Aalto, Alvar

The Finnish architect Alvar Aalto, whose work exemplifies the best of 20th-century Scandinavian architecture, was one of the first to depart from the stiffly geometric designs common to the early period of the modern movement and to stress informality and personal expression. His style is regarded as both romantic and regional. He used complex forms and varied materials, acknowledged the character of the site, and gave attention to every detail of building. He also was active in city planning and furniture design. Aalto achieved an international reputation through his more than 200 buildings and projects, ranging from factories to churches, a number of them built outside Finland.

By courtesy of the Consulate General of Finland, New York

Aalto, 1970.

Early work. Hugo Alvar Henrik Aalto was born in Kuortane, in west central Finland, on February 3, 1898. His architectural studies at the Technical Institute of Helsinki in Otaniemi were interrupted by the Finnish War of Independence, in which he participated. Following his graduation in 1921, Aalto toured Europe and upon his return began practice in Jyväskylä, in central Finland. In 1927 he moved his office to Turku, where he worked in association with Erik Bryggman until 1933, the year in which he moved to Helsinki. In 1925 he married Aino Marsio, a fellow student, who served as his professional collaborator until her death in 1949. The couple had two children.

Important early commissions

The years 1927 and 1928 were significant in Aalto's career. He received commissions for three important buildings that established him as the most advanced architect in Finland and brought him worldwide recognition as well. These were the Turun Sanomat Building (newspaper office) in Turku, the tuberculosis sanatorium at Paimio, and the Municipal Library at Viipuri (now Vyborg). His plans for the last two were chosen in a competition, a common practice with public buildings in Finland. Both the office building and the sanatorium emphasize functional, straightforward design and are without historical stylistic references. They go beyond the simplified classicism common in Finnish architecture of the 1920s, resembling somewhat the building designed by Walter Gropius for the Bauhaus school of design in Dessau, Germany (1925–26). Like Gropius, Aalto used smooth white surfaces, ribbon windows (that is, windows in a continuous band), flat roofs, and terraces and balconies.

The third commission, the Viipuri Municipal Library, although exhibiting a similar dependence on European prototypes by Gropius and others, is a significant departure marking Aalto's personal style. Its spatially complex interior is arranged on various levels. For the auditorium portion of the library Aalto devised an undulating acoustic ceiling of wooden strips, a fascinating detail that, together with his use of curved laminated wood furniture of his own design, appealed both to the public and to those professionals who had held reservations about the clinical severity of modern architecture. The warm textures of wood provided a welcome contrast to the general whiteness of the building. It was Aalto's particular success here that identified him with the so-called organic approach, or regional interpretation, of modern design. He continued in this vein, with manipulation of floor levels and use of natural materials, skylights, and irregular forms.

By the mid-1930s Aalto was recognized as one of the world's outstanding modern architects; unlike many of his peers, he had an identifiable personal style.

Finnish pavilions for two world's fairs (Paris, 1937; New York, 1939–40) further enhanced Aalto's reputation as an inventive designer of free architectural forms. In these designs, both chosen in competition, he continued to use wood for structure and for surface effects. Further renown came in 1938, when the Museum of Modern Art in New York City held an exhibition of his work, showing photographs of his buildings and examples of his furniture.

Experiments in furniture

Aalto's experiments in furniture date from the early 1930s, when he furnished the sanatorium at Paimio. His furniture is noted for its use of laminated wood in ribbonlike forms that serve both structural and aesthetic ends. In 1935 the Artek Company was established by Aalto and Mairea Gullichsen, the wife of the industrialist and art collector, to manufacture and market his furniture. The informal warmth of Aalto's interiors is best seen in the much admired country home Villa Mairea, which he built for the Gullichsens near Noormarkku, Finland.

Mature style. The decade of the 1940s was not productive; it was disrupted by war and saddened by his wife's death. In 1952 he married Elissa Mäkiniemi, a trained architect, who became his new collaborator.

Aalto's commissions after 1950, in addition to being greater in number, were more varied and widely dispersed: a high-rise apartment building in Bremen (1958), a church in Bologna (1966), an art museum in Iran (1970). His continuing work in Finland, however, remained the measure of his genius. Many of his projects involved site planning of building groups. Two such projects were the master plans of colleges at Otaniemi (1949–55) and at Jyväskylä (1952–57). Aalto's experience in planning originated early with such industrial commissions as the Sunila cellulose factory (designed 1936–39, built 1951–54), which included workers' housing and was a triumph of comprehensive planning.

The single work that epitomizes Aalto's mature style is perhaps the Säynätsalo town hall group. Modest in scale in its forest setting, it nonetheless asserts a quiet force. Its simple forms are in red brick, wood, and copper, all traditional materials of Finland. Viewing it, a person feels the achievement of a perfect building, in that the essence of the time, the place, the people, and their purpose is brought into focus by the awareness of the architect.

There are two buildings by Aalto in the United States: Baker House dormitory, at the Massachusetts Institute of Technology in Cambridge, where Aalto was professor of architecture from 1945 to 1949; and the library of Mount Angel Abbey (a Benedictine college and seminary), in Oregon. Baker House, on the embankment of the Charles River, takes the form of a six-story serpentine wall of rough red brick. Each of the dormitory rooms, some of which are wedge-shaped, has a view either up or down the river. Like Baker House, the Mount Angel library is an example of Aalto's response to the site. Its interior construction follows the downward-sloping terrain, enclosing a dramatic, multilevel room that fans out from the entrance. The bookcases are arranged in radial pattern, and the room is lighted by curved skylights that repeat the rhythmic lines of the balconies.

Aalto received many honours. He was a member of the Academy of Finland (Suomen Aketemia) and was its president from 1963 to 1968; he was a member of the Congrès Internationaux d'Architecture Moderne from 1928 to 1956. His awards included the Royal Gold Medal for Architecture from the Royal Institute of British Architects (1957) and the Gold Medal from the American Institute of Architects (1963). He died in Helsinki on May 11, 1976.

Assessment. Aalto's preliminary plans were freely sketched, without the use of T-square and triangle, so that the unfettered creative urge for inventive shapes and irregular forms was allowed full play before functional relationships and details were resolved. The absence of theoretical rigidity revealed itself in his final designs, which happily retained the spontaneity and individuality of his early sketches. As a Swiss art historian expressed it, he dared "the leap from the rational–functional to the irrational–organic." Since Aalto's staff was small (some six to eight architects), all of the work bore the imprint of his personality.

Aalto wrote little to explain his work, but his architecture conveyed a variable, lively temperament, free from dogma and without monotony. His work was said to express the spirit of Finland and its people, primitive yet lyrical. His friendships with such artists as Fernand Léger, Jean Arp, and Constantin Brancusi may have nourished his fondness for curvilinear shapes. While his work was never compulsively innovative, neither was it static. His late designs showed an increased complexity and dynamism that some regarded as incautious. In particular, his work of the late 1960s was marked by splayed, diagonal shapes and clustered, overlapping volumes. Energy and imagination were ever present.

MAJOR WORKS

Turun Sanomat Building, Turku, Finland (1930); Municipal Library at Viipuri, now Vyborg in the Russian Soviet Federated Socialist Republic (designed 1927, built 1930–35, destroyed 1943); Sulfate Paper Mill at Toppila, Finland (1931); Sanatorium at Paimio, Finland (1933); cellulose factory at Sunila, Kotka, Finland (1936–39; extended 1951–54); Villa Mairea (Gullichsen House) at Noormarkku, Finland (1938–39); sawmill at Varkaus, Finland (1945); Baker House (senior dormitory), Massachusetts Institute of Technology, Cambridge, Massachusetts (1947–48); town hall group, Säynätsalo, Finland (1950–52); House of Culture, Helsinki, Finland (1955–58); house for Louis Carré, Bazoches, France (1956–58); church at Vuoksenniska, Imatra, Finland (1956–58); Nordjyllands Kunstmuseum, Ålborg, Denmark (1958–72); post and telegraph office, Baghdad, Iraq (1958); Community Centre, Wolfburg, Germany (1959–62); Community Centre, Seinäjoki, Finland (1962; theatre added, 1967); Edgar J. Kaufmann Conference Rooms, Institute of International Education, New York City (1965); Mount Angel Abbey Library, near Salem, Oregon (designed 1965–66, built 1967–70).

BIBLIOGRAPHY. A definitive review of Aalto's work, extremely well illustrated with photographs and plans, is the two-volume work edited by KARL FLEIG: *Alvar Aalto* (1963) and *Alvar Aalto 1963–1970* (1971). A brief essay by FREDERICK GUTHEIM, *Alvar Aalto* (1960), contains descriptive and critical comments as well as many photographs. A similar book is GEORGE BAIRD, *Alvar Aalto* (1970). A substantial chapter on Aalto appears in SIGFRIED GIEDION, *Space, Time and Architecture*, 5th ed. rev. (1967), and is an excellent critical treatment of Aalto's architecture. No purely biographical work exists.

(H.F.K.)

Aaron

Aaron is the traditional founder and head of the Jewish priesthood, who, in company with Moses, led the Israelites out of Egypt.

By courtesy of the Direction Generale des Antiquites et des Musees, Damascus

Aaron, detail of a fresco by an unknown artist, 3rd century, from the synagogue at Doura-Europus. In the National Museum, Damascus.

Life. Aaron is described in the Old Testament book of Exodus as a son of Amram and Jochebed of the tribe of Levi, three years older than his brother Moses. He acted together with his brother in the desperate situation of the Israelites in Egypt and took an active part in the Exodus. Although Moses was the actual leader, Aaron acted as his "mouth." The two brothers went to the Pharaoh together, and it was Aaron who told him to let the people of Israel go, using his magic rod in order to show the might of Yahweh. When the Pharaoh finally decided to release the people, Yahweh gave the important ordinance of the Passover, the annual ritual remembrance of the Exodus, to Aaron and Moses. But Moses alone went up on Mt. Sinai, and he alone was allowed to come near to Yahweh. Moses later was ordered to "bring near" Aaron and his sons, and they were anointed and consecrated to be priests "by a perpetual statute." Aaron's sons were to take over the priestly garments after him. Aaron is not represented as wholly blameless. It was he who, when Moses was delayed on Mt. Sinai, made the golden calf that was idolatrously worshipped by the people.

Aaron as "mouth" for Moses

Once a year, on Yom Kippur (the Day of Atonement), Aaron was allowed to come into the Holy of Holies, the most sacred part of the tabernacle, or sanctuary, in which

the Hebrew tribes worshipped, bringing his offering. Together with his sister, Miriam, Aaron spoke against Moses because he had married a foreigner (a Cushite woman); but as in the episode of the golden calf, the narrative tells how Aaron was merely reproved, though Miriam was punished, for the offense. In the rebellion of Korah the Levite, however, Aaron stood firmly at the side of Moses. According to Numbers 20, Aaron died on the top of Mt. Hor at the age of 123; in Deuteronomy 10, which represents another tradition, he is said to have died in Moserah and was buried there.

Aaron is a central figure in the traditions about the Exodus, though his role varies in importance. At the beginning he seems to be coequal with Moses, but after the march out of Egypt he is only a shadow at Moses' side. Moses is obviously the leading figure in the tradition, but it is also clear that he is pictured as delegating his authority in all priestly and cultic matters to Aaron and "his sons."

Aaron and the biblical critics. Scholars have long been aware that the figure of Aaron as it is now found in the Pentateuch, or first five books of the Old Testament, is built up from several sources or layers of traditions. According to Julius Wellhausen, a German biblical scholar, and his followers, the Jahwist source was the oldest one, followed in order by the Elohist, Deuteronomist, and Priestly code. Scholars have attributed the passages about Aaron to one or the other of these sources. Although their results differ, they do agree in ascribing about 90 percent of the material about Aaron to the Priestly source. According to Wellhausen, Aaron was not mentioned at all in the Jahwist narrative, but he may have been inserted by later redactors. It was Moses who was the hero of the priests before the exile, and it was Joshua, not Aaron, who officiated in the tabernacle.

Major source or tradition

Other scholars, such as Sigmund Mowinckel, believe that the narrative about the golden calf, which presents Aaron in an unfavourable light, was part of the ancient tradition in the Jahwist work, being the only passage in it that mentions him. This narrative, according to these scholars, originally came from the northern kingdom of Israel and described Aaron as the ancestor of the priests in northern Israel; later it was rewritten in a way defamatory to Aaron. But there are also features in the narrative that may indicate that a later source (or traditionist), the Elohist, tried to excuse Aaron and to put the main responsibility on the people. The Elohist narrator was credited with making Aaron the brother and helper of Moses, who stood at the side of Moses in the conflict with the Pharaoh and assisted him as a leader in battles and in the cult. It may also be the Elohist who provides the unfavourable story about Aaron's objection to Moses' wife. On the other hand, it seems to be the same narrator who mentions Aaron at the side of Moses in the revolt at Meribah, but here also Aaron, together with Moses, is actually reproached. There is reason to believe that Aaron was not mentioned in the Deuteronomist work by the original author but that his name has been added by a redactor. The main bulk of the traditions about Aaron and the frequent addition of "and Aaron" after the mention of Moses are found in the Priestly source, which was written at a time when the priests had a more dominant position in Judah than they had before the exile. By then Moses had ceased to be the hero of the priests, and Aaron had taken over that role.

Many modern scholars prefer to speak of traditions and layers of traditions where their predecessors spoke of sources, but, apart from this terminology, the view concerning Aaron has not greatly changed. There have been new attempts, however, to see the contrasting figures of Moses and Aaron in a new light. It has been suggested that the traditions about Moses represent a southern Judean tradition, while the old traditions about Aaron originated in the northern kingdom. It has also been indicated that the traditions about Moses are primarily concerned with a prophet, while those about Aaron are connected with priesthood. There may be a kernel of truth in all these suggestions, as also in the theory of Ivan Engnell that Moses represents the royal ideology while Aaron stands for priesthood, and priesthood alone. The standing struggle between the king and the leading priests is reflected both in the laws and in the narratives of the historical books.

Aaron in later Jewish and Christian thought. Aaron continued to live as a symbol in Jewish religion and traditions, and the position of the priests was strengthened after the exile. Also in the Qumrān sect, a Jewish community that flourished in the era immediately before and contemporary with the birth of Christianity, Aaron was a symbol for a strong priesthood, as can be seen from the Dead Sea Scrolls. At the end of time, men of the community should be set apart, as a select group in the service of Aaron. Only the sons of Aaron should "administer judgment and wealth," and according to the *Manual of Discipline* two messiahs were expected, one of Aaron, the priestly one, and one of Israel. According to a fragment found near Qumrān, the priest would have the first seat in the banquets in the last days and bless the bread before the Messiah of Israel. Here "the sons of Aaron" have the highest position.

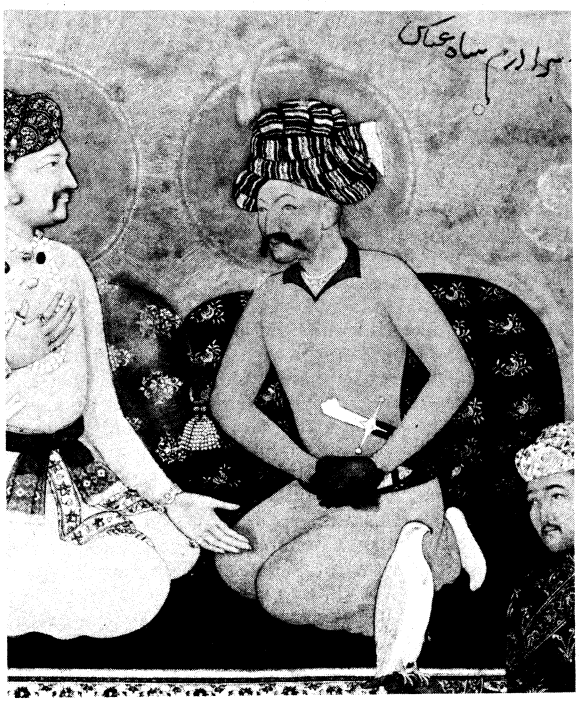
Aaron as a symbol

In Talmud and Midrash (Jewish commentative and interpretative writings), Aaron is seen less as a symbol than as the leading personality at the side of Moses. The relationship between the two brothers is painted as prototypical in the *Haggada* ("Narrative"—the nonlegal parts of Talmud and Midrash). Rabbi Hillel, the great liberal sage, praised Aaron as peace loving, a man of goodwill, who wanted to teach his fellow men the Law.

In Jewish exegesis little is said about him, though he is mentioned as a man who created peace among men. Many attempts have been made to explain the episode of the golden calf. According to some exegetes, Aaron had to make the calf in order to avoid being killed. In the early 14th century, Gersonides explained that this would have been fatal not only for Aaron but even more for the people. Earlier, in the 11th century, Rashi contended that the calf was a symbol of the leader, Moses, who was at that time on the mountain. The relationship between Moses and Aaron is also discussed in the Talmud. Some traditionists have wondered why Aaron, and not Moses, was appointed high priest. The answer has been found in an indication that Moses was rejected because of his original unwillingness when he was called by Yahweh. It also seems to have been hard for some traditionists to accept that Aaron was described as older than Moses. The death of Aaron is related in the Midrash *Petirat Aharon.*

The first Christian communities admitted that Aaron, "the sons of Aaron," or "the order of Aaron" were symbols of the highest priesthood. But in the Letter to the Hebrews, Christ is described as a high priest according to the order of Melchizedek, which was set against "the order of Aaron." Of the Church Fathers, Cyril of Alexandria says that Aaron was divinely called to a priesthood in spirit and in truth and that he was a type of Christ. Gregory the Great translates the name Aaron as "mountain of strength" and sees in him a redeemer who mediated between God and man.

BIBLIOGRAPHY. F.S. NORTH, "Aaron's Rise in Prestige," in *Zeitschrift für die alttestamentliche Wissenschaft*, 66:191–199 (1954), is a short paper discussing Aaron's position; ROLAND DE VAUX, *Les Institutions de l'Ancien Testament*, 2 vol. (1958–60; Eng. trans., *Ancient Israel: Its Life and Institutions*, 1961), a comprehensive work, also gives a picture of Aaron and his place in ancient Israelite life and cult. WALTER BEYERLIN, *Herkunft und Geschichte der Ältesten Sinaitraditionen* (1961; Eng. trans., *Origins and History of the Oldest Sinaitic Traditions*, 1966), is mostly concerned with the traditions behind the story of Moses and Aaron. HAROLD H. ROWLEY, *Worship in Ancient Israel* (1967), gives a picture of religious life in Israel, including Aaron and his role. BERTIL GARTNER, *The Temple and the Community in Qumran and the New Testament* (1965), treats the religious cult in the Qumrān society, in which "Aaron" was synonymous with the chief priest.



(A.S.K.)

ʿAbbās I the Great, of Persia

ʿAbbās I, styled "the Great," shāh (king) of Persia of the Ṣafavid dynasty, the first Ṣafavid monarch to create a standing army, won back substantial territory lost under

his predecessors to the Uzbeks and the Ottoman Turks. Although a just and courageous ruler whose reign was distinguished by its high artistic level, he tarnished his reputation by the murder and mutilation of many members of his family.

By courtesy of the Smithsonian Institution, Freer Gallery of Art, Washington, D.C.

ʿAbbās I (right) seated with the emperor Jahāngīr, detail of a painting by the Mughal school of Jahāngīr, *c.* 1620. In the Freer Gallery of Art, Washington, D.C.

Early years

The third son of Solṭān Moḥammad Shāh, ʿAbbās was born on January 27, 1571, and came to the throne in October 1588, at a critical moment in the fortunes of the Ṣafavid dynasty. The weak rule of his semi-blind father had allowed the tribal emirs, or chiefs, of the Turkmen tribes, who had brought the Ṣafavids to power and still constituted the backbone of Ṣafavid military strength, to usurp the authority of the shāh. Moreover, the inter-tribal factionalism of these Turkmens (known as Kizilbash, "Red Heads," because of the distinctive red headgear they had adopted to mark their adherence to the Ṣafavids) had so weakened the state that its traditional enemies, the Ottoman Turks to the west and the Uzbeks to the east, had been able to make large inroads into Persian territory.

Shāh ʿAbbās thus had two immediate tasks: to restore internal security and reassert the authority of the monarchy and to expel Ottoman and Uzbek troops from Persian soil. Since he was unable to fight a war on two fronts simultaneously, in 1589–90 he signed a peace treaty with the Ottomans, thus freeing himself for an offensive against the Uzbeks. By the treaty, large areas in west and northwest Persia were ceded to the Ottomans. Despite the breathing space thus gained, ʿAbbās for ten years was unable to launch a major offensive against the Uzbeks, and Iran suffered further loss of territory both to the Uzbeks and to the Mughals of India.

The delay was caused by ʿAbbās' decision to create a standing army—a concept novel to Ṣafavid kings, who traditionally levied armies in time of need from the tribal cavalry. The creation of a standing army immediately caused a budgetary problem, because the old tribal cavalry had been paid from the revenues of the provinces governed by Kizilbash chiefs. ʿAbbās solved the problem in the short term by bringing a number of these provinces directly under the control of the Shāh; the taxes in these new "crown" provinces were remitted to the royal treasury. In the long run the inevitable result of this policy, the reduction in the numbers of Kizilbash troops, seriously weakened the country's military strength.

The new standing army was composed mainly of Georgians, Armenians, and Circassians, who had been brought to Persia as prisoners during the reign of ʿAbbās' grandfather, and their descendants. After their conversion to Islām, they were trained for service either in the army or in the administration of the state or the royal household. Shāh ʿAbbās felt he could rely on the loyalty of these *ghulāms* ("slaves") of the Shāh, as they were known, and he used them to counterbalance the influence of the Kizilbash, whom he distrusted. *Ghulāms* soon rose to high office and were appointed governors of crown provinces.

Eventually, ʿAbbās was able to take the offensive against his external foes. In 1598 he inflicted a major defeat on the Uzbeks and regained control of Khorāsān. From 1602 onward he conducted a series of successful campaigns against the Ottomans and recovered the territory lost to them.

Rebuilding of Isfahan

After his great victory over the Uzbeks, ʿAbbās transferred the capital from Kazvin to Isfahan. Under his guidance, Isfahan rapidly became one of the most beautiful cities in the world. He adorned the city with many mosques and theological colleges and constructed numerous caravansaries and public baths. He laid out the city with spacious boulevards and a splendid square. The Shāh's building energies were not confined to Isfahan; the extension and restoration of the famous shrine at Meshed and the construction, along the swampy littoral of the Caspian Sea, of the celebrated stone causeway, designed to give access to his favourite winter retreats, were among his most notable achievements.

To the new capital at Isfahan came ambassadors from European countries, merchants seeking to establish trade relations, representatives of foreign monastic orders seeking permission to found convents at Isfahan and elsewhere, and gentlemen of fortune, such as the brothers Sir Anthony and Sir Robert Sherley—the former an adventurer, the latter a loyal servant of the Shāh who distinguished himself in the wars against the Ottomans. The reign of Shāh ʿAbbās was a period of intense commercial and diplomatic activity, and, in the Persian Gulf, the Portuguese, the Dutch, and the English strove to make themselves masters of trade there and in the Indian Ocean.

ʿAbbās' reign also marks a peak of Persian artistic achievement. Under his patronage, carpet weaving became a major industry, and fine Persian rugs began to appear in the homes of wealthy European burghers. Another profitable export was textiles, which included brocades and damasks of unparalleled richness of colour and intricacy and freedom of design. The production and sale of silk was made a monopoly of the crown. In the illumination of manuscripts, bookbinding, and ceramics, the work of the period of ʿAbbās is without equal; in painting it is among the most notable in Persian history.

Assessment

Shāh ʿAbbās was a courageous and energetic man and a ruler with a passionate zeal for justice and the welfare of his subjects. He frequented teahouses and other meeting places of the ordinary people in order to learn of extortion and oppression on the part of his officials; his punishment of corrupt officials was swift. He showed unusual religious tolerance, granting privileges to many Christian groups.

The dark side of his character was reserved for his own sons and members of his own family. The experiences of his youth, when he was marked for execution by his uncle, Shāh Esmāʿīl II, had left him with a morbid fear of conspiracy. Originally, he followed the practice of his predecessors in appointing the princes of the blood royal as provincial governors, but after a series of revolts and intrigues in favour of his sons, the royal princes were confined to the harem, where their only companions were women and eunuchs. As his obsessive fear of assassination increased, ʿAbbās began to put to death or to blind any member of the royal family who caused him anxiety in this regard. In this way, one son was executed (an act that caused ʿAbbās bitter remorse) and two were blinded, and his father and brothers were blinded and imprisoned.

ʿAbbās died on January 19, 1629, without an heir capable of succeeding him.

Though ʿAbbās possessed great stature as a monarch—even in an age notable for its outstanding rulers—his great achievement in first saving the Ṣafavid Empire from collapse and then raising it to new heights of splendour is marred by his treatment of his own family and the fact that his reforms contained within them the seeds of the future decay of both dynasty and state.

ʿAbd al-Malik ibn Marwān

The reign of ʿAbd al-Malik ibn Marwān (685–705), the fifth caliph of the Umayyad Arab dynasty (661–750), witnessed the re-establishment of Umayyad power throughout the Muslim Empire as well as a major reorganization of government administration. A wise and tenacious ruler, ʿAbd al-Malik was able to bring peace and prosperity to an empire torn by civil war and to ensure the continuation of the rule of his dynasty for the next half century. (For a discussion of religious and dynastic conflicts that divided the Muslim world in this period see CALIPHATE, EMPIRE OF THE.)

Early years and life in Medina

ʿAbd al-Malik was born in 646 or 647, the son of Marwān ibn al-Ḥakam, fourth Umayyad caliph. He spent the first half of his life with his father in Medina, where he received religious instruction and developed friendly relations with the pious circles of that city that were to stand him in good stead in his later life. At the age of 16, he was entrusted by his kinsman, the caliph Muʿāwiyah, with administrative responsibilities. He remained at Medina until 683, when he and his father were driven out of the city by Medinese rebels in revolt against the central government in Damascus. He then met the Syrian Umayyad army that was marching on Medina and gave its commander advice about the best means of attacking the city, advice that was followed and proved successful. When the caliph Yazīd died in November 683, Marwān was proclaimed caliph in 684 and was able to effect a partial rally of Umayyad rule, but at the cost of a bitter feud that arose between northern and southern Arab tribes. When Marwān died in 685 and ʿAbd al-Malik succeeded to the caliphate, the forces opposing the Umayyads were still formidable.

There were, first, the northern Arab tribes who, under their leader Zufar, were holding out in northern Syria and Iraq. They were finally pacified only in 691. The second focus of resistance was in Iraq, where three main groups, opposed to each other but united in their resistance to the Umayyads, held sway: the Khārijites, the Shīʿites, and the forces of the anticaliph ʿAbd Allāh ibn az-Zubayr, who was proclaimed caliph in Mecca in 685 and had received at least nominal allegiance from many provinces. The initial attempts by the former Umayyad governor of Iraq, ʿUbayd Allāh ibn Ziyād, to regain the province failed, and he was killed by the Shīʿites in 686. For three years ʿAbd al-Malik made no further attempt to interfere in Iraq but bided his time as the various groups in Iraq exhausted themselves in internecine warfare. Muṣʿab, the brother of the anticaliph Ibn az-Zubayr, defeated the Shīʿites in 687 but then had to deal with the Khārijites, committing a large part of his forces.

The decisive battle with Muṣʿab in 691

ʿAbd al-Malik first took the field against Muṣʿab in 689 but had to turn back to quell a rebellion in Damascus. In the following year, the campaign again proved fruitless. Only after the defeat of the northern Arab tribes in 691 was ʿAbd al-Malik finally able to face Muṣʿab. The decisive battle took place at Dayr al-Jā Thalīq. The forces of Muṣʿab were weakened by their wars against the Khārijites, and ʿAbd al-Malik bribed many of them to desert Muṣʿab, who was then killed in battle. The whole of Iraq now fell into his hands, and the only remaining centre of opposition was the now aging anticaliph, Ibn az-Zubayr. ʿAbd al-Malik publicly chided him for his temerity and then sent his famous governor al-Ḥajjāj to Arabia. Al-Ḥajjāj besieged Ibn az-Zubayr in Mecca and killed him in September 692. The Muslim community was finally unified.

At first, the re-establishment of Umayyad rule was more apparent than real. The Khārijites were still either restless or in open revolt. The Khārijites in Persia were especially dangerous. It was only after ʿAbd al-Malik had appointed al-Ḥajjāj to govern Basra that campaigns against them began to prove successful (the Persian Khārijites were finally wiped out in 697). But north of Kūfah, another Khārijite trouble centre developed. In 695, these Khārijites captured Mosul and occupied large areas of central Iraq. Al-Ḥajjāj, leading his Syrian troops, defeated them too in 697. The Khārijite movement, however, remained strong, especially among the Bakr tribes between Mosul and Kufah.

Al-Ḥajjāj had now become governor of all the eastern provinces. He was a ruthless and efficient administrator, intent upon pacifying all the provinces entrusted to him by ʿAbd al-Malik. A great Muslim army, led by an Arab aristocrat, Ibn al-Ashʿath, and operating in the Afghanistan region, mutinied, swore allegiance to its commander, and turned back to Iraq. Al-Ḥajjāj, with the aid of Syrian reinforcements, was able to defeat the rebels, and their leader was murdered in 704 in Afghanistan. Al-Ḥajjāj, realizing that he could no longer trust the Iraqis, built a new city, Wāsiṭ, which he planned as a garrison city for Syrian troops and as his private residence. Thereafter, he ruled Iraq as enemy territory.

Under ʿAbd al-Malik, the conquest of North Africa was resumed in 688 or 689. There, the Arabs were opposed by both the native Berbers and the Byzantines. The governor appointed by ʿAbd al-Malik succeeded in winning the Berbers over to his side and then captured Carthage, seat of the Byzantine province, in 697. Other coastal cities fell, and the work of pacification and Islāmization continued apace. ʿAbd al-Malik also resumed campaigns against the Byzantines in Anatolia in 692, but no permanent conquest ensued. These campaigns were partly designed to keep the Syrian troops fit.

Assessment of ʿAbd al-Malik as an Umayyad ruler

In general, Umayyad rule was greatly strengthened by ʿAbd al-Malik, who enjoyed good relations with the Medinese religious circles, an element with considerable moral influence in the Islāmic world. ʿAbd al-Malik was more pious than any of his Umayyad predecessors. His long sojourn in Medina had enabled him to know the sentiments of Medinese religious scholars. As caliph, he treated them respectfully, and his private life was close to their ideals. As a result, many were to abandon their earlier opposition to Umayyad rule.

