsmen, which were also religious fraternities. More and more secular interludes crept into the dramas—to such an extent that the dramas moved out of the church and onto the steps in front of it. Eventually, the plays moved away into the public square, which was thus turned into a theatre, and the individual plays performed became linked in cycles, often beginning with the story of the creation and ending with that of the Last Judgment. Each play within the cycle was performed by a different trade guild. Many of these cycles have survived and are valuable in their own right as dramatic literature. Another theme receiving dramatic attention in the Middle Ages was martyrdom of saints. Realistically acted scenes were performed in the public square on the appropriate saint's day as part of the feast-day celebrations.

Educative function of liturgical drama

Secularization of performance sites

Theatre in the marketplace. *Mansion stages.* The simplest way of presenting the plays was a straightforward development of the mansion system that had been used in the churches, as can be seen from a mid-15th-century engraving of the "Martyrdom of St. Apollonia" and from a 16th-century illustration of the Valenciennes mystery play (Figure 4). It appears that several mansions were erected about a raised platform, which was evidently the main acting arena, while the audience stood below the mansions (and possibly in the spaces between them). Some temporary seating was erected for the occasion, and no doubt nearby balconies and windows were also put to good use. Each episode in a play began in front of an appropriate mansion that depicted the setting for that scene; in the course of playing the scene, the actors spilled out in front of and around the mansion into the main acting arena. The principle is not unlike the modern theatre's "simultaneous setting," in which, for example, two or more locations are visible throughout, though only one may be lit or in use. The medieval settings were not usually realistic; place was suggested by a naïve artistic symbolism.

Pageant wagons. This was not necessarily the case, however, in another method of presentation, especially

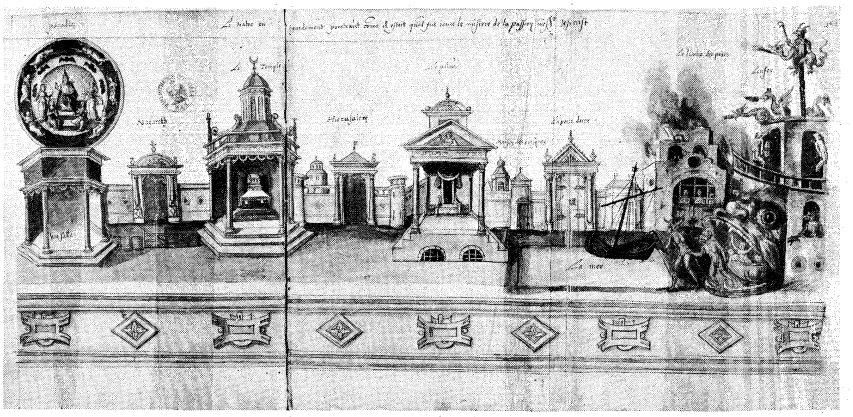

Figure 4: The setting for the Valenciennes mystery play, miniature by Hubert Cailleau, 1547. In the Bibliothèque Nationale, Paris.
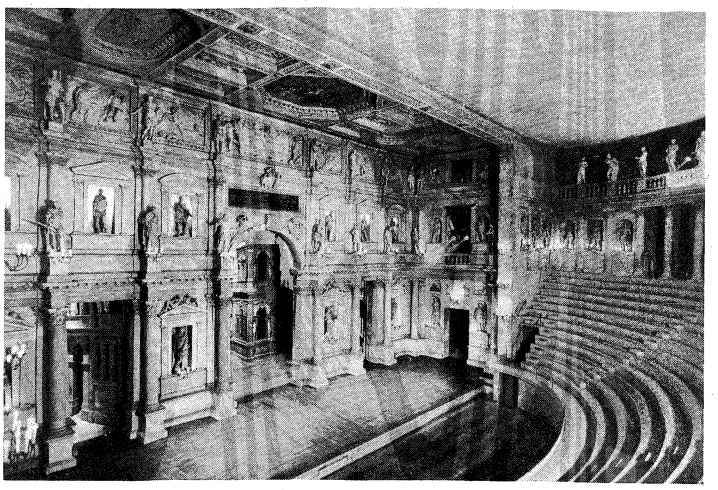
By courtesy of the Bibliotheque Nationale, Paris

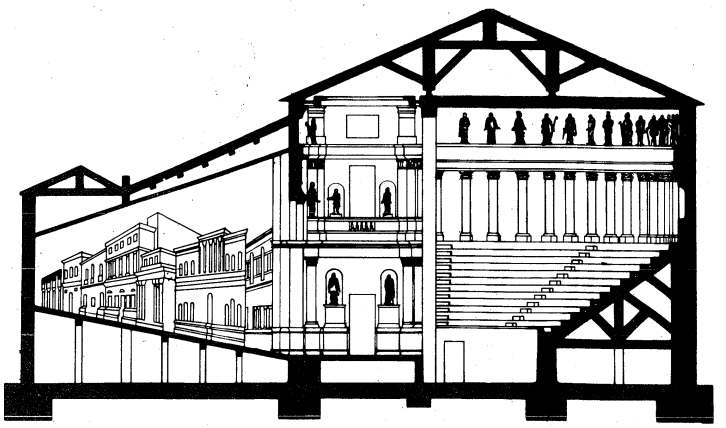
popular in England and the Netherlands. There, the mansions were portable, in England called pageant wagons and in the Netherlands *wagonseel*. Beneath the raised platform was a curtained space with room for the actors. Although the number of settings available was the same as for the mansion presentation, in this case only one wagon was visible at a time; the audience remained where it was, and the pageant was wheeled to it. Sometimes the pageant wagons were far from simple structures; many incorporated practical effects to enliven the proceedings. A realistic replica of the ark, complete with animals and possibly floated on water, might be constructed for the story of Noah and the Flood; or an ingenious model of a whale, able to contain an actor within its belly, might be used for the story of Jonah; fire-breathing mechanics were employed for a representation of "Hell's Mouth" in Last Judgment plays.

Ingenious scenic effects of pageants

Courtly diversions. The religious drama performed on mansion or pageant wagon constituted the principal public theatre of the Middle Ages, and it flourished until the late 15th and early 16th centuries. At the same time, another kind of theatre was associated with the courts, where more or less impromptu and unrehearsed entertainments, deriving from the medieval love of tournament, were much in vogue. Essentially planned as diversions, they were most sumptuously costumed and caparisoned, with the emphasis on spectacle. In some cases, wooden seating arrangements were specially provided for spectators, many of them distinguished guests of the royal or ducal household. This type of theatrical entertainment grew in popularity throughout Europe, culminating during the 16th century with such buildings as the Boboli Gardens theatre in Florence, associated with the court of the Medici family. Another manifestation of this essentially courtly theatrical display took place on the triumphant return to a city in his own realm of some royal person and entourage after victory in war or on the occasion of a neighbouring ruler's visit. Public participation was then often invited and, sometimes, enforced, to help swell the sense of occasion. It was followed by private festivities held at court—disguisings and masquerades, with jugglers and troubadours. On occasion, a group of strolling players would also be invited to perform, improvised facilities being set up in the great hall or courtyard of the palace.



Like all primitive theatre, that of the Middle Ages was one of participation, and throughout its development it never lost the close proximity of actors and audience. It was a theatre of symbolism rather than of illusion, and, like the Classical theatre, it essentially took place in the open air, with none of the magic associated with enclosed space, where a half-darkened stage can bestow mystery and illusion upon scenic display.



THEATRES OF THE RENAISSANCE

The revival of theatre building, first sponsored by 16th-century ducal courts and academies in northern Italy, was part of the general Renaissance interest in the newly discovered Classical heritage of Greece and Rome. The ruins of Classical theatres were studied as models, along with Vitruvius' treatise on Classical architecture. There were, however, new conditions that fundamentally affected design as compared with the procedures of Classical architects. First of all, the theatre's move indoors gave rise to problems of lighting and room acoustics. The laws of geometric perspective were discovered and, when applied by artists to stage and scenic design, brought about a profound change in the effect of a stage on an audience. The first Renaissance theatres, like those of early antiquity, were temporary wooden constructions in gardens, ballrooms, and assembly halls. Sometimes, they were hastily erected affairs, put up to celebrate the birth and weddings of ducal offspring or to commemorate victories in war. The theatrical performances given were mostly of allegorical pageantry, but the scenic spectacle was calculated to dazzle the eye and often succeeded. One court vied with another for the services of clever innovators, painters, sculptors, and architects who could, on order, devise stages, audience-seating constructions, scenery, costumes, pageant wagons, fireworks displays, and the assorted trappings of theatrical extravaganza. Famous names from the world of art contributed their talents to the theatrical entertainments at the courts of popes, cardinals, dukes, and lesser nobility. Leonardo da Vinci, Michelangelo, Vasari, Bramante, Raphael, and a host of other Italian painters, sculptors, and architects, as well as poets, such as Tasso, and musicians, such as Monteverdi, strove to please and exalt the reputations, real or imaginary, of their princely patrons.