ʿAbd al-Malik adopted Arabic instead of the local languages as the language of administration. Government officials had been mostly non-Muslim, but the measures of ʿAbd al-Malik enabled Arab Muslims more easily to control affairs of government. A new Muslim currency was also struck, modelled on Greek and Persian coinage, but with Muslim inscriptions. A wave of Islāmization set in, but the privileged position of the Arabs was maintained. In fact, the problem of non-Arab Muslims grew more acute and was to become one of the main threats to Umayyad rule in later years.

The Umayyad family lived in Damascus and surrounded the Caliph. Many of them were appointed as governors, but many were also recalled for inefficiency. ʿAbd al-Malik enjoyed the support of his clan, but he was more autocratic than Muʿāwiyah, the first Umayyad caliph, with whom he is often compared. He abandoned the policy of consulting with a council of advisers and reserved all major decisions for himself. Despite his religious interests and ideals (*e.g.*, he built the Dome of the Rock in Jerusalem), he was a master politician. In Syria, he succeeded in placating the northern Arab tribes, to the chagrin of the southern Arabs.

ʿAbd al-Malik was a shrewd judge of character. His choice of al-Ḥajjāj as viceroy of the East was a wise one, and he supported his lieutenant loyally. In appearance, he was dark, thickset, and had a long beard. He was nicknamed "Dew of the Stone" for his miserliness. The sources describe him as eloquent in his speech and a lover of poetry. He maintained his calm during periods of crisis and was decisive in his opinions but was capable of great cruelty if necessary. He pursued his enemies relentlessly and closely supervised all affairs of state.

Shortly before his death, the question of succession became acute. His brother, ʿAbd al-ʿAzīz, governor of Egypt, had been designated by their father to succeed ʿAbd al-Malik. Against the advice of his courtiers, ʿAbd al-Malik had begun to take steps to exclude his brother from succession in favour of his own children. He had tried to pressure ʿAbd al-ʿAzīz to renounce his claims, but without success. Luckily for ʿAbd al-Malik, ʿAbd al-ʿAzīz died in May 705. ʿAbd al-Malik now felt free to name three of his own children to succeed him, al-Walīd, Sulaymān, and Yazīd. ʿAbd al-Malik died in Damascus shortly thereafter, in October 705, and was succeeded without difficulty by his eldest son, al-Walīd.

ʿAbd al-Muʾmin

No Berber sovereign of the Middle Ages achieved as much or exerted a greater influence on the course of events than the Almohad caliph ʿAbd al-Muʾmin, who in the second half of the 12th century founded an Islāmic empire that included most of Spain and North Africa.

Early life

ʿAbd al-Muʾmin was born (date unknown) at Tāgrā, a small village near Oran, in what is now Algeria. He came from a humble family: his father had been a potter. He seems to have been well instructed in the Muslim faith, and must have had a good knowledge of Arabic, for he wished to continue his studies at one of the centres of Muslim learning in the East. A chance meeting with Ibn Tūmart, a Berber religious reformer, made him abandon this idea and begin his brilliant career.

Around 1117, Ibn Tūmart, the founder of the Almohad movement, was returning from a long stay in the East. He landed at Mahdīyah in Tunisia, and began a journey to southern Morocco, his native country. Wherever he stopped along the way, he proclaimed a twofold message: strict adherence to the doctrine of the oneness of God (hence the name Almohads or al-Muwaḥḥidūn, Unitarians) and scrupulous observance of Islāmic law. ʿAbd al-Muʾmin heard Ibn Tūmart preach at Mellala, near Bejaïa, Algeria. He was an attentive listener, and from that time attached himself to the man who had revealed to him the true doctrine.

ʿAbd al-Muʾmin does not seem to have played any special role among Ibn Tūmart's disciples during the slow journey that took them to Marrakesh. But when his master declared his opposition to the ruling Almoravid regime, proclaimed himself the *mahdī* ("divinely-guided one"), and took refuge in the remote High Atlas region, ʿAbd al-Muʾmin went with him. Ibn Tūmart won a following in the mountains and founded a small Almohad state there, centred around the village of Tinmel. When al-Bashīr, the reformer's second in command, was killed in an attack on Marrakesh, ʿAbd al-Muʾmin took his place and became Ibn Tūmart's designated successor. The *mahdī* died in 1130. His death was kept secret at first to allow ʿAbd al-Muʾmin—a stranger to the High Atlas—time to win support from the Almohad leaders. When he was proclaimed leader of the Almohads, he assumed the prestigious title of caliph.

His first task was to carry on the struggle against the Almoravids. Learning from the failure at Marrakesh, he realized that he must conquer Morocco from the mountains. On the plains, the Christian knights who served the Almoravids could easily repulse the Almohads' Berber infantry. He spent the next 15 years winning control of the High Atlas, Middle Atlas, and Rif regions, finally moving into his native country, north of Tlemcen.

Near that town, the Almoravids, having suffered the loss of Reverter, the leader of their Catalan mercenaries, were defeated by ʿAbd al-Muʾmin in open battle in 1145. The Almohad forces then moved west, subjugating Morocco's Atlantic coastal plain. They then laid siege to Marrakesh and took it by storm in 1147, massacring the Almoravid inhabitants.

Conquest of the empire

Arab historians have left a description of the man who had now become master of Northwest Africa. He was a sturdy Berber of medium height, with dark hair and regular features. A good soldier, with great courage and endurance, he was at the same time learned in Islām and a gifted orator. Although he had personal charm and could, when necessary, show patience and moderation, he was at times as harsh as his master, Ibn Tūmart. When a revolt broke out in the Atlantic plain area following the capture of Marrakesh, he conducted a methodical purge there in which more than 30,000 people were executed.

ʿAbd al-Muʾmin left neither memoirs nor a political testament; his ideas must be deduced from his actions. His newfound power and his very success raised problems that demanded immediate solutions.

The capture of Marrakesh posed the moral question of whether to abandon this city founded by the Almoravid heretics, whom he had exterminated without pity. He contented himself with destruction of their palace and mosques and retained Marrakesh as the capital of his new empire.

Soon he had to choose between two imperial policies: to complete the conquest of North Africa or to concentrate his energies on Spain, where the Christians were threatening the former Almoravid domains. Showing good judgment as well as feeling for his native country, he gave priority to North Africa.

In 1151 he subjugated the area around Constantine and on his way home fought a battle near Sétif against a coalition of Arab tribes that had been wandering over the Berber country for a century, gradually destroying its peasant and sedentary way of life. ʿAbd al-Muʾmin was victorious, but instead of punishing these people who had showed themselves to be the worst enemies of the Berbers and the Almohad government, he thenceforth came to rely on them to strengthen his dynasty against opposition from the family of Ibn Tūmart. He also wished to use the Arab cavalry in his holy war against the Christians in Spain.

In 1158–59, ʿAbd al-Muʾmin conquered Tunisia and Tripolitania. This marked the zenith of Berber power in Islām: a Berber caliph reigned over all of North Africa west of Egypt, and his authority was acknowledged by most of Muslim Spain as well.

ʿAbd al-Muʾmin's government

Even while he was pursuing his conquest, ʿAbd al-Muʾmin had established a central government for his empire. To the traditional clan organization of the Maṣmudah and other Berber peoples supporting the Almohads, he added an organization to promote the spread of Almohad doctrine and a central administration (the *makhzan* modelled on those of Muslim Spain, which was staffed largely by Spanish Muslims. A government land registry was established to assure the dynasty regular revenue. ʿAbd al-Muʾmin fully accepted the responsibilities of an art patron, but remembering the puritanical austerity of Ibn Tūmart, he sometimes imposed on the mosques built for him by Andalusian artisans a plainness that became more artificial than elaborate ornamentation.

ʿAbd al-Muʾmin died at Rabat, Morocco, in the spring of 1163. His work, faithfully carried on by his successors Abū Yaʿqūb Yūsuf (reigned 1163–84) and Abū Yūsuf Yaʿqūb al-Manṣūr (1184–99), was maintained for more than half a century. Disturbances caused by the rebellious Arab tribes impoverished the country without endangering the dynasty. After their defeat by the Spanish Christians at Las Navas de Tolosa in 1212, however, the Almohads began to decline, and their empire soon disintegrated.

Though in the long run ʿAbd al-Mu'min's successors proved unable to perpetuate his achievements, he himself had written one of the most glorious chapters in the history of the Muslim West.

ʿAbd ar-Raḥmān III an-Nāṣir

ʿAbd ar-Raḥmān III an-Nāṣir (reigned 912–961), the eighth prince and first caliph of the Umayyad Arab Muslim dynasty of Spain, is generally regarded as the greatest ruler of his dynasty and the one who restored and enhanced the power and prestige of Umayyad rule in Spain and beyond.

Early years of ʿAbd ar-Raḥmān's reign

ʿAbd ar-Raḥmān was born in January 891. He succeeded his grandfather ʿAbd Allāh as amir (prince) of Córdoba in October 912 at the age of 21. Because of his intelligence and character he had been the obvious favourite of his grandfather, who had designated him heir presumptive in preference to the other royal princes. In appearance he is described as having been light-skinned, handsome, thickset, and short-legged. He appeared to be very short when he walked but was imposing on horseback.

Public homage was paid to him in Córdoba immediately after his accession. He set about at once and with great energy to restore the authority of Córdoba in Spain—an authority that had been curtailed during the latter years of the reign of his grandfather by a host of rebels entrenched in mountain forts throughout the land. Ten days after his accession he had the head of the first rebel exhibited in Córdoba. Thereafter, for a score or so of years, he led almost annual expeditions against the rebels, first in southern and later in central and eastern Spain.

His greatest enemy was a crypto-Christian rebel, ʿUmar ibn Ḥafṣūn, lord of Bobastro. ʿAbd ar-Raḥmān's strategy was one of continuous harassment of Ibn Ḥafṣūn's forts. Beginning with the campaign of Monteleón, ʿAbd ar-Raḥmān captured 70 forts in the provinces of Elvira, Granada, and Jaén—all of which had been directly or indirectly controlled by Ibn Ḥafṣūn. In 913 Seville was captured, followed by Algeciras, Rayyu, Sidonia, and Carmona. When Ibn Ḥafṣūn died in 917, the rebellion collapsed. His children were captured or killed, and the centre of the rebellion, Bobastro, was finally stormed in 928. In 933 Toledo fell after a bitter siege, and, with its fall, the last Muslim centre of resistance to Cordoban hegemony disappeared.

Campaigns against the Christian north

Meanwhile, ʿAbd ar-Raḥmān also had to check threats from the Christian north. The main danger came from the Kingdom of Leon. An expedition commanded by Ordoño II, then vassal king of Galicia and later king of Leon, into Muslim territory in the summer of 913, especially his sack of Evora (Talavera) and the massacre of its Muslim population, produced widespread resentment in Muslim Spain. ʿAbd ar-Raḥmān decided to counterattack, which he began in earnest in 920, leading the campaign of Muez in person. He captured the forts of Osma and San Esteban de Gormaz and then inflicted a crushing defeat on the combined armies of Leon and Navarre at Valdejunquera on July 26, 920. Four years later, in the spring of 924, he led another campaign into Navarre and sacked the capital, Pamplona. With these two campaigns, ʿAbd ar-Raḥmān was able to secure his frontiers with Christian Spain for the next seven years. But the next King of Leon, Ramiro II, who ascended the throne in 932, proved a formidable adversary and began immediately to mount attacks against Muslim territory. The encounter between the two rulers finally took place in 939, when, at the "ditch" of Simancas, Ramiro severely defeated the Muslims and ʿAbd ar-Raḥmān barely escaped with his life. After that defeat ʿAbd ar-Raḥmān resolved never to personally lead another expedition. The Christian victory, however, was not followed up. When Ramiro died in 950 and civil war broke out in the Christian territories, ʿAbd ar-Raḥmān made good his earlier losses so thoroughly that in 958 Sancho, exiled king of Leon, Garcia Sánchez, king of Navarre, and his mother, Queen Toda, all paid personal homage to ʿAbd ar-Raḥmān in Córdoba.

In North Africa the policy of ʿAbd ar-Raḥmān was directed against the Fāṭimids in al-Qayrawān (now in modern Tunisia). In order to check their control over North Africa he financed rebellions against them and sent naval expeditions to sack the coastal cities. The city of Ceuta was fortified in 931 as a base of operations in North Africa. Toward the end of his reign, however, Fāṭimid power increased, and the Fāṭimid general Jawhar was able to repulse the allies of ʿAbd ar-Raḥmān. The struggle with the Fāṭimids, however, was inconclusive and was to continue throughout the 10th century.

Significance of the man and his reign

As a result of his early successes, and probably at his own suggestion, some of his court poets urged ʿAbd ar-Raḥmān to adopt the title of caliph. He assumed that dignity in 929, shortly after the fall of Bobastro, and chose the honorific title an-Nāṣīr li-Dīn Allāh (He Who Fights Victoriously for the Religion of God). His reasons were, internally, to enhance his prestige and, externally, to counter the Fāṭimid claim to this honour. The consolidation of power brought great prosperity to Muslim Spain—one indication of which was his building of a mint where pure gold and silver coins were struck. ʿAbd ar-Raḥmān was also a great builder; he renovated and added considerably to the Great Mosque at Córdoba and to the royal palace. At vast expense he built a new royal city, Madīnat az-Zahrā', to house his household and government. He kept a very strict control over the affairs of state and his civil service, changing his governors frequently to avoid the growth of local dynasties. In 949 he executed his own son for conspiring against him.

Christian and Jewish communities flourished during his tolerant reign. His fame spread so far beyond his domains that Córdoba by the end of his reign enjoyed almost as much fame as Constantinople in the Mediterranean world. In Córdoba he received emissaries from such distant rulers as Otto I of Germany and the Byzantine emperor. Córdoba was said to have contained 3,000 mosques and more than 100,000 shops and houses. His reign, the second longest of any Muslim caliph, afforded his wise and courageous policies the fullest chance of development. ʿAbd ar-Raḥmān died in October 961, at the height of his power and fame.

BIBLIOGRAPHY. The best account of ʿAbd ar-Raḥmān's reign is in E. LEVI-PROVENCAL, *Histoire de l'Espagne musulmane*, vol. 2, pp. 1–164 (1950). Also useful are W.M. WATT, *A History of Islamic Spain* (1965); and S. LANE-POOLE, *The Story of the Moors in Spain* (1886; reprinted as *The Moors in Spain*, 1967).

Abdelkader

Abdelkader (ʿAbd al-Qādir), born September 6, 1808, the son of the head of the Qādirīyah Muslim brotherhood Mahieddin (Muḥyī ad-Dīn), became a well-known military figure after the French occupation of the Algerian coast, leading the Algerians in their battle against the invading French until 1847. A political leader who founded a modern state, and a religious leader as well, Abdelkader embodied the resistance and growing nationalism of the Algerian people.

His physical handsomeness and the qualities of his mind had made him popular even before his military exploits. Of medium height, lithe and elegant, with regular features and a black beard, his demeanour was exceptionally refined, and his life-style simple. He was known as a religious and educated man, who could excite his coreligionists with his poetry and oratorical eloquence.

Algeria was an Ottoman regency when the French army landed there in 1830. The government was controlled by a dey (governor) and by the Turkish Janissaries who had chosen him. These rulers, supported by the Koulouglis (people of mixed Turkish and Algerian ancestry) and by certain privileged tribes, and aided by the fact that they

were of the same religion as the people, long held Algeria firmly in their grip.

Nevertheless, the Algerians detested them, and there were continual rebellions in the early 19th century. As a result, the country was left too divided to oppose the Christian invaders.

The western tribes laid siege to Oran and tried to organize themselves, unified by their common Muslim religious sentiment, which was cultivated by the schoolmasters and particularly by members of the religious brotherhoods. The leader of one of the brotherhoods, Mahieddin, director of the *zāwiyah* (religious school) near Mascara, was asked to lead the harassment of the French troops in Oran and Mostaganem.

In November 1832, the aging Mahieddin had his young son Abdelkader elected in his place. The youth, already renowned for his piety and military prowess, took over the war of harassment. The ensuing Desmichels Treaty of 1834 gave him the whole interior of the Oran, with the title commander of the believers. In a move to unify his new territories, Emir Abdelkader, taking advantage of this treaty, imposed his rule on all the tribes of the Chelif, occupied Miliana and then Médéa, and succeeded in defeating Gen. Camille Trézel at Macta. Although pressed by generals Bertrand Clauzel and T.R. Bugeaud, he managed to rally support from Algerians who had become indignant over the French use of violence. By able negotiation, he convinced General Bugeaud to sign the Treaty of Tafna (1837), which further increased his territory and made him master of the whole interior of the provinces of Oran and the Titteri, with the French having to be content with a few ports.

Creation of a new state

In two years the Emir had organized a true state, the capital of which was sometimes Mascara and sometimes the fortress of Tiaret, (now Tagdempt). He established juridical equality among population groups by suppressing the privileges of the warlike tribes (*makhzen*) and by imposing equal taxes on all his subjects. First he extended his influence to the Sahara by fighting at-Tijīnī, who dominated the southern oases, and rallying the desert peoples to him. Then he strengthened his authority in the valley of the Chelif and in the Titteri as far as the borders of the province of the east, where he was resisted by the *bey* of Constantine, Hajj Ahmed. He also exacted harsh punishment of the Koulouglis of Zouatna, who had joined the French. By the winter of 1838, his authority extended across the borders of Kabylie and, in the south, from the oasis of Biskra to the Moroccan border. To destroy the power of at-Tijīnī, he besieged his capital, Aïn Mahdi, for six months and demolished it, while all the Saharan tribes paid him homage.

Abdelkader was an absolute leader, who only rarely called in the grandees to advise him. Algerian religious sentiment was his support, the one force that could bring his subjects together and unify them in the face of the invader. But that did not prevent him from employing competent persons of all nationalities, whether Jews or Christians, to help him build a modern state. The best known of these Europeans was the future diplomat Léon Roches, who later recounted his adventures in a fanciful book, *Trente-deux ans à travers l'Islam* ("Thirty-two Years Through Islām"). Abdelkader organized a regular army of approximately 2,000 men, to be supported by either volunteers or contingents furnished by the tribes. As towns near French territory would have been too vulnerable, he fortified interior sites, such as Sebdou, Saïda, Tiaret, Taza, and Boghar, where he opened arsenals, warehouses, and workshops, and where he stored surplus crops whose sales were to finance his arms purchases, mainly in England. He set up a new administration, with officials on fixed salaries. He taught his people austerity and set a personal example, living without ceremony in a tent. By expanding education, he slowly spread the concepts of independence and nationality to his people.

When the columns of the Duc d'Orléans crossed the Iron Gates, the Emir took it as a violation of the territories granted him by the Treaty of Tafna. Even though he was still far from having completed his own work of organization, he made a surprise attack and destroyed the French colonization of the Mitidja Plain. From then on the war languished until General Bugeaud was named governor general in 1840. Bugeaud convinced the French government to arm him for the conquest of all Algeria. The resulting war was bitter and lasted seven years. The Emir avoided big battles, preferring to use his rifle-armed cavalry in incessant skirmishes, from which it would retreat almost as soon as it had fired. But he was fighting a French army composed of infantry that Bugeaud had organized into extremely mobile columns, and he had to contend with the ruinous devastation of the countryside practiced by Bugeaud and his lieutenants so as to force the starving inhabitants to desert their leader.

Responses to the French policy of conquest

In 1841 the French destroyed the Emir's fortified sites, and he was forced to become a nomad in the interior of Oran. The following year he lost Tlemcen, and communication with his Moroccan allies became difficult. Yet, despite further reverses and French penetration in the south, he succeeded in reaching Morocco. But after Bugeaud's defeat of the Moroccans at Isly, the Sultan was forced to hold Abdelkader in the midst of his empire. The Emir, however, proved to have unflagging energy. Taking advantage of a revolt in the Dahra, he re-entered Algeria, took the Sidi Brahim outpost, and penetrated deep into the interior, all the while escaping the pursuing French columns. In July 1846, with only a handful of men left, Abdelkader again took refuge in Morocco, the sultan of which by then considered him to be a burden. Deprived of this last area of support, Abdelkader returned to Algeria and with great dignity turned himself over to Gen. Christophe de Lamoricière and to Bugeaud's successor, King Louis-Philippe's son, the Duc d'Aumale, who promised him transport to the east.

Surrender and later life

Louis-Philippe, however, failed to respect his son's promise. Abdelkader was held prisoner in France, first at the Château de Pau, where he learned the principles of Freemasonry, and later at Amboise. It was the prince-president Louis-Napoléon who, in 1852, authorized his return to Bursa, and then to Damascus, where he led an exemplary life and wrote *Rappel à l'intelligent, avis à l'indifférent* ("Call to the Intelligent, Warning to the Indifferent"). The French government provided him with a large pension and with a Kabyle guard, and even attempted to obtain a throne for him somewhere between Turkey and Egypt, which they wished to remove from Ottoman control. At the time of the 1871 Algerian insurrection, he disowned one of his sons who had tried to arouse the tribes of southern Constantine.

When he died on May 26, 1883, he was respected by all. French efforts to make him the symbol of Algerian support for colonial rule were erroneous. Abdelkader believed he was carrying out God's will in admitting that his political role had ended. Present-day Algerians consider him to be the greatest hero of their people.

ʿAbduh, Muḥammad

An Egyptian religious scholar and liberal reformer, Muḥammad ʿAbduh laid the foundations for a generation of Muslim intellectuals of the late 19th and early 20th centuries who sought to revitalize Islāmic teachings and institutions and to reconcile them with the demands of modern civilization. ʿAbduh's achievement was to stimulate the conviction among the new secularly educated classes of Egypt and other Muslim countries that their style of life was compatible with religious faith and that Islāmic principles, properly understood, required vigorous efforts to improve the conditions of their society.

ʿAbduh was born in 1849 in a village of the Nile Delta. He attended the mosque school in Ṭanṭā and subse-

quently al-Azhar University in Cairo, receiving the degree of *ʿālim* (scholar) from the latter in 1877. After an early infatuation with mysticism, in 1872 he fell under the influence of Jamāl ad-Dīn al-Afghānī, the revolutionary pan-Islāmic preacher of Persian origin who had settled in Cairo and who stimulated ʿAbduh's interest in theology, philosophy, and politics. In punishment for political activity, Afghānī was expelled from Egypt in 1879 and ʿAbduh was exiled to his village, but the next year ʿAbduh's fortunes changed. He became editor of the government's official gazette, which he made a platform for preaching resistance to Anglo-French political encroachment and the need for social and religious reform. He was implicated in ʿUrābī Pasha's rebellion against foreign control in 1882 and, following the British military occupation of Egypt, was exiled. Rejoining Afghānī in Paris for several months in 1884, ʿAbduh helped his mentor publish the revolutionary journal *al-ʿUrwat al-wuthqā* ("The Firmest Bond"), which was smuggled to Egypt, India, and elsewhere. After brief visits to England and Tunisia, ʿAbduh settled for three years in Beirut and taught in an Islāmic college there.

Early career and exile

In 1888 ʿAbduh was permitted to return to Egypt, where he began a judicial career that spanned the rest of his life. He was appointed a judge in the National Courts of First Instance, then in 1891 at the Court of Appeal; in 1899, with British help, he became *muftī* (Islāmic legal counsellor) of Egypt. In the latter post he effected several reforms in the administration of Islāmic law and of religious endowments. He also issued advisory opinions to private petitioners, including such controversially liberal judgments as the permissibility of eating meat slaughtered by Christian and Jewish butchers and of accepting interest paid on loans. ʿAbduh also lectured at al-Azhar and, against much conservative opposition, induced reforms in the administration and curriculum of that ancient institution. He established a benevolent society that operated schools for poor children. He served on the Legislative Council, preaching political cooperation with Britain and a long-term effort to bring about legal and educational reforms in Egypt; these views, differing markedly from those he had espoused earlier in life under Afghānī's influence, earned him the approval of Lord Cromer, the British Resident, but also the hostility of the khedive (ruling prince) ʿAbbās Ḥilmī and of the nationalist leader Muṣṭafā Kāmil. Late in life ʿAbduh learned French and pursued an interest in European thought.

Judicial career

In addition to his numerous articles in the official gazette and *al-Urwat al-wuthqā*, ʿAbduh's most important writings included *Risālat at-tawḥīd* ("Treatise on the Oneness of God"); a polemic on the superiority of Islām to Christianity in its inherent receptivity to science and civilization; and a fragmentary commentary on the Qurʾān, completed after his death by a disciple. In theology ʿAbduh sought to establish the harmony of reason and revelation, the freedom of the will, and the primacy of the ethical implications of religious faith over ritual and dogma. He deplored the blind acceptance of traditional doctrines and customs and asserted that a return to the pristine faith of the earliest age of Islām would not only restore the Muslims' spiritual vitality but would provide an enlightened criterion for the assimilation of modern scientific culture.

Religious and philosophical beliefs

In matters of Islāmic law, which governed Muslim family relationships, ritual duties, and personal conduct, ʿAbduh tried to break through the rigidities of scholastic interpretation and to promote considerations of equity, welfare, and common sense, even if this occasionally meant disregarding the literal texts of the Qurʾān. From his death to the present day ʿAbduh has been widely revered as the chief architect of the modern reformation of Islām. ʿAbduh died on July 11, 1905, in a suburb of Alexandria.

BIBLIOGRAPHY. The only full-length biography of ʿAbduh is in Arabic: MUHAMMAD RASHID RIDA, *Tarīkh al-Ustūdh al-Imām ash-Shaikh Muḥammad Abduh*, vol. 1 (1931). The most extensive western-language treatment is CHARLES C. ADAMS' classic, *Islam and Modernism in Egypt* (1933), which also deals at length with Ridā and other followers of ʿAbduh. A substantial analysis of ʿAbduh's thought and legacy is found in MALCOLM H. KERR, *Islamic Reform: The Political and Legal Theories of Muhammad ʿAbduh and Rashīd Ridā* (1966); ELIE KEDOURIE, *Afghani and ʿAbduh* (1966), portrays ʿAbduh as a clandestine religious and political subversive. An authoritative summary of ʿAbduh's life and work is by JOSEPH SCHACHT in *The Shorter Encyclopaedia of Islam* (1953).

Abel, Niels Henrik

Niels Henrik Abel was a Norwegian mathematician, recognized only after his death as a pioneer in the development of modern mathematics.

Abel was born on August 5, 1802, on the island of Finnøy, near Stavanger, Norway, where his father was a poor Protestant minister. The family soon moved to the parish of Gjerstad, near the town of Risør (southeast Norway), where the boy grew up. In 1815, when he entered the cathedral school in Oslo, his mathematical talent was recognized by a teacher who introduced him to the classics in mathematical literature and proposed original problems for solution. Thoroughly challenged, Abel studied the works of the 17th-century English mathematician and physicist Isaac Newton and the contemporary mathematicians Leonhard Euler (German), Joseph-Louis Lagrange (French), and Carl Friedrich Gauss (German) and learned to detect gaps in their mathematical reasoning.

Early recognition of his talent

Although when Abel's father died in 1820 the family was left in straitened circumstances, the boy was able to enter the University of Christiania (Oslo) in 1821 because his teacher contributed and raised funds.

On graduation from the University in 1822, Abel continued his studies with further subsidies obtained by his teacher. His first papers, published in 1823 in the new periodical *Magazin for Naturvidenskaberne*, were on functional equations and integrals, his solution of an integral equation being the first. Abel's friends urged the Norwegian government to grant him a fellowship for study in Germany and France. While waiting for the royal decree to be issued, in 1824 he published at his own expense his proof of the impossibility of solving algebraically the general equation of the fifth degree, which he hoped would bring him recognition. He sent the pamphlet to Gauss, who dismissed it, failing to recognize that the famous problem had indeed been settled.

Abel spent the winter of 1825–26 with Norwegian friends in Berlin, where he met August Leopold Crelle, civil engineer and self-taught enthusiast of mathematics, who became his close friend and mentor. With Abel's warm encouragement, Crelle founded the *Journal für die reine und angewandte Mathematik* ("Journal for Pure and Applied Mathematics"), the first volume of which (1826)

contains papers by Abel, including a more elaborate version of his work on the quintic equation. Other papers dealt with equation theory, functional equations, integration in finite forms, and problems from theoretical mechanics.

Abel's early mathematical training had been in the formal school typified by Euler. In Berlin new directions in mathematics stimulated him to do further independent work. Soon distracted socially, however, Abel travelled throughout Europe.

Arriving in Paris in the summer of 1826, he called on the foremost mathematicians and completed a memoir on transcendental functions. In this major work he presented a theory of integrals of algebraic functions, in particular the result known as Abel's theorem: there is a finite number, or genus, of independent integrals of this nature. This theorem forms the basis for the later theory of Abelian integrals and Abelian functions. Abel was accepted with restrained civility in Paris, for his work was still unknown. He submitted his memoir for presentation to the Academy of Sciences, hoping that it would establish his reputation; but he waited in vain. Before leaving Paris thinking he had a persistent cold, Abel consulted a physician, who informed him he had tuberculosis.

Abel's theorem

Abel returned to Norway heavily in debt. He subsisted by tutoring, by receiving a small grant from the university, and, in 1828, by accepting a substitute teaching position. His poverty and ill health did not decrease his production; he wrote a great number of papers, principally on equation theory and elliptic functions. Among them are the theory of the Abelian equations with Abelian groups. He rapidly developed the theory of elliptic functions in competition with Karl Gustav Jacobi.

By this time Abel's fame had spread to all mathematical centres, and strong efforts were made to secure a suitable position for him by a group from the French academy, who addressed Bernadotte, the king of Norway–Sweden; Crelle worked to secure a professorship for him in Berlin.

In the fall of 1828, Abel became seriously ill, and his condition deteriorated on a sled trip at Christmas time to visit his fianceé at Froland, where he died on April 6, 1829. The French Academy of Sciences published his memoir in 1841.

BIBLIOGRAPHY. The *Oeuvres complètes de N.H. Abel* (1839; new ed., 2 vol., 1881) contains all his works. For biographical discussions, see OYSTEIN ORE, *Niels Henrik Abel, Mathematician Extraordinary* (1957), with bibliography; ERIC T. BELL, *Men of Mathematics* (1937, reprinted 1961); and GANESH PRASAD, *Some Great Mathematicians of the Nineteenth Century*, vol. 1 (1933). A translation of a portion of Abel's memoir on the quintic is contained in DAVID E. SMITH, *A Source Book in Mathematics* (1929). See also C.A. BJERKNES, *Niels Henrik Abel: Mémorial publié à l'occasion du centenaire de sa naissance* (1902).

(Ed.)

Abelard, Peter

Peter Abelard, the most famous and the most controversial teacher of his age, was a logician, moral philosopher, and theologian. He was also a gifted and original poet, the founder of a famous convent for women, and the tragic lover of Héloïse. He was twice condemned for heresy by ecclesiastical councils in France.

Early life

The outline of Abelard's career is well-known, largely because he described so much of it in his famous *Historia calamitatum* ("History of My Troubles"). He was born the son of a knight in 1079 at Le Pallet in Brittany south of the Loire River. He sacrificed his rights of inheritance and the prospect of a military career in order to study philosophy, particularly logic, in France. He provoked bitter quarrels with two of his masters, Roscelin of Compiègne and William of Champeaux. The two men represented opposite poles of philosophy. Roscelin was a Nominalist who asserted that universals are nothing more than mere words; William in Paris upheld a form of Platonic Realism according to which universals exist. Abelard in his own logical writings brilliantly elaborated an independent philosophy of language. While showing how words could be used significantly, he stressed that language itself is not able to demonstrate the truth of things (*res*) that lie in the domain of physics.

Abelard was a peripatetic both in the manner in which he wandered from school to school at Paris, Melun,

Abelard, with Héloïse, miniature portrait by Jean de Meun, 14th century. In the Musée Condé, Chantilly, France.

Corbeil and elsewhere and as one of the exponents of Aristotelian logic who were called the Peripatetics. In 1113 or 1114 he went north to Laon to study theology under Anselm of Laon, the leading biblical scholar of the day. He quickly developed a strong contempt for Anselm's teaching, which he found vacuous, and returned to Paris. There he taught openly but was also given as a private pupil the young Héloïse, niece of one of the clergy of the cathedral of Paris, Canon Fulbert. Abelard and Héloïse fell in love and had a son whom they called Astralabe. They then married secretly. To escape her uncle's wrath Héloïse withdrew into the convent of Argenteuil outside Paris. Abelard suffered castration at Fulbert's instigation. In shame he embraced the monastic life at the royal abbey of Saint-Denis near Paris and made the unwilling Héloïse become a nun at Argenteuil.

Career as a monk

At Saint-Denis Abelard extended his reading in theology and tirelessly criticized the way of life followed by his fellow monks. His reading of the Bible and of the Fathers of the Church led him to make a collection of quotations that seemed to represent inconsistencies of teaching by the Christian Church. He arranged his findings in a compilation entitled *Sic et Non* ("Yes and No"); and for it he wrote a preface in which, as a logician and as a keen student of language, he formulated basic rules with which students might reconcile apparent contradictions of meaning and distinguish the various senses in which words had been used over the course of many centuries. He also wrote the first version of his book called *Theologia*, which was formally condemned as heretical and burned by a council held at Soissons in 1121. Abelard's dialectical analysis of the mystery of God and the Trinity was held to be erroneous, and he himself was placed for a while in the abbey of Saint-Médard under house arrest. When he returned to Saint-Denis he applied his *Sic et Non* methods to the subject of the abbey's patron saint; he argued that St. Denis of Paris, the martyred apostle of Gaul, was not identical with Denis of Athens (also known as Dionysius the Areopagite), the convert of St. Paul. The monastic community of Saint-Denis regarded this criticism of their traditional claims as derogatory to the kingdom; and, in order to avoid being brought for trial before the King of France, Abelard fled from the abbey and sought asylum in the territory of Count Theobald of Champagne. There he sought the solitude of a hermit's life but was pursued by students who pressed him to resume his teaching in philosophy. His combination of the teaching of secular arts with his profession as a monk was heavily criticized by other men of religion, and Abelard contemplated flight outside Christendom altogether. In 1125, however, he accepted election as abbot of the remote Breton monastery of Saint-Gildas-de-

Rhuys. There, too, his relations with the community deteriorated, and, after attempts had been made upon his life, he returned to France.

Héloïse had meanwhile become the head of a new foundation of nuns called the Paraclete. Abelard became the abbot of the new community and provided it with a rule and with a justification of the nun's way of life; in this he emphasized the virtue of literary study. He also provided books of hymns he had composed, and in the early 1130s he and Héloïse composed a collection of their own love letters and religious correspondence.

Final years

In about 1135 Abelard went to the Mont-Sainte- Geneviève outside Paris to teach and to write in a blaze of energy and of celebrity. He produced further drafts of his *Theologia* in which he analyzed the sources of belief in the Trinity and praised the pagan philosophers of classical antiquity for their virtues and for their discovery by the use of reason of many fundamental aspects of Christian revelation. He also wrote a book called *Ethica* or *Scito te ipsum* ("Know Thyself"), a short masterpiece in which he analyzed the notion of sin and reached the drastic conclusion that human actions do not make a man better or worse in the sight of God, for deeds are in themselves neither good nor bad. What counts with God is a man's intention; sin is not something done (it is not *res*); it is uniquely the consent of a human mind to what it knows to be wrong. Abelard also wrote *Dialogus inter philosophum, Judaeum et Christianum* ("Dialogue between a Philosopher, a Jew, and a Christian"), and a commentary on St. Paul's letter to the Romans, the *Expositio in Epistolam ad Romanos*, in which he outlined an explanation of the purpose of Christ's life, which was to inspire men to love him by example alone.

On the Mont-Sainte-Geneviève Abelard drew crowds of pupils, many of them men of future fame, such as the English humanist John of Salisbury. He also, however, aroused deep hostility in many by his criticism of other masters and by his apparent revisions of the traditional teachings of Christian theology. Within Paris the influential Abbey of Saint-Victor was studiously critical of his doctrines, while elsewhere William of Saint-Thierry, a former admirer of Abelard, recruited the support of Bernard of Clairvaux, perhaps the most influential figure in Western Christendom at that time. At a council held at Sens in 1140, Abelard underwent a resounding condemnation, which was soon confirmed by Pope Innocent II. He withdrew to the great monastery of Cluny in Burgundy. There, under the skillful mediation of the abbot, Peter the Venerable, he made peace with Bernard of Clairvaux and retired from teaching. Now both sick and old, he lived the life of a Cluniac monk. His death at the nearby priory of Saint-Marcel at Chalon-sur-Saône probably occurred in 1144. His body, first sent to the Paraclete, now lies alongside that of Héloïse in the cemetery of Père-Lachaise in Paris. Epitaphs composed after his death suggest that Abelard impressed some of his contemporaries as one of the greatest thinkers and teachers of all time.

BIBLIOGRAPHY. *The Letters of Abelard and Héloïse have* been translated into English by C.K. SCOTT MONCRIEFF (1925, reprinted 1964) and by J.T. MUCKLE (1947), who has also published separately a translation of *The Story of Abelard's Adversities* (1954). The historical novel *Peter Abelard*, by HELEN WADDELL (1933), is justly popular and has been reprinted many times. More general studies are ETIENNE GILSON, *Héloïse et Abélard* (1938; Eng. trans., 1953); and LIEF GRANE, *Peter Abélard* (1964; Eng. trans., 1970). Information concerning editions of Abelard's writings and studies of his thought may be found in D.E. LUSCOMBE's edition and English translation of *Peter Abelard's "Ethics"* (1971). On the reception of Abelard's thought and teaching in his own time, see D.E. LUSCOMBE, *The School of Peter Abelard* (1969). The best study of Abelard's philosophy is JEAN JOLIVET, *Arts du langage et théologie chez Abélard* (1969).

(D.E.L.)

Abraham

Abraham, the first of the Hebrew patriarchs, is the father of faith for the three great monotheistic religions: Judaism, Christianity, and Islām. He is a central figure in the biblical accounts as the recipient of a divine call, revelation, and promise; the prototype of the faithful man tested by God; and the founding ancestor of the chosen people, the first of the patriarchs of Israel. He is presented as a seer or prophet and the paradigmatic "friend of God."

The critical problem of a "biography" of Abraham. There can be no biography of Abraham in the ordinary sense. The most that can be done is to apply the interpretation of modern historical finds to biblical materials so as to arrive at a probable judgment as to the background and patterns of events in his life. This involves a reconstruction of the patriarchal age (of Abraham, Isaac, Jacob, and Joseph; early 2nd millennium BC), which until the end of the last century was unknown and considered virtually unknowable. It was assumed, based on a presumed dating of hypothetical biblical sources, that the patriarchal narratives in the Bible were only a projection of the situation and concerns of a much later period (9th–5th centuries BC) and of dubious historical value. Several theses were advanced to explain the narratives; *e.g.*, that the patriarchs were mythical beings or the personifications of tribes or folkloric or etiological (explanatory) figures created to account for various social, juridical, or cultic patterns. However, after World War I, archaeological research made enormous strides with the discovery of monuments and documents, many of which date back to the period assigned to the patriarchs in the traditional account. The excavation of a royal palace at Mari, an ancient city on the Euphrates, for example, brought to light thousands of cuneiform tablets (official archives and correspondence and religious and juridical texts) and thereby offered exegesis a new basis, which specialists utilized to show that in the biblical book of Genesis, narratives fit perfectly with what, from other sources, is known today of the early 2nd millennium BC, but imperfectly with a later period. A biblical scholar in the 1940s aptly termed this result "the rediscovery of the Old Testament."

Thus, there are two main sources for reconstructing the figure of father Abraham: the book of Genesis, from the genealogy of Terah, Abraham's father, and his departure from Ur to Harran in chapter 11 to the death of Abraham in chapter 25; and recent archaeological discoveries and interpretations, concerning the area and era in which the biblical narrative takes place.

The biblical account. According to the biblical account, Abram (The Father [or God] Is Exalted), who is later named Abraham (The Father of Many Nations), a native of Ur in Mesopotamia, is called by God (Yahweh) to leave his own country and people and journey to an undesignated land, where he will become the founder of a new nation. He obeys the call unquestioningly and (at 75 years of age) proceeds with his barren wife, Sarai, later named Sarah (Princess), his nephew Lot, and other companions to the land of Canaan (between Syria and Egypt). There the childless septuagenarian receives repeated promises and a covenant from God that his "seed" will inherit the land and become a numerous nation. He not only has a son, Ishmael, by his wife's maidservant Hagar but, at 100 years of age, by Sarah, a legitimate son, Isaac, who is to be the heir of the promise. Yet, he is ready to obey God's command to sacrifice Isaac, a test of his faith, which he is not required to consummate in the end because God substitutes a ram. At Sarah's death, he purchases the cave of Machpelah near Hebron, together with the adjoining ground, as a family burying place. It is the first clear ownership of a piece of the promised land by Abraham and his posterity. Toward the end of his life, he sees to it that his son Isaac marries a girl from his own people back in Mesopotamia rather than a Canaanite woman. He dies at the age of 175 and is buried next to Sarah in the cave of Machpelah.

Personal characteristics

Abraham is pictured with various characteristics: a righteous man, with wholehearted commitment to God, a man of peace (in settling a boundary dispute with his nephew Lot), a quick-acting warrior (he rescues Lot and his family from a raiding party), compassionate (he argues and bargains with God to spare the people of Sodom

and Gomorrah), hospitable (he welcomes three visiting angels), and an unscrupulous liar to save his own skin (he passes off Sarah as his sister and lets her be picked by the Egyptian pharaoh for his harem). He appears as both a man of great spiritual depth and strength and a person with common human weaknesses and needs.

The Genesis narrative in the light of recent scholarship. The saga of Abraham unfolds between two landmarks, the exodus from "Ur of the Chaldeans" (Ur Kasdim) of the family, or clan, of Terah and "the purchase of" (or "the burials in") the cave of Machpelah. Tradition seems particularly firm on this point. The Hebrew text, in fact, locates the departure specifically at Ur Kasdim, the Kasdim being none other than the Kaldu of the cuneiform texts at Mari. It is manifestly a migration of which one tribe is the centre. The leader of the movement is designated by name: Terah, who "takes them out" from Ur, Abram his son, Lot the son of Haran, another son of Terah, and their wives, the best known being Sarai, the wife of Abram. The existence of another son of Terah, Nahor, who appears later, is noted.

Ur Kasdim seems to have been the Sumerian city of Ur, today Tall al-Muqayyar (or Mughair), about 200 miles (300 kilometres) southeast of Baghdad in Lower Mesopotamia, which was excavated with great success from 1922 to 1934. The identification is disputed by some scholars, but most scholars continue to locate Ur of the Chaldeans at Tall al-Muqayyar, and therefore in the Sumerian city of Ur, capital of the 3rd dynasty of Ur (*c.* 2112–*c.* 2004 BC), which the patriarchal tribe left either at that time or soon after, for reasons that are impossible to determine. At any rate, it is certain that the cradle of the ancestors was the seat of a vigorous polytheism whose memory had not been lost and whose uncontested master in Ur was Nanna (or Sin), the Sumero-Akkadian moon god. "They served other gods," Joshua, Moses' successor, recalled, speaking to their descendants at Shechem.

After the migration from Ur, the first important stopping place was Harran, where the caravan remained for some time. The city has been definitely located in Upper Mesopotamia, between the Tigris and the Euphrates, in the Balikh Valley, and can be found on the site of the modern Harran in Turkey. It has been shown that Harran was a pilgrimage city, for it was a centre of the Sin cult and consequently closely related to the moon god cult of Ur. The Mari tablets have shed new light on the patriarchal period, specifically in terms of the city of Harran.

The Hebrews and Benjaminites in the Mari tablets

There have been many surprising items in the thousands of tablets found in the palace at Mari. Not only are the Ḫapiru ("Hebrews") mentioned but so also remarkably are the Banu Yamina ("Benjaminites"). It is not that the latter are identical with the family of Benjamin, a son of Jacob, but rather that a name with such a biblical ring appears in these extrabiblical sources in the 18th century BC. What seems beyond doubt is that these Benjaminites (or Yaminites, meaning "Sons of the Right," or "Sons of the South," according to their habits of orientation) are always indicated as being north of Mari and in Harran, in the temple of Sin. The patriarchs at Harran noted in chapter 11 of Genesis and the Benjaminites at Harran mentioned in the Mari text provide a perfect concordance. There are also other parallels: these Benjaminites were in the habit of using fire beacons, which their descendants were to employ much later in Israel. They are pillagers and raiders like the people of Jacob's blessing listed in chapter 49 of Genesis, in which the tribe of Benjamin is described exactly in this way. And in the tablets of Mari, there is frequent mention of "the city of Nakhur" (probably the equivalent of Nahor), of a Laba-an (Laban) and of several Aramu (Aramaeans). It is impossible not to be reminded that Laban, Jacob's father-in-law, is called "the Aramaean" several times in Genesis and that the nomadism of the ancestors applies just as well to the incessant movings of the tribes (the Haneans, Sutaeans, Ḫapiru, Benjaminites, and Benê-sim'âl) that abound in the Mari texts. All of this documentation leads so close to the image reflected in the book of Genesis that it is possible to understand the enthusiasm of William F. Albright, an eminent biblical archaeologist, when he writes: one can no longer doubt the substantial correctness of the Hebraic tradition which has Abraham's family come from the Harran region, between the Euphrates and Khabur. The portrait of the customs and relationships rings true in the light of the newly discovered sources.

From Harran toward Canaan

The Bible has given no information on the itinerary followed between Ur and Harran. Scholars think that the caravan went up the Euphrates, then up the Balikh. After a stay of indeterminate length in Harran, the Bible says only that Terah died there, at the age of 205, and that Abraham was 75 when he took up the journey again with his family and his goods. This time the migration went from east to west, first as far as the Euphrates, which they may have crossed at Carchemish, since it can be forded during low-water periods. Here again, the Mari texts supply a reference, for they indicate that there were Benjaminites on the right bank of the river, in the lands of Yamhad (Aleppo), Qatanum (Qatna), and Amurru. Since the ancient trails seem to have been marked with sanctuaries, it is noteworthy that Nayrab, near Aleppo, was, like Harran and Ur, a centre of the Sin cult and to note that a few kilometres south of Aleppo, on the road to Ḥamāh, there is still today a village that bears the name of Benjamin. The route is in the direction of the "land of Canaan," the goal of the journey. If the tribe made a slight detour then, since it was to settle in Sichem (Shechem) and pass on to Damascus, this would explain the presence of a foreigner, Eliezer, a native of Damascus, who became the "servant" of Abraham, a sort of majordomo or steward, having authority over Abraham's entire household. However, this is uncertain, for the text is unreliable, specifically on the subject of the origins of the steward, whose name, Eliezer (My God is Help), presents no difficulty.

If a stop in Damascus is assumed, the caravan must next have crossed the land of Bashan (the Ḥawrān of today), first crossing the Jabboq, then the Jordan at the ford of Dāmiyā, arriving in the heart of the Samaritan country, to reach at last the plain of Shechem, today Balāṭah, at the foot of the Gerizim and Ebal mountains. Shechem was at the time a political and religious centre, the importance of which has been perceived more clearly as a result of recent archaeological excavations. From the mid-13th to the mid-11th centuries BC, Shechem was the site of the cult of the Canaanite god Baʿal-Berit (Lord of the Covenant); at this site a magnificent *matzeva* (sacred stone pillar) was discovered. There was also the "oak of Moreh" mentioned in the account of Abraham's journey to Shechem, an essential element in the local Semitic cult. The architecture uncovered by archaeologists, at least that of the palace, would date back to the 18th century, the period in which the presence of the patriarchs in Shechem is placed.

Bethel, Hebron, and the oaks at Mamre

The next stopping place was in Bethel, identified with present-day Baytīn, north of Jerusalem. Bethel was also a holy city, whose cult was centred on El, the Canaanite god *par excellence*. Its name does not lend itself to confusion, for it proclaims that the city is the *bet*, "house" or temple, of El (God). The Canaanite sanctuary was taken over without hesitation by the patriarchs, who built their altar there and consecrated it to Yahweh, at least if the Yahwistic tradition in Genesis is to be believed. Certainly this memory remained particularly alive in the hearts of the Israelites. Bethel remained for centuries the sanctuary *par excellence* for them. Even more than Abraham, they associated Jacob with it when, on the road to Harran, he had the dream of the ladder. But if Jacob stopped to spend the night in this place, it was because the spot had been marked in the past by the presence of an ancestor, namely, Abraham.

The latter had not yet come to the end of his journey. Between Shechem and Bethel he had gone about 50 kilometres. It was about as far again from Bethel to Hebron, or more precisely to the oaks of Mamre, "which are at Hebron" (according to the Genesis account). The location of Mamre has been the subject of some indecision. At the present time, there is general agreement in setting it 1.5

miles (two kilometres) northwest of Hebron at Rāmat al-Khalīl, an Arabic name which means the Heights of the Friend, the friend (of God) being Abraham.

Mamre, where there was an oak (if not a grove of oaks), marked the site of Abraham's encampment, but this did not at all exclude episodic travels in the direction of the Negeb, to Gerar and Beersheba. Life was a function of the economic conditions of the moment, of pastures to follow and to find, and thus the patriarchs moved back and forth between the land of Canaan and the Nile delta. They remained shepherds and never became cultivators. It was in Mamre that Abraham received the revelation that his race would be perpetuated, and it was there that he learned that his nephew Lot had been taken captive. The latter is an enigmatic episode, an "erratic block" in a story in which nothing prepared the way for it. Suddenly, the life of the patriarch was inserted into a slice of history in which several important persons ("kings") intervene: Amraphel of Shinar, Arioch of Ellasar, Ched-or-laomer of Elam, and Tidal of Goiim. Scholars of previous generations tried to identify these names with important historical figures—*e.g.* Amraphel with Hammurabi of Babylon—but little remains today of these suppositions. The whole of chapter 14 of Genesis, in which this event is narrated, differs completely from what has preceded and what follows. It may be an extract from some historical annals, belonging to an unknown secular source, for the meeting of Melchizedek, king of Salem and priest of God Most High (El ʿElyon), and Abraham is impressive. The king-priest greets him with bread and wine on his victorious return and blesses him in the name of God Most High.

The meeting with Melchizedek, king-priest of Salem

In this scene, the figure of the patriarch takes on a singular aspect. How is his religious behaviour to be characterized? He swears by "the Lord God Most High"—*i.e.*, by both Yahweh and El ʿElyon. It is known that, on the matter of the revelation of Yahweh to man, the biblical traditions differ. According to what scholars call the Yahwistic source (J) in the Pentateuch (the first five books of the Bible), Yahweh had been known and worshipped since Adam's time. According to the so-called Priestly source (P), however, the name of Yahweh was revealed only to Moses. It may be concluded that it was probably El whom the patriarchs, including Abraham, knew. As noted before, in Mesopotamia the patriarchs worshipped "other gods." On Canaanite soil, they met the Canaanite supreme god, El, and adopted him, but only partially and nominally, bestowing upon him qualities destined to distinguish him and to assure his pre-eminence over all other gods. He was thus to become El ʿOlam (God the Everlasting One), El ʿElyon (God Most High), El Shaddai (God, the One of the Mountains), and El Roʾi (God of Vision). In short, the god of Abraham possessed duration, transcendence, power, and knowledge. This was not monotheism but monolatry (the worship of one among many gods), with the bases laid for a true universalism. He was a personal god too, with direct relations with the individual, but also a family god and certainly still a tribal god. Here truly was the "God of our fathers," who in the course of time was to become the "God of Abraham, Isaac, and Jacob."

It is not surprising that this bond of the flesh should still manifest itself when it came to gathering together the great ancestors into the family burial chamber, the cave of Machpelah. This place is venerated today in Hebron, at the Ḥaram al-Khalīl (Holy Place of the Friend), under the mosque, and seems to have retained all its mystery. Abraham, "the friend of God," was forevermore the depositary of the promise, the beneficiary of the Covenant, sealed not by the death of Isaac but by the sacrifice of the ram that was offered up in place of the child on Mount Moriah.

BIBLIOGRAPHY. A study of the patriarch Abraham is based on scriptural documentation and particularly on Genesis. One should therefore first consult a critical translation of the first book of the Old Testament as one finds in a basic work such as: EPHRAIM A. SPEISER (ed. and trans.), *Genesis: Introduction, Translation, and Notes*, "Anchor Bible" (1964). Also worthwhile are the atlases and albums that give illustrated introductions: L.H. GROLLENBERG, *Atlas van de Bijbel*, 3rd ed. (1955; Eng. trans., *Atlas of the Bible* 1956); and G.E. WRIGHT and F.V. FILSON (eds.), *The Westminster Historical Atlas to the Bible*, rev. ed. (1956). Articles under "Abraham" in several dictionaries on the Bible, such as *The Interpreter's Dictionary of the Bible* (1962) and *The Westminster Dictionary of the Bible* (1944) are also useful.

The world of the patriarchs has called forth numerous works, among which these take into account the most recent archaeological discoveries: H. CAZELLES, "Patriarches" in *Supplément au Dictionnaire de la Bible*, 7 (1961); WILLIAM F. ALBRIGHT, *The Biblical Period from Abraham to Ezra* (1963); H.H. ROWLEY, "Recent Discovery and the Patriarchal Age," *Bulletin of the John Rylands Library*, 32:44–79 (1949); ROLAND DE VAUX, "Les Patriarches hébreux et les découvertes modernes," *Revue Biblique* (1946–49); and *Les Institutions de l'Ancien Testament*, 2 vol. (1958–60; Eng. trans., *Ancient Israel: Its Life and Institutions*, 2nd ed., 1965). Centred on the city of Ur and the discoveries that were made there is SIR LEONARD WOOLLEY, *Abraham: Recent Discoveries and Hebrew Origins* (1936); some of his analogies must be rejected. On the texts gathered at Mari and dating from the 18th century BC, which are of very great importance for biblical exegesis, see G. DOSSIN, "Benjaminites dans les textes de Mari," *Mélanges syriens*, 2:981–996 (1939); and J.R. KUPPER, *Les Nomades en Mésopotamie au temps des rois de Mari* (1957). A. PARROT, *Abraham et son temps* (1962; Eng. trans., *Abraham and His Times*, 1968), presents a synthesis of the double archaeological and epigraphical documentation.

(A.Pa.)

Abrasives

Abrasives are sharp, hard materials used to wear away the surface of softer, less resistant materials. Included within the term are both natural and manufactured substances ranging from the relatively soft particles used in household cleansers and jeweller's polish to the hardest known material, the diamond. Abrasives are indispensable to the manufacture of nearly every product made today.

Abrasives are used in the form of grinding wheels, coated abrasives (sandpaper), honing stones, polishes, cutoff wheels, tumbling and vibratory mass-finishing media, sandblasting, pulpstones, ball mills, and still other tools and products. Only through the use of abrasives is industry able to produce the highly precise components and ultrasmooth surfaces required in the manufacture of automobiles, airplanes, and space vehicles, mechanical and electrical appliances, and machine tools.

HISTORY

The use of abrasives goes back to earliest man's rubbing of one hard stone against another to shape a weapon or a tool. The Bible mentions a stone called *shamir* that was very probably emery, a natural abrasive still in use today. Ancient Egyptian drawings show abrasives being used to polish jewelry and vases. A statue of a Scythian slave, called "The Grinder," in the Uffizi art gallery in Florence, shows an irregularly shaped natural sharpening stone used to whet a knife.

Sand and pieces of flexible hide were early man's sandpaper. Later, craftsmen tried to fix abrasive grains to flexible backings with crude adhesives. A 13th-century Chinese document describes the use of natural gums to fix bits of seashell to parchment. About two centuries later, the Swiss began coating crushed glass on a paper backing.

Early sand and glass abrasives lacked sharpness, and by the 19th century early abrasive products like the natural sandstone that man had formed into the "grinding wheel" no longer met the needs of developing industry. In 1873 Swen Pulson, working in the Norton and Hancock Pottery Company, Worcester, Massachusetts, won a jug of beer by betting that he could make a grinding wheel by combining emery with potter's clay and firing them in a kiln. Pulson succeeded on his third try; this incident signalled the end of unsatisfactory glue-and-silicate bonded products and the birth of the vitrified grinding wheel.

Just before the turn of the century, when nature's abrasives emery, corundum, and garnet were falling short of industry's demands, man discovered how to make aluminum oxide and silicon carbide with the electric fur-

First synthetic diamonds

nace. In 1955 the General Electric Company succeeded in manufacturing diamond. Like other man-made abrasives synthesized diamond proved superior, in many applications, to the natural product, which had been used in grinding wheels since 1930.

Once used only when precise dimensional accuracy and smooth surfaces were necessary, abrasives have become a widely applied industrial tool. Higher grinding-wheel speeds, higher horsepowered grinding machines, and improved abrasives and abrasives products have steadily augmented their role.

NATURAL ABRASIVES

Most natural abrasives have been replaced by manufactured or synthetic abrasives. This is because nearly all industrial applications demand consistent properties from lot to lot for uniform manufacturing results. With the exception of natural diamond, most of nature's abrasives are too variable in their properties. Natural abrasives, however, are still important.

Diamond. Diamond is the hardest abrasive, and in fact the hardest material known. India was the main source of diamonds until the 1860s when they were discovered in South Africa, which still supplies 95 percent of all diamonds mined. Lesser quantities are found in Brazil, Australia, Guyana, and Venezuela.

Stones not suitable for use as gems (called bort or boart) are designated for industrial purposes. The portion used as abrasive is crushed into various sizes for grinding wheels, lapping (fine polishing) powders, coated abrasive belts, and polishing disks. Industrial diamonds vary in colour from off-white to black.

The shape of a diamond particle is important to its performance. Natural diamonds are sorted for shape. Blocky shapes are suited for more severe grinding operations such as cutting concrete building blocks. More splintery shapes are reserved for grinding the cemented tungsten-carbide cutting tools used in industry.

Corundum. Corundum is a naturally occurring form of aluminum oxide, found mainly in South Africa. Other deposits have been found in India, Canada, and the southern part of the United States. Corundum varies in its properties from location to location and even from within the same location, making it unsuitable for use in grinding wheels. Its principal utility is in polishing and glass grinding.

Emery. Also a natural form of aluminum oxide, emery is generally more impure than corundum. It consists of smaller aluminum oxide crystals, imbedded in an iron oxide matrix. Principal sources are Turkey and Greece. Its rather round grain shape makes it more suitable for polishing than for grinding. Along with corundum, emery was an important early abrasive and is still used in emery cloth sandpaper.

Garnet. Far superior to flint, and still valuable for coated abrasive products in the woodworking, leather, and shoe industries, garnet possesses considerable toughness. When its cutting crystal edges break down, garnet fractures sharply to present new cutting edges.

Of the seven known forms of garnet, the best for abrasive use comes from the Adirondack Mountains in New York and is mined by a process similar to panning for gold.

Flint. Flint, or flint quartz, is the most commonly used abrasive in the manufacture of coated abrasive paper (sandpaper). Though flint is found all over the world, not all varieties are suitable as abrasives. The best type varies in colour from a dull grayish white to a faint pink and comes from the eastern United States, where it is mined from open pits. Lumps, varying in size from four to ten inches (ten to 25 centimetres) in diameter, are crushed into sharp crystals. Flint lacks durability and hardness and loses its abrasive cutting action rather quickly.

Quartz. Quartz is the main ingredient of sandstone, which was for years hewn from natural deposits and formed into the first grinding wheels. Until recently these were used in the glass, cutlery, and woodworking edge-tool industries. The best stones came from Ohio and West Virginia. Although still in use where production rate is not a factor, as on a farm, they have been replaced by higher speed, higher efficiency manufactured grinding wheels and equipment.

In other forms, quartz is found in dense stones in the United States and in Belgium. These are used as honing and sharpening stones for putting the final, keen edge on cutlery and various cutting tools and are used for honing machined parts and products to accurate size and smooth finish.

Quartz in the form of sand is used as an inexpensive, disposable abrasive for sandblasting buildings and metal structures such as bridges, when it is impractical to recover the abrasive. In a crushed or grain form, it is used in buffing and polishing wheels.

Pumice. Volcanic in origin, pumice is the frothy part of lava. The best quality, in lump form, is mined in Italy. Its mild action is utilized in metal polishing, glass cutting, furniture finishing, scouring powders, and soaps.

Tripoli. Tripoli (or Diatomite) is also used in scouring powders and soaps, in grease sticks for buffing, and as a polish ingredient. The principal United States sources are Missouri and Oklahoma. Other sources are Iceland and Kenya.

Other natural abrasives. Talc is the softest and mildest abrasive. It was used in the past to polish grains of rice. In addition to sandstone, other varieties of silica, such as rottenstone, which comes from the weathering of impure limestones, and diatomite, an opaline silica consisting of the fossilized remains of microscopic plants, are used in polishes. Calcined (roasted) diatomite is an effective polishing agent for use on nickel plate. Others include feldspar, chert, and chalk.

MANUFACTURED ABRASIVES

By the 1970s, manufactured abrasives represented the larger share of world production and use. The two most important manufactured abrasives, silicon carbide and aluminum oxide, were developed in the late 19th century by use of the electric furnace. These proved to have the consistent quality required by industry. Their principal value is for use in grinding wheels, coated abrasive products, and polishing and buffing wheels. Because large amounts of electric power are required in their manufacture, electric furnace abrasives are made where power is cheap and plentiful.