The Renaissance attempt to dazzle the spectators

First large-scale indoor theatres. A more sober attempt to revive the Classical theatre was made by the academies, organized by upper class gentlemen who assembled to read and, on occasion, to participate in and to support financially productions of Classical drama. The plays were generally of three kinds: contemporary poetic dramas based on ancient texts; Latinized versions of Greek dramas; and the works of Seneca, Terence, and Plautus in the original. The Olympic Academy in the little town of Vicenza, near Venice, commissioned a famous late Renaissance architect, Andrea Palladio, to design a theatre for them. This, the Teatro Olimpico, was the first permanent, modern, indoor theatre, and it has survived intact (Figure 5). Palladio thoroughly researched his subject (the outdoor Classical theatre of Rome) and without knowing it designed for his clients something very close to a Roman odeum. It is a scaled-down version of an outdoor Roman theatre, with shallow open stage and a heavily sculptured, pedimented, permanent background. A colonnade of heroic proportions, surmounted by sculptured figures, surrounds a steeply stepped bank of seating. Overhead is a painted sky. To promote an intimate stage–auditorium relationship, he used a flattened ellipse in planning the seating, rather than the classic half circle. The interior was to be lit by tallow candles mounted in wall sconces. Palladio died before the building was finished, and his follower Vin-

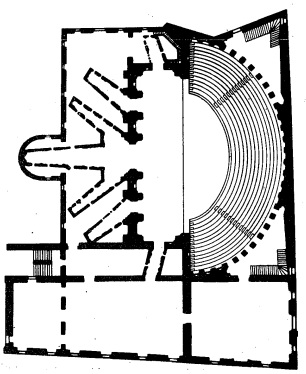


Figure 5: *The first permanent indoor theatre.*
Teatro Olimpico, Vicenza, Italy, designed by Andrea Palladio and completed by Vicenzo Scamozzi, 1585. (Top) View of stage and auditorium. (Centre) Section. (Bottom) Plan.

cenzo Scamozzi completed the work (1585). Behind the five stage entrances (attributed to Scamozzi) are static, three-dimensional-perspective vistas of streets disappearing to their separate vanishing points; it is not certain whether this was the intent of the original design. In performance, the theatre is efficient if the auditorium is full, and speech carries quite well because of the small volume, flat ceiling, modulated sidewalls, excellent vertical sight lines, and direct hearing lines from all seats to the stage. The exterior is an ungainly, masonry-walled structure with wood-trussed, tiled roof. Inside this primary structure, the theatre is constructed of wood and plaster and bears scarcely any relation to the primary structure. This brings up a point fundamental even to modern theatre buildings. Because of its interior function, a theatre makes for ungainly, difficult, and, at best, anonymous exterior architecture. The problem central to successful theatre design concerns its interior functions, involving solution of sight lines, acoustics, provision of adequate stage facilities, audience comfort, and the like. This usually results in an exterior architecture that is oppressively monumental, formalistic, and characteristic of a "one-building-inside-the-other" construction.

Scamozzi's theatre at Sabbioneta

In 1588–89 Scamozzi designed a small court theatre for the Gonzaga family at Sabbioneta. Unlike the Teatro Olimpico the stage here is a single architectural vista behind a shallow-raked open platform, after the manner of the stage illustrated by the architect-theoretician Sebastiano Serlio in his treatise *Architettura* published in 1545 (Figure 6). Serlio's influence was felt in France and England, notably in the work of Inigo Jones, architect to the court of King James I. At Sabbioneta, a divided horseshoe-shaped bank of seating leaves an empty arena, at floor level, in front of the stage. This space, backed by the permanent bank of seating, can be used for more seating, but it also permits other uses and paves the way for the most famous and influential of all Renaissance theatre buildings, the Teatro Farnese.

This lies about 12 miles (20 kilometres) west of Sabbioneta at Parma, in a palace of the Farnese family. Teatro Farnese was designed by the architect Giovanni Battista Aleotti and is the first proscenium theatre in the world to be designed for movable scenery (Figure 7). Designed and built in 1618 (but not used until 1628, to celebrate the marriage of a Medici daughter to a Farnese son), it is the earliest large-scale indoor facility for theatrical activities to have survived. It was severely damaged by fire bombing in World War II but has since been restored to its former glory. There has also survived an extensive catalog giving details of events held there, including some contemporary comment on performances. It describes the variety of use to which the theatre was put. Drama, opera, and ballet were performed on stage; equestrian acts and sumptuous balls were held in the spacious arena between stage and seating, which could also be flooded to a depth of 2 feet (0.6 metre) and used for mock naval battles. Other court functions requiring ceremony, such as reviews, ambassadorial receptions, proclamations of state, and a variety of princely extravaganzas, round out the theatre's multiple uses. Lighting was still a problem and remained so for all interior theatres until the 19th century. Teatro Farnese has windows (as did the Teatro Olimpico and the Teatro all'Antica at Sabbioneta before it) behind and above the banked seating. This helped to illuminate the space when used in daytime, but at night tallow candles or animal-fat lamps, in wall and overhead fixtures, were the source of illumination for all theatres until the introduction of gas lighting in the 19th century. Teatro Farnese set the style for stage and auditorium design over the next 250 years, except for the courtyard-patio (*corrales*) theatre in Spain and the Elizabethan and Jacobean theatre of England.

Shakespeare's theatre. Curiously, more is known about the theatres and stages of Greece and Rome than about those of Elizabethan England. Scholars have put forward a variety of theories about the origin of the theatre of Shakespeare. One theory suggests that it stemmed from the pits used for animal baiting, a popular Elizabethan sport; another has it as an elaboration of the 16th-century English innyard; yet another seeks to establish some connection with Vitruvian theory of theatre design. All are inconclusive, however, because of the lack of direct archaeological evidence. Literary documentation is limited, and graphic evidence consists of one poorly drawn sketch (the so-called DeWitt sketch) copied from a firsthand description by an artist who did not see the building it purports to show. Unlike the Italian court and academy theatres, it was a public theatre; the first, built by James Burbage in 1576, was called the Theatre. The Elizabethan stage is established beyond all doubt as being thrust forward, surrounded on three sides by the audience, backed by a stagehouse, or inner stage, which was, according to some authorities, on two levels (though on this point there has been much controversy). Behind the inner stage were dressing rooms, property rooms, and storage space for the limited scenic elements used in connection with plays in the repertoire. The thrust-platform stage was partially covered by a canopy, referred to as the heavens, supported by the primary structure upstage and two narrow columns about halfway downstage. A downstage trapdoor, or trapdoors, permitted appearances from below and could be used, for example, in graveyard scenes. Like the public theatre of Greece and Rome, it was open to the sky, subject to vagaries of weather. Britain's climate dictated time and length of the theatrical season. In all probability, an Elizabethan theatre like the Globe in London was essentially a wooden-framed, thatched-roofed building, seating and standing fewer than 1,800 persons in three tiered balconies and a ground floor referred to as the pit or yard (Figure 8).

Origin of the Elizabethan playhouse

"Golden Age" of Spanish theatre. The great flowering of Spanish theatre parallels that of Shakespeare in time, but its origins are still more obscure, with even less documentation upon which to base theories of its existence and appearance. Like its famous English counterpart, it was an open-air, public theatre. It was not, however, confined to one city, as theatre in England had been confined to London: all large urban centres in Spain had

permanent theatres. The stage was an open platform set at one end of a rectangular patio or courtyard, and it was surrounded by shallow balconies on two levels. The ground-level area next to the stage was perhaps supplied with rough benches; if not, the audience in that part stood —as in the pit of a Shakespearean theatre. The background to the stage was, for the most part, architectural, probably somewhat simple and austere, containing entrances at two levels to an inner stage. Occasionally, a curtain might have been used to augment the scenic effect, being drawn aside to permit upstage action. As with Shakespeare, however, locale was suggested by poetic discourse rather than by visual symbolism. The stage was most probably in direct descent from the medieval wagon platform that had been used in the public square. Backstage were the actors' dressing rooms and stage property rooms. A shallow roof, supported by the primary backstage structure, extended some way over the platform, though probably not far enough to require any additional support. After a period of time, awnings were rigged over the seating, and, eventually, the addition of a permanent roof made it an indoor theatre. Seville at one time boasted seven permanent theatres; the most important in Madrid was the Corral de la Cruz, opened in 1579. This style of theatre finally succumbed to the importation of Italian Baroque, which became the rage for both public and private court theatres, as opera and ballet became the principal entertainments.

Commedia dell'arte. The most popular public theatre of the late Renaissance was commedia dell'arte, literally, the "comedy of art," as opposed to the "comedy of learning" performed in the academies; it is referred to by some theatre historians as "the rough theatre of the Renaissance." It was not served by theatre building in any formal sense. Bands of strolling players, musicians, jugglers, and acrobats performed in public squares and in the courts, especially at carnival time in Venice, Rome, Florence, and other large cities where they were in great demand. Depending on what was at hand, they would perform on a flat wagon, a bare platform set up on trestles in the public squares, or simply on no stage at all. The technique of the commedia left its mark on acting styles, but it exerted no influence on stage or theatre architecture.

The "rough theatre of the Renaissance"

THEATRE OF THE BAROQUE

The Baroque style, beginning in Italy and spreading across Europe, dominated theatre building between about 1650 and 1790. Its chief characteristics are basically refinements in detail of the proscenium stage and of the Renaissance horseshoe-shaped auditorium and seating plan. As many as five shallow balconies were stacked vertically in the auditorium, but these were more closely coupled with the stage than had been the case in, for example, the Teatro Farnese. For the first time, an orchestra pit in front of the stage, sunk below ground level, made an appearance. At first, these new features were seen in private court theatres; later, they appeared in the large, new public theatres that were built in many capital cities of western Europe. Such buildings parallel the rise of grand opera and ballet, and they reveal a preoccupation with theatrical show and spectacle. Inventors and designers were called upon to provide elaborate, portable, perspective scenery and complicated stage machinery, both above and below stage, to effect scene changes (nearly always carried out in full sight of the audience). Famous names of this period include the Italians Giacomo Torelli and the Bibiena family, whose ingenious settings were unrivalled for originality. A rigid court etiquette dictated that the lines of perspective should provide a perfect stage picture from the point of view of the royal box, which directly faced the stage. Since, moreover, the building of theatres was controlled by the ducal or imperial purse, a rigid architectural formalism, differing only in detail, became the fashion, not to be broken until late in the 19th century. The auditorium was planned in tiers, a vertical stratification that reflected a rigid court etiquette and the ordering of society by class. A good example is the French court theatre at Versailles (1769), designed by King Louis XV's architect, Jacques-Ange Gabriel (Figure 9). For a court theatre, its stage is exceptionally well equipped, mechanized in the manner of the Bibiena family, with an overhead pulley system for flying drops and borders, while the flat wings and shutters making up the elaborate scene were mounted on frames attached to carriages that ran on rails beneath the stage and so could easily be changed. Engravings of the time indicate that the court theatres were used for balls, concerts, and the like, as well as for stage performance. Though of limited seating capacity, these costly little court theatres witnessed the first productions of many operas by composers such as Haydn and Mozart, and they also played an important part in sponsoring the development of classical ballet.