Silicon carbide. Silicon carbide was first produced by Edward G. Acheson, an electrical engineer in Monongahela City, Pennsylvania. In 1891 he combined a mixture of clay and powdered coke in a small electric furnace. The resulting hard, shiny crystals were able to scratch glass and were first used for polishing precious stones. Initially, the price of silicon carbide was nearly equal to that of the gemstones it polished.

In the manufacture of silicon carbide, a mixture of pure silica sand and carbon in the form of finely ground coke is built up around a carbon electrical conductor within a brick furnace. Electrical current is passed through the carbon conductor, generating heat and bringing about a chemical reaction in which the carbon in the coke and silicon in the sand combine to form silicon carbide. A little sawdust is added to the mixture. The sawdust burns, making the mixture porous and permitting the escape of great quantities of inflammable gas.

At the completion of the furnace run the product consists of a core of silicon carbide crystals loosely knitted together, surrounded by partially or entirely unconverted raw material. The quality of the abrasive produced depends largely upon the choice of raw materials and the accuracy of the control and operation of the furnace.

A number of companies produce silicon carbide under such trade names as Carborundum, Crystolon, Carbolon, etc.

Silicon carbide manufacture

The method used to manufacture silicon carbide today is basically the same as that developed by Acheson. The major changes are in the size of the furnace and control of the ingredients, techniques, and the understanding of the process. Time for a furnace run is about 36 hours, during which temperatures vary from 4,000° to 4,500° F (2,200° to 2,480° C) in the core and drop to about

2,500° F (1,370° C) at the outer edge. The furnaces are the shape of a large trough with electrodes at either end. The power amounts to over 100,000 kilowatt-hours per run. Furnaces are about 40 feet long, 10 feet high, and 10 feet wide and can produce about 25,000 pounds of silicon carbide per run.

Aluminum oxide. Manufacture of aluminum oxide abrasive closely followed the development of silicon carbide. Although there are records of previous experiments to produce emery and corundum abrasives, the world's first successful attempts were made in the laboratories of the Ampere Electro-Chemical Company at Ampere, New Jersey, in 1897. Rock bauxite, the main ingredient of which is aluminum oxide, was used as the raw material.

The results were sufficient to arouse interest. Several hundred tons of the new abrasive were distributed throughout industry for testing, and the outcome of this testing was the construction of a plant at Niagara Falls in which the manufacture of crystalline aluminum oxide on a commercial scale was begun in 1901.

Bauxite is a claylike substance. Found near the surface, it is one of earth's most plentiful minerals. It is also the source of aluminum. Principal mines are in Surinam, Guyana, and the United States. Bauxite consists of aluminum oxide, Al_2O_3, combined with water and associated with varying quantities of other impurities. By heating the ore to drive off the combined water before the material goes into the electric furnace (an operation called calcining), the percentage of aluminum oxide is greatly increased over its content in the natural state.

Arc-type electric furnaces are used for manufacturing aluminum oxide. Two carbon electrodes are suspended in the furnace. The furnace is charged with the crude ore. Current passes from one electrode to the mass, passes through it, then arcs back to the other electrode. This produces an intense heat of over 2,000° F, which melts the bauxite and reduces the major portion of the impurities to their base metals. Small percentages of coke and iron borings combine with the impurities, thus helping to settle them to the bottom of the mass. During the furnace run of approximately 16 hours, fresh bauxite charges are continually added.

At the end of the furnace run, the large steel jacket or outer shell of the furnace is lifted and the hot chunk of aluminum oxide is allowed to cool. Cooling time varies from one day to one week depending on the type of crystal structure desired.

Both the chemical composition and the crystalline structure of the abrasive are important in the control and variation of the abrasive properties. A wide variation is possible; this characteristic has been utilized in tailoring aluminous abrasives to specific industrial applications. The types vary in colour from one that is pure, snow-white, of large crystals, and friable, used for the grinding of heat-sensitive metals, to the nearly black, finely crystalline, less pure kinds used for heavy-duty operations in foundries and steel mills.

Recent developments include alloy abrasives, made by adding, for example, zirconium oxide to aluminum oxide and the spinel (a hard crystalline mineral) and aluminum oxide combinations.

Produced by a number of companies under a variety of trade names, aluminum oxide is the most important abrasive used.

Synthetic diamond. Synthetic diamonds, initially more expensive than natural diamonds, have proved to be more efficient in the grinding wheels used for manufacturing and sharpening cutting tools made of cemented tungsten carbide. Because of the more irregular surface of the synthesized diamond, the bond between the grinding wheel and the diamond particles lasts longer.

Diamond is now manufactured in a variety of shapes and sizes for different types of grinding operations. By changes in the process, the diamond can be manufactured in shapes suitable for cutting ceramics and glass.

Metallic coating on the surface of the manufactured diamond also improves bonding. Nickel and copper have proved to be the most successful coatings. Both are heat conductors and serve to dissipate the heat of grinding and, thus, act as a bonding interlayer, which improves bonding strength.

Boron carbide. A product of the electric furnace, boron carbide is harder than silicon carbide but is not suitable for use in grinding wheels or coated abrasive products. It does have some utility as a lapping (fine polishing) abrasive, substituting for diamond in the polishing of hard materials. It is made from the combination of coke and boric acid at very high temperature. In solid form, boron carbide becomes extremely wear resistant.

Boron nitride. Cubic boron nitride was first synthesized by the General Electric Company. Its hardness is reported to be twice that of silicon carbide and two and one half times that of aluminum oxide. High-pressure techniques are used in making the material, which has strong crystals and sharp points with clearly defined edges. Despite its hardness, the initial forms of boron nitride did not have the mechanical strength necessary for grinding.

Cubic boron nitride with a bonded nickel coating is a useful abrasive. Although more expensive than industrial diamond abrasive, its grinding efficiency on certain tool-steel applications has made it economically feasible to use. Continued experiments in its manufacture may result in lower costs for this newest of manufactured abrasives.

Other manufactured abrasives. Other manufactured materials employed as abrasives are neither as hard nor as abrasive on work surfaces as those listed above. Glass beads manufactured specifically for use in blasting machines, utilizing air pressure to propel them against a workpiece, remove rust and scale. Basically a cleaning abrasive, they do not materially alter the dimensions of the workpiece.

Metal shot made of bronze, iron, steel, and steel alloy is used for shot blasting and cleaning in foundries, and by forging companies to clean castings and parts and to alter surface finishes. Shot is also used for relieving internal stresses.

Steel wool, made by combing the wire that forms steel fibres (with equipment similar to that used in carding wool), is used to clean and finish wood and many other materials. The size of the steel fibres is changed by varying the size of the teeth in the card-clothing, the more abrasive product being the one with coarser wires.

ABRASIVE PROPERTIES AND MANUFACTURE

One of the most important properties necessary in an abrasive material is hardness. The abrasive must be harder than the material it is to grind, polish, or remove. Hardness of the various abrasive materials is measured on either the Mohs scale or the Knoop hardness scale. The Mohs scale, first described in 1812, measures resistance to indentation as judged by which material will scratch another. This scale, which assigns numbers to natural minerals, has been widely accepted and is used by mineralogists. The Knoop hardness test employs an elongated diamond-shaped indenting device and measures the indentation it makes in a given test material. With the Knoop test, the hardness of extremely brittle materials including glass and even diamonds can be measured without harming either the indenter or test piece (see MATERIALS TESTING).

Measuring hardness

Toughness or body strength characteristics are significant to abrasive function. Ideally, a single abrasive particle resharpens itself by the breakdown of its dull cutting or working edge, which exposes another cutting edge within the same particle. In manufactured abrasives it is possible to achieve some degree of control over this property by varying grain shape during the crushing or sizing operation, by making changes in the purity of the abrasive, by alloying abrasives, and by controlling the crystal structure within abrasive grains. Thus abrasives can be developed to meet the operating conditions found in a variety of applications.

Interaction between the abrasive and the material being ground prevents the use of one abrasive as a universal medium. When silicon carbide is used on steel, or alu-

minum oxide on glass, there is some reaction, which has yet to be clearly defined. Regardless, the effect is rapid dulling and inefficient abrasive action. Attrition resistance is the name given to this third, very significant property.

Preparation and sizing. All abrasives, with the exception of the naturally appearing fine powders such as talc and iron oxide, must be crushed to the particle size required for use. Sizes in use vary from 4 grit, which measures about ¼ inch (six millimetres) in diameter, to as fine as 900 grit, which measures about six microns (0.00024 inch) or about one-tenth the thickness of a human hair. In some cases, even finer powders are required when used for the polishing of scratch-free surfaces on high-quality optical lenses and mirrors for high-power telescopes.

For the coarser sizes the crushed grain is measured by a series of test screens as established in most countries by government standards. For sizes 240 grit and smaller, the size of the grains is usually measured by a settling rate or sedimentation test.

Crushing methods have a significant effect on the cutting action and the strength of abrasive grains. Heavy crushing pressures, for example, tend to create splintery, sharp, and weak grains. These penetrate easily, remove material at a fast rate, and their cutting edges break down easily for resharpening. This shape is required in many coated abrasive products.

When a grinding wheel or coated abrasive belt is to be used to grind away large amounts of material, under heavy pressures, a strong pulverized abrasive grain stands up longer. The sharp edge is not as necessary because heavy pressures are used that effect the penetration of the abrasive into the material being ground.

Abrasive product manufacture. The most important abrasive product manufactured is the grinding wheel. Made of abrasive grain and a binder, or "bond," it is a self-sharpening cutting tool. As the grains on the periphery become dull, they are shed from the surface of the grinding wheel and fresh, sharp cutting edges are exposed. The ability to resharpen is controlled by the nature of the bond used and the ratio of abrasive to bond, measured by volume.

In the manufacture of grinding wheels, abrasives of the proper size and bonding materials are weighed out and mixed together in a power mixing machine. When thoroughly mixed, measured amounts of the abrasive and bond mixture are evenly distributed in steel molds. The mold is placed in a powerful hydraulic press, and the mixture is compressed to the desired wheel size, allowing some oversize in dimensions for finishing operations. Pressures vary with wheel size and may be upward of several hundred tons. Some shaving and shaping of the wheels is done before they are baked or fired.

The majority of grinding wheels made have a vitreous, ceramic bond, made of clays and feldspars. The so-called vitrified wheel is fired in high-temperature kilns at temperatures of 2,300° F (1,260° C). Electric-, oil-, and gas-fired kilns are used. The length of the "burn" varies with wheel size and can be as long as two weeks.

The remaining 35–40 percent of the grinding wheels manufactured have organic type bonds using either resins, rubber, or shellac as the bonding material. These wheels are baked at temperatures between 300° and 400° F (150° and 200° C).

The lower temperature permits the inclusion of steel rings, molded-in threaded bushings, or fibreglass reinforcements, which become baked into the wheel and serve to make it more resistant to breakage from side pressure. The bushings help to hold the wheel in place on certain grinding machines.

Organic wheels can be made much thinner than vitrified wheels, and they are used in place of metal saw blades for cutting a great variety of materials.

Truing a grinding wheel

Nearly all grinding wheels must be finished after they have been baked or fired. In a process called truing, the wheels are cut to final size, and the outside glazed layers resulting from the kiln are removed, making the sides of the wheel parallel, and the size of the arbor hole accurate; at the same time the working surface of the wheel is sharpened. Wheels are trued with conical steel cutters, by rubbing in beds of steel shot, and by actually grinding them with grinding wheels.

Grading of wheels assures they have the correct resistance to wear. Grade or hardness, determined by the amount of bond, permits the grinding wheel to keep itself sharp and free cutting in a variety of conditions. Grinding wheels used for heavy grinding operations are "harder" and are made with greater amounts of bond, retaining the abrasive particles longer under severe conditions such as those found in steel mills and foundries. In the tool room where industrial cutting tools are sharpened, softer wheels, with less bond per unit of abrasive, are required so that as soon as the abrasive grains start to dull, and the possibility of building up heat develops in the sensitive cutting tool being ground, the wheel will resharpen and shed the dulled grains.

Finally, grinding wheels are checked for balance to assure that they will run without vibration.

Grinding wheels six inches in diameter and larger are usually speed tested. The wheel is rotated at a speed at least 50 percent greater than the maximum allowable operating speed. This is a nondestructive measure of the wheel's bursting strength.

The same basic processes are used in the manufacture of abrasive bricks, sticks, and formed shapes. These are used as rubbing blocks, sharpening stones, honing stones, and shaped abrasive media for tumbling or mass finishing.

Sandpapers (coated abrasive) are the next most significant abrasive product. They consist, basically, of a single layer of abrasive particles held to a flexible backing material.

Manufacture begins with huge rolls of backing material, either paper, cloth, or a combination of the two. The backing is fed to the making machine where the first layer of adhesive is applied. Next, the layer of abrasive is applied, either by gravity or electrostatically. The electrostatic method orients the slivery type of abrasive used, with the sharp ends facing out. The process can also control the spacing of the grains. This is an advantage in that wide spacing helps to alleviate loading problems when grinding soft, stringy, or gummy materials.

After being coated with the abrasive layer, the product is draped in long festoons in which it dries partially. Then it is run through another sizing operation and a second layer of adhesive is applied. The product is draped, allowed to dry thoroughly, and wound into large-diameter rolls.

The adhesives used to bond the abrasive to the backing are water soluble, waterproof, or a combination of the two. Water-soluble types are used for dry grinding operations and in household sanding, and occasionally on wood-sanding commercial operations. Resin or resin-over-glue types currently in use have the flexibility associated with the soluble types. The all-resin is best for severe operations; its properties are such that the heat of grinding actually increases the adhesive's holding strength.

Disks for right-angle grinders are die cut. Sheets are cut in the standard lengths and widths used in production and household applications. Strips are slit, cut to length and their ends joined to make up the coated abrasive belts that have become an essential part of industry, replacing several kinds of abrasive wheels used previously.

The cutting action of coated abrasive products is determined by the abrasive used, the grit size, the density or spacing of the grit, the strength of the adhesive, and the flexibility of the backing material. Flexibility can be achieved by flexing or breaking the bond.

Other products use the abrasive in the form of grains or powders. In addition to the sizing operation, many types are specifically treated, by calcining, acid, or heating, to make them more suitable for use as lapping abrasive or perhaps as sandblasting grain. For use in lapping and polishing, the abrasive is usually mixed with a vehicle such as mineral or seal oil. Polishing sticks consist of waxes or greases impregnated with various-sized abrasive

grains, depending on the particular requirements of the work.

Two materials used really for cleaning rather than grinding are still abrasive in nature. Glass beads, pressure blasted onto a surface, remove rust, scale, and carbon. These have replaced much hand cleaning with steel wool. Steel wool still has some applications.

INDUSTRIAL APPLICATIONS

Grinding, the most important abrasive application, is in some way involved in the manufacture of almost every product. This use may be direct, as when the product requires pieces that must be made within close dimensional tolerance limits, or a very smooth surface, or when used on materials too hard to be machined by conventional cutting tools, or indirect, as when, for example, grinding wheels are used to sharpen cutting tools. The materials that are used to make cutting tools must of course be hard in order for the cutting tool to cut and retain its sharp edge. Abrasive grinding wheels are the only means for sharpening the dull edges of such tools.

Grinding wheels in use in industry today rotate at peripheral speeds up to 180 miles (290 kilometres) per hour. The abrasive wheel may throw a 40-foot stream of bright yellow sparks and remove upward of 1,000 pounds (450 kilograms) of metal per hour while grinding out the imperfections from the surface of a bar of stainless steel. Or the grinding wheel may be as small as 0.022 inch (0.55 millimetre) in diameter, may rotate at 150,000 revolutions per minute, and may grind miniature precision ball bearings to accuracies measured in millionths of an inch.

In the automotive industry, only abrasives can produce the tight fit required between piston rings and cylinders to prevent the escape of compressed gasoline vapours. Valves and valve seats are ground. Bearing surfaces in the engine, transmission, and wheels need specific finish, size, and roundness to assure frictionless rotation. These can be achieved only with abrasive tools.

Abrasive machining, the use of abrasives rather than high-speed steel or tungsten carbide cutting tools, makes use of the self-sharpening grinding wheel and eliminates tool sharpening costs. The ability to grind hardened materials without the previously necessary prehardening machining saves intermediate part-handling operations.

Speed and improved grinding systems, machines, and grinding tools are the main reason for the increased importance of grinding. One-hundred-horsepower motors, automatic loading equipment, high-speed grinding wheels removing unbelievable amounts of hard-to-grind materials, ultrafine tolerances, and machines costing $100,000 and more are part of the new abrasives systems that are capable of fantastic rates of production. Yet, the abrasive products portion of the total cost to grind the part may be as low as 5 percent, even though the grinding wheel, with diamond as the abrasive, might cost $14,000. Or the wheel might cost 28 cents and be used to shape a die used in the manufacture of tableware.

Relatively new products, such as plastic bonded tumbling media for mass finishing a multitude of parts, have eliminated time-consuming, hand-deburring operations, a plague to the aircraft industry, in which the high cost of labour makes handwork prohibitively expensive. Parts with rough edges are tumbled in a rotating barrel of loose abrasive or preshaped abrasive pieces. As the mass slides, burrs are ground away, surfaces are finished, and edges are smoothed. When the same parts and media are mixed in a vibrating tub, the process becomes even more productive.

Abrasive wheels have replaced steel saws in many places. Thin, abrasive cutoff wheels are capable of sawing through nearly every material known, at rates faster than those of metal saws, while generating less heat and producing a better cut surface. Some space-age metals, because of their hardnesses, can be cut only with abrasive wheels. Granite, marble, slate, and various building blocks are cut to size with diamond abrasive wheels. Grooves for expansion joints and for the reduction of wet-weather skidding accidents are cut in concrete runways and highways by blades with a metal centre, onto which are brazed metal segments with the diamond abrasive mixed throughout.

Tool sharpening

The sharpening of all types of tools continues to be a major grinding operation. Drills, saws, reamers, milling cutters, broaches, and the great spectrum of knives are kept sharp by abrasives. Coarser grit products are used for their initial shaping. Finer grit abrasives produce keener cutting edges. Ultrasharp tools must be hand honed on natural sharpening or honing stones. Even grinding wheels themselves may require some sharpening. Specially designed steel disks or diamond tools are used to remove dull abrasive cutting edges and create a sharp cutting surface.

In foundries and steel mills, grinding wheels and coated abrasive belts remove the unwanted portions of castings, forgings, and billets. Abrasive grit is pressure blasted against the metal to clean it in preparation for painting. Metal shot is used on softer metallic castings.

The roster of unusual applications for abrasives includes frozen fish cut into fish sticks; animal-gut sutures and guitar strings ground to constant diameters; human skin blemishes and birthmarks removed or bones shaped by plastic surgery; spots and discolorations removed from suede clothing; toothpicks ground round; and stairs made skidproof by abrasive grain.

STATISTICS

Grinding wheels range in size from ten-ton pulpstones used to chew pulpwood into 80 tons of newsprint per day to 0.022-inch-diameter mounted wheels grinding miniature bearings. Some abrasives used for polishing are so tiny that if scented the minute particles would pass for talcum powder. Yet, when made into a polishing compound, they grind as surely, yet minutely, as the 72-inch-diameter wheels used to grind files and saws.

Competition in the abrasives market (about $1,000,000,000 annually in the non-Communist world) has prompted manufacturers throughout the world to develop more efficient abrasive tools and machines. Technological advances have increased the efficiency of diamond abrasive wheels five times in the last 14 years. The zirconia–aluminum oxide abrasive wheel used in steel mills grinds eight times faster, at one-tenth the abrasive cost, and, despite a fivefold increase in labour and overhead rates, at 25 percent of the total cost of 1948.

Yet, despite many advances, the basics of the grinding operation are not clearly understood and are still the subject of research. One industry problem is the multiplicity of sizes and varieties. One leading abrasive manufacturer stocks 1,000 different types and sizes, 38,000 sandpapers, and 250,000 grinding wheels. Experts are still unable to specify the exact optimum combination of inputs for a well-defined grinding operation on a specific part. There are still too many variables.

Even in the 1970s, when an exceptionally smooth, polished finish or an especially sharp edge is required, the job usually calls for the highly skilled craftsman employing hand tools and methods essentially similar to those used centuries ago.

BIBLIOGRAPHY. KENNETH B. LEWIS, *The Grinding Wheel* (1959), published by the Grinding Wheel Institute, contains general information on the various types of grinding operations, presented from a nontechnical point of view. Another nontechnical source is P.S. HOUGHTON, *Grinding Wheels and Machines* (1963). The Norton Company, Worcester, Massachusetts, publishes, and updates annually, about 16 booklets of general and semitechnical information on abrasives; titles include *Lectures on Grinding, Lectures on Coated Abrasives,* and *Abrasives and Grinding Wheels.* Another source of nontechnical information is the booklet series published by the Abrasive Grain Association, Cleveland, Ohio; titles include *History of Abrasive Grain, Physical and Chemical Properties of Abrasive Grain, Use of Abrasive Grain in the Manufacture of Coated Abrasives, Use of Abrasive Grain in Polishing,* and *Use of Abrasive Grain in Lapping and Metallographic Polishing. Proceedings* of the INDUSTRIAL DIAMOND ASSOCIATION and of the AMERICAN SOCIETY FOR ABRASIVE METHODS are published annually with contents consisting of reprinted versions of papers presented at their conferences. Topics vary from very general to highly technical. An important periodical, published eight times each year, is *Grits and Grinds.*

Various papers on abrasives are also available from technical societies such as the Society of Manufacturing Engineers; the American Foundrymen's Society; and the American Society for Abrasive Methods.

Abū Ḥanīfah

Abū Ḥanīfah an-Nuʿmān ibn Thābit, 8th-century theologian and jurist, founded the first of four orthodox Islāmic schools of law. As a jurist, he reviewed the then existing body of legal doctrines, formulated views on new questions, and integrated these into a coherent system by anchoring them to a well-defined legal theory. The school of Abū Ḥanīfah acquired such prestige that its doctrines were applied by a majority of Muslim dynasties. Even today it is widely followed in India, Pakistan, Turkey, China, Central Asia, and Arab countries.

Abū Ḥanīfah was born in 699 in Kūfah, an intellectual centre of Iraq. He belonged to the *mawālī*, the non-Arab Muslims, who pioneered intellectual activity in Islāmic lands. The son of a merchant, young Abū Ḥanīfah took up the silk trade for a living and earned renown for honest dealing. It provided him with a steady and handsome income, out of which he donated generously to charity, helping scholars particularly.

Abū Ḥanīfah had a well-rounded education. In early youth he was attracted to theological debates, in which his sharp wit and logical mind won him laurels. Disenchanted with theology, he turned to law and for about 18 years was a disciple of Ḥammād (died 738), then the most noted Iraqi jurist. After Ḥammād's death, he became his successor. He also learned from several other scholars, notably the Meccan traditionist ʿAṭāʾ (died *c.* 732), and the founder of the Shīʿite law, Jaʿfar aṣ-Ṣādiq (died 765). Abū Ḥanīfah's mind was also matured by extensive travels, contacts with a variety of people, exposure to the stimulating influences of the heterogeneous, dynamic, and advanced society of Iraq, and conversance with business practices.

Tall, of medium weight, Abū Ḥanīfah was impressive in his bearing and dignity. He had a serious and sober disposition and was known for piety and religious earnestness and devotion. Having an independent income, he neither needed nor cared for governmental patronage, and this helped Islāmic law develop independently of political authority. His independence and fearlessness, his disregard for worldly vanities, and, above all, his piety made him a paragon of Muslim scholarship.

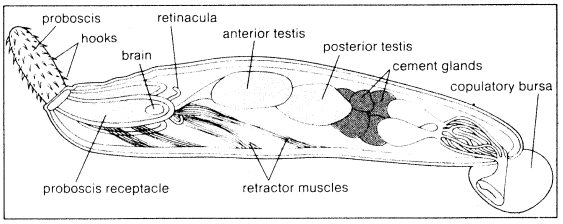
By Abū Ḥanīfah's time a vast body of legal doctrines had accumulated as a result of the endeavour to apply Islāmic norms to legal problems. The disagreements in these doctrines had rendered the development of a uniform code, based on sound principles, a need of the hour. Abū Ḥanīfah responded by thoroughly scrutinizing the current doctrines in collaboration with his students, several of them outstanding scholars. He had each legal problem discussed thoroughly before formulating doctrines definitively.

Contribution to Islāmic legal thought

Being a speculative jurist, Abū Ḥanīfah brought about systematic consistency in legal doctrines. In his doctrines, emphasis shifts from material to systematic considerations. Again and again he disregarded established practices and considerations of judicial and administrative convenience in favour of systematic and technical legal considerations. His legal acumen and juristic strictness were such that Abū Ḥanīfah reached the highest level of legal thought achieved up to his time. Compared with his contemporaries, the Kufan Ibn Abī Laylā (died 765), the Syrian Awzāʿī (died 774), and the Medinese Mālik (died 795), his doctrines are more carefully formulated and systematically consistent and his technical legal thought more highly developed and refined.

Before Abū Ḥanīfah's time, doctrines had been formulated mainly in response to actual problems, whereas he attempted to solve problems that might arise in the future. By the introduction of this method—a characteristic of Abū Ḥanīfah—the area of law was considerably enlarged. The method presupposed advanced legal thought—thought that was further refined by the practice of this method. It was presumably because of this, coupled with Abū Ḥanīfah's somewhat rationalist orientation and his reserve about traditions that were not highly authenticated, that his school was denounced as the school of *raʾy* (independent opinion) as opposed to that of Ḥadīth (authoritative tradition). This, however, was a polemical allegation rather than an objective statement of the school's standpoint.

Although it was not Abū Ḥanīfah's primary concern, his contribution to theology was also significant. He took distinct and moderate positions on several theological questions, stimulating the development of the Māturīdī school.



Thanks to his temperament and academic preoccupation, Abū Ḥanīfah took no direct part in power struggles, despite his antipathy toward the Umayyads and ʿAbbāsids, the ruling dynasties of that time. His sympathies lay with the ʿAlids, whose revolts he supported with both words and money. This partly explains why Abū Ḥanīfah adamantly refused to accept a judgeship and, consequently, suffered severe persecution under both the dynasties. In 767 he died in Baghdad, either while imprisoned or soon after release.

BIBLIOGRAPHY. For bibliographical information on Abū Ḥanīfah, see the article by J. SCHACHT in the *Encyclopaedia of Islam*, vol. 1, pp. 123–124, new ed. (1960); and *An Introduction to Islamic Law* (1964). For most authentic sources of Abū Ḥanīfah's legal doctrines, see the works of his disciples, Abū Yūsuf (d. 798) and al-Shaybānī (d. 805). For theological doctrines, see A.J. WENSWINCK, *The Muslim Creed* (1932); and J.A. WILLIAMS (ed.), *Islam* (1961).

Acanthocephala

The spiny-headed worms constitute the phylum Acanthocephala. A proboscis, which bears hooks, gives the group its name. There are about 600 recorded species, all of which are parasites in vertebrates as adults and in arthropods as juveniles. The adults are usually less than one centimetre in length, but some reach half a metre or more. Acanthocephalans are found throughout the world, especially in fish.

Male *Acanthocephalus ranae*, internal structure.

Natural history. Acanthocephalans are bisexual, and mating occurs in the intestines of vertebrate hosts. The eggs, which actually are shelled larvae, are excreted with the feces of the host. No further development occurs until the eggs are eaten by an arthropod, which is the intermediate host. After its release in the gut of the arthropod, the larva, called an acanthor, bores through the gut wall into the host's blood cavity (hemocoel), is encapsulated there, and develops into a new stage called an acanthella. The acanthella, a miniature version of the adult, withdraws its armed proboscis before entering a resting stage during which it is known as a cystacanth. Once again, no further development occurs until the cystacanth has been ingested by its definitive host, a vertebrate. The young acanthocephalan emerges inside the vertebrate's intestine, uses its proboscis to bore into the gut wall, and matures there.

If a cystacanth is swallowed by the wrong host, it may bore through the gut wall into the body cavity where it encysts and remains infective until the accidental host is eaten; then the cystacanth emerges again in its new host. This behaviour, incorporated into some acanthocephalan life cycles, may provide the only means for completing the life cycle if the definitive host does not feed directly on the intermediate host. Although usually fish parasites,

acanthocephalans also occur in amphibians, reptiles, birds, and mammals. Man is only rarely infected and then accidentally. Because they do little damage to their hosts, acanthocephalans are of no economic importance.

Form and function. The body of an acanthocephalan is divided into a proboscis and an elongated cylindrical trunk. The proboscis, which usually bears backwardly pointing hooks, can be withdrawn into the trunk, which may also bear hooks or spines. Usually white, acanthocephalans may occasionally be yellow, orange, or red in colour. The internal anatomy is simple; there is no gut, and the bulk of the trunk is occupied by a proboscis receptacle and the muscles used to retract it. Passing backward from the base of this receptacle are structures known as ligament sacs. One of these sacs in the male encloses two testes and a number of cement glands. The female has two sacs that do not necessarily persist after she matures. Externally the male possesses an eversible copulatory bursa, the female a simple vagina.

Evolution and classification. The affinities of the acanthocephalans are uncertain. They possess a pseudocoelom; thus, although they are closely related to members of the phylum Aschelminthes and possibly to the rotifers or priapulids, acanthocephalans are sufficiently different from these groups to justify their classification as a distinct phylum. Attempts to derive the acanthocephalans from the tapeworms have not been accepted.

Features used in the classification of acanthocephalans include the nature and distribution of hooks and spines, which are not of any proved phylogenetic significance. For this reason a number of classifications exist. The classification given below is based on the one accepted by Libbie Henrietta Hyman (1951) and Pierre-Paul Grassé (1961) in their widely used textbooks.

Annotated classification.

PHYLUM ACANTHOCEPHALA

Adults parasitic, usually in fish; juveniles parasitic in arthropods; usually one centimetre long; about 600 species; proboscis with hooks; bisexual; worldwide distribution.

Order Archiacanthocephala

Small proboscis hooks, arranged concentrically; males usually with eight cement glands; excretory system often present; ligament sacs persist in mature female; parasites of terrestrial vertebrates and arthropods.

Order Palaeacanthocephala

Proboscis hooks alternate in radial rows; males usually with six cement glands; no excretory system; ligament sacs do not persist in females; parasites of aquatic vertebrates and crustaceans.

Order Eoacanthocephala

Proboscis hooks arranged radially; cement gland cells difficult to distinguish; no excretory system; ligament sacs persist in female; parasites of fishes, reptiles, and aquatic arthropods.

Alternative classifications are given by references listed by W.L. Nicholas (1967).

Acarina

Mites and ticks, close relatives of spiders, scorpions, and harvestmen, constitute the Acarina (Acari, Acarida), which is part of the arthropod class Arachnida. The acarines may be separated into three orders, Opilioacariformes, Parasitiformes, and Acariformes, consisting of seven suborders and 333 families.

General features. *Size range and diversity of structure.* Some mites are less than 0.5 millimetre in length; the largest ticks are slightly over 30 millimetres. Nymphs and adults generally have four pairs of legs, the larvae three. Members of some families have a dense covering of stiff hairs, or setae, while others are almost nude. Soft-bodied mites and ticks have only a few hardened plates or shields; others that are strongly sclerotized have numerous hardened plates. Acarines range in shape from minute, soft-bodied, elongated or circular individuals to large, hard-bodied spider-like ones. Some are flattened; others assume grotesque body shapes as they become engorged with food or filled with eggs.

(D, left) *Myobia musculinus*, female, dorsal view; (D, centre) *Sarcoptes scabiei*, female, dorsal view; (D, right) *Parhypochthonius aphidinus*, female, dorsal view.

Distribution and abundance. Mites and ticks are distributed throughout the world in almost every conceivable habitat and frequently occur in large numbers. They are recorded as high as 5,000 metres on the slopes of Mt. Everest and as deep as 5,200 metres in the northern Pacific Ocean. Over 50 terrestrial species are known from the Antarctic. A few mites have been found drifting high in the atmosphere.

Acarines have been found in diverse habitats that include hot springs, caves, harsh deserts, and tundras. Although many of the approximately 30,000 species described thus far are free-living, some are parasites of animals. The total number of species of mites and ticks has been estimated at more than 500,000.

Importance. The Acarina are an economically important arachnid group; the ticks (Metastigmata), for example, surpass all other arthropods (except mosquitoes)

Carriers of disease

in the number of diseases they transmit to man. Many mites also are intermediate hosts of diseases transmissible to man, his domesticated animals, and his crops. Others are pests as a result of their biting or feeding habits or the damage they cause to food and related products.

In the mite suborder Tetrastigmata (order Parasitiformes), one species of *Holothyrus* is known to secrete an irritant substance that is toxic to fowl and man. The house-mouse mite (*Liponyssoides sanguineus*), which transmits the disease rickettsialpox to man, probably is the most important species in the suborder Mesostigmata (order Parasitiformes) from a medical standpoint. Widespread species such as the tropical fowl mite (*Ornithonyssus bursa*), northern fowl mite (*Ornithonyssus sylviarum*), and chicken mite (*Dermanyssus gallinae*) also are important pests of poultry and man.

Eriophyid and tetranychid mites (Prostigmata), widespread and abundant plant-feeding species, frequently cause serious injury to, or death of, the host plant; the former are the only phytophagous Acarina known to transmit plant viruses. The mange, itch, or scab mites (Astigmata) occur on many different animals including man. House-dust allergy is caused by species of *Dermatophagoides*, a common domestic arthropod.

The beetle mites (Cryptostigmata), among the most numerous soil arthropods, are important in the development of soil fertility and also act as intermediate hosts for important tapeworm parasites of domestic animals.

Rocky Mountain spotted fever, a rickettsial disease that occurs in the United States, is transmitted to man by the bite of several species of hard ticks (Ixodidae), especially the Rocky Mountain wood tick (*Dermacentor andersoni*) and the American dog tick (*Dermacentor variabilis*). Relapsing fever, an important bacterial disease throughout the world, is transmitted to man by certain species of soft ticks (Argasidae) of the genus *Ornithodoros*. Texas cattle fever is a widespread protozoan disease transmitted by cattle ticks (*Boophilus*); the disease, no longer prevalent in the U.S. because the tick has been eliminated, remains important in many tropical and subtropical countries. Other diseases transmitted to animals by ticks include anaplasmosis, tularemia, Q fever, Colorado tick fever, hemorrhagic fever, and tick-borne encephalitis (see DISEASE, HUMAN; and DISEASES OF ANIMALS).

The chiggers (Prostigmata), important pests of man, also transmit scrub typhus (tsutsugamushi disease), a rickettsial disease occurring in the Asiatic-Pacific region.

Natural history. *Reproduction and life cycle.* The sexes occur separately in Acarina; *i.e.*, there are both males and females. Most species lay eggs (oviparity), but, in some parasitic ones, the eggs hatch within the female, and the young are born alive (ovoviviparity). Many species also can reproduce by parthenogenesis; *i.e.*, by the development of unfertilized eggs. At least one tick, *Amblyomma rotundatum*, is exclusively parthenogenetic, and males are unknown; another, *Haemaphysalis longicornis*, has a distinct parthenogenetic population in which males are extremely rare and infertile.

Fertilization

Although there is considerable diversity in mating behaviour throughout the Acarina, the actual process of sperm transfer occurs directly or in packets called spermatophores. The male spermatozoa may be introduced by the male copulatory structure (aedeagus) directly into the female genital opening or, as in some Astigmata, into a special female copulatory structure called a bursa copulatrix. The males of species that use the latter method may have special copulatory structures (*e.g.*, suckers, spurs, or enlarged legs) for grasping the female. Some males produce a sealed packet containing spermatozoa (spermatophore) that is transferred to the female genital opening, either directly by the mouthparts of the male or indirectly by deposition on a surface, after which the female places it in her genital opening. Eggs begin to develop after mating and fertilization; although only a few eggs develop simultaneously in many Acarina, large numbers develop at the same time in ticks and some mites. Eggs are deposited haphazardly on food material by many plant- and grain-feeding species, and are hidden in the soil by predatory soil-inhabiting species. One predatory mite, *Cheyletus eruditus*, broods her small cluster of eggs and drives other arthropods from them.

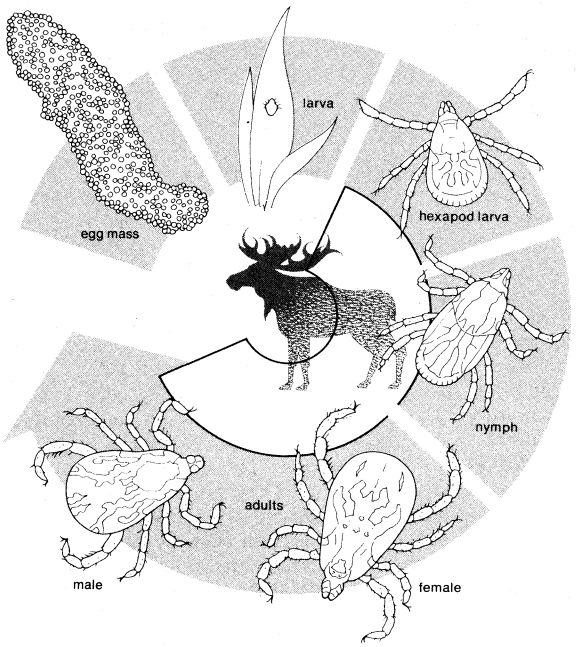

Figure 2: Life cycle of the hard tick (*Dermacentor*). All stages except those of egg and larva require an animal host. Based on H.D. Pratt and K.S. Littig, *Ticks of Public Health Importance and their Control* (1967)

The primitive life cycle among species that lay eggs has four active immature stages—hexapod larva, protonymph, deutonymph, and tritonymph. There are many deviations from this primitive type of life cycle, which is found only in the Cryptostigmata and some Prostigmata. The hexapod larva, characterized by three pairs of legs, is common to all families of Acarina except Eriophyidae (Prostigmata), whose members have only two pairs of legs in all active stages. Among the Parasitiformes, the Mesostigmata lack the tritonymphal stage; the Metastigmata may have only one nymphal stage (Ixodidae) or as many as eight (Argasidae). Some Prostigmata (Podapolipidae) develop directly from egg to larviform adults; others have from one to three nymphal stages. Many Astigmata (order Acariformes) have a nonfeeding, or hypopal, stage between the protonymphal and tritonymphal stages; it frequently occurs during adverse environmental conditions.

Ecology. The Acarina are a diverse group of the class Arachnida, in both habits and habitats. Based on habits, they may be considered either free-living or parasitic.

Free-living Acarina

The free-living Acarina include species from all of the suborders except Metastigmata (ticks). The beetle mites (Cryptostigmata), largely fungal feeders, are extremely numerous in the surface layers of soil; it is estimated that as many as 6,000,000 members of one species occur in an acre of pasture soil. One interesting species (*Symbioribates papuensis*) lives in fungi that grow on the backs of large weevils found in high altitude moss forests of New Guinea.

Some families of free-living mites have specialized stylet-like feeding organs (chelicera), which can pierce plant cells and are used to suck out their contents; feeding by members of the family Eriophyidae (Prostigmata), for example, causes the formation of galls, dwarfing of shoots, and malformation of fruits and leaves. The family Tetranychidae (Prostigmata) contains the spider mites, which are foliage feeders; several species, capable of producing silk, spin a light web over plant leaves.

The families Acaridae and Glycyphagidae (Astigmata), pests of stored grain and cereal products, have blunt, toothed chelicera that enable them to scrape and gouge their food material; certain species of these two families frequently increase to tremendous numbers in foodstuffs, causing "grocers' itch" or "copra itch" in man.

A large group of free-living predatory mites lives in

soil, humus, other organic matter, and water; these mites prey on small arthropods, their eggs, and other small invertebrates. Some species of Macrochelidae (Mesostigmata), for example, feed on housefly eggs or other arthropods; the Phytoseiidae (Mesostigmata) are important predators of plant-feeding mites. Predatory mites typically are long-legged, fast-moving acarines, with specialized chelicera. Ground-inhabiting species usually have well-developed hard plates, or shields; those found on vegetation are not so heavily sclerotized. Many aquatic species have long swimming hairs, or setae, on the legs.

Many free-living mites utilize insects or other arthropods to disperse themselves; this nonparasitic association is known as phoresy. Adults of the genus *Dinogamasus* (Laelapidae), for example, live in a special mite pouch (acarinarium) on an abdominal segment of certain carpenter bees.

Parasitic Acarina

Parasitic species are known in all acarine groups except the beetle mites (Cryptostigmata). The majority are external parasites, including those most important to man and his domesticated animals. A few species are internal parasites of animals. One ecological group contains families found only on the skin surface or feathers of the host. Psoroptidae (Astigmata), or scab mites, for example, attack the skin surface of mammals and feed on skin scales; the continuous abrasion of the skin causes a lesion over which a protective scab eventually forms. The families Analgidae, Proctophyllodidae, and many Dermoglyphidae (Astigmata), which are found on the feathers of birds and feed on body and feather scales, apparently do not harm the host. Different genera of feather mites prefer certain types of feathers and specific locales on the feathers.

A second ecological group contains several families of mites that burrow into skin, hair follicles, or quills of the host and feed on fatty secretions, lymph material, or, occasionally, blood. The families Sarcoptidae (Astigmata) and Psorergatidae (Prostigmata) contain species that burrow just beneath the skin of a mammalian host, causing mange or itch; Demodicidae (Prostigmata), Audycoptidae, and Rhyncoptidae (Astigmata) also occur in hair follicles or skin of mammals. Members of the family Ophioptidae (Prostigmata) form small pits in the scales of snakes; and Syringophilidae (Prostigmata) infest the quills of birds. The Knemidocoptidae (Astigmata), skin inhabitants of birds, may attack the legs of the host, causing a condition called scaly leg.

A third ecological group contains species that pierce the skin and suck up tissue fluid or blood without actually invading the tissues. These species may spend either short or long intervals on the host.

The larvae of Trombiculidae (Prostigmata), the chiggers, parasitize many different types of vertebrates and a few invertebrates, feeding on host tissues; chigger nymphs and adults, however, are free-living and predatory. Species of Dermanyssidae, Macronyssidae, and many Laelapidae (Mesostigmata) feed on blood or tissue secretions of mammals, birds, and reptiles. Some species, which spend much of their time off the host and in the nest, frequently are referred to as nest parasites, or nidicolous species. The protonymph of one species of Macronyssidae, found in the mouth of a long-nosed bat, causes destruction of tissues and loss of teeth; and a species of Spinturnicidae (Mesostigmata) is found in the anal opening of certain species of cave-dwelling bats. Most members of the tick families Argasidae and Ixodidae (Metastigmata) are obligate blood-sucking parasites of vertebrates; most Argasidae nymphs and adults feed on the host only a few minutes, but most stages in the life cycle of Ixodidae remain attached to the host for several days.

A few families of mites are found in additional parasitic associations with vertebrates. Rhinonyssidae, Entonyssidae, and Halarchnidae (Mesostigmata), for example, are respiratory parasites of birds, snakes, and mammals, respectively. Gastronyssidae (Astigmata) occur in the stomach, nasal openings, or eyes of bats, and the nonfeeding (hypopal) stage of certain species of Hypoderidae (Astigmata) occurs in the tissues of birds.

Several families of mites have established a parasitic relationship with invertebrates. Larvae of Trombidiidae and Erythraeidae (Prostigmata), as well as those of other families, are parasitic on insects; later stages are free-living. In contrast, nymphs and adults of the aquatic family Unionicolidae (Prostigmata) parasitize mollusks and sponges, and the larval stage is free-living. Certain species of Pyemotidae and Tarsonemidae (Prostigmata) and other families are parasitic on invertebrates throughout the life cycle. The breathing tubes (tracheae) of some Hymenoptera (bees, wasps) and Orthoptera (grasshoppers) may be invaded by certain species of Scutacaridae and Podapolipidae (Prostigmata); one species, for example, causes suffocation in honeybees (Isle of Wight disease). Otopheidomenidae (Mesostigmata), which occur in the auditory structures of moths and beneath the wings of bugs, may cause deafness in the moth host. Ewingidae (Astigmata) are parasites on the gills of crabs.

Form and function. *External features.* The subclass Acarina is distinguished by the lack of body segmentation (secondarily developed in a few families), a characteristic shared only with the spiders among the arachnids. An anterior region called the gnathosoma contains the mouth, specialized feeding appendages (chelicerae), and segmented structures called palps or pedipalps. The mouth or buccal cavity joins the pharynx internally; paired salivary glands may discharge into the mouth or in front of its opening. The chelicerae are basically three-segmented pincerlike appendages; as a result of the diverse feeding habits of some mites, however, chelicerae sometimes are modified as piercing organs or stylets. The palps, which may be simple sensory structures or predatory organs modified for grasping or piercing, usually have six segments—coxa, trochanter, femur, genu, tibia, tarsus; frequently there also is a clawlike apotele (modified distal segment of appendage).

Major body regions

Behind the gnathosoma is a large region (idiosoma), which bears the legs, the genital and anal openings, and an assortment of tactile and sensory structures; respiratory pores (spiracles) and sclerotized shields of various shapes and sizes usually are present. The functions of the idiosoma parallel those of the abdomen, thorax, and portions of the head of insects. Although nymphs and adults commonly have four pairs of legs, some Prostigmata (Eriophyidae, Podapolipidae, Tenuipalpidae) and Astigmata (Evansacaridae, Teinocoptidae) have one to three pairs. Legs have the same basic segmentation as palps; fusion or division of segments frequently occurs. The tarsus may be terminated either by several sensory hairs (setae) or by a clawlike or suckerlike apotele. The legs, which frequently bear ridges and spurs, always have tactile and sensory setae that follow a fixed pattern in position and number; the arrangement of leg setae is helpful in establishing systematic relationships. The first pair of legs usually functions in locomotion but sometimes is modified as a sensory or predatory structure.

The genital opening, usually located on the underside between the legs, frequently is protected by one or more shields or flaps and has two or three pairs of discs; in some Prostigmata (Cloacaridae, Demodicidae, Myobiidae, Ophioptidae, Podapolipidae), however, the male genitalia (aedeagus) is located on the dorsal side. The anal opening, also generally on the underside, is surrounded by a shield in the Mesostigmata and is always closed by a pair of valves; in some Prostigmata (Penthaleidae) and Astigmata (Chirorhynchobiidae, Knemidocoptidae), the anal opening is located on the dorsal side. As in all arthropods, the cuticle of acarines is secreted by an outer cell layer called the epidermis and contains numerous pore canals. The cuticles of many Acarina absorb water from the air, enabling them to avoid desiccation.

There are many different types of sensory receptors, most of which are setal. The setae, of many shapes and sizes, may be hollow chemoreceptors or solid, tactile structures. Other specialized setae, known as trichobothria, pseudostigmatic organs, eupathidia, or famuli, occur only in the Acariformes. A sensory pit called Haller's organ contains sensory setae and is found on the tarsal

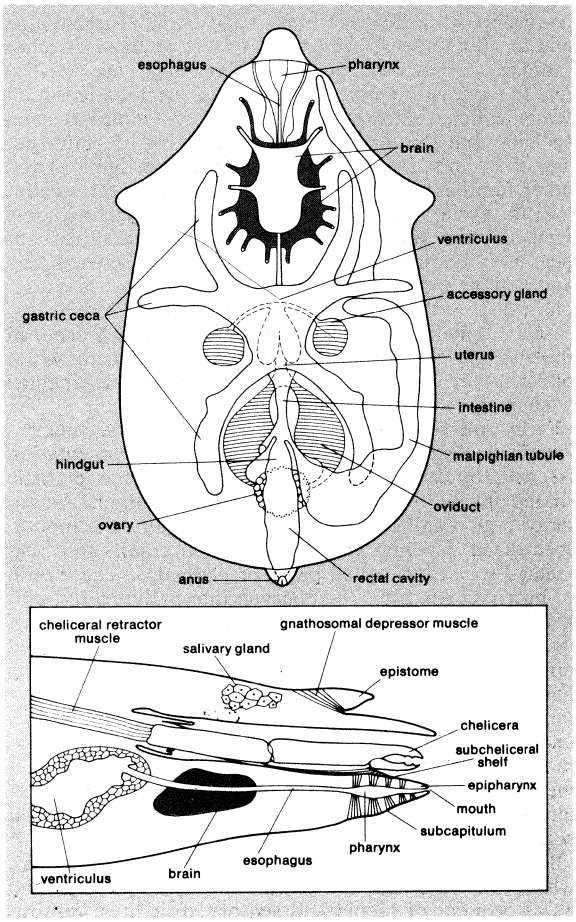

Figure 3: *Internal features of a mite.*
(Top) Dorsal internal aspect. (Bottom) Midsagittal section through the anterior region.
From G.W. Krantz, *A Manual of Acarology*

segment of the first pair of legs of all ticks (Metastigmata). One to three pairs of eyes are present on the anterior of the idiosoma in Notostigmata, a few Astigmata, and many Metastigmata and Prostigmata. A single median eye also may be present in some Prostigmata.

Internal features. One, three, or four pairs of spiracles (respiratory pores) are present in the idiosomal region of all acarine suborders except Astigmata and some Prostigmata and Cryptostigmata, which respire through the cuticle or have other types of respiratory organs. The spiracles open internally into a system of tubes (tracheae) that radiates throughout the body. Tracheae function in the exchange of oxygen and carbon dioxide and help to control water loss in certain species.

The idiosomal body cavity contains various organ systems bathed in blood, or hemolymph. Circulation of blood carrying the products of digestion and excretion may be by the movement of muscles or by a heart, which is present in some suborders. The blood of some soft ticks (Argasidae) differs from that of other acarines biochemically, although similar morphologically.

Digestive system

The digestive system consists of an anterior muscular pharynx, long narrow esophagus, ventriculus (stomach), short intestine, hindgut, and posterior rectal cavity. The ventriculus may have several paired gastric cecae (blind sacs), which function partly as food storage organs and enable some acarines to go long periods without feeding. One or two pairs of excretory organs (malpighian tubules), which may open into the hindgut, absorb waste material from the body cavity and transform it into an organic compound called guanine, which passes into the hindgut, is mixed with other residues, and eventually excreted from the anal orifice. Some Metastigmata and Prostigmata have no connection between the ventriculus and hindgut, and the latter serves as an excretory organ.

The male and female reproductive systems vary in structure and position. The gonads may be paired (primitive condition), united, or multiple (testes in some Prostigmata). There usually are accessory glands associated with the reproductive systems, especially in males.

A well-developed central nervous system surrounds the esophagus in the idiosoma. A series of nerves radiating from one part of the brain innervates the legs, digestive system, musculature, and genitalia. The mouthparts are innervated by another part of the brain.

Classification. *Distinguishing taxonomic features.* Features used by acarologists to distinguish the orders and suborders of Acarina include the presence or absence of spiracles; if present, the type, relative position, and structures associated with the spiracles are important. Other distinguishing features include the position and form of the palpal apotele (modified distal segment of palpus) when present, the type and location of sensory organs, the type of mouthparts, and the presence or absence of eyes.

Annotated classification. The ordinal classification presented here is after Gerald W. Krantz (1970). The process of evolution in mites and ticks has resulted in a degree of specialization and morphological diversity not found in any other group of arachnids. Acarina, believed to be derived from two lines of descent, have a long, though meagre, fossil history dating from the Devonian Period (about 395,000,000 years ago).

SUBCLASS ACARINA (Acari, Acarida; mites and ticks)
Arachnids usually without visible segmentation; mostly minute in size; larvae usually with 3 pairs of legs, adults usually with 4 pairs; diverse habitats include plants, soil, animals, stored foods, fresh and marine water; parasitic forms may transmit diseases; worldwide distribution; about 30,000 described species.

Order Opilioacariformes (mites)
Weakly sclerotized mites superficially resembling members of arachnid subclass Opiliones; 1,000–2,500 microns (μ) in size; body divided into hairy anterior portion bearing 2 or 3 pairs of simple eyes and nude posterior portion with over 200 pores, 4 pairs of spiracles, and 12 secondarily developed segments; terminal palpal apotele a pair of claws; rutellae (hypertrophied setae) present; all coxae of legs movable; first 2 pairs of legs with 6 segments, last 2 with divided trochanter, 7 segments; tritosternal base divided.

Suborder Notostigmata
Terrestrial, under stones and other debris in semi-arid habitats; recorded from southwestern U.S., South America, Central Asia, Africa, and the Mediterranean region; carnivorous and possibly omnivorous; of no economic importance; 1 family, Opilioacaridae, and about 11 species.

Order Parasitiformes (mites and ticks)
Small to large in size; usually heavily sclerotized mites; 1 or 2 pairs of spiracles on posterior portion of body; peritremes, or grooves, present or absent; palpal apotele present or absent; tarsi of 1st pair of legs with sensory organs.

Suborder Tetrastigmata
Heavily sclerotized; 2,000–7,000 μ in size; eyes absent; pair of coxal glands opening at base of coxae of 1st pair of legs; pair of spiracles behind coxae of 3rd and 4th pair of legs, peritremes present; palpal apotele present; terrestrial, under stones and decaying vegetation; recorded from Indo-Pacific region; carnivorous; of minor economic importance; 1 family, Holothyridae, and about 10 species.

Suborder Mesostigmata
Generally with a number of sclerotized plates; 200–2,000 μ in size; eyes absent; pair of spiracles between coxae of 2nd to 4th pair of legs; usually associated with elongated peritremes; palpal apotele present; tritosternum usually well developed but reduced to absent in some parasitic families; majority free-living in soil or decaying organic matter; many parasites of vertebrates (except amphibians and fish) and invertebrates; some economically important; cosmopolitan; about 60 families, 8,000 species.

Suborder Metastigmata (ticks)
Largest Acarina; adults 2,000–30,000 μ in size, eyes present or absent; pair of lateral spiracles enclosed in spiracular plate (modified peritreme) anterior or behind coxae of 4th pair of legs; palpal apotele and tritosternum absent; sensory organ on tarsus of 1st pair of legs a pit (Haller's organ); mouthparts modified to form hypostome (holdfast organ) with teeth turned backward; active stages mostly external parasites

(some nonfeeders), feeding primarily on blood of vertebrates (except fish); many members economically important as disease carriers; cosmopolitan; 3 families, Argasidae (soft ticks), Nuttalliellidae, and Ixodidae (hard ticks); about 850 species.

Order Acariformes (mites)

Small to large in size; generally weakly sclerotized mites (except most Cryptostigmata); palpal apotele and posterior body spiracles absent; anterior portion of body with or without sensory organs that are specialized setae.

Suborder Prostigmata

Most heterogeneous suborder includes chiggers; 100–16,000 μ in size; weakly sclerotized with few plates; eyes present or absent; spiracles, when present, at or between bases of chelicerae or on anterior portion of body; chelicerae stylet-like, chelate (pincerlike), or reduced; diverse in habitat and habits —terrestrial, aquatic, marine, parasitic, predatory, phytophagous; many species economically important; cosmopolitan; about 113 families, 10,000 species.

Suborder Astigmata

Homogeneous group includes mange, itch, or scab mites; weakly sclerotized and slow moving; 200–1,500 μ in size; eyes rarely present, spiracles absent; palps single segmented (sometimes with 2 false segments); chelicerae chelate; true claws absent; rodlike sensory setae on tarsus of 1st pair of legs; wide range of terrestrial habitats; parasitic, predatory, or feed on decaying material; some species economically important; cosmopolitan; about 41 families, 6,100 species.

Suborder Cryptostigmata (oribatid, or beetle, mites)

Usually strongly sclerotized and slow moving, 200–1,500 μ in size; eyes and spiracles absent; pseudospiracles generally present, palpi without claws, 3–5 segmented; chelicerae usually chelate; rutella present; tarsi with 1–3 claws; ventrally with various shields; majority terrestrial in forest humus and soil, a few aquatic; feed on algae, fungi, or decaying material; of some economic importance; cosmopolitan; about 114 families, 5,000 species.

Critical appraisal. Acarologists are not in total agreement as to the classification of mites and ticks. Much of the disagreement concerns the levels at which taxonomic divisions should be made and the use of ordinal names; consequently, seemingly different classifications are actually more alike than they may initially appear to be. Knowledge of Acarina systematics is so incomplete that any classification proposed below the ordinal level is difficult and may quickly become obsolete.

Three major classifications, including that used above, have been proposed for the mites and ticks. One classification (1952) considered the mites and ticks as members of the order Acarina, with five suborders (Onychopalpida, Mesostigmata, Ixodides, Trombidiformes, and Sarcoptiformes). Another system (1961) gave the mites and ticks subclass rank under the name Acari, with seven orders, listed as suborders above.

Accelerators, Particle

A particle accelerator is a device that produces a beam of fast-moving, electrically charged atomic or subatomic particles. The effectiveness of an accelerator usually is characterized by the kinetic energy, rather than the speed, of the particles. The unit of energy commonly used is the electron volt (eV), which is the energy acquired by a particle that has the same magnitude of charge as has the electron, when it passes between electrodes that differ in potential by one volt. Related larger units are the kiloelectron volt (keV), which is 1,000 eV; the megaelectron volt (MeV; 1,000,000 eV); and the gigaelectron volt (GeV; 1,000,000,000 eV; formerly called the BeV in the U.S.). Compared with the quantities of energy encountered in everyday experience, even the GeV is a very small amount, about that gained by a grain of salt as it drops one millimetre under the influence of gravity. The masses of the particles accelerated are so small, however, that kinetic energies in this range correspond to very high speeds: the speed of the particles in the smallest ion accelerators is about 5,000 miles (8,000 kilometres) per second, about 3 percent of the speed of light.

The particles that are accelerated are electrons, positrons (positive electrons), or ionized atoms such as protons (ionized hydrogen), deuterons (ionized heavy hydrogen), alpha particles (ionized helium), or heavier ionized atoms. Sometimes the primary beam is used; in other cases, the primary beam is directed onto a target to produce a beam of secondary particles, such as gamma rays, neutrons, mesons, hyperons, or neutrinos. A few accelerators are operated as sources of the intense radiation, called synchrotron radiation, emitted by electrons moving at almost the speed of light along curved paths.

Uses of accelerators

Physicists use accelerators in fundamental research on the structure of nuclei, the nature of nuclear forces, and the properties of nuclei not found in nature, such as the transuranic (heavier than uranium) elements and other unstable elements. Accelerators are also used for radioisotope production, industrial radiography, cancer therapy, sterilization of biological materials, and polymerization of plastics. The largest accelerators are used in research on the fundamental interactions of the elementary subatomic particles.

Every accelerator has three essential parts: a source of the particles to be accelerated, a vacuum chamber in which to accelerate them, and a source of the electric fields needed to effect the acceleration. Thermionic emission (the emission of electrons from the surface of a heated solid) is the process used to provide electrons. Positrons are produced as secondary particles by an electron accelerator and then further accelerated. Positive and negative ions are produced by electric arc or glow discharges in a gas at low pressure in a chamber; a high-voltage electrode extracts the ions from the gas through a hole in the chamber. The region in which the particles are accelerated must be highly evacuated to keep the particles from being scattered out of the beam, or even stopped, by collisions with molecules of air.

Accelerators are differentiated by the arrangements of the accelerating electric fields. In a linear accelerator, the path of the particles is a straight line, and the final energy of the particles is given by the sum of the voltages produced by the accelerating devices along that line (see ELECTRICITY: *The conduction of electricity: The motion of charged particles in an electric field*). In a cyclic accelerator, the path of the particles is bent by the action of a magnetic field into a spiral or a closed curve that is approximately circular (see MAGNETISM: *The motion of charged particles in magnetic and electric fields*). In this case, the particles pass many times through the accelerating devices; the final energy depends on the magnitude of the voltages and on the number of times the particles pass through. Because the total distance travelled by the particles in a cyclic accelerator may be as much as a million miles, the cumulative effect of minute deviations from the desired trajectory would be dissipation of the beam. Therefore, the beam must be continually focussed by the magnetic fields, which are precisely shaped by powerful magnets.

HISTORY

The motivation for most of the development of the various types of particle accelerators has been their application to research into the properties of atomic nuclei and subatomic particles. Starting with Ernest (later Lord) Rutherford's discovery, in 1919, of a reaction between a nitrogen nucleus and an alpha particle, all re-

search in nuclear physics until 1932 was performed with alpha particles from naturally radioactive elements. The natural alpha particles have kinetic energies as high as 8 MeV. It was not possible, however, to form natural alpha particles into a well-defined beam in which all the particles were of equal energy without reducing the number of particles so much that they were useless. Further experimentation required a beam of artificially accelerated ions, but there seemed little hope of generating laboratory voltages sufficient to accelerate ions to the desired energies. A calculation made by George Gamow (then at the University of Göttingen) in 1928, however, indicated that considerably less energetic ions could be useful, and this stimulated attempts to build an accelerator that could provide a beam of particles suitable for nuclear research. The first successful experiments with artificially accelerated ions were performed at the University of Cambridge, England, by J.D. Cockcroft and E.T.S. Walton in 1932. Using a voltage multiplier, they accelerated protons to energies as high as 710 keV and showed that these react with the lithium nucleus, the products being two energetic alpha particles. Other developments of that period demonstrated principles still employed in the design of particle accelerators. For example, Robert J. Van de Graaff had constructed the first belt-charged electrostatic high-voltage generator at Princeton University, in New Jersey, by 1931.