Public theatres. *The opera house.* There were two kinds of theatre in the 18th century. One was a logical

18th-century theatres

development of the earlier private court theatres and was the outcome of a sophisticated, urban, upper class demand for theatre as entertainment. The Teatro alla Scala of Milan in Italy is a good example of the style adopted (Figure 10). Built in 1776–78, it was one of many similar structures erected by 18th-century nobility in the major capitals of western Europe. Public theatres such as La Scala differ from private court theatres only in the size of auditorium and stage. Opera, generally including a ballet, was by this time the most popular form of entertainment, especially in Italy, demanding and receiving the ostentatious kind of production that styled it "grand." Whereas Versailles had seated fewer than 700 in the auditorium, La Scala seats more than 2,000.

The Restoration playhouse. The other kind of public theatre, peculiar to England, was the Restoration playhouse. The Baroque horseshoe-shaped auditorium, with its deep stage and orchestra pit, was generally in favour all over western Europe, fixing the design and style of opera houses, in particular. In it, the actor played in front of elaborately painted scenery and behind the proscenium arch. The Restoration playhouse, however, while borrowing the fully rigged stage of the Baroque theatre, provided, in addition, a deep apron stage thrusting out from the proscenium, upon which most of the action took place. Thus, the actor played, as it were, in the auditorium and away from the scenic backing; the English, with their Shakespearean tradition, were loath to abandon the intimate contact between actor and audience that the Elizabethan theatre had allowed. At either side of the forestage were doors by which actors entered; above these doors were additional boxes, for spectators, stacked one above the other in the Baroque manner.

Influence of lighting and technical achievements. Theatre lighting in this period was provided by wick-fed illuminants concealed behind the wings and proscenium arch and at the edge of the stage apron. In the auditorium either a large, single, central fixture, as at La Scala, or a number of smaller ceiling fixtures, as at Versailles, was the custom. All were kept burning during performance, and the habit of lighting the auditorium persisted until late in the 19th century.

From the 18th century there survives some commentary on the subject of theatre design and construction, notably by the Italian count Francesco Algarotti, the Frenchman Pierre Patte, and the Englishman George Saunders. Algarotti, a diplomat by profession, comments as an interested amateur; Patte and Saunders were dilettante architects, neither of whom actually built a theatre. These treatises, which largely parrot one another, clearly demonstrate their authors' inability to go beyond Vitruvius' naïve technology. Pronouncements on sight lines and acoustics were limited to superficial geometrical details of the prevailing techniques for constructing horseshoe-shaped banked seating. There is no evidence that men of genuine science were at all involved or even interested in theatre problems. It is notable that, despite the intense theatre-building activity, the 18th and 19th centuries produced no innovation in auditorium design and made no significant addition to the basic knowledge of acoustics as derived from Greece and Rome. Another century was to pass before the shape of the auditorium and its relation to the stage was altered and before any real contribution was made toward an understanding of the acoustics of enclosed spaces.

THEATRE IN THE 19TH CENTURY

Theatre design in the 19th century continued the 18th-century horseshoe plan in auditorium design, and until late in the century there were few other changes apart from steady improvements in stage machinery, notably the overhead flying system for handling scenery.

Rejection of the Baroque theatre. There were two major departures from the norm, however. Richard Wagner's Festspielhaus, built at Bayreuth, in Germany, in 1876, and Adler and Sullivan's Auditorium theatre, in Chicago, built in 1889. Wagner's Festspielhaus, designed specifically for the composer's music dramas, is, for its time, an inexpensive brick and timber building in a rural setting. The Auditorium theatre is a massive, masonry-structured, wrought-iron, truss-spanned, multipurpose building for concerts, opera, drama, and other occasions requiring large assembly. It is the first example of an urban theatre as the principal component in a complex modern structure that also accommodates commercial office space and a hotel. Both the Festspielhaus and the Auditorium theatre rejected the Baroque stratified auditorium, returning instead to democratic, classical principles of auditorium design. The seating plan is in the shape of a fan, a belated recognition of the fact that good lateral sight lines are essential for comfortably watching performances on a proscenium stage. Bayreuth is the more radical departure, with a steeply stepped, fan-shaped auditorium in which all seats face the stage. Side boxes, another feature of the horseshoe plan, are also eliminated. At the rear of the auditorium, however, two shallow seating levels remain, the lower of which is divided into nine large boxes. Another striking feature is the absence of any radial or parallel aisle. Access to seating is via side aisles and two vomitory exits only, thereby further concentrating and compressing the main body of seats in front of the proscenium. The stage has a double proscenium, one behind the other, while the orchestra pit is deep and partially covered (Wagner called it "the mystic gulf"), so that the musicians are hidden from view of the audience. This design thus broke away completely from the prevailing seating plan and from the open orchestra pit favoured since the 17th century. It has exerted a powerful influence on proscenium theatre design ever since. Wagner's theatre was at first lighted by gas, both on the stage and in the auditorium. At Wagner's insistence, it was the first theatre to darken its auditorium during performance.

The Festspielhaus at Bayreuth

These new ideas were elaborated by a succession of German architects, principal among them Max Littman, who designed the Prinzregententheater in Munich, the Schiller Theatre in West Berlin, the Hoftheater in Weimar, and, at the turn of the century in collaboration with George Fuchs, the Künstler Theatre in Munich.

Figure 11: The Penthouse theatre at the University of Washington, Seattle, designed by John Ashby Conway; architect Carl F. Gould, 1940.

Further effects of technical achievement. Late in the 19th century, electric lighting was introduced, and, for the first time, stages could be brightly illuminated without the constant danger of fire that had existed while candles, oil lamps, and gas jets were in use.

Studies in acoustics. The problem of acoustics was not studied until the turn of the century, so the architect's chief concern until then was with interior detail and ornament, while his exterior vied for attention in the urban scene with other public buildings, such as churches, city halls, and railroad stations. The overthrow of principles of acoustics stemming from ancient Greece or based on architectural fancy and their replacement by a theoretical explanation of the acoustical field and the resulting mathematical analysis of the acoustics of enclosed spaces was achieved by Professor Wallace Sabine of Harvard University. In 1896 he discovered the reverberation equation, which is the foundation of all subsequent studies in acoustical engineering. Eighteenth- and 19th-century designers and theoreticians had repeated Vitruvius' theories on the subject, adding their own "commonsense" observations, thereby confusing the subject further. These men had been, for the most part, amateurs, whereas Sabine was a professional physicist. His contribution has since been expanded and refined by researchers in the United States, Great Britain, Germany, France, and Denmark. Now, detailed acoustical studies are usually undertaken concurrently with architectural planning before concert halls, opera houses, theatres, and other such buildings are designed.

Sabine's reverberation equation

The Festspielhaus at Bayreuth and the Auditorium theatre in Chicago also have excellent acoustics, which were achieved before Sabine's work. This is attributed to the great care which was taken to provide good sight lines to the stage from all seats and to eliminate all large, concave-shaped architectural elements in the flat-domed, horseshoe-shaped auditorium. Simple, flat, modulated surfaces were favoured instead. Modern acoustical theory since Sabine states that good sight lines are basic to good hearing lines. Scrutiny of these earlier designers' papers reveals no goal other than a desire that spectators should be able to have a clear view of the stage and that

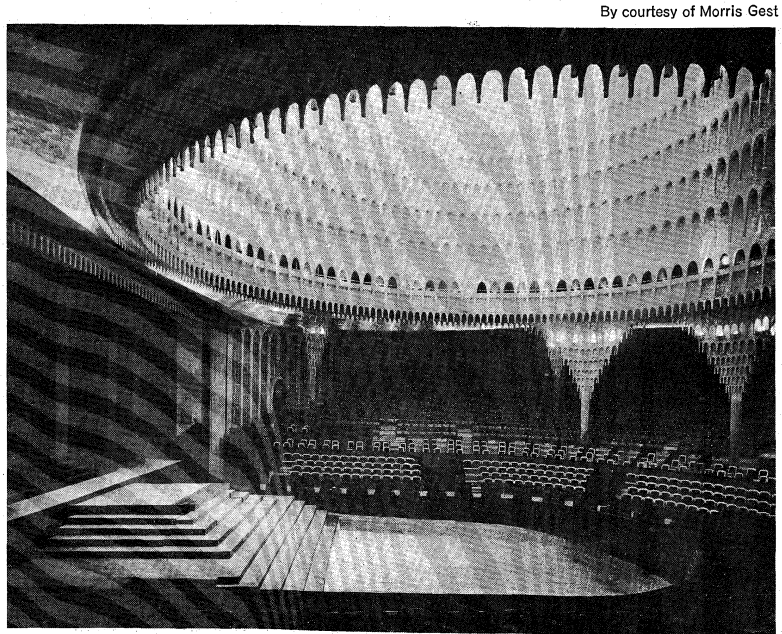

Figure 12: The Grosses Schauspielhaus, Berlin, designed by Hans Poelzig, 1919.

the auditorium design should distract from the performance as little as possible.