First proton accelerator

The principle of the resonance linear accelerator was disclosed by Rolf Wideröe in 1928. At the Rhenish-Westphalian Technical University in Aachen he had used alternating high voltage to accelerate ions of sodium and potassium to energies twice as high as those imparted by one application of the peak voltage. In 1931, Ernest O. Lawrence and his assistant David H. Sloan, at the University of California, Berkeley, employed high-frequency fields to accelerate mercury ions to more than 1.2 MeV; this work augmented Wideröe's achievement in accelerating heavy ions, but the ion beams were not useful in nuclear research.

The magnetic resonance accelerator, or cyclotron, was conceived by Lawrence as a modification of Wideröe's linear resonance accelerator. Lawrence's student M.S. Livingston demonstrated the principle of the cyclotron in 1931, producing 80-keV ions; in 1932, Lawrence and Livingston announced the acceleration of protons to more than 1 MeV. Later in the 1930s cyclotron energies reached about 25 MeV and Van de Graaff generators, about 4 MeV. In 1940 Donald W. Kerst, applying the results of careful orbit calculations to the design of magnets, constructed the first betatron, a magnetic-induction accelerator of electrons, at the University of Illinois.

The rapid advance in the science of accelerating particles to high energies that has occurred since the end of World War II was initiated by E.M. McMillan, at Berkeley, and V.I. Veksler, at Moscow, who in 1945 independently described the principle of phase stability, which removed an apparent limitation on the energy of resonance accelerators for protons (see below *Classical cyclotrons*) and made possible the construction of magnetic-resonance accelerators (called synchrotrons) for electrons. The principle was promptly demonstrated by the construction of a small synchrocyclotron at the University of California and an electron synchrotron in England. The first proton linear resonance accelerator was constructed soon thereafter. The large proton synchrotrons that have been built since then all depend on this principle.

In 1947 William W. Hansen, at Stanford University, California, constructed the first travelling-wave linear accelerator of electrons, exploiting microwave technology that had been developed for radar during World War II.

Developments since the 1940s

The progress in research made possible by raising the energies of protons led to the building of successively larger accelerators; the trend was ended only by the cost of fabricating the huge magnet rings required—the largest weighs nearly 40,000 tons. A means of increasing the energy without increasing the scale of the machines was provided by the demonstration, in 1952, by Livingston, E.D. Courant, and H.S. Snyder of the technique of alternating-gradient focussing (sometimes called strong focussing). Synchrotrons incorporating this principle needed magnets only 1/100 the size that would be required otherwise. All recently constructed accelerators make use of alternating-gradient focussing.

In 1956 Kerst realized that, if two sets of particles could be maintained in intersecting orbits, it should be possible to observe interactions in which one particle collided with another moving in the opposite direction with the same energy. Application of this idea requires the accumulation of accelerated particles in loops called storage rings. The highest reaction energies now obtainable have been produced by the use of this technique.

Particle storage rings

CONSTANT-VOLTAGE ACCELERATORS

The simplest type of particle accelerator is constructed by mounting a particle source on one end of an insulated, evacuated tube and creating a high voltage between the ends, with the polarity such that the particles are impelled from the source toward the far end of the tube. Such an accelerator is necessarily linear, and the electrostatic field can be applied to a given particle but once (unless, as in the tandem accelerator described below, the charge of the particle undergoes change in sign). The simplicity of concept soon gives way to complexity in execution when the electric potential exceeds 1,000,000 volts (one megavolt, or 1 MV): these high voltages produce corona discharges and lightning-like sparks outside the accelerator, which dissipate the potential needed to accelerate the particles. Even more difficult to control are sparks within the equipment and, in positive-ion accelerators, unwanted secondary beams produced when the accelerated ions strike the end of the tube.

Because these discharges and sparks generally originate at sharply curved or pointed places on the surface of an electrode, the high-voltage electrode of a modern accelerator is made in the shape of a sphere or a cylinder with rounded ends or, in the case of a low-energy device, a box with rounded edges. The insulating columns that support the terminals are meticulously designed to suppress corona or sparking. Care also is devoted to the design of the accelerator tube to ensure the uniform distribution of the voltage along its length. The voltage that a structure will withstand is increased if the pressure of the gas surrounding it is increased, so direct-voltage accelerators commonly are mounted in tanks pressurized with mixtures of nitrogen and carbon dioxide or, in certain cases, the gas sulfur hexafluoride.

Voltage multipliers (cascade generators). The source of the high voltage for Cockcroft and Walton's pioneering experiments was a four-stage voltage multiplier assembled from four large rectifiers and high-voltage capacitors. Their circuit, in effect, combined four rectifier-type direct-voltage power supplies in series. The alternating voltage supplied by a high-voltage transformer was changed to higher, direct voltages through an array of heavy-duty capacitors; a second group of capacitors kept the direct voltage constant. The final direct voltage would have been four times the peak voltage available from the transformer (200,000 volts) if corona discharge had not drained away considerable power. Nevertheless, the apparatus did accelerate protons to energies of 710 keV, sufficient to bring about the hoped-for result, a reaction with lithium nuclei. Their achievement, the first nuclear reaction effected by artificially accelerated particles, was recognized by the award of the Nobel Prize for Physics in 1951.

Cockcroft-Walton generator

Cockcroft and Walton's system for building up high direct voltages can be extended to multiplication factors many times that originally demonstrated. Commercially available accelerators that reach 4 MeV are based on this circuitry.

Van de Graaff generators. In Van de Graaff generators, electric charge is transported to the high-voltage terminal on a rapidly moving belt of insulating material driven by a pulley mounted on the grounded end of the structure; a second pulley is enclosed within the large, spherical high-voltage terminal, as shown in Figure 1.

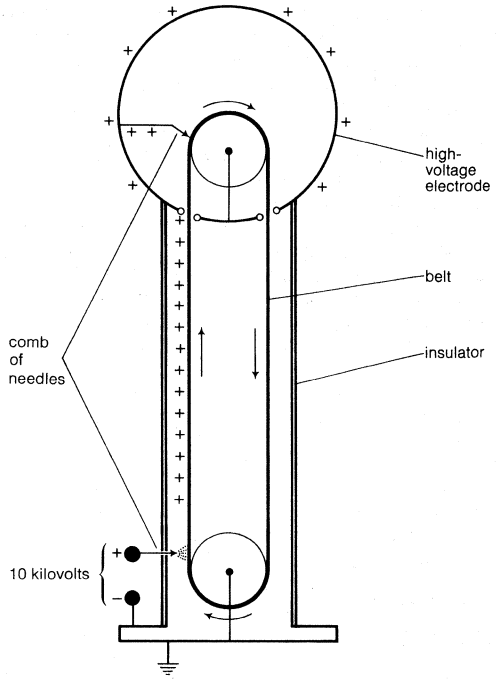

Figure 1: Simplified version of a Van de Graaff high-voltage electrostatic generator (see text).

The belt is charged by a comb of sharp needles with the points close to the belt a short distance from the place at which it moves clear of the grounded pulley. The comb is connected to a power supply that raises its potential to a few tens of kilovolts. The gas near the needle points is ionized by the intense electric field, and in the resulting corona discharge the ions are driven to the surface of the belt. The motion of the belt carries the charge into the high-voltage terminal and transfers it to another comb of needles, from which it passes to the outer surface of the terminal. A carefully designed Van de Graaff generator insulated by pressurized gas can be charged to a potential of about 20 MV.

Tandem Van de Graaff accelerators

In most constant voltage accelerators, Van de Graaff generators are the source of high voltage, and most of the electrostatic proton accelerators still in use are two-stage (*tandem*) accelerators. These devices provide a beam with twice the energy that could be achieved by one application of the high voltage. Figure 2 is a diagram of a tandem accelerator. An ion source yields a beam of protons, which are accelerated to a low energy by an auxiliary high-voltage supply. This beam passes through a region containing a gas at low pressure, where some of the protons are converted to negative hydrogen ions by the addition of two electrons. As the mixture of charged particles moves through a magnetic field, those with negative charge are deflected into the accelerator tube, and those with positive charge are deflected away. The beam of negative ions is then accelerated toward the positive high-voltage terminal. In this terminal, the particles pass through a thin carbon foil that strips off the two electrons, changing many of the negative ions back into positive ions (protons). These, now repelled by the positive terminal, are further accelerated through the second part of the tube. At the output end of the accelerator the protons are magnetically separated, as before, from other particles in the beam and directed to the target. In three- or four-stage tandem accelerators, two Van de Graaff generators are combined with the necessary additional provisions for changing the charge of the ions.

Adapted from R. J. Van de Graaff, *Nuclear Instruments and Methods*, vol. 8, p. 195 (1960); North-Holland Publishing Co.

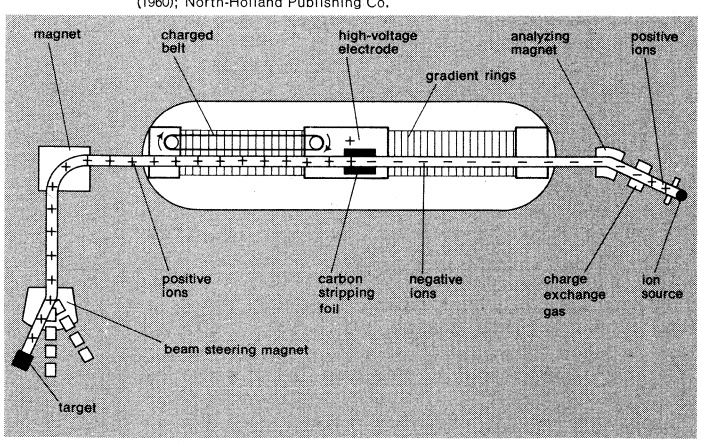

Figure 2: Two-stage tandem accelerator (see text).

Van de Graaff and Cockcroft–Walton generators also are utilized for accelerating electrons. The rates at which charge is transported in electron beams correspond to currents of several milliamperes; the beams deliver energy in magnitudes best expressed in terms of kilowatts. These intense beams are used for sterilization, industrial radiography, cancer therapy, and polymerization of plastics.

BETATRONS

The name betatron connotes the most practical application of a type of accelerator that acts upon beta particles, as electrons are alternatively called. The motion of an electron in a betatron is the consequence of two forces that are exerted on it by a magnetic field that is symmetrical about the axis of the device. At any instant during its motion in a plane perpendicular to this axis, the electron is attracted toward the centre with a force that is proportional to the product of the magnitudes of its charge, its speed at that instant, and the strength of the field. The strength of the field, however, is not maintained at a constant value but is caused continuously to increase. The change induces an electric field directed along circles concentric with the axis; these fields exert a force on the electron that accelerates it along the circle. On only one such circle, termed the orbit of the electron, do the two forces act to cause the electron to remain in the circle while continuously increasing its speed. This circumstance results if the average magnetic field *inside* the orbit is always twice the magnetic field *on* the orbit. Because this so-called equilibrium orbit is circular, the acceleration chamber is made in the shape of a torus, or doughnut, as shown in Figure 3. The magnetic field is produced by a magnet designed to minimize the time lag in the response of the field to the variations in the alternating current in the windings. The poles of the magnet are tapered to cause the field near the orbit to decrease with increasing radius. This focusses the beam by ensuring that any particle that strays from the orbit is subjected to forces that restore it to its proper path. The theory of controlling these deviations was first worked out for the betatron; by analogy, the oscillations of particles about their equilibrium orbits in all cyclic accelerators are called betatron oscillations.

Betatron oscillations

From *Jaderna Energie* (1958)

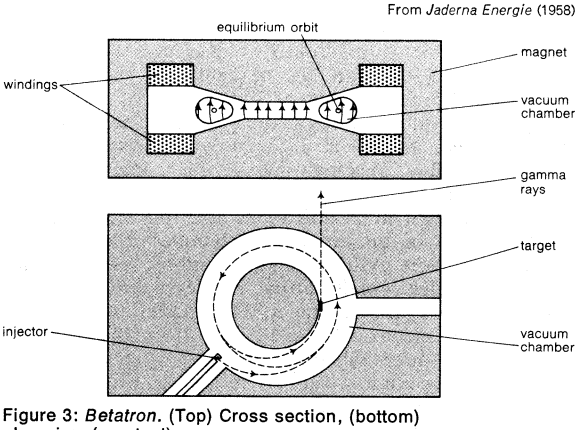

Figure 3: *Betatron.* (Top) Cross section, (bottom) plan view (see text).

Just as the varying magnetic field assumes the direction necessary to cause acceleration, a burst of electrons is sent into the doughnut, where—in a 20-MeV betatron—they gain about 100 eV per revolution. The acceleration lasts for one-quarter of the magnet cycle, until the magnetic field has increased to its maximum value, whereupon the orbit is caused to shrink, causing the electrons to strike a target, producing a beam of intense X-rays.

The practical limit on the energy imparted by a betatron is set by the radiation of electromagnetic energy by electrons moving in curved paths. The intensity of this radiation, commonly called synchrotron radiation (see below *Electron synchrotrons*), rises rapidly as the speed of the electrons increases. The largest betatron accelerates electrons to 300 MeV, sufficient to produce pi mesons in its target; the energy loss by its electrons through radiation (a few percent) is compensated by changing the relation between the field on the orbit and the average field inside the orbit. At higher energies this compensation would not be feasible.

Betatrons are now commercially manufactured, principally for use as sources of highly energetic ("hard") X-rays for industrial and medical radiography.

CYCLOTRONS

The magnetic resonance accelerator, or cyclotron, was the first cyclic accelerator and the first resonance accelerator that produced particles energetic enough to be useful for nuclear research. For many years the highest particle energies were those imparted by cyclotrons modelled upon Lawrence's archetype. In these devices, commonly called classical cyclotrons, the accelerating electric field oscillates at a fixed frequency and the guiding magnetic field has a fixed intensity.

Classical cyclotrons. The key to the operation of a cyclotron is the fact that the orbits of ions in a uniform magnetic field are isochronous; that is, the time taken by a particle of a given mass to make one complete circuit is the same at any speed or energy as long as the speed is much less than that of light. (As the speed of a particle approaches that of light, its mass undergoes the increase—predicted by the theory of relativity—that is called the relativistic increase.) This isochronicity makes it possible for a high voltage, reversing in polarity at a constant frequency, to accelerate a particle many times. As shown in Figure 4, an ion source is located at the centre of an evacuated chamber that has the shape of a short cylinder, like a pillbox, between the poles of an electromagnet that creates a uniform field perpendicular to the flat faces. The accelerating voltage is applied by electrodes, called dees from their shape: each is a D-shaped half of a pillbox. The source of the voltage is an oscillator—similar to a radio transmitter—that operates at a frequency equal to the frequency of revolution of the particles in the magnetic field. The electric fields caused by this accelerating voltage are concentrated in the gap between the dees; there is no electric field inside the dees. The path of the particle inside the dee is therefore circular. Each time the particle crosses the gap between the dees it is accelerated, because in the time between these crossings the direction of the field reverses. The path of the particle is thus a spiral-like series of semicircles of continually increasing radius.

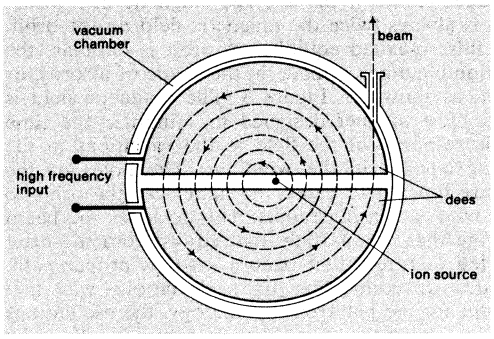

Figure 4: Plan view of the classical cyclotron.

Some means of focussing is required, as otherwise a particle that starts out in a direction making a small angle with the orbital plane will spiral into the dees and be lost. While the energy of the particle is still low, this focussing is supplied by the accelerating electric fields; after the particle has gained significant energy, focussing is a consequence of a slight weakening of the magnetic field toward the peripheries of the dees as in the betatron, but to a much smaller degree.

Cyclotron energy limitations

The energy gained by a particle in a classical cyclotron is limited by the relativistic increase in the mass of the particle, a phenomenon that causes the orbital frequency to decrease and the particles to get out of phase with the alternating voltage. This effect can be reduced by applying higher accelerating voltages to shorten the overall acceleration time. The highest energy imparted to protons in a classical cyclotron is less than 25 MeV, and this achievement requires the imposition of hundreds of kilovolts to the dees. The beam current in a classical cyclotron operated at high voltages can be as high as 5 milliamperes; intensities of this magnitude are very useful in the synthesis of radioisotopes.

Synchrocyclotrons. Cyclotrons in which the frequency of the accelerating voltage is changed as the particles are accelerated are called synchrocyclotrons, frequency-modulated (FM) cyclotrons, or, in the Soviet Union, phasotrons. Because of the modulation the particles do not get out of phase with the accelerating voltage, so that the relativistic mass increase does not impose a limit on the energy. Moreover, the magnetic focussing can be made stronger, so that the magnetic field need not be so precisely shaped.

Phase stability

Because of the phenomenon of phase stability, the frequency of the accelerating voltage need not be made to coincide with the decreasing frequency of revolution of the particles as they are accelerated. To see how phase stability affects the operation of a cyclotron, consider a particle moving in an orbit. Let the frequency of the accelerating voltage match the orbital frequency of this particle. If the particle crosses the accelerating gap at the time the accelerating voltage is zero, its energy and orbital radius will remain unchanged—it is said to be in equilibrium. There are two such times during each cycle of the accelerating voltage; only one of these (that at which the voltage is falling, rather than rising, through zero) corresponds to *stable* equilibrium. If a particle should arrive a short time before the voltage has fallen to zero, it is accelerated. Its speed therefore increases, but the radius of its orbit increases by an even larger proportion, so that the particle will take longer to reach the gap again and will next cross it at a time closer to that at which it would receive no acceleration. If, on the other hand, the particle reaches the gap a short time *after* the voltage has fallen through zero, its speed is diminished, and the radius of its orbit is diminished even more, so that it takes *less* time to reach the gap again, arriving—like the other particle—at a time closer to that at which it receives no acceleration. This phenomenon, by which the trajectories of errant particles are continually corrected, confers stability on the entire beam and makes it possible to accelerate the particles uniformly, by modulating the frequency, without dispersing them. The small periodic variations of the particles about the equilibrium values of phase and energy are called synchrotron oscillations.

Synchrotron oscillations

In the operation of a synchrocyclotron, particles are accelerated from the ion source when the frequency of the accelerating voltage is equal to the orbital frequency of the particles in the central field. As the frequency of the voltage falls, the particles, on the average, encounter an accelerating field. They oscillate in phase, but around a value that corresponds to the average acceleration. The particles reach the maximum energy in bunches, one for each time the accelerating frequency goes through its program. The intensity of the beam is a few microamperes, much lower than that of a classical cyclotron.

Large synchrocyclotrons have been constructed in many countries. They are used primarily for research with

secondary beams of pi mesons. The practical upper limit of the energy of a synchrocyclotron, set by the cost of the huge magnets required, is about 1 GeV.

Sector-focussed cyclotrons. The sector-focussed cyclotron is another modification of the classical cyclotron that also evades relativistic constraint on its maximum energy. Its advantage over the synchrocyclotron is that the beam is not pulsed and is more intense. The frequency of the accelerating voltage is constant, and the orbital frequency of the particles is kept constant as they are accelerated by causing the average magnetic field on the orbit to increase with orbit radius. This ordinarily would cause the beam to spread out in the direction of the magnetic field, but in sector-focussed cyclotrons the magnetic field varies with the angular position as well as with the radius; this produces the equivalent of alternating-gradient focussing (see below *Synchrotrons*). This principle was discovered in 1938 by L.H. Thomas, then at Ohio State University, but was not applied until the alternating-gradient synchrotron was invented in 1952. Several of these devices, sometimes called azimuthally varying field (AVF) cyclotrons, have been built for use in nuclear and medical research.

LINEAR RESONANCE ACCELERATORS

The technology required to design a useful linear resonance accelerator was not developed until after 1940. These accelerators require very powerful sources of radio-frequency accelerating voltage. Further, a practical linear accelerator for heavy particles, such as protons, must make use of the principle of phase stability.

Linear accelerators fall into two distinct types: standing-wave linear accelerators (used for heavy particles) and travelling-wave linear accelerators (used to accelerate electrons). The reason for the difference is that after electrons have been accelerated to a few MeV in the first few feet of a typical accelerator, they have speeds very close to that of light. Therefore if the accelerating wave also moves at the speed of light, the particles do not get out of phase, as their speeds do not change. Protons, on the other hand, must reach much higher energies before their speeds can be taken as constant, so that the accelerator design must allow for the prolonged increase in speed.

Linear electron accelerators. The force that acts on electrons in a travelling-wave accelerator is provided by an electromagnetic field with a frequency near 3,000 MHz (1 MHz = 1,000,000 Hertz, or 1,000,000 cycles per second)—a microwave. The acceleration chamber is an evacuated cylindrical pipe that serves as a waveguide for the accelerating field. The phase velocity of an electromagnetic wave in a cylindrical pipe is greater than the velocity of light in free space, so the wave must be slowed down by the insertion of metal irises a few centimetres apart in the pipe, as shown in Figure 5. In the intense field, the electrons gain about two MeV per foot. The microwaves are produced by large klystrons (high-frequency vacuum-tube amplifiers) with power outputs of 20–30 megawatts. Because sources of radio-frequency power of this magnitude must be operated intermittently (they will not survive continuous service), the beams from these accelerators are delivered in short bursts.

Pulses of electrons are injected at energies of a few hundred keV (that is, speeds about half that of light). The accelerator is so designed that, during the first part of the acceleration, the electrons are caused to gather into bunches, which then are accelerated nearly to the speed of light. Subsequently, the electrons move with the crest of the electromagnetic wave.

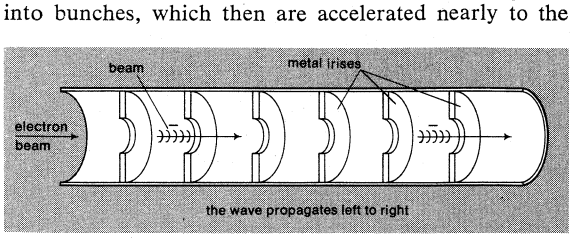

Figure 5: Waveguide acceleration chamber of an electron linear accelerator showing the irises, which decrease the phase velocity of the wave (see text).

Linear electron accelerators are manufactured commercially. They are used for radiography, for cancer treatment, and as injectors for electron synchrotrons.

The two-mile-long linear electron accelerator at Stanford University (called SLAC, an initialism for *S*tanford *l*inear *a*ccelerator *c*entre) is the source of the most energetic beams of electrons (almost 25 GeV) and positrons (almost 15 GeV) now available. Electron-beam currents of 50 microamperes and positron-beam currents of more than 1 microampere can be obtained. The accelerator is used for research on subatomic particles and for filling the electron-positron storage ring called SPEAR (*S*tanford *p*ositron-*e*lectron *a*symmetric *r*ing).

Linear electron accelerators constructed of superconducting materials were being developed in the late 1970s. The advantage offered by such a device is low power consumption, allowing production of a continuous, rather than a pulsed, beam.

Linear proton accelerators. The design principle applied in linear accelerators for protons was originated by Luis Alvarez at Berkeley in 1946. It is based on the formation of standing electromagnetic waves in a long cylindrical metal tank, or cavity, as it is sometimes called. In the design that has been adopted, the electric field is parallel to the axis of the tank. Most of these accelerators operate at frequencies of about 200 MHz.

During the time required for a proton to traverse one of these tanks, the accelerating electric fields undergo many reversals of direction. In Alvarez' design, the decelerating effect of the field during the intervals when it opposes the motion of the particles is prevented by installing on the axis of the tank a number of "drift tubes," as shown in Figure 6. The electric field is zero

Use of drift tubes

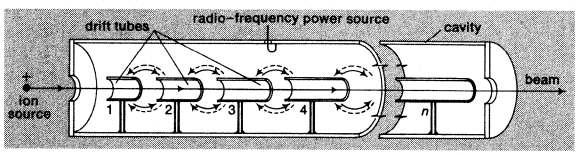

Figure 6: Proton linear resonance accelerator containing *n* metallic drift tubes (see text).

inside the drift tubes, and if their lengths are properly chosen, the protons cross the gap between adjacent drift tubes when the direction of the field produces acceleration and are shielded by the drift tubes when the field in the tank would decelerate them. The lengths of the drift tubes are proportional to the speeds of the particles that pass through them.

It would appear that any error in the magnitude of the accelerating voltages would cause the particles to lose the synchronism with the fields needed for proper operation of the device, but the principle of phase stability reduces to a manageable magnitude the need for precision in construction. It also makes possible an intense beam, because protons can be accelerated in a stable manner even if they do not cross the gaps at exactly the intended times. The principle is the same as that of a synchrotron, except that the gap-crossing time for stable phase oscillations coincides with the rise, rather than the fall, of the voltage wave. If a proton arrives at the accelerating gap late, it receives a larger-than-normal increment of energy, enabling it to "catch up."

A very large amount of radio-frequency power is required to produce the accelerating voltages. This makes it necessary for linear proton accelerators to be operated in a pulsed mode. They are supplied with protons accelerated to about 750 keV by a Cockcroft–Walton generator. The entering beam passes through an accelerating radio-frequency cavity a short distance upbeam from the main linear accelerator, so that as the particles pass through the first drift tubes, they are already bunched.

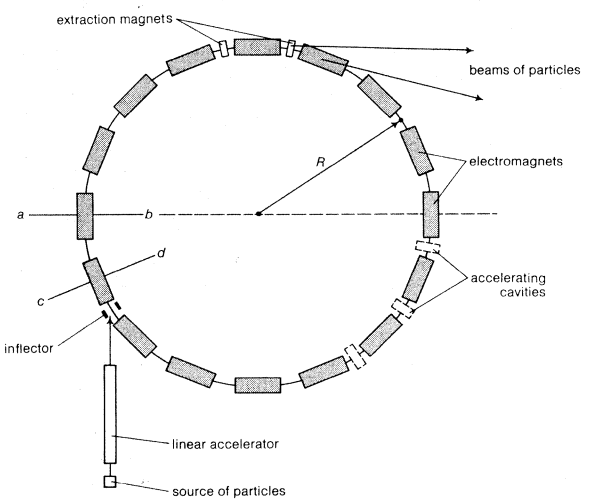
The intense pulses of protons emerging from linear accelerators make these devices ideal as injectors for proton synchrotrons. Their relatively high cost has prevented their construction except for use as meson

factories. The largest linear accelerators used as injectors are located at the Brookhaven National Laboratory, Upton, N.Y., and at the Fermi National Accelerator Laboratory ("Fermilab"), Batavia, Ill. These accelerators are very similar in construction, and each is 475 feet long. The beam energy is 200 MeV, and the peak beam current is more than 100 milliamperes. They are needed as injectors only for a short time every few seconds; most of the time the beams are used for radioisotope production and medical applications.

At the Los Alamos Meson Physics Facility in New Mexico, a linear proton accelerator has been constructed for nuclear research and as a meson factory. The protons are accelerated to 100 MeV in Alvarez-type tanks and then to 800 MeV in a travelling-wave linear accelerator similar to those used for electrons but operated at a frequency of 805 MHz. The apparatus was designed to produce a beam carrying a current of 1 milliampere and a power of 800 kilowatts. The highest current yet achieved is 200 microamperes. Its intense secondary beam of low-energy pi mesons has been applied in experimental cancer therapy.

Heavy-ion linear accelerators. For research with ions more massive than the alpha particle, a relatively high energy per unit of atomic weight is desirable. The production of beams of heavy charged particles at a reasonable cost is practical only if the particles are highly ionized, because the energy gained by an ion is proportional to its charge. The SuperHILAC at Berkeley ("hilac" is an acronym from *h*eavy-*i*on *l*inear *ac*celerator) consists of two Alvarez accelerators operating at 70 MHz. The ions, after acceleration by the first of these machines, have a kinetic energy of 1.2 MeV per unit of atomic weight; this energy corresponds to a speed one-twentieth of the speed of light. These ions then pass through a thin carbon foil, which strips off many electrons. After stripping, the ions (now more highly charged) are accelerated by the second machine to an energy of 8.5 MeV per unit atomic weight, corresponding to a speed about one-seventh of the speed of light. Ions as heavy as those of uranium may be accelerated by the SuperHILAC. Heavy ion beams have been used in the search for possible stable transuranic elements.

SYNCHROTRONS



As the particles in a synchrotron are accelerated, the strength of the magnetic field is increased to keep the radius of the orbit approximately constant. This technique has the advantage that the magnet required to form the particle orbits is much smaller than that needed in a cyclotron to produce the same particle energies. The acceleration is effected by radio-frequency voltages, while the synchronism is maintained by the principle of phase stability. The rate of increase of the energy of the particles is set by the rate of the increase of the magnetic field. The peak accelerating voltage is ordinarily about twice as large as the average energy gain per turn would require, to provide the margin for phase stability. Particles can be stably accelerated with a range of energies and phases with respect to the accelerating voltage, and very intense beams can be produced.

The magnetic field must be shaped so as to focus the beam of particles. In early synchrotrons the field was caused to decrease slightly with increasing radius, as in a betatron. This arrangement resulted in a weak focussing effect that was adequate for machines in which the dimensions of the magnet gap could be appreciable in comparison with the radius of the orbit. The magnitude of the magnetic fields that may be used is limited by the saturation of the iron components that shape the field and provide a path for the magnetic flux. Therefore, if the energy of accelerators is to be increased, their radius must be increased correspondingly. For relativistic particles, the radius is proportional to the kinetic energy. The magnet of a synchrotron with weak focussing, designed to have a reasonable intensity, would have a mass proportional to the cube of the radius. It is clear that increasing the energy beyond some point—in practice, about 10 GeV—would be very expensive.

The introduction of alternating-gradient focussing provided the solution to this problem and made possible the development of synchrotrons with much higher energies. The idea was promptly incorporated in the designs of the 33-GeV proton synchrotron at the Brookhaven National Laboratory and the 28-GeV machine at the European Organization for Nuclear Research (CERN), near Geneva, Switz.