Auditorium reform. Theatre history indicates that, by the end of the 19th century, the time was ripe for change. Auditorium reform had already been proposed by German architects, beginning with Karl Friedrich Schinkel early in the 19th century and later by others. Chief among them was Gottfried Semper, who exerted great influence on Wagner and to whom the design of Bayreuth is sometimes erroneously attributed; in fact, a Dresden architect, Otto Brückwald, working with Wagner, is responsible for it. The United States, Great Britain, and France were slow to take up the idea of arranging seating in unbroken continuous rows, now called "continental seating," partly because of rigid interpretation of building codes. The Goodman Theatre at the Art Institute of Chicago (1925) represents the first use of "continental seating" in the United States, but it did not become really popular in the Western Hemisphere until after World War II.

20TH-CENTURY THEATRE: TRENDS IN MODERN DESIGN

Twentieth-century theatre design has followed two principal developments. First of all comes electromechanization of the proscenium stage, mainly for lighting and scenic control but sometimes introducing a flexible, mechanized apron and caliper stages in front of and to the right and left of the main proscenium stage. In these respects, Germany has led the way. Next, there has been an avant-garde movement away from proscenium theatre design altogether. The first manifestations were in France (*c.* 1920), then in the United States (*c.* 1930); they harked back to the open stage of the Renaissance, to the Shakespearean theatre, and, indeed, to the roots of theatre itself. Jacques Copeau was the first to design a nonrepresentational theatre, with Théâtre du Vieux-Colombier (Paris, 1913). Its intimate, architectural, open stage owed much to Palladio's Teatro Olimpico and to the stage of Shakespeare. In the 1920s Gilmor Brown, director of the Pasadena (California) Playhouse, designed a small, unconventional, private theatre (the "play-box theatre") and in so doing provided the United States with its first departure from the proscenium-style theatre. He was followed there by Glenn Hughes, who initiated theatre-in-the-round at the University of Washington at the Penthouse theatre designed in 1940 by J.A. Conway; C.F. Gould, architect (Figure 11). Their lead has been followed by others since World War II, particularly in the educational and regional repertory theatre.

Departure from proscenium-style stages

Perfection of stage equipment. From a technical point of view, the perfection of electric light, its instrumentation and control, has exerted a more profound effect on contemporary theatre design than any other single invention. Stage lighting, as opposed to stage illumination, has now been raised to the status of an art form and has revolutionized stage decoration, stage design, and stage form, in that order. For the first time since theatre moved indoors at the Renaissance, adequate and safe illumination became possible. But, beyond mere function and safety, there is inherent in the medium a flexibility and subtlety that has allowed it to become an integral part of scenic effect and to heighten visual expression for artistic purpose. Early in the 20th century, pioneer work was done by Adolphe Appia in Switzerland and by Edward Gordon Craig in England. Though largely theoretical, it had a profound effect on design of and for the stage. Machinery was invented and instrumentation devised that made practical many of the theoreticians' ideas, and these were adapted by scenic designers, directors, and theatre engineers on both sides of the Atlantic. There was also a movement toward more plastic setting, and an effort was made to free the actor from the restrictions of the proscenium stage. As early as 1890 in Germany, first at Worms and later at the Hoftheater at Weimar, theatres began to incorporate mechanized orchestra-pit apron lifts, which provided a means for altering the point of contact between stage and auditorium (actor and spectator). At the same time, elevators, revolving stages, slip stages, and an expanded and more versatile overhead flying system for handling scenice elements, both flat and plastic, were introduced. All this meant larger backstage facilities, higher fly towers, greater depth and width of stages, and increased understage volume. By World War I Germany led the Western world in mechanized stages and lighting systems, while in the auditorium even better sight lines were achieved and the continental seating system perfected.

Setbacks to theatre building. Between the two world wars the live theatre faced increasing competition for public attention from the cinema, especially in the United States, where a gigantic industry, centred on Hollywood, produced motion pictures for worldwide distribution. The invention of sound on film created a demand for

Competition from the cinema

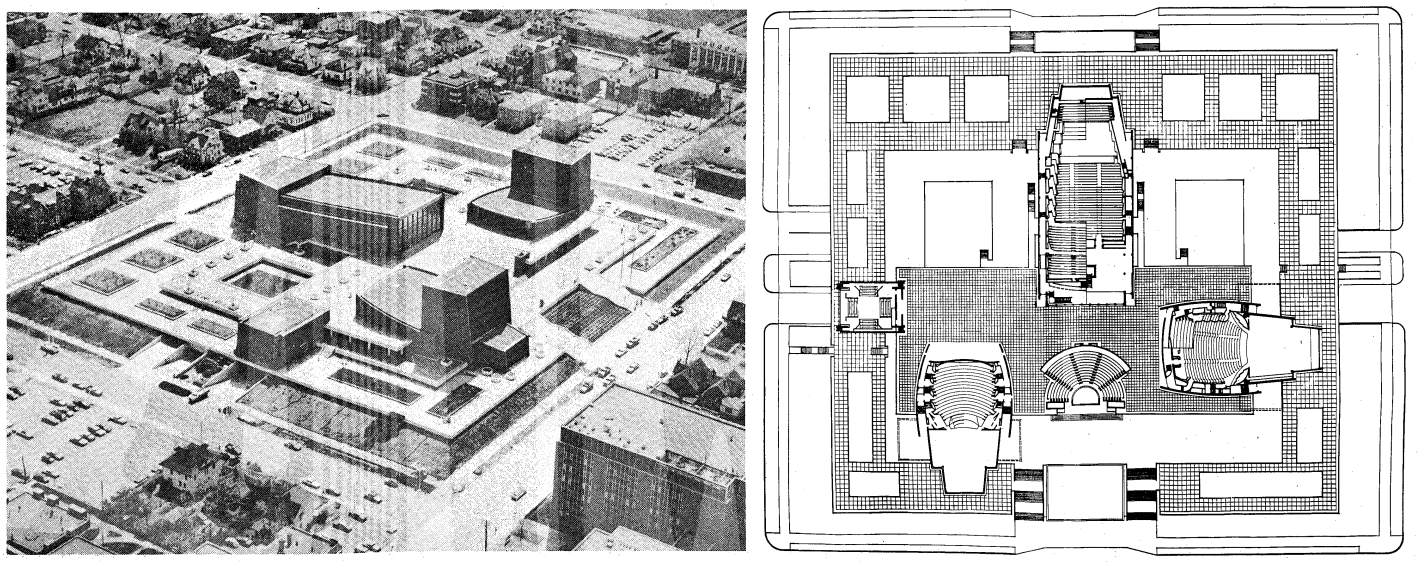

Figure 14: *Multipurpose performing arts centre.*

more cinema theatres with ever larger seating capacities, suited only for showing commercially canned products. As a consequence, professional live theatre in the United States between 1920 and 1940, concentrated in New York City, was greatly reduced in quantity. Touring productions, or "road shows," were drastically reduced in number. Only grass roots movement, beginning in the colleges, in universities, and in the Little Theatre movement of the 1920s, kept theatre alive. During this time the Broadway professional theatre in New York City did not produce a playhouse design or theatre building worthy of note. Theatre building, in New York and other large cities, for the purpose of providing commercial theatre, became the province of real estate speculation. Since World War II, however, there have emerged dozens of municipal and educational arts centres and a number of theatres built under the aegis of the regional repertory-theatre movement, financed by both public and private subsidy or a combination of the two. Had it not been for the educational theatre-building programs carried out between World Wars I and II, theatre building in the United States would have progressed scarcely at all; most contemporary technical innovation has stemmed from there.

German theatre enjoyed a short-lived renaissance between the two wars but produced only one building of note—the Grosses Schauspielhaus in Berlin, designed by architect Hans Poelzig for the director Max Reinhardt, who made early experiments to bring theatre outside the proscenium (Figure 12). Of special note among architects and theatre innovators active on both sides of the Atlantic were Walter Gropius (Germany) and Norman Bel Geddes (United States; Figure 13), both of whom produced theatre-design projects, though neither of them was to realize a building. The economic depression of the 1930s stifled further innovation, and the onset of World War II brought to an end all theatre-building activity on both sides of the Atlantic.

Postwar activity. After World War II, Germany was left with hundreds of bombed-out theatres and opera houses; within 20 years (1950–70) more than 100 of them had been restored to their former state or else had been redesigned and rebuilt along contemporary lines. In Great Britain, the director Tyrone Guthrie advocated a return to the open-stage techniques in his productions of Shakespeare at the Edinburgh (Scotland) International Festival of Music and Dance. Moving to Stratford, Ontario (Canada), and assisted by stage designer Tanya Moiseyevich, Guthrie designed and built the Shakespeare Festival Theatre. This attempted a fusion of the classical auditorium with the stage of Shakespeare. The experiment, with modifications, was repeated in 1963 at Minneapolis, where the Guthrie Theater was especially designed for him to work in. The Guthrie Theater, as indicated in the plan and section, while it is reminiscent of his earlier theatre at Stratford, exhibits a studied asymmetry in plan and section in place of the older theatre's ordered symmetry.

Experimental Guthrie Theater in Minneapolis

German theatre design after the war took up where Littman and others had left off: apron flexibility was further extended. The chief innovator in backstage design and mechanization was Walther Unruh, whose work is exemplified by the Deutsch Oper, West Berlin. Here, the stage is cruciform in plan, employing lifts under the main stage, a trapped revolving slip stage upstage, and slip stages right and left of the main stage: thus, it completes the process toward mechanization begun at the turn of the century by providing means for shifting complete and wholly plastic settings with great speed. The combination of 20th-century engineering, contemporary knowledge of auditorium design principles of sight and sound, and continental seating system makes this building the best modern opera house in the world.