The magnetic fields in an alternating-gradient synchrotron vary much more strongly with radius than those used for weak focussing. A magnet with pole-tips shaped as shown in cross section *ab* in Figure 7 produces a magnetic field that sharply decreases with increasing radius. To the particle beam, this magnetic field acts like a lens with a very short focal length. In the vertical direction (the orbital plane is horizontal) it focusses the beam, but in the radial direction, it is almost equally defocussing. A magnet with the pole-tip shapes shown in cross section *cd* in Figure 7 produces a field that strongly *increases* with increasing radius. This field is defocussing in the vertical direction and focussing in the radial direction. Although pairing such magnetic fields results in partial cancellation, the overall effect is to provide focussing in both directions. The ring of magnetic field is created by a large number of magnets, with the two types of pole-tips alternating, as shown at the top of Figure 7. The beam, in effect, passes through a succession of lenses as the particles move around the ring, producing a large beam current in a vacuum chamber of small cross section.

Particles accelerated in a large synchrotron are commonly injected by a linear accelerator and are steered into the ring by a device called an inflector. They begin

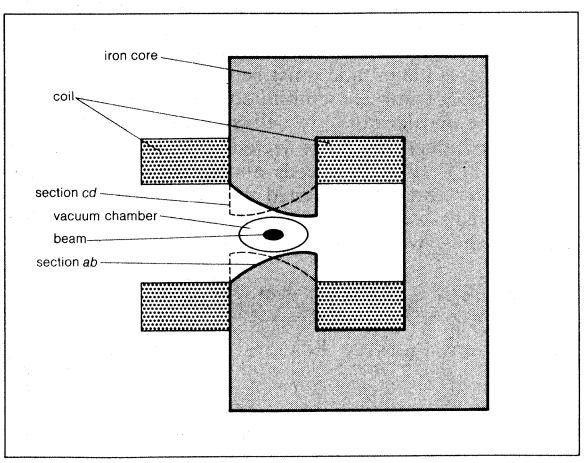


Figure 7: Synchrotron with alternating-gradient focussing, showing the placement of the two types of magnets. Shown at the bottom is a cross section of a typical magnet with the two different types of pole-tips used (see text).

their acceleration in the ring when the magnetic field is small. As the field created by the ring magnets increases, the injection pulse is timed so that the field and the energy of the particles from the linear accelerator are properly matched. The radio-frequency accelerating devices, usually called cavities, operate on the same principle as a short section of a linear accelerator. The useful beam may be either the accelerated particles that have been extracted from the ring by special magnets or secondary particles ejected from a target that is introduced into the beam.

Electron synchrotrons. The invention of the synchrotron immediately solved the problem of the limit on the acceleration of electrons that had been imposed by the radiation of electrons moving in circular orbits. This radiation has been named "synchrotron radiation" because it was first observed during the operation of a 70-MeV electron synchrotron built at the General Electric Company research laboratory, Schenectady, N.Y. A betatron can accelerate electrons to 300 MeV only if the radiation is carefully compensated, but a synchrotron needs only a modest increase in the radio-frequency accelerating voltage. As the particles lose energy by radiation, their average phase with respect to the accelerating voltage simply shifts slightly so as to increase their average energy gain per revolution.

Synchrotron radiation

Several similar electron synchrotrons with energies near 300 MeV were constructed in several countries, the first being the one built at Berkeley under McMillan's direction. In these accelerators, the electrons were injected by a pulsed electron gun, and the initial acceleration from 50–100 keV to 2–3 MeV was induced as in a betatron. The magnets were specifically designed to provide the accelerating flux in the initial part of the magnet cycle; during this time, the speed of the electrons increased from about 50 percent of the speed of light to more than 95 percent. At this point, acceleration by the radio-frequency cavity supervened, and the small further change in speed was accommodated by a 5 percent change in the radius of the orbit.

Strong focussing was first applied to the electron synchrotron in the 1.2-GeV device at Cornell University, Ithaca, N.Y. All large electron synchrotrons now are equipped with linear accelerators for injectors. The practical limit on the energy of an electron synchrotron is set by the cost of the radio-frequency system needed to restore the energy the electrons lose by radiation. To minimize this energy loss, the acceleration time is made as short as possible (a few milliseconds) and the magnetic fields are kept low. Recently, superconducting radio-frequency accelerating cavities have been applied to the electron synchrotron. The characteristics of some electron synchrotrons are given in Table 1.

Table 1: Electron Synchrotrons with Energies Greater Than 5 GeV

location	Hamburg	Daresbury, Cheshire, U.K.	Yerevan, Armenian S.S.R.	Ithaca, N.Y.
Energy (GeV)	7.5	5.2	6.1	12.2
Intensity (electrons per second)	2.5×10^{13}	1.2×10^{13}	3.5×10^{12}	1.8×10^{12}
Radius of the orbit (metres)	50.4	35	34.5	125
Repetition rate (pulses per second)	50	53	50	60
Weight of the magnets (tons)	647	400	427	125
Year of first operation	1964	1966	1967	1967

Proton synchrotrons. The mode of operation of a proton synchrotron is very similar to that of an electron synchrotron, but there are two important differences. First, because the speed of a proton does not approach the speed of light until its energy is well above 1 GeV, the frequency of the accelerating voltage must be modulated to keep it proportional to the speed of the particle during the initial stage of the acceleration. Second, protons do not lose a significant amount of energy by radiation at energies attainable by present-day techniques. The limit on the energy of a proton synchrotron is therefore set by the cost of the magnet ring, which increases only as the first power of the energy, or even more slowly. The highest-energy particle accelerators yet built are proton synchrotrons.

The first proton synchrotron to operate (1956) was the 3-GeV Cosmotron at Brookhaven. It, and other accelerators that soon followed, had weakly focussing magnets. The 28-GeV proton synchrotron at CERN and the 33-GeV machine at Brookhaven made use of the principle of alternating-gradient focussing, but not without complications. Such focussing is so strong that the time required for a particle to complete one orbit does not depend strongly on the energy of the particle. Therefore, for the energy range (which may extend to several GeV) within which acceleration appreciably affects the speed of the particle, phase stability operates as it does in a linear accelerator: the region of stable phase is on the rising side of the time curve of the accelerating voltage. At higher energies, however, the speed of the proton is substantially constant and the region of stable phase is on the falling side of the voltage curve, as it is in a synchrocyclotron. At the point that divides these regions, called the transition energy, there is no phase stability. At Brookhaven a model electron accelerator was built to demonstrate that the beam could be accelerated through the transition energy in a stable manner.

Fermilab 500-GeV proton synchrotron

The large proton synchrotron at Fermilab regularly operates at 400 GeV, though 500 GeV has been attained, accelerating 2.5×10^{13} protons in each magnet cycle. The proton beam originates in a 750-keV Cockcroft–Walton generator and is next accelerated to 200 MeV in a linear accelerator. The protons pass from the linear device into a "booster" synchrotron in which they are accelerated to 8 GeV (99.6 percent of the speed of light). While the magnetic field in the main accelerator ring is held at a strength of 400 gauss, 13 pulses of protons are injected into the ring from the booster. When the main ring has been filled in this way, the radio-frequency accelerators and the steering and focussing

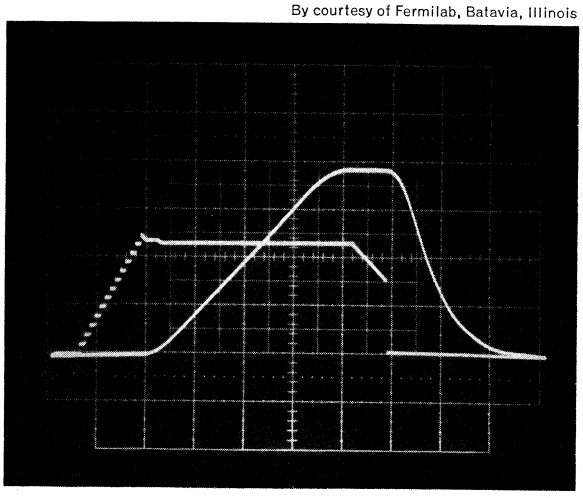

Figure 8: Oscilloscope traces representing the magnet current (which indicates the energy of the circulating protons) and the number of protons in the main accelerator ring at the Fermi National Accelerator Laboratory. One trace shows the stepwise increase in the number of protons corresponding to the injection of 13 bunches of protons from the booster. The number of circulating protons remains constant during acceleration to 400 GeV (shown by the steady rise of the other trace), slowly decreases while one-third of the protons are extracted and sent to counter experiments, then falls abruptly as the remainder of the protons are sent in a short pulse to the 15-foot bubble chamber. (The horizontal scale is one second for each large square.)

magnets are actuated, raising the energy of the protons from 8 GeV to 400 GeV in four seconds, or to 500 GeV in a somewhat longer time. Figure 8 shows how the magnetic field in the main accelerator ring and the intensity of the circulating beam vary during one cycle of operation, which includes injection, acceleration, and extraction of the beam of protons.

The main accelerator ring at Fermilab is 1,000 metres in radius, making its circumference 6.3 kilometres (almost 4 miles). In this ring, the functions of bending the beam around its orbit and focussing the beam are separated. There are 774 bending magnets, each weighing 11 tons, and 180 focussing magnets, each weighing 5 tons. Injection, acceleration, and extraction of the beam take place in six straight sections, free from magnets. The beam from this accelerator is divided to serve many experimental areas. Figure 9 shows a plan of the accelerator and the experimental areas.

An accelerator very similar to that at Fermilab went into operation in 1976 at CERN, where a 28-GeV proton synchrotron serves as the booster accelerator. Proton synchrotrons are in operation in laboratories in several countries; they all are used for research into the properties of subatomic particles (see Table 2).

OTHER TYPES OF ACCELERATORS

Microtrons. Microtrons are cyclic electron accelerators that in some respects resemble cyclotrons in their operation. Their invention and early development took place in the Soviet Union. The magnetic field is constant in time, and the accelerating microwave cavity is mounted near the edge of the field, as shown in Figure 10. The source of electrons is a thermionic cathode installed in, or very close to, the cavity. After being accelerated by the electric fields in the cavity, the electrons are guided in a circular path by the magnetic field, so that they pass again through the beam aperture in the cavity and are accelerated again. The time during which an electron completes one orbit is greater than the time for its previous orbit by exactly one cycle (or a larger integral number of cycles) of the radio-frequency accelerating voltage. The synchronism depends on the principle of phase stability. The electron orbits are a set of tangent circles, the point of tangency being the acceleration gap in the cavity. To produce the high voltages in the cavity, much power is required, so that microtrons are pulsed.

Microtrons have been constructed with energies up to a few tens of MeV. They have the advantage that the beam is easily guided out of the magnetic field; for this reason, they are used as injectors for electron synchrotrons. Recently, a modified microtron has been built in which the accelerating cavity is a short superconducting linear accelerator. The magnet is divided into halves, and the orbits are semicircles joined by straight lines; the straight line common to all the orbits passes through the linear accelerator. This microtron can operate almost continuously, and it achieves 19 MeV.

Storage rings. Although particles are sometimes accelerated in storage rings, the main purpose of these rings is to make possible energetic interactions between beams of particles moving in opposite directions. When a moving object strikes an identical object that is at rest, at most half of the kinetic energy of the moving object is available to produce heat or to deform the objects: the remainder is accounted for by the motions of the objects after the encounter. If, however, the two objects are in motion in opposite directions with equal speeds, then all the kinetic energy is available to produce heat or deformation at the instant of collision. If the objects stick together, the combination is at rest after the collision. For particles with speeds close to that of light, the effect is accentuated. If a 400-GeV proton strikes a proton at rest, only 27.4 GeV are available for the interaction; the remainder produces motion of the particles. On the other hand, if two 31.4-GeV protons collide, as in the CERN storage rings, 62.3 GeV are available for the interaction (the collision is not quite "head on").

When an accelerated beam strikes liquid or solid matter, the number of particles per unit volume of the target is very large, but when the target of one beam is another beam, the number of particles interacting is very much smaller: the rate of interactions is proportional to the product of the currents in the two beams. Kerst realized in 1956 that, although the beam current in a high-energy accelerator is small, the currents circulating in the magnet rings are effectively very much larger because of the high orbital frequency of the particles. Thus, if the colliding beams are circulating in such rings, useful experiments on the interactions could be carried out. Kerst's

Colliding beams of particles

original proposal was to accumulate a large circulating current in the same device used for the acceleration, but most colliding beams are now collected in storage rings separate from the accelerators.

Many storage rings have been constructed to study the interactions of electrons with positrons. The principal centres of this research are Stanford, California; Orsay, France; Hamburg, West Germany; Frascati, Italy; and Novosibirsk, Russian S.F.S.R. The only large operating proton-proton storage ring is at CERN.

The manner of operation of a typical electron-positron colliding-beam device is shown in Figure 11. Since the

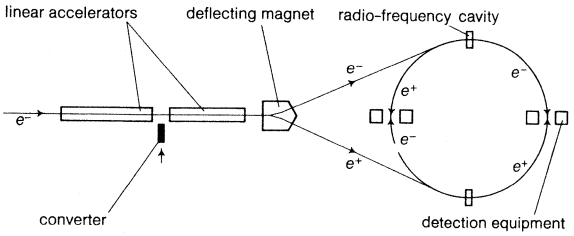

Figure 11: Storage ring with electron-positron colliding beams (see text).

signs of their electrical charges are opposite, electrons and positrons circulate in opposite directions in a magnet ring. Shown is an electron linear accelerator for filling the ring; a synchrotron can be used instead. The deflecting magnet sends electrons to an injection point on the ring so that they circulate in a clockwise sense. Positrons are created by high-energy electrons in a target, usually called a converter, and then accelerated by the second stage of the linear accelerator. The deflecting magnet sends them to an injection point so that they circulate counterclockwise. Because of the radiation of energy by the particles, it is necessary to have accelerating cavities if the energy of the particles is to be kept fixed. The accelerating system causes the particles to circulate in bunches, so that the collisions take place in only a few (commonly only two) places in the ring. This sparsity of intersections simplifies the operation by minimizing the disruption of each beam caused by interactions with the other, allowing more intense beams to be collected and used in the ring. The detection equipment for the experiments is located near the points where the beams intersect.

The highest interaction energies are at present, and will be in the future, achieved in storage rings. This places the research with them at the very forefront of the quest for knowledge, even though many types of experiments cannot be conducted with storage rings. This is true partly because the number of interactions in a storage ring is a small fraction of that occurring in a stationary target and partly because storage rings do not produce intense beams of secondary particles.

The electrons and positrons in a storage ring emit synchrotron radiation in very large amounts—more than a megawatt in some installations. From a high-energy storage ring, the wavelength of this radiation extends into the X-ray region. Nowadays, these storage rings constitute the brightest sources of electromagnetic radiation available in the ultraviolet as well as the X-ray region. This radiation has become increasingly useful for research in solid-state physics, biophysics, and chemical physics; a few electron storage rings of relatively low energy are operated solely for this purpose.

Impulse accelerators. Primarily for use in research on thermonuclear fusion of hydrogen isotopes, several high-intensity electron accelerators have been constructed. One type resembles a string of beads in which each bead is a torus of laminated iron and the string is the vacuum tube. The iron toruses constitute the cores of pulse transformers, and the beam of electrons, in effect, forms the secondary windings of all of the transformers, which are connected in series. The primaries are all connected in parallel and are powered by the discharge of a large bank of capacitors. These accelerators produce beams with energies between 1 and 9 MeV and currents between 200 and 200,000 amperes. The pulses are very brief, lasting about 50 nanoseconds. Besides their application to thermonuclear fusion, such accelerators are utilized for flash radiography, research on collective ion acceleration, microwave production, and laser excitation.

FUTURE DEVELOPMENTS

The next large accelerators to be built will probably be associated with the proposed electron-positron storage rings in which the energy in each beam will lie in the range 15–20 GeV. To keep the power radiated by the stored beam within reason, their magnetic fields will be low, so that ordinary iron magnets wound with copper wire will be adequate. The energies required by this next generation of accelerators, however, will test the limits of conventional radio-frequency techniques. If the energy were to be made significantly higher, the power losses in the accelerating cavities would become prohibitive, and the use of superconducting components would be imperative.

High-energy (200–400 GeV per beam) proton-proton storage rings, with beam currents of about 10 amperes, have been seriously proposed. A small radio-frequency accelerating system would be needed to move the bunches of injected protons to the centre of the vacuum chamber; since protons radiate very little, a large system would be needed only if a part of the acceleration of the beams to high energy were to take place in the storage ring. The overall size and operating cost of such devices would prove to be excessive if superconducting magnets were not used.

There has been a proposal for adding a superconducting ring—in the same enclosure as the main ring at Fermilab—that would be filled with 200–400 GeV protons that could be accelerated slowly to 1,000 GeV. There also has been discussion of larger accelerators, with energies up to 4,000 GeV, that could fit on the Fermilab site if superconducting magnets were used.

Future accelerators of low energy will be designed to produce more intense beams, especially in meson factories; those of higher energy will be designed for the acceleration of heavy ions. In another direction, new, higher-energy electron-storage rings will be built especially for the production of synchrotron radiation.

In a more speculative field, ways are being sought to accelerate protons to very high energies without using huge magnet rings. Veksler in 1956 suggested the formation of a very dense cloud of electrons, which would stay in a stable configuration if they had relativistic energies. In the centre of this cloud there is a point of low potential energy in which protons could be trapped; if then the cloud were to be accelerated to a very high velocity—not a particularly high energy per electron, and therefore attainable with modest energies—the protons, which are carried along, would have very high energies. So far, protons have been accelerated only to a few MeV by application of this principle.

If history can be used as a guide, one can predict that research on the properties of subatomic particles will uncover new phenomena that will require even higher energies for their study. A way will be found to produce those higher energies.

(Y.M.A./F.C.S.)

Acclimatization

Every organism is capable of adjusting to changes that occur in its environment. Some changes are gradual and elicit long-term responses—or the capability of responses—that are collectively grouped under the term acclimatization. Such responses are more or less habitual and reversible should environmental conditions revert to an earlier state. The numerous sudden changes that evoke rapid and short-term responses via the nervous and hormonal systems are not examples of acclimatization.

An individual organism can regulate its internal processes rapidly to sustain itself within the usual range of environmental changes that it encounters hourly or daily. But this rapid regulation, or homeostasis, is limited in its operation to a small range of environmental variations. Homeostatic regulation usually cannot meet effectively large environmental changes such as those that would allow a plant or animal living in the warmth of summer to function in the cold of winter. As summer wanes, organisms change their substance and their habits in seeming anticipation of the coming winter. This gradual adjustment to conditions is acclimatization. Acclimatization occurs commonly and is necessary in changing environments. Some of its manifestations, essential for the continuance of life, are especially interesting because they reveal the great flexibility of vital reactions.

GENERAL FEATURES

Although acclimatization refers basically to adaptation to climate, the term can also be used to describe the adjustments that a person makes to urban, social, or political conditions or the adaptation of a population of plants to conditions of cultivation or of an animal to the unnatural conditions of captivity. (Adaptations to strange or artificial conditions, however, are often difficult to describe, and only in a few cases can such adaptations be compared with acclimatization.) The following account is restricted to acclimatization in which the environmental conditions that evoke the change can be measured and in which the intrinsic changes in the organism can be described.

Because organisms do not have unlimited combinations of adaptations, they may use a similar process to adapt to changes of different origins. For example, in acclimatization to the low pressure of oxygen (hypoxia) in high mountains, animals, including man, improve the capacity of blood to transport oxygen by increasing the number of red blood cells (polycythemia); in the chronic disease emphysema, the inadequate supply of oxygen to the lungs is to some degree compensated for by a similar polycythemia.

Hypoxia and polycythemia

Acclimatization does not necessarily mean that a plant or animal is adapted to function at its maximum rate. In the hot summer, acclimatized birds and mammals often rest in the shade, and in winter cold some animals and all plants become dormant. Acclimatization often requires modification of activity, but the adaptive changes allow the individual to live normally and to utilize a greater variety of habitats than would otherwise be available. At extreme limits an organism may suffer some impairment of vigour, but it survives; if the impairment is overt, acclimatization is considered inadequate.

In contrast to changes that occur during growth and development, acclimatization refers to an adaptive change that is reversible when conditions return to their former condition. Acclimatization does not leave a lasting impression upon the genetic mechanisms of the acclimatized organism. The adaptation of populations to change that effects evolution by the selection of genetic capability is a different process from the acclimatization of an individual (see EVOLUTION).

INFLUENCES OF ENVIRONMENT

Environmental conditions change with the seasons, as from winter to summer or, in the tropics, from periods of humid to dry weather. Sedentary animals and plants adjust readily to the local seasons. But winds, rivers, currents, locomotion, and human beings have been operating for ages to disperse individual organisms into new environments. Those individuals that acclimatize to their newfound circumstances thrive and reproduce; those that fail to acclimatize perish.

In dealing with acclimatization, the influence of climate upon life can be treated under headings of adjustments to temperature, humidity, salinity, light, pressure, and certain chemical substances in the environment.

Because animals and plants can be successfully introduced to new regions, it can be said that species do not necessarily thrive at their best potential in their native regions. Dandelions and Scotch broom, native to Europe, have spread successfully over large areas in North America, as have starlings and house sparrows. Muskrats from North America have been dispersed widely through Europe and Asia. Monterey pine, a small tree native to a few thousand acres of California, grows into a large tree in New Zealand. Not every introduction of a plant or animal succeeds, of course. Of those that do succeed, only a few are useful to humans; many more become costly nuisances.

The hidden potential of organisms

Adjustments to temperature. Considering that sunshine, moisture, and wind, among other conditions, greatly affect weather, it is remarkable that temperature alone can be a principal indicator of the suitability of climates for life. Rates of reactions in cells and tissues are critically affected by temperature. In addition to their obvious influence upon life, the effects of temperature are favoured for study by scientists because of the clear-cut relationship between reactions of organisms and changes in temperature.

Plants. As the weather warms in spring, plants that have been cultivated in the shelter of a greenhouse can be made to tolerate the daily changes in outdoor temperature by being gradually exposed to such conditions. This process, called hardening, readies them for planting in the field or garden. Pansies and cabbages are readily acclimatized to the variable weather of a temperate climate. More sensitive plants such as squashes and begonias need a longer time. Plants originating in the tropics commonly do not become acclimatized readily to the weather pattern in temperate regions.

Early in the history of agriculture, useful plants were transported to climates differing from that to which they were native. In order to become established, the first transplants had to survive the transition and produce seeds. Thereafter, natural or artificial selection could operate to favour variants among the progeny best adapted to the new climate.

Plant response to seasonal changes

In nature the distribution of plants is obviously related to climate, in which temperature is the most easily recognizable factor. Many plants of temperate regions are able to thrive within a considerable range of seasonal temperatures. In areas nearer to the poles, many species of trees fail to acclimatize to the extreme seasonal changes. A few species, however, such as spruce, larch, and willow, can survive the coldest winters of the interior Arctic. They become acclimatized to endure very cold weather (−50° C, or −58° F), provided that the short summer is warm enough to allow sufficient photosynthesis for growth and for the production of seeds.

The fertilization of ova (eggs) by pollen in flowers seems to be a part of the life history in many plants that can be

acclimatized only to a very small range of warm temperatures. Flowers of tomatoes do not set fruit without sufficient warmth. Wild Arctic and Alpine plants, however, flower abundantly in regions with intermittent freezing and warmer periods in summer. Acclimatization for cold may start even before seasonal cooling occurs. In temperate regions, as the days of late summer shorten, the leaves of some deciduous plants diminish their growth; but, before they drop, they transmit an influence, probably through regulating substances (*e.g.*, hormones), that induces cold tolerance in woody stems. Thus an influence other than cold can initiate hardening for winter.

The changing length of daylight is a more reliable indicator of average progress of the seasons than is the day-by-day fluctuation in temperature. Sensitivity to the duration of daylight or to the duration of darkness indicates that somehow time and thus season can be measured by organisms. By reference to the environmental signal of day length, organisms can prepare for the temperatures of the oncoming season. Doubtless, factors other than light are also involved in transmitting signals for acclimatization to approaching seasonal change.

Insects. Many insects pass through several stages in their life cycles. As adults and larvae they usually are active; as pupae they usually remain dormant. Many sub-Arctic insects, however, are now known to become dormant in their adult, or reproductive, forms. A very small carabid beetle winters in stumps in northern Alaska exposed to temperatures as low as −40° C (−40° F). As the weather cools in autumn, the beetle accumulates glycerol in its body and thereby acquires tolerance to cold, very much as antifreeze provides cold tolerance in automobiles. As the days of spring become warmer, the amount of glycerol diminishes, and cold hardiness is gradually lost.

Glycerol as protection against freezing

Insects are the most diverse class of animals in numbers, forms, and natural ranges. The tolerance of cold differs in each species, as does tolerance of heat. Possible acclimatization to heat differs with species and with stage of growth. The beetle example above, although not representative, illustrates the processes involved in acclimatization in some insects.

It is thought that glycerol prevents cell damage from freezing. Glycerol preparations of spermatozoa from bulls, of human red blood cells, and of tissues of the cornea from the eye of rabbits can be preserved for long periods in liquid carbon dioxide (−80° C or −112° F) and successfully restored for use. Several other substances with properties resembling glycerol also serve as cryoprotectants (*i.e.*, protectants against severe cold).

Fish. Fish of temperate and Arctic waters gradually adjust their activity and metabolism to yield peak effectiveness in the temperatures that prevail; some fishes of perpetually cold Antarctic seawater, however, can perform most effectively only at temperatures from −2° to +4° C (28° to 39° F). In temperate and Arctic zones, large bodies of water, near freezing in winter, may warm 10° C (18° F) in summer, whereas small bodies of water may warm more than 20° C (36° F). In the cold season fish tolerate colder temperatures than they do in summer. Conversely, in the warm season they tolerate warmer water than they do in winter. Not only does ability to survive a given warm or cold temperature change with experimental acclimatization (often called acclimation by physiologists) but maximal activity, measured by speed or metabolic use of oxygen, also changes.

The results of experiments on acclimatization of certain fishes to water temperatures generally agree with the natural temperatures of the seasonal habitats of the various species. There are, of course, hazards in referring to temperature as a single environmental factor for acclimatization—*i.e.*, temperature affects the amount of water that must be pumped over the gills for respiratory exchange, and, in the course of the year, growth and reproductive condition also exert their influences.

Birds. Birds maintain their bodily warmth in all climates and seasons. In the Arctic winter, small common redpolls keep warm in temperatures as low as −40° C (−40° F) by increasing their metabolic rate three or four times the normal rate at average winter temperatures. In summer, however, they cannot produce heat adequate for life in air at −40° C, even with an abundant supply of food. Evidently their metabolic processes become acclimatized for winter and summer conditions.

A striking illustration of acclimatization has been provided by an Arctic glaucous gull that was kept in a warm laboratory at Barrow, Alaska, during a midwinter month. It escaped outdoors in a temperature of −20° C (−4° F); although it was found a very short time later, its feet were frozen. Several other gulls kept in open outdoor cages and thus exposed to temperatures as low as −30° C (−22° F) survived without any freezing injury.

Mammals. The thickening of the fur of northern dogs, horses, and wild mammals in anticipation of winter is as familiar and useful an acclimatization as is the shedding of fur in summer. In nature, change in various properties of fur accompanies the change in seasonal temperature. Several species that live in snowy climates, such as weasels, varying hares, and Arctic foxes, assume white coats in winter. This transition to white can be unseasonably accelerated in weasels by experimentally shortening the duration of daylight. In some mammals, as in some plants, detection by the organism of the seasonal change of illumination seems to serve as a signal to initiate seasonal change. Several other species of mammals lengthen their fur on exposure to cold even when there is no noticeable change in illumination, as in laboratory experiments.

Northern varying hares change in spring from white to brown fur; if the snow cover melts early, the white hares may be conspicuous against the dark-coloured ground. Thus, when seasonal conditions are out of phase with the average state, the variation in light may not correctly signal a change of coat colour. As with other gradual processes of seasonal acclimatization, the change may not be in good relation to the momentary condition of the environment.

The economy of adaptation

Many adaptive processes seem to operate by reducing rather than by eliminating erroneous adaptation. When Australian dingoes were experimentally exposed to cold of about −20° C, their fur thickened noticeably; in addition, their measured metabolism in cold was less than for dingoes that had been kept warm. It was concluded that the ancestors of these dogs, introduced to Australia several thousand years ago, had remained in that warm climate long enough to become recognized as a distinct species, but they also retained the capability to acclimatize to temperatures far colder than their species had experienced in many centuries.

Seals acclimatize to ice water primarily by insulating their body with layers of fat instead of with fur. There is a gradual rise in temperatures through five or six centimetres of blubber before the internal body temperature of 37° C (99° F) is reached.

As temperatures rise above about 30° C (86° F), and depending upon the humidity, birds and mammals gradually lose their ability to dissipate sufficient heat to regulate body temperature and resort instead to evaporative cooling or sweating. Man is one of the most effective users of this mechanism, the effectiveness of which improves after a few days' exposure to hot weather. Acclimatization involves activation of more sweat glands, compensatory conservation of water excreted through kidneys, and some reduction in the outflow of salt through kidneys and sweat glands. The fullest acclimatization for heat probably involves alteration of the signals that evoke sweating and circulation of blood in the skin.

Adjustments to illumination. Plants react markedly to changing illumination. The most conspicuous reactions, which involve growth and development of new structures, are not properly acclimatizations. But the changing schedule of day length provides the signal that induces development of cold tolerance. Changing day length appears to be a signal that permits the acclimatization mechanisms to anticipate adaptation for extremes of temperatures that depart from average conditions.

Light as an environmental signal

Migratory birds prepare early in spring for the flight northward to their breeding grounds by accumulating fat

in amounts that may nearly double their body weight. Preparations of the reproductive organs are, likewise, initiated early and are complete soon after arrival on the nesting grounds. In the western American white-crowned sparrow, the signal that sets in motion this behaviour is the gradually increasing length of day during spring. The environmental signal acts through complex neural and hormonal paths centred in the bird's brain.

Later in summer, as the days shorten, the birds fatten again, but this time in preparation for the southward migration. In this highly adaptive behaviour of birds, day length provides a signal for activity appropriate to the usual seasonal habits both of species and of local populations. The whole system is so elaborate and is apparently such an effective guide in avian behaviour that it is not usually dealt with under the designation of acclimatization; nevertheless, it represents the best known of the complicated systems of reactions that keep each individual in a population in accord with the changing seasonal conditions of the environments upon which it so precisely depends.

Adaptations to meet changes of the seasons encounter the vagaries of weather, which at any date may differ widely from average conditions. In preparing to meet the coldness of November in the north, there is an almost even chance that the weather will be colder than average and a smaller chance that it may be much colder. Acclimatization for cold, therefore, must exceed the average of local conditions. In another sense, acclimatization must anticipate both the progress and degree of seasonal cold—that is, a plant or animal must change its outlook upon the oncoming seasons by referring to the seasons in its past experience. This would require reference to annual cycles of the past and expectations on which to predict the future. It is certain that seasonal change in length of day gives a clue as to the date, and hence time, for initiating the processes of acclimatization. Degrees of acclimatization for the future appear to require margins for error or departure from average environmental conditions.