North American initiative. Beginning in the late 1950s, the United States and Canada constructed theatres, concert halls, and a variety of multipurpose facilities by the hundreds, in the greatest theatre building boom ever known in the Western Hemisphere. The two fundamentally opposing conceptions of theatre design—proscenium style and open stage—predominate. The Alley Theatre, Houston, Texas, is a fine example of the more radical school, favouring outright rejection of the proscenium along with its stagehouse and backstage machinery. The building, opened in 1968, houses two theatres: one is a modified thrust stage surrounded by a banked seating limited to a viewing angle of 90°; the other is an arena with in-the-round envelopment of stage by audience.

The opposing school, basing its main design principles on the proscenium form but making provision for an extended apron in front of a proscenium opening, is exemplified by the music and drama theatres of the Krannert Center for the Performing Arts, opened in 1969 at the University of Illinois in Champaign–Urbana (Figure 14). Between these extremes are many buildings that permit the flexible use of space, which can be arranged to mount productions in-the-round, on the thrust stage principle, or with the proscenium-apron relationship to an auditorium. Other buildings, especially those of the educational and regional repertory-theatre move-

ment, attempt a compromise between strict proscenium design and fixed theatre-in-the-round.

Public acceptance of radical departures from the traditional proscenium form was widespread during the 1960s, as private and public philanthropy together backed many successful theatre-building projects. Performing-arts centres began to appear throughout North America, usually sponsored in one of two ways: (1) as part of capital expansion in educational institutions (colleges and universities) and (2) as part of urban renewal by municipalities attempting to revitalize the decaying core of cities. There are either separate buildings for each of the performing arts (theatre, concert, recital, ballet, and so on) or else a single multipurpose building that, by electromechanical means and engineering design, can provide adequate facilities for all types of performance. In the United States, Canada, and elsewhere, gigantic arts complexes to house the performing arts are being sponsored by government and private philanthropy. Examples include the Canadian National Arts Centre at Ottawa, the Kennedy Center for the Performing Arts in Washington, D.C., and London's South Bank arts centre. Practically speaking, an argument can be advanced for concentrating on the building of sufficiently adjustable facilities that can be shared by all the performing arts in turn, and this has been the most outstanding development in theatre design, especially in the United States, since World War II. (An excellent example is the Jesse H. Jones Hall, in Houston, Texas.) Modern knowledge of building techniques, mechanization and control, understanding of room acoustics, and related problems of sight and sound has for the first time in theatre history made this kind of building a striking innovative reality.

BIBLIOGRAPHY

General works: GEORGE FREEDLEY and JOHN A. REEVES, *A History of the Theatre*, 3rd rev. ed. (1968), good, concise, factual information (moderately well illustrated) that places theatre building in proper perspective with theatre in a more general sense; PHYLLIS HARTNOLL (ed.), *The Oxford Companion to the Theatre*, 3rd ed. (1967), standard work on theatre history; ALLARDYCE NICOLL, *The Development of the Theatre*, 5th ed. rev. (1966), the best work in English on the physical theatre by the outstanding scholar of modern times (well illustrated); ROBERTO ALOI, *Architetture per lo spettacolo* (1958), a well-illustrated work on theatre building of all periods, including the cinema (written in Italian but captioned in English); DONALD C. MULLIN, *The Development of the Playhouse* (1970), an excellent student reference work; MARTIN HURLIMANN (ed.), *Das Atlantisbuch des Theaters* (1966), a collection of essays in German by recognized authorities in all branches of theatre including architecture, stage mechanics, and stage design among others (well illustrated); A.M. NAGLER, *Sources of Theatrical History* (1952), the recognized work in English for original source material in all branches of theatre.

Ancient theatres: MARGARETE BIEBER, *The History of the Greek and Roman Theater*, 2nd ed. rev. (1961), a profusely illustrated work by the recognized scholar in the field—translated and expanded from her earlier work in German (excellent for students because of its direct style of writing).

Medieval theatre: E.K. CHAMBERS, *The Mediaeval Stage*, 2 vol. (1903), an out-of-date but most exhaustive treatment of the subject, with a good bibliography.

Renaissance theatre: ALLARDYCE NICOLL, *Stuart Masques and the Renaissance Stage* (1937), excellent and exhaustive for advanced students interested in the fine points of scholarship of a difficult period in theatre history; GEORGE R. KERNODLE, *From Art to Theatre* (1944), interesting light on the subject of royal entries—also on pagentry, showing its derivation in the fine arts; A.M. NAGLER, *Theatre Festivals of the Medici, 1539–1637* (1964), profusely illustrated, footnoted, and cross-referenced from original documents of the period (not for beginners); CYRIL HODGES, *The Globe Restored* (1953), the best conjectural restorations of all the theatres of Elizabethan England, including excellent drawings and exhaustive graphic treatment of the subject.

Baroque theatre: JOHN L. HOTSON, *The Commonwealth and Restoration Stage* (1928), the best treatment of the period (illustrated); MARGARETE BAUR-HEINHOLD, *Theater des Barock* (1966; Eng. trans., 1967), the best work in English on this period, beautifully illustrated, much of it in colour, with excellent chronology and bibliography; PER BJURSTROM, *Giacomo Torelli and Baroque Stage Design* (1961), complete documentation, literary and graphic, of one of the most prolific of the Baroque theatre designers; GIULIANA RICCI, *Teatri d'Italia* (1970), a beautifully illustrated work on Italian opera houses and their origin; A.M. NAGLER, *Shakespeare's Stage* (1958), a compilation of all the facts concerning Shakespeare's theatre.

19th- and 20th-century theatre: EDWIN O. SACHS and ERNEST A.E. WOODROW, *Modern Opera Houses and Theatres*, 3 vol. (1896–98, reprinted 1968), an exhaustive treatment of the subject, including drawings in plan and section—the definitive work on theatre-building activity of the century; MAXWELL SILVERMAN, *Contemporary Theatre Architecture*, with a checklist of theatre architectural publications (1946–64) by NED BOWMAN (1965), an excellent (but not critical) record of contemporary theatre building for general use—mostly photographs and drawings; J. MIELZINER, *The Shapes of Our Theatre* (1970), a good work by a famous designer of scenery; G. CALLWEY, *Theaterbau Aufgabe und Planung* (1968), an excellent short work that gives a good conception of German theatre building since World War II; WALTHER UNRUH, *Theater technik* (1969), a German text by the acknowledged master of the German stage and its engineering (good illustrations); HAROLD BURRIS-MEYER and EDWARD C. COLE, *Theatres and Auditoriums*, 2nd ed. (1964), the best work in English on theatre building in North America—designed as a handbook for architects and students; TYRONE GUTHRIE, *A New Theatre* (1964), a personal account of the building of the Guthrie Theater by its founder and artistic director; WALTER R. FUERST and SAMUEL J. HUME, *Twentieth-Century Stage Decoration*, 2 vol. (1927, reprinted 1967), the best general work detailing continental stagecraft and buildings of the period after World War I and before the 1930s.

(G.C.I.)

Theatrical Production

Any work presented to an audience at a particular time and place by living performers using themselves as the medium of presentation can be described as a theatrical production. The term theatrical production in general refers to the process of planning, rehearsing, and presenting such a work.

Dramatic and nondramatic theatrical production

A theatrical production can be either dramatic or nondramatic. Whether it is the one or the other is determined by the kind of activity presented. It is often assumed that the distinguishing feature of drama is a written text; in fact, it is the fictional mimetic (from Greek *mimēsis*, "imitation, representation") nature of the performer's behaviour that makes a work dramatic. Thus, a person who walks a tightrope is performing an acrobatic act. A person who pretends to be an acrobat walking a tightrope is performing a dramatic act. Both performers are engaged in theatrical presentation. The difference between them is the difference between actual and illusory activity. Though a dramatic performance may include dancing, singing, juggling, and other nondramatic acts, it is mainly concerned with representing actual or imagined life.

In nondramatic theatrical presentation, on the other hand, there is no imitation of "another existence" but simply the pleasure or excitation of one human being by another. Whether acrobatic or musical, gestural or vocal, nondramatic activity is theatrical because it is presented by a living performer to an audience. But it remains nondramatic so long as it has a purely presentational quality rather than a representational one.

In any single theatrical production, one or another type of activity may so prevail that there is little difficulty in determining the aesthetic nature of the final work. A play by the 19th-century Norwegian dramatist Henrik Ibsen, with its depiction of middle-class behaviour, minimizes nondramatic activity; the recital of a song by the 19th-century Romantic composer Franz Schubert, by contrast, with its emphasis upon musical values, may ignore dramatic elements and, to a great extent, even the act of presentation itself. Between these extremes, however, there are many types of theatrical production where the aesthetic is not so simple to determine. Opera brings into relief the tenuous line between dramatic and nondramatic presentation, for in opera it is sometimes the dramatic values that are stressed and at other times the musical.

A further complication is the mixed nature of many theatrical productions. Within any one presentation, for

instance, dramatic and nondramatic material may alternate. Vaudeville, or music hall, employs a succession of fictional sketches, musical and dance numbers, feats of dexterity, and other acts some of which are representational, others not. This variety is also characteristic of the Oriental stage, where dramatic moments are elaborated into dance-like exhibitions. Given this perspective, the definition of what constitutes "theatrical production" must remain elastic. The present article first examines the chief elements of theatrical production and then some of the ways in which these elements have at various times been combined to create distinctive kinds of theatrical production.

This article is divided into the following sections:

I. Elements of theatrical production
The performer
Space and time
Arrangement of performer, space, and time: the principle of contrast
II. Methods of theatrical production
The piece and its performance
Collaboration of participants: preparing and rehearsing the piece
III. Kinds of theatrical production
Kinds according to their nature
Kinds according to occasion and purpose
Kinds according to system of production
Kinds according to the controlling artist
Kinds according to style
IV. Theatrical production as a coherent art

I. Elements of theatrical production

The central feature of a theatrical production is the living performer. There are, of course, many theatrical-like presentations, such as architectural and lighting displays, in which the performer is virtually eliminated, but these are occasional and special kinds of entertainment. In the main, theatrical production—whether it involves one person speaking directly to an audience in a nightclub or an ensemble of actors half-enveloped by scenery and viewed by spectators in a playhouse—has certain common elements: the living performer or performers, his or their acting in space (a stage of some sort) and time (a performance of some limited duration), and a producing process and organization.

The common elements

THE PERFORMER

In nondramatic theatre, the performer's nature is entirely his own. He presents his work in his own person and to an audience that exists in the same time and space as he does. This is true of the acrobat, the magician, the rock 'n' roll singer, the orator, and many other performers. By comparison, the dramatic actor exists in two worlds. He presents himself as a performer who is aware of an audience and sharing time and space with it. But the dramatic performer also presents himself as an actor of fictitious events and responses, as though living in another place and time. All dramatic theatre necessitates the double presentation of actor as performer and of actor as character.

Relation to the audience. Whether dramatic or nondramatic, the performer attempts to astonish the audience in some way, for an audience will observe him only so long as he offers an unusual spectacle. This is especially evident in the circus. When a freak of nature is exposed in a sideshow, the wonder, of course, resides in the performer himself. But more often the circus performer presents acts that are uncommon, acts that the average person in the audience cannot emulate. These may be acts of dexterity, such as tumbling, or of daring, such as lion taming.

Allied to the presentation of these uncommon feats is the enactment of a more ancient type of wonder: sympathetic magic. For some historians the roots of theatre are to be traced to such enactment. Ritual in form and secret in manner, the performance of traditional tribal acts had the double purpose of binding the collective and invoking hidden powers. Whether dance or mime or song, the actual behaviour was a means of releasing or manifesting forces that had to be approached with awe and caution. Something of this magical property attaches to every theatrical performance.

On a third level, there is a type of wonder induced not by the unusualness or secretiveness of the performance but by its degree of perfection. In performance an actor or singer stirs admiration not so much by the rarity of the act (although that may be a factor) as by the quality of his rendition. This is somewhat different from the tumbler who, though graceful in movement, stirs response by the feats he can accomplish. The more naturalistic performance of actors, being inherently less wondrous, must compensate by being aesthetically more pleasing. The performer who presents more or less ordinary behaviour is likely to lose his audience's interest, a danger that is often circumvented by the content of the material he performs. Drama presents bizarre or extreme acts: the murder of husbands, the debates of gods, or the mistaken wooing of lovers. In the 19th century, when drama began to discard the more bizarre, melodramatic situations that had formerly been much presented, it substituted material that was calculated to shock or attack the audience, either because it was subject matter generally regarded as unsuitable for public presentation or because the material embodied social attitudes uncongenial to most of the playgoers. However the actor manages it, then, through the strangeness of his acts—the mystery they involve, the beauty they express, or the challenge they convey—the performer must work to provoke a response of wonder from his audience.

Impulse to create astonishment

Along with the impulse to create astonishment, the performer has an opposite impulse to display familiar acts. This is less true of the nondramatic performer than it is of the dramatic. Whereas the acrobat or the conjuror may deliberately, in a showman-like manner, seem to falter and thus remind his audience that they share a common frailty, this side of his act is of minimal importance. In drama, on the other hand, it is a very necessary part of the presentation that some features of recognizable behaviour be displayed so that even the most grotesque happenings find some echo in the audience and engage its sympathetic recognition and understanding. This may be done through familar events, emotions, allusions, or characters. A chorus provided the link between the familiar and wondrous in Greek tragedy. Secular interludes and miraculous events were combined in the medieval mystery play. Whatever the mixture, however, aspects of the strange and the familiar are present in every drama.

Skills and attributes. Occasionally, the performer himself can initiate a new style of presentation, but more frequently the demands of his times dictate the skills and attributes he must have. Skills include the specific physical and vocal behaviour that the performer can control and produce at will, such as a dance step or a facial reaction. Attributes refer to aspects of the performer's presence, which he projects to the audience but which he may or may not be able fully to control, such as degree of intensity. Certain performers are required to develop what may be a strictly limited skill (flying the trapeze or juggling balls) to a high pitch of proficiency. They systematically cultivate the necessary physical and temperamental qualities for performing such a traditional act, and, if able and talented, they may transcend its conventional features to create variations or elaborations. Success in this kind of nondramatic presentation, however, is not dependent upon skill alone. Showmanship —a broad term that describes any one or more attributes of personality, such as audaciousness, humour, charm— is equally necessary.

The high degree of physical skill associated with nondramatic performance can sometimes be found also in drama, particularly in the drama of East Asia. Chinese opera and Japanese drama alike require the actor to play one type of role for his entire professional life. He must play this role in a manner strictly determined by tradition, reproducing specific patterns of movement and speech that he can only master by first gaining control of complex and arduous physical skills. Later, if he is especially gifted, he may bring to his role certain refinements

The role of the actor in the Orient

of the tradition, and these refinements he hands down to a succeeding generation.

Western drama, however, does not usually provide the actor with quite so defined a repertory of movements and utterances. It is true that actors in the Italian commedia dell'arte specialized in one role and transmitted to their successors a body of situations, speeches, and *lazzi* (stage sketches, or routines). But, nevertheless, they seem to have had more leeway than their Oriental counterparts in exercising invention and expressing personal attributes. Great rhetorical skill has been demanded of the Western actor, however, for the metrical rhythms of Greek, Latin, French, English, and Spanish drama are intricate and were part of the glory of their respective theatres.

Naturalistic theatre, which flowered in the late 19th century, made rhetoric obsolete, and it expected the actor to hide his virtuoso performing skills by creating the illusion of everyday behaviour. This meant that more weight was given to the actor's attributes. Instead of exercising his personal magnetism through patterned behaviour, he had to do it through intense personal revelation. Among his attributes the actor counts a marked ability to focus his energies, to concentrate intently either upon the audience directly or upon a fellow actor and, thereby, indirectly upon the audience. All good actors, whatever their other limitations, can in one way or another project a concentrated force. This power of concentration became increasingly important to the actor in performance as set patterns of playing disappeared.

Actor as performer. In nondramatic theatrical production the performer invariably acknowledges the presence of the audience. He plays directly to it. In dramatic theatre, on the other hand, the actor may or may not recognize the audience as audience. In Greek Old Comedy, an actor speaking for the author would at one point of the play cajole, advise, or challenge the spectators. By contrast, the naturalistic actor plays as though a fourth wall separates him from the audience. Between these two extremes fall a variety of relationships. At times, although direct contact is made, the audience is itself assumed to be playing a role, as in trial plays where the audience is treated as a jury or as spectators in the court of justice. At other times, the actor may address the audience one moment and play as though there were a fourth wall the next.

The nature of the actor's place and role

The quality of the contact between performer and audience is subtly modified by the nature of the performer's place and role in society. In the broadest terms, the performer may be seen as a celebrant, servant, or critic of society. As a celebrant, the actor performs a priestly function. In fact, at some points in history, he was a priest. He thus mediated between the audience and its faith. In Greek tragedy, Japanese Nō, and medieval mystery plays, the performer enacted quasi-religious actions. But the actor as celebrant need not be a "priestly" figure. Equally, the celebrants were the magnificent star performers of the 19th century, such as Sarah Bernhardt, who proved to be the apotheosis of Bohemian romanticism.

More often, the actor has been a servant, allied to the court jester and household retainer. In classical Rome he was a slave or lowly freedman. In Elizabethan England he was nominally a great man's underling or, if he lacked the protection of the nobility, was classified as a rogue and vagabond. Consequently, direct contact with the audience was invariably couched in supplicatory terms.

It was not until the 19th century that the actor as a rebel began to appear. Performing in plays critical of society, he himself addressed the audience indirectly and so avoided committing himself to the plays' views. But with the 20th century, direct assault on the audience occurs. Troupes such as the Living Theatre from the United States and writers such as the Austrian dramatist Peter Handke (one of whose plays is known in English as *Offending the Audience*) castigate the audience deliberately in order to force its members to choose sides in a sociopolitical struggle.

Actor as character. The second aspect of the dramatic performer's work has to do with mimesis, or representation. He is actor as character. In this sense, "character" includes both the enactment of representational behaviour and the portrayal of human types. In enacting representational behaviour, the performer adopts a fictional framework and acts according to his text's demands. When playing Macbeth, for instance, he behaves "as if" he sees the phantom dagger referred to in the text. Working carefully in rehearsal, he correlates selected gesture and vocal delivery with his sense of the character's internal processes in order to produce an image of Macbeth vainly endeavouring to grasp the dagger. In portraying character, the actor must often work within established categories of stock or generic types. Roman comedy, for instance, utilized a limited number of stock characters (including the cunning slave, the passionate young lover, the suspicious old father). The generic type is less specific in behaviour and sentiment than is the stock character. The king, the wise counsellor, the raging tyrant are examples coming from historical and biblical sources; the leading man, the juvenile, the ingenue, and the villain are examples from theatrical tradition itself.

Characters in "slice-of-life" drama

Some characters, however, do not stem from tradition but are native to a particular playwright. This is especially true in naturalistic "slice-of-life" drama, which modelled its roles on field observation or personal experience. Stock and generic types stressed those features of personality common to human beings. Naturalistic drama, however, sought to particularize each role in order to stress what separates one individual from another. At the same time, comprehensive theories of acting were evolved, notably those of Konstantin Stanislavsky, who was director of the Moscow Art Theatre. While the actor might start with a given "type" of the most general sort (a country doctor, for example), his efforts during rehearsal were bent on differentiating this doctor from any other. Directors encouraged external observation and internal probing as techniques to enable the actor to create a character whose behaviour is idiosyncratic and drawn from experience. This style of acting demanded extensive preparation, with the result that lengthy rehearsal periods of from six months to a year became the ideal.

Naturalistic acting raises questions about the relation between the actor's self and the role he performs. Does the actor merely simulate behaviour or does he experience the passions and thoughts of the character? Central to the actor's art though this question is, it has never been satisfactorily answered. Some theorists say that the actor must blend his own personality with features called for by the role, using techniques of emotional recall and psychological probing. Others say that the actor ought to rely upon his physical technique in order to create an illusion of life.

SPACE AND TIME

The distinction between actor as performer and actor as character is matched by a distinction between the presentational and representational nature of space and time in theatrical production.

The playhouse area. As a matter of geographical fact, performer and audience exist together in a common area. Within this common area there is a clearly delineated performing space (ring, stage platform, pit) and an audience space, the two structurally related. Some of the more common patterns of relationship are (1) an amphitheatre, with a bank of spectators half surrounding a playing area; (2) a circle of spectators standing or sitting about a ring in which the performance takes place; and (3) rows of seated spectators facing a raised platform. Theatre space is often associated with a special building, but this has not always been the case, nor is it always the case in modern times. Often theatre space has embraced a town square or even an entire town so that performers and audience are able to mingle. Modern attempts to create a space within which the distinction between performer and audience is blurred (called environmental theatre) echo earlier examples from the popular theatre.

Division of audience and performers

Isolation of performer. Yet, despite the innumerable variations in the form and use of geographical space in the theatre, it is possible to discern two conditions that all

productions endeavour to meet. First, every production seeks to impart a special quality to the theatrical area. If a theatrical building is used, that in itself may provide a heightened sense of locale. Otherwise, special decoration of familiar locales (town, market square) or procession through them might transform them into ceremonial or festive spaces. Again, the urge to create wonder is at work. Next, every production tries to make the performer visible and audible to the audience. This is largely a practical matter. On flat ground, the circle or ring has often proved to be most efficacious. In hilly country, the amphitheatre is the readiest solution. When a playing area is to be permanent, some means of raising the performer above the level of the crowd is often introduced, such as boards laid over trestles. The degree to which the performer is to be isolated depends partly on how complete and detailed a view of the presentation the audience expects.

The isolation of the performer has, however, another property. Marking out a playing area was often a religious act: in classical Greece, for instance, the dancing circle surrounded the altar of the god Dionysus. Thus, the performing space had a symbolic character. Even when the direct religious tie was broken, stepping into the ring or onto the stage was still regarded as a passage from one world into another, a world of magical or spectacular properties. This is equally true of the sawdust ring of the circus and of the bare boards of the trestle stage. Existing traditional theatres, especially those of the Orient, still regard the act of preparing to go on stage (putting on makeup, for instance) as sacred. Because of this, the isolation of the actor is more than utilitarian; it is transformational. He becomes greater than life.

Illusion of place. In dramatic production, this geographical space takes on another dimension, a behavioral character: the magical property already belonging to it as a performing area is further augmented by the fictional action that now takes place. The stage becomes another locale by an act of imagination in which both actors and audience participate. It may be done simply, by speech: at the opening of a scene in *Twelfth Night*, one of the characters asks "what country, friends, is this?" and is told "this is Illyria, lady." Thus, the subsequent action is set firmly in the context of Illyria. It may be done visually, by the designer's ingenuity (the audience sees a room or a garden). The actor as character inhabits not the theatre but Illyria, the room, the garden. Although the audience may not be deluded into believing that it inhabits another place, it does gain a double vision. Its focal attention is fixed on the hypothetical locale, while its peripheral attention is fixed on the performing space. Apparently, though how it is not clear, human beings can sustain such paradoxical perception.

Transformation of locale through the actor's speech

There are varying degrees to which the geographical or behavioral property of space dominates in any one theatrical production. In some productions, especially those that are inspired by the anti-naturalistic theories of the Russian director Vsevolod Meyerhold, the audience is constantly reminded that it is in a theatre. Naturalistic productions, in contrast, following the principles of Stanislavsky, put greater stress on behavioral space and encourage a clear distinction between performing area and viewing area. On the other hand, the theatre has often reconciled the paradoxical features of dramatic space. The Greek theatre combined the actor's platform with a more public dancing circle that gave ready access to an amphitheatre of seats. The 18th-century English stage moved out from a recessed picture of a representational locale to a projecting apron that merged with the auditorium. In both examples, the theatre found a physical convention for fusing geographical and behavioral space and for mediating between the actor and the audience.

Real and illusory time. Time likewise has a dual character in drama. The performer and audience exist together in chronological time. But the actor as character exists in a behavioral time that is generally different from the chronological time. Neoclassical drama of the 17th century, especially in France, endeavoured to make the duration of play going (chronological time) coincide with the duration of a play's action (behavioral time). But, as a rule, drama has achieved its effects by accentuating the discrepancy between "real" and "illusory" time.

On one hand, the performer projects a sequence of activity upon which the audience concentrates intensely. Because it is difficult to maintain full attention over very long periods, it must be modulated; that is, stimulated, relaxed, and stimulated again. Contrast and suspense give spice and direction to the audience's awareness of passing moments, thereby making the "real" time spent at a performance absorbing and deeply felt. These performing experiences are further heightened by the illusion that another time scheme is also operating, that of the fictional event. Some drama gains its effects by suggesting that chronological and behavioral time differ between scenes but not within scenes; that is, months may pass between Act I and II of *Three Sisters* by the Russian playwright Anton Chekhov, but within any act the time scale in which the actor as character exists is exactly the same as that in which the actor as performer operates. Shakespeare, however, presents a scene in *Othello* (Act II, scene 2) that takes about 25 minutes to play, yet during this scene an entire night has supposedly passed. One of the most extensive temporal schemes in drama is to be found in the medieval cycles of miracle plays, which unfolded over a period of two to four days and which covered the history of the universe from a time before Genesis to the Day of Judgment yet to come.

In contrast to this awesome inclusion of all time is the handling of time in Japanese Nō drama, in which "real" time, with its inevitable passage, is retarded to create a sensation of timelessness. The deliberate pace of the performer, the reiteration of the drum, and the unchanging facade of the stage all contribute to this impression. Here, again, the audience's awareness of real time passing accentuates the meaning of illusory time.

Deliberate slowing of time in Japanese Nō drama

ARRANGEMENT OF PERFORMER, SPACE, AND TIME: THE PRINCIPLE OF CONTRAST

The fundamental elements of theatrical production, then, are performers and their activities, the space they fill, and the time they define. The aesthetician Suzanne Langer, in her book *Feeling and Form* (1953), describes how they are arranged to produce an effect of the imminent future, and, indeed, one of the liveliest feelings that drama can excite is that of expectation. In its more obvious manifestation such expectation is experienced as suspense. But imminence as a sensation exists in the spectator; the organizing principle that stimulates that sensation is contrast.

Being a temporal and spatial art, theatre employs both temporal and spatial contrast. A scene that builds from expectation of a crisis, through the crisis, and into the denouement exhibits temporal contrast. This contrast is experienced as degrees of intensity. A scene that reveals a prince dressed in black amidst a festive court, as in *Hamlet*, illustrates spatial contrast. In the composition of any presentation, theatrical production employs a mosaic of contrasts—dozens of temporal and spatial fragments are deliberately organized to create a total impression. The trapeze artist employs a spatial contrast (balance and imbalance) and a temporal one (a preliminary easy feat and a difficult finale). A play offers contrasts between one character and another, between actor as performer and actor as character, between actor and scenic space, and between a topical allusion and the audience's social awareness (all spatial). It also offers contrasts between the intensity of one moment and that of another, between the actor's appearance from one scene to another, between what a character thinks will happen and what an audience has been told will happen (all temporal).

Contrast, of course, is a principle of all art. Theatrical production, however, stresses its own peculiar contrasts, those between the fixed and the dynamic (static space and moving actor), the visible and the invisible (the actor's words and gestures and the character's thoughts and feelings), the actual and the fictional (what the actor does and what his acts represent), and finally the possible and

the impossible (an actor as character presenting the dead Romeo and the actor as performer being alive and well). It is by the artful manipulation of these contrasts that theatre produces its effects.

The principle of contrast in the cinema

The cinema, which is often mistakenly thought of as another theatrical form, shows quite a different handling of contrast. The fusion of the possible and impossible in the same act no longer obtains. Film is hypnotic; what is shown can be—in fact, exists, even if only as an image. Initiative shifts from the performer to the viewer; that is, to the camera's eye. In theatre the performer has to assert himself in a defined space. His energy, directed at the spatial frame, fellow performers, and the audience, shapes the performance. In the cinema this energy belongs to the lens. Its gaze, its shift of attention, its opening and fading play upon the surface of nature and of man as part of nature. Instead of emphasizing the essential contradiction of man's condition, which is so much a part of theatre, cinema harmonizes place and person within its visual frame. On film, only the expert technical eye can usually distinguish location from studio shots. Wherever the lens turns seems to be part of a unified sequence of viewing. On stage, no matter how skillful the scenic artist may be, the audience is aware of the tension between reality and appearance, a tension that does not exist in film, where all elements of the frame express a single visual reality.

Because the cinema's popularity has helped to reduce the amount of theatrical production, it is often asserted that the cinema is superior to the theatre as a performing art. But this superiority only applies to certain aspects of storytelling—those involving man's adventures, for instance. Storytelling is common to several literary and performing arts. The novel nurtures an interior sensitivity to unfolding events that is not quite shared by either theatre or film, while theatre fosters narrative dependent upon a character's assertiveness. Ultimately, it is not the superiority of one medium's stories to another that is pertinent but the distinctiveness of one mode of storytelling from another.

II. Methods of theatrical production

Aesthetically, the theatrical production of drama appears to involve autonomous persons enacting a fiction. The preparation and execution of a production, however, require the coordination of many individual contributions. These contributions may be discussed according to the people involved (actors, dramatists, designers, and so on) or according to the functions performed (devising a piece to be performed, playing the action, providing a theatrical setting, and so on). Theatrical personnel and their division of responsibilities have varied widely in the course of theatrical history. Function, however, tends to remain fairly constant.

THE PIECE AND ITS PERFORMANCE

Scenario or script. Traditionally, the dramatic piece has always been planned in advance and rehearsed, although there are degrees of advance planning and rehearsal. The theatre of the commedia dell'arte was basically impromptu. Nonetheless, it involved considerable preparation of constituent elements, such as character type, set speeches, and highly polished routines, even though the exact sequence and interplay of these elements would vary from performance to performance. Contemporary "happenings" reduce advance planning to a minimum but do not eliminate it completely. Normally, however, advance planning is so extensive that it appears in the form of a written script, perhaps devised by the actors, perhaps created by a single dramatist. Depending on the writer's involvement with the actors and the theatre as a whole, the script may be either a tentative prospectus for a piece to be created in rehearsal (a scenario) or a fairly finished blueprint of the final presentation (a play).

Whether scenario or play, a piece consists of segments of activity arranged in a meaningful sequence. More often than not it is a narrative sequence, and thus each segment of activity presents a step in the unfolding of a story. But the sequence may also be based on a common motif or recurrent characters. The segments of activity, usually termed episodes or scenes, can include many kinds of behaviour—such as persuasion of one person by another, delivery of a speech, singing of a song, engaging in hand-to-hand combat. According to the conventions of a theatre and the genius of its creative artists, dramatists and actors alike, these activities assume distinct form.

Determining the scope of the material

To a significant extent, theatrical tradition and social practice determine the scope of the material to be presented. In the theatre of ancient Greece, for example, legendary stories provided a fictional framework for its tragedy, while episodes of debate, lamentation, prophecy, and choral comment constituted the main activities. In other theatres, storytelling, singing, acrobatics, as well as a wide variety of passionate speeches make up the presentation. In short, the ingredients of a particular theatrical production already exist in the playing tradition. Whoever performs the function of maker of the piece (dramatist, manager, actor) operates within that context of performing routines and production conditions. With these he perhaps fuses material drawn from other arts (poetry, dance, architecture) and from other more personal experiences. While in the process of devising the piece, he may work closely with his fellow artists or he may compose the piece privately and leave its execution to others.

Relation of production to occasion. The nature of a theatrical production and the way in which it evolves are governed by the nature of the occasion for which it is presented. The occasion may exist prior to the theatrical production and give rise to it, or the production may be prepared in the expectation of finding an occasion for its presentation. Annual festivals, such as the Dionysia of ancient Greece or Corpus Christi in medieval Europe, are examples of established occasions that predate any specific theatrical production. Other such ready-made occasions may be civic or aesthetic in purpose rather than religious. Yet all normally possess social agencies that subsidize and, in part, manage production. There are also special events, such as royal entries or marriages, that provide unique occasions for some sort of production. When the occasion already exists, the type and subject matter of a production are frequently selected to glorify an accepted social and aesthetic ideal.

Commencing with the Renaissance, there developed a professional theatre of the marketplace. Productions were offered in large population centres or were taken to villages and towns where a potential audience already existed. With a shift from theatre devised for an independently existing occasion to speculative theatre, seeking to create its own occasion, there is a shift from a communal to a cosmopolitan audience. Instead of presenting plays at times that inherently held sacred or civic meaning and, therefore, drew together the entire populace, actors presented plays with some regularity and frequency in order to attract a public large enough to support them. Instead of fulfilling a recognized social purpose, the theatre had to justify itself and persuade people to attend by providing novelty and excitement.

Performing the piece. Occasion naturally determines the exact role of the actor with regard to his audience. Not only does it affect the manner in which the actor addresses the audience or represents a character, but it also influences the physical appearance of the actor. As a religious official or as descendant of a priest, a status belonging to performers in Japanese Nō drama and in the tragedy of classical Greece, the actor is often transformed by costume into an extrahuman or superhuman figure. Raised headdresses, painted or masked faces, enveloping robes, all contribute to the creation of a daemonic figure. As a servant, however—the status actors held in Elizabethan England—he often apes the master, playing the role not of hero or demigod but the epitome of contemporary society. Whatever the adornment, however, the actor's appearance is intimately connected with his social role, the image portrayed fulfilling audience expectation.

Earlier it was noted that the actor is the central figure in

theatrical production, and indeed it is true that, while performing, he is the focus of attention. During the preparatory and rehearsal phases of production, however, he may be a subordinate. In the Renaissance, for instance, the actors themselves were in control of all phases of production, but with the coming of capitalism they yielded the reins to theatrical managers and, much later, to stage directors. Ultimately, they discovered that, if nonperformers control the production process, the performer's spontaneous interaction with the audience becomes subordinate to a prescribed scheme.

Transforming the performance area

The importance of stage scenery in theatrical production is determined by the degree to which either the auditorium or playing area needs to be transformed for or during a performance. Four possibilities exist: little or no change is introduced into either area (as in the Elizabethan public theatre); the playing area remains unaltered while the audience area is changed (as in erecting banks of seating in a town square); the playing area is changed while the audience area remains fixed (as in proscenium theatre); both areas are transformed (as in Renaissance court theatre and contemporary environment theatre).

The fixed playing space often has greater or lesser emblematic significance. In Japan, the Nō stage had three pine trees symbolizing heaven, Earth, and man; the kabuki stage employed the convention that the right-hand side is more eminent than the left; the Elizabethan playhouse used trap doors for heaven and hell. The practice of changing the visual and physical arrangement of the playing area became widespread during the Renaissance. At first, designers generalized the correspondence between play and setting by devising scenery appropriate to tragic, comic, and pastoral dramas. Later they created a setting unique to one play alone. With the emergence of designed space and changeable scenery, there arose an entire profession of scenic architects and mechanics whose work at times overshadowed that of the actors in importance. By the 20th century the designer's task became so complex that it was often divided among scenic, costume, and lighting personnel and involved technicians, electricians, stagehands, prop masters, wardrobe mistresses, and many others working together.

COLLABORATION OF PARTICIPANTS: PREPARING AND REHEARSING THE PIECE

Because it is a public art, theatre is buffeted by many forces external to the artistic process. Moreover, that process is itself subject to internal strain as various contributors to a performance strive to achieve their individual goals. Clashes of temperament are not unusual, and, given the intensity and intimacy of theatrical work, this is not surprising. Yet there are striking instances of close, harmonious, and enduring collaboration among theatre people.

No single pattern for production exists. There are too many social and personal variables at work during planning and rehearsals. What may be the procedure in one case or at one time may not be of use in another. Certain broad observations may be made, however.

First, any individual production is normally, though not invariably, part of a more continuous enterprise. The continuity may be provided by the civic or religious life of the community, the stable association of an acting troupe, the permanence of a producer's office, some other element, or a combination of these. Whatever it may be, it influences and even determines the mode of planning a production, conducting rehearsals, and giving performances.

Next, the production process tends to be either cooperative or hierarchical. True cooperation is rare, and there are few instances in theatrical history when it existed. The company for which Shakespeare wrote and to which he belonged seems to have been one of those rare collectives. A partnership of actors, it remained for more than 25 years a well-knit community of professional associates and friends. More usual is the hierarchical organization. Whether by force of talent, right of possession, or exercise of authority, a single individual takes the initiative and controls a production. In most instances, the professional speciality of that leader is dictated by conditions of the particular theatre in which he works. In 17th-century France, for instance, the leader virtually had to be an actor (Molière was an actor turned actor-manager-dramatist); in 20th-century America he virtually has to be a producer or director.

Finally, the mode of planning and rehearsing a production may be influenced by the artistic concept of an individual or a group. As long as theatre was part of a continuing tradition, its mode of production varied little. The mode was partly conditioned by the social role of theatre and partly by the type of material the actor performed. Thus, the actor who played one type of role for his entire professional life concentrated on perfecting recurrent stage routines, while the actor who handled many different roles within a brief season had to work rapidly and with facility.

19th-century theories of production

New theories of production evolved during the 19th century that affected both styles of performance and methods of rehearsal. Gradually, the idea of ensemble arose, an ensemble that stressed harmony of ideal and craft among the actors and between the actors and the stage environment in order to achieve a unity of effect. These ideas necessitated the careful orchestration of all elements of production. In the 18th and earlier 19th centuries, the charismatic figure was the star actor; it then became the star ensemble (the Moscow Art Theatre, for instance) and, through the ensemble, the director.

III. Kinds of theatrical production

The development of telecommunication and the complications of international relations have extended horizons in every field of art and science, including theatre. Not only do theatrical troupes travel readily from one part of the world to another, thereby giving audiences firsthand contact with an extensive repertoire, but these troupes, stimulating one another, are experimenting with a wide variety of theatrical forms. As a consequence, the concept of what constitutes theatrical production has broadened considerably.