How the length of day influences man's life is shown impressively during rapid travel by air westward, when the duration of daylight becomes prolonged. Customary times for meals and sleep become deranged, and for a few days the newly arrived traveller's internal condition is out of phase with the strange new program of environmental events. Even more disturbing to the rhythmical changes that occur according to time of day are the shortening of length of daylight and the shortening of corresponding schedules that result from travel eastward. After travelling from San Francisco to London, a person may require several days to become adapted to his normal efficiency.

Means of conserving water

Adjustments to humidity. Rain that falls on the desert promotes sudden germination of seeds and rapid new growth and flowering of plants that lay dormant through the dry period. Many of these transitions are concerned with growth of new structures and are not generally regarded as examples of acclimatization. Perennial stems and roots resume transport of water and dissolved material by reactivating functions that were inactive during the dry season. Perennial stems of cactus and some other desert plants are said to store water in humid seasons. During periods of high humidity, water available in the soil rises rapidly as a result of transpiration of water from leaves. Substances elaborated in leaves by photosynthesis are in turn distributed to all growing parts. It can be considered that activation of these transport systems during a humid period involves acclimatization of the systems of transport for special activity.

In winter, in northern regions, evaporation from twigs, buds, and needles of conifers can still occur. If the water in soil and transport systems is immobilized by freezing, the lost water is not replaced. If, furthermore, the stems, twigs, and needles are warmed by the late winter sun, the resulting drying out of buds and needles would be lethal; but the winter structures retain their ability to adjust to varying levels of water vapour. Buds of Arctic trees retain moisture well during winter; water resumes its movement into buds as adequate stores in large stems melt.

The lungfish (*Protopterus*) of the swampy overflows of the Nile River burrows in the mud and encases itself in an impervious covering as dry weather approaches. In this covering the fish can resist drying until the next flooding of the rivers. In a similar manner, numerous invertebrates evade drying out by special impervious structures in which they remain dormant during dry seasons.

Insects that breathe through respiratory systems consisting of air tubes guard against drying by changing the openings to their air tubes in such a way as to reduce loss of water vapour while still permitting the inward diffusion of oxygen and the outward escape of carbon dioxide waste.

Warm-blooded birds and mammals in climates with prolonged warm, dry periods must conserve water by reducing its use in sweating. Some kinds of cattle and sheep in hot desert lands are especially adapted for the economical use of water. The camel is one well-known example. On a hot, dry summer day, it allows its body temperature to rise several degrees above normal. During the night, when radiation through the clear atmosphere to the cold dark sky cools the air, the camel loses the heat stored by day and cools several degrees below its usual temperature. By utilizing its massive body in this manner, it loses less water by evaporative cooling. In the cooler season the camel does not show daily alterations of body temperature. A number of African and Australian herbivores regulate body temperature to conserve water in dry seasons. Man cannot manipulate his body temperature for significant economy of water but is well adapted for hot climates by his ability to sweat copiously.

Adjustments to chemicals. *Salts.* Closely related to acclimatization for humidity are the adjustments that must be made for salts dissolved in a watery environment. Mammals and birds regulate their intake of salts and water to a considerable extent by choice of food and drink. In addition, they excrete the excess salt and water mainly through kidneys and thus maintain the concentration of salts in their body fluids to an equivalent of about a 0.9 percent solution of sodium chloride. Because seasons affect the balance of nutritional intake of salts and water and the use of water for evaporative cooling, intricate adaptive regulatory processes are necessary. Organisms differ so widely that there is no single good example of a common process of this type of acclimatization.

Estuarine organisms

Animals of estuaries, where freshwater mixes with seawater, are exposed to changing concentrations of salt water as currents change seasonally or as the animals themselves move about. Trout and salmon swim from the sea, which contains dissolved salts equivalent to about 3.5 percent sodium chloride, into practically saltless freshwater. With the first encounter with diluted seawater, their blood becomes slightly diluted, but as they gradually reach freshwater, excess water is actively excreted to maintain their internal salt level at about 0.8 percent. Among the species of fishes that can become acclimatized to such changes are salmon, trout, sturgeon, and whitefish.

The ability to adjust to changes in salt concentration in the environment is found in many invertebrates in degrees varying from those that withstand very little change to a few, such as the brine shrimp (*Artemia*), that can endure saturated sodium chloride solutions or freshwater.

Other chemical substances. Mammals require various specific minimal quantities of proteins, fats, and carbohydrates, along with vitamins and inorganic elements (*e.g.*, calcium, iodine). There appears to be no adaptation that permits a species to thrive on nutritional deficiencies or excesses and hence no important acclimatization for variation in the essential composition of diet. Outright deficiencies or excesses cause overt defects. There is, however, vagueness regarding the upper and lower limits of nutrition for a species or for a population living in special circumstances. What was once generally regarded as acclimatization to diet is now known in part to be brought about by development of immunity to local infectious illnesses transmitted perhaps in foods and water.

Herbivorous animals such as domesticated cattle and wild deer accomplish preliminary digestion in the rumen by the action of micro-organisms that break down plants to substances that can be digested by the animal. In addition, the micro-organisms growing in the rumen furnish nitrogenous nutrients and vitamins. In spring the fresh green feed differs in digestibility from the dry feed of winter, and a dietary adjustment must be made in the digestive processes of the animal; part of this is accomplished by a gradual change in the microbial population of the animal's rumen. In a general way this adjustment represents acclimatization for diet.

Tolerance to pollutants

A long list of other substances, derived mainly from industrial processes and uses, now appears to be accumulated by plants and animals and transferred through chains of food consumption to man in dangerous amounts. Mercury and arsenic, for example, have been transferred through aquatic food chains and have caused illness and even fatalities in man. The fishes, however, that accumulate and transfer these poisons must presumably tolerate them long enough to reproduce stable populations. Their tolerance can be considered a form of acclimatization.

Adjustments to changes in pressure. The history of the conquests of the Inca Indians in the high Andes of South America included accounts of the suffering of the Spanish invaders and their horses from the altitude and its diminished atmospheric pressure. The residents native to the high mountains appeared to have no handicap. On the other hand, the Incas were acclimatized to the high altitudes and could not safely move to lower ones. For many years no births occurred among the Spaniards newly arrived in the high Andes, although the native people were prolific. Some European domesticated animals also were at first unsuccessful at breeding in the high Andes. The native Andean races of people and animals resident for many generations at high altitudes probably developed selectively inherited adaptive capabilities. As modern people become more mobile, and as scientific breeding makes possible transfers of stocks of domesticated animals, the heritable factors that allow adaptability to altitude in populations will be able to be contrasted with the acclimatization of individuals.

Aviators who rise rapidly to altitudes for which they cannot adequately compensate also suffer the discomfort of high altitudes. Some acclimatization is observed after repeated high flights, but provision of oxygen and pressurized cabins have now extended the limited ability of man. In very low atmospheric pressures, the entire body must be enclosed in a pressurized suit in order to maintain pressures that permit normal circulation of blood.

Because the pressure of oxygen in mountain air is reduced, oxygenation of the blood of a new arrival from the seacoast is diminished. In an attempt to compensate, the subject breathes rapidly, which, although somewhat increasing the oxygen content of blood, abnormally lowers the pressure of carbon dioxide and increases blood alkalinity, resulting in a condition called hypoxic hypoxia. Some persons suffer headaches and many symptoms of mountain sickness at high altitudes, the severity and duration of the discomfort varying among individuals. After a period of time (a week or months), newcomers lose the acute symptoms of mountain sickness and begin to regain their ability for activity.

Some of the early compensatory physiological adjustments to altitude illustrate the mechanisms involved in acclimatization. The number of red blood cells increases, thereby improving the capacity of the blood for transporting oxygen. Blood circulation increases, improving the blood supply to the tissues, and apparently even the intracellular utilization of oxygen is increased.

Limits of habituation to sound waves

Rapid pulsations of air pressure are detected by the ear as sound. Adaptations for exposure to sound can diminish the sensitivity of the ear; in fact, many kinds of sensory receptors show diminishing discharge as a stimulus continues to operate. This adaptation of sense organs is usually too sudden to be regarded as acclimatization. But the persistent disturbance of a noisy airport, factory, or building site may become less disturbing in time, and some tolerance develops that is perhaps a type of acclimatization. Such habituation to noise is seen among many animals, including numerous birds that nest and successfully raise young in the presence of almost unbearable noise. As the world becomes more noisy, the limits to which acclimatization can extend short of allowing physical damage and mental disturbance are of utmost importance to the well-being of man.

THE BIOLOGICAL SIGNIFICANCE OF ACCLIMATIZATION

Although increase in scientific knowledge has resulted in precise terms for many adjustments formerly considered under acclimatization, many other adjustments to environmental changes still remain obscure and are covered under that designation.

Acclimatization can gradually alter homeostatic capabilities for average circumstances that are altered by seasons or by movement to a new locality. If acclimatization cannot adjust to allow for active function in the altered circumstances, dormancy may be induced until suitable conditions recur.

Acclimatization thus permits an organism to exploit regions of great seasonal variation and, on occasion, to move in wholly new environments. Only the new settlers that acclimatize can survive to produce progeny from which a new population may become established. Ability to become acclimatized differs greatly among species of plants and animals. Some breeds of domesticated animals and cultivated plants are quite versatile in this ability, whereas others are narrowly restricted.

An interesting characteristic of seasonal acclimatization appears in animals and plants that become adjusted to cold beyond that which they are likely to encounter. Not only does acclimatization prepare them with a margin of safety but some micro-organisms, insects, and plants tolerate experimental exposure at temperatures far colder or warmer than ever occur in nature. It seems strange that adaptability enables these organisms to be prepared to encounter conditions beyond their natural experience.

The anticipation of change

Another surprising characteristic of acclimatization is its anticipatory nature—it can develop before the change occurs. It would seem that anticipation of the need for change would be required in order to make the slow physiological preparations for climatic changes that often set in very suddenly. Anticipation of acclimatization seems to require a sense of time by which the coming environmental conditions can be predicted. Length of day is one external signal, but it seems to impinge upon intrinsic rhythms that provide clues from within as to the passage of time (see also PERIODICITY, BIOLOGICAL). Consideration of acclimatization reveals many processes by which animals and plants prepare to function or to exist in dormant survival in the various and changing circumstances of the world.

(L.I.)

Accounting, Principles of

The purpose of accounting is to provide information about the economic affairs of an organization. It is a means of recording facts or forecasts about the economic aspects of an organization's activities and translating them into a useful form for further action. The information thus dealt with may be used in a number of ways: (1) by the organization's managers to help them plan and control the organization's operations; (2) by owners and legislative or regulatory bodies to help them appraise the organization's performance and make decisions as to its future; (3) by owners, lenders, suppliers, employees, and others to help them decide how much time or money to devote to the organization.

Accounting provides information for all these purposes through the maintainance of files of data and the preparation of various kinds of reports. Most accounting information is historical—that is, the accountant observes the things that the organization does, records their effects, and prepares reports summarizing what he has recorded. In addition, however, his reports often summarize the anticipated results of the things the organization plans to do. Accounting information can be developed for any kind of organization, not just for privately-owned, profit-seeking businesses. One branch of accounting deals with the economic operations of entire nations. The remainder of this article, however, will be devoted primarily to business accounting.

COMPANY FINANCIAL STATEMENTS

Some accounting reports are issued only to the company's management (see below, *Managerial Accounting*); others are also sent to owners and others outside the management group. The reports most likely to go outside the company are called the company's financial statements, and their preparation is the province of the branch of accounting known as financial accounting. Four kinds of financial statements will be discussed: the balance sheet, the income statement, the statement of changes in retained earnings, and the statement of sources and uses of funds.

The balance sheet. A balance sheet describes the resources that are under the organization's control on a specified date and indicates where these resources have come from. It consists of three major sections: (1) the assets: valuable rights owned by the firm; (2) the liabilities: the funds that have been provided by outside lenders and other creditors in exchange for the company's promise to make payments or provide services in the future; (3) the owners' equity: the funds that have been provided by or on behalf of the company's owners.

The list of assets shows the forms in which the organization's resources are lodged; the lists of liabilities and the owners' equity indicate where these same resources have come from. The balance sheet, in other words, shows the organization's resources from two points of view, and the following relationship must always exist: total assets equals total liabilities plus total owners' equity.

This same identity is also expressed in another way: total assets minus total liabilities equals total owners' equity. In this form, the equation emphasizes that the owners' equity in the organization is always equal to the net assets (assets minus liabilities). Any increase in one will inevitably be accompanied by an increase in the other, and the only way to increase the owner's equity is to increase the net assets.

Assets and liabilities

Assets are ordinarily subdivided into current assets and noncurrent assets. The former include cash, amounts receivable from customers, inventories, and other assets that are expected to be consumed or can be readily converted into cash during the next operating cycle (production, sale, and collection). Noncurrent assets may include noncurrent receivables, fixed assets (such as the value of land and buildings), and long-term investments, usually shares of stock and bonds of other companies.

The liabilities are similarly divided into current liabilities and noncurrent liabilities. Most amounts payable to the firm's suppliers (accounts payable), to employees (wages payable), or to governments (taxes payable) will be included among the current liabilities. Noncurrent liabilities consist mainly of amounts payable to holders of the company's long-term bonds and such items as the firm's obligations to employees under company pension plans.

The difference between the total of the current assets and the total of the current liabilities is known as net current assets, or working capital.

The owners' equity of a United States company is divided between paid-in capital and retained earnings. Paid-in capital represents the amounts paid to the corporation in exchange for shares of the company's preferred and common stock. The major part of this, the capital paid in by the common shareholders, is usually divided into two parts, one representing the par value, or stated value, of the shares, the other representing the excess over this amount, often referred to as capital surplus. The amount of retained earnings is the difference between the amounts earned by the company in the past and the dividends that have been distributed to the owners. In other words, the amount of retained earnings shows how much of the company's assets have come from the reinvestment of the company's own earnings.

A slightly different breakdown of the owner's equity is used in most of continental Europe and in other parts of the world. The classification is a legal one, distinguishing between those amounts that cannot be distributed except as part of a formal liquidation of all or part of the company (capital and legal reserves) and those amounts that are not restricted in this way (free reserves and undistributed profits).

A simple balance sheet is shown in Table 1. Because the two sides of this balance sheet represent two different aspects of the same entity—the corporation's capital—the totals must always be identical. Thus a change in the amount for one item must always be accompanied by an equal change in some other item. For example, if the company pays $40 to one of its trade creditors, the cash balance will go down by $40, and the balance in accounts payable will go down by the same amount.

The income statement. The firm uses its assets to produce goods and services. Its success will depend on whether it is wise or lucky in the assets it chooses to hold and in the ways it uses these assets to produce goods and services.

Net income

The firm's success is measured by the amount of profit it earns—that is, the growth or decline in its stock of assets from all sources other than contributions or withdrawals of funds by owners and creditors. Net income is the accountant's term for the amount of profit that is reported for a particular time period.

The firm's income statement for a period of time shows how the net income figure for that period was derived. For example, the first line in the income statement in Table 2 shows the company's sales revenues for the period: the assets obtained from its customers in exchange for the goods and services that constitute the firm's ordinary stock in trade. The second line summarizes the company's revenues from other sources.

Next, the income statement shows the expenses of the period: the assets that were consumed while the revenues were being created. The expenses are usually broken down into several categories indicating what the assets were used for. In Table 2, six expense items are distinguished, starting with the cost of the merchandise that was sold during the period and continuing down through the provision for income taxes.

The bottom portion of the income statement is reserved for gains and losses from extraordinary events. In this case, the company sold some of its long-term investments for more than their original purchase price. Because this was not part of the company's normal business, the sale price, costs, and taxes on the sale were kept separate from the ordinary revenue and expense totals; the income statement shows only a single figure, the net gain on the sale.

Table 1: Any Company, Inc.: Balance Sheet as of Dec. 31, 19__

assets			liabilities and owners' equity		
Current assets			Current liabilities		
Cash		$100	Wages payable		$ 20
Marketable securities		50	Accounts payable		160
Accounts receivable		150	Total current liabilities		$180
Inventories		180	Long-term bonds payable		80
Total current assets		$480	Total liabilities		$260
Long-term investments		70	Owners' equity		
Plant and equipment			Common stock	$200	
Original cost	$300		Retained earnings	280	
Less: accumulated depreciation	110	190	Total owners' equity		480
Total assets		$740	Total liabilities and owners' equity		$740

Table 2: Any Company, Inc.: Income Statement for the Year Ending Dec. 31, 19__

Net sales revenues		$800
Interest and other revenues		14
Total revenues		$814
Expenses		
Cost of merchandise sold	$492	
Salaries of employees	116	
Depreciation	30	
Interest expense	4	
Other expenses	78	
Provision for taxes on ordinary income	47	767
Net earnings before extraordinary item		$ 47
Extraordinary item: gain on sale of investment (less applicable income taxes)		5
Net income		$ 52

The net income figure summarizes all of the gains and losses recognized during the period, including both the results of the firm's normal, day-by-day activities and any extraordinary events. If net income is negative, it is referred to as a net loss.

The statement of changes in retained earnings. Like the income statement, the statement of changes in retained earnings refers to a period of time rather than to a single date. It explains the change from one balance sheet date to the next in the amount shown as retained earnings.

The retained earnings statement is the link between the income statement and the balance sheet. This relationship can be demonstrated by rewriting the accounting equation in the following way: assets minus liabilities equals paid-in capital plus retained earnings. Whenever the firm reports net income, it means that more assets have come in as revenues than went out as expenses; more precisely, it means that the net asset total (assets minus liabilities) has increased. Therefore, if the accounting equation is to remain balanced, an amount equal to net income must be added to the retained earnings figure.

Similarly, the distribution of cash dividends reduces net assets, and this change again is usually balanced by a reduction in the retained earnings to keep the equation in trim. Thus the typical statement of changes in retained earnings will consist of the items shown in Table 3. Starting with retained earnings of $263 at the beginning of the year, the company added $52 in net income during the year (from Table 2). Dividends amounting to $35 were distributed to shareholders during the year, leaving a year-end balance of $280. This is the amount to be carried to the year-end balance sheet (Table 1).

Table 3: Any Company, Inc.: Statement of Changes in Retained Earnings for the Year Ending Dec. 31, 19__

Retained earnings, Jan. 1, 19__	$263
Net income earned during 19__	52
	$315
Less: dividends distributed to shareholders during 19__	35
Retained earnings, Dec. 31, 19__	$280

The statement of the sources and uses of funds. The statement of sources and uses of funds, or funds statement, identifies the major flows of funds during the period. In most corporate reports, "funds" means working capital. The idea is easier to understand, however, from an illustration in which the flow of funds means the flow of cash. If a salesman earns $18,000 in salary and commissions and pays $5,000 for airline tickets, hotel rooms, meals, and other travel expenses, his operations have provided him with funds amounting to $13,000. Further investigation reveals that he borrowed $2,000 from the bank during this same year, bought a car for $3,000, purchased stock for $4,000, and spent $9,000 on ordinary living expenses. At the end of the year, he had $1,000 less in his bank account than he had had at the beginning. A funds statement for the year would show the following:

The flow of funds

sources of funds		uses of funds	
from operations	$13,000	to purchase car	$3,000
from bank borrowing	2,000	to buy stock	4,000
from past savings	1,000	to pay living expenses	9,000
total sources	$16,000	total uses	$16,000

This is very different from an income statement. The sources of funds include amounts borrowed from the bank and taken from past personal savings. These are, of course, not thought of as current revenues. Similarly, the purchases of stock and of the car would not be thought of as current expenses: the purchases are made in the expectation of a future benefit, not mainly to produce current revenues.

The figure referred to as funds from operations ($13,000) comes from the income statement but it is not the same as net income. For example, the salesman may say that his expenses should include some recognition of depreciation on the automobile that he used in his business. If depreciation is estimated to be $600 for the year, his net income would be $12,400, not $13,000.

The purpose of the funds statement is to permit an examination of the firm's financial activities during the period. For example, Table 4 shows the funds statement of Any Company, Inc., for the year 19___. This shows that $77 flowed in from ordinary operations, $20 came from the issuance of the company's own bonds, and $5 came from the sale of securities that the company had held as a long-term investment. Almost half of these funds were used to buy a new plant and equipment. Another $35 went to stockholders in the form of dividends, and the remaining $17 was invested in working capital.

The statement itself serves merely to identify existing relationships. It reveals, for instance, that operations did not generate enough funds to cover the company's dividend and capital investment requirements. An observer may reasonably ask whether this seems to be the result of an aggressive and imaginative expansion program or the product of competitive weaknesses that limit the company's fund-generating capacity. Similarly, the amount of funds going into working capital is a statement of fact; whether it is good or bad depends on the reasons for it.

Disclosure and auditing requirements. A corporation's obligations to issue financial statements are prescribed in

Table 4: Any Company, Inc.: Statement of the Sources and Uses of Funds for the Year Ending Dec. 31, 19__

Sources of funds	
From ordinary operations	$ 77
From sale of investments	5
From sale of bonds	20
Total sources of funds	$102
Uses of funds	
To pay dividends	$ 35
To acquire plant and equipment	50
To increase working capital	17
Total uses of funds	$102

the company's own statutes or bylaws and in public laws and regulations. The financial statements of most large and medium-sized companies in the United States fall primarily within the jurisdiction of the Securities and Exchange Commission (SEC), a federal government agency. The SEC has a good deal of authority to prescribe the content and structure of the financial statements that are submitted to it.

A company's financial statements are ordinarily prepared initially by its own accountants and then reviewed, or audited, by outsiders. In most countries, including the United States, these outside auditors are selected by the company's shareholders. The audit of the statements of a company is ordinarily performed by professionally qualified, independent accountants who bear the title of Certified Public Accountants (CPA) in the United States, and Chartered Accountants in Great Britain and many other countries with British-based accounting traditions. Their primary task is to investigate the company's accounting figures and methods carefully enough to permit them to give their opinion that the financial statements are complete and that the figures are measured on the basis of acceptable measurement principles. This opinion is intended to protect the investor and others who must use the statements in decision making.

MEASUREMENT PRINCIPLES

In preparing financial statements, the accountant has many different measurement systems to choose from. Assets might, for example, be measured at what they cost in the past or what they could be sold for now, to mention only two possibilities. The choice must be based upon concepts of income and capital that are relevant to the purposes of measurement outlined above.

The concept of value. The economic value of an asset is the maximum amount that the firm would be willing to pay for it. This amount depends on what the firm expects to be able to do with it. For business assets, these expectations are usually expressed in terms of forecasts of the future inflows of cash that the company would receive if it owned the assets in the future. If, for example, the company believes that by spending $1 on advertising and other forms of sales promotion it can sell a certain product for $5, then this product is worth $4 to this firm.

When the cash inflows to be produced by an asset are expected to be delayed, value is less than the anticipated cash flow. For example, if the firm has to pay interest at the rate of 10 percent a year, an investment of $100 in a one-year asset today will not be worthwhile unless it will return at least $110 a year from now ($100 plus 10 percent interest for one year). In this example, $100 is the present value of the right to receive $110 one year later. Present value is the maximum amount the firm would be willing to pay for a future inflow of cash after deducting interest on the investment at a specified rate for the length of time the firm has to wait before it receives its cash.

Value, in other words, depends on three factors: (1) the amount of the anticipated future cash flows, (2) their timing, and (3) the interest rate. The lower the expectation, the more distant the timing, or the higher the interest rate, the less valuable the asset will be.

Value may also be represented by the amount the firm could obtain by selling its assets. This sale price is seldom a good measure of the assets' value to the firm, however, because few firms are likely to keep many assets that are worth no more to the firm than their market value. Continued ownership of an asset implies that its present value to the owner exceeds its market value, which is its apparent value to outsiders.

Cost and depreciation

Asset cost. Accountants are traditionally reluctant to accept value as the basis of asset measurement in the going concern. Although monetary assets such as cash or accounts receivable are usually measured by their value, all other assets are measured at cost. The reason for this difference is that the accountant finds it difficult to verify the forecasts upon which a generalized value measurement system would have to be based.

Even so, the cost of a nonmonetary asset is not always easily measurable. If for example, a company has built a special-purpose machine in one of its own factories for use in manufacturing other products, and the project required logistical support from all parts of the factory organization, from purchasing to quality control, then a good deal of judgment must be reflected in any estimate of how much of the costs of these logistical activities should be "capitalized" (*i.e.*, placed on the balance sheet) as part of the cost of the machine.

Some assets give up their services gradually rather than all at once. Such assets are reported on the balance sheet at their original cost, less an allowance for depreciation. The allowance for depreciation represents the cost of the portion of the asset's anticipated lifetime services that has already been used up. To measure this, the accountant must try to predict both how long the asset will continue to provide useful services and how much of its potential to provide these services will be used up in any one period.

Estimates of useful life are generally based on past experience with other assets of the same general type. This evidence is seldom wholly conclusive, but a far greater degree of uncertainty ordinarily attaches to the estimates of how much of the asset's services will be consumed each year. The depreciation charge is usually computed by some simple formula. The two most popular formulas in the United States are straight-line depreciation, in which the same amount of depreciation is recognized each year, and declining-charge depreciation, in which more depreciation is recognized during the early years of life than during the later years, on the assumption that the value of the asset's service declines as it gets older.

The role of the independent accountant is to see whether the company's estimates are based on formulas that seem reasonable in the light of whatever evidence is available and that these formulas are applied consistently from year to year. Again, what is "reasonable" is clearly a matter of judgment.

Income. One possible method of income measurement would be to measure the value of the firm's assets from time to time and measure income as the difference between successive measurements of value, adjusted for additions or withdrawals of investment capital during the period. Thus if value has gone from $1,000 to $1,200 and dividends of $100 have been distributed, income would be $300 ($1,200 minus $1,000, plus $100).

Accountants generally have rejected this approach for the same reason that they have found value an unacceptable basis for asset measurement: such a measure would rely too much on estimates of what will happen in the future, estimates that would not be readily susceptible to independent verification. Instead, the accountant has adopted what might be called a transactions approach to income measurement. He recognizes as income only those increases in wealth that can be substantiated from data pertaining to actual transactions that have taken place with persons outside the firm. In such systems, income is measured when work is performed for an outside customer, when goods are delivered, or when the customer is billed.

Recognition of income at this time requires two sets of estimates: (1) revenue estimates, representing the value of the cash that the company expects to receive from the

customer; and (2) expense estimates, representing the resources that have been consumed in the creation of the revenues. Revenue estimation is the easier of the two, but it still requires judgment. The main problem is to estimate the percentage of the gross sale price that will never be received, either because the customer will not pay his bills or because he will demand and receive credit for returned merchandise or defective work.

Expense estimates are generally based on the historical cost of the resources consumed. The net income figure, in other words, is the difference between the value received from the use of resources and the cost of the resources that were consumed in the process. As with asset measurement, the main problem is to estimate what portion of the cost of an asset has been consumed during the period in question.

The inclusion of holding gains

From an economic point of view, income can be defined as the change in the firm's wealth during a period of time, from all sources other than the injection or withdrawal of investment funds. Income is the amount that the firm could consume during the period and still have as much real wealth at the end of the period as it had at the beginning.

In concept, any increase in wealth increases the well-being of the firm and thus fits this definition, whether it comes from the firm's use of its assets or from a holding gain. A holding gain occurs whenever an asset's market value increases. Conversely, a holding loss occurs when the market value declines. For example, construction of a superhighway may increase the value of the company's land. This is a holding gain. Construction of a glue factory in the vicinity, on the other hand, may decrease land values. Such decreases are holding losses.

The accountant ordinarily reports holding gains only when assets are sold. Such gains are said to be realized. Unrealized holding gains are seldom reported to management and are reported even less frequently to the outside public. Holding losses, on the other hand, are ordinarily reported as soon as they can be identified, whether they are realized or not. Thus if land values have fallen below cost, the company will transfer a portion of the cost from the balance sheet to the income statement as a loss.

Accounting measurements of capital and income have been criticized on the grounds that they are not responsive enough to the dynamic influences in the modern economy. In some cases the strength and growth of the firm may depend as much or more on the wealth changes it excludes from reported income as on those it includes. To an oil producer, for instance, finding the oil may be a far more important economic event than bringing it out of the ground, refining it, or selling it. A measure of income that excludes wealth increments from this source is a poorer measure of overall economic performance than a broader measure that encompasses all wealth increases, no matter what their source.

To remedy this condition, proposals have been made to recognize all holding gains and losses, realized and unrealized, and report them in a separate section of the income statement. To accomplish this, all nonmonetary assets would have to be restated periodically, either by independent appraisal or by the application of price index numbers to the historical cost figures.

Price changes. Accounting reports have also been criticized on the grounds that they confuse monetary measures with the underlying realities when the prices of many goods and services have been changing rapidly. For example, if the wholesale price of an item has risen from $100 to $150 between the time the company bought it and the time it is sold, many accountants and businessmen claim that $150 is the better measure of the amount of resources consumed by the sale. The $50 is simply a holding gain that should not be classified as ordinary income.

This proposal to measure expense on the basis of current replacement cost rather than the original cost of the resources consumed is supported by the proponents of recognizing all holding gains as income. The support is not always reciprocated, however. Not all advocates of replacement costing would agree to the recognition of unrealized holding gains as current income, and many would exclude all holding gains that arise from increases in replacement prices.

This latter attitude often reflects a confusion between changes in the replacement prices of specific resources and changes in the average level of all prices. An increase in value that results solely from a rise in the general price level is not a real increase and therefore is not really income. The bridge from this to the belief that all holding gains are unreal and unearned is easy to understand but difficult to defend. Holding gains are real gains to the extent that they exceed the amount that would have resulted if the prices of the company's assets had advanced in proportion to the increase in prices generally.

Units of purchasing power

To adjust for the effects of an inflation in general price levels, many accountants advocate the use of units of constant purchasing power instead of ordinary monetary units. Upon acquisition, an asset would be stated as the equivalent of a given amount of purchasing power. Its replacement cost would then be estimated periodically, again in terms of the number of purchasing power units it represented. The holding gain or loss would then be measured by the change in the amount of purchasing power the asset represented.

If, for example a piece of land is purchased for $10,000 at a time when $10,000 can be used to buy the same basket of goods and services that could have been obtained for $8,000 in some base period, the general price level is $\$10{,}000/\$8{,}000$ or 125 percent of the level prevailing in the base period. The land will then be recorded as having cost 8,000 purchasing power units (designated $*).

If a year later an appraisal indicates that the land could be replaced at a price of $11,700 but the general price level has risen by 5 percentage points to 130 percent of the base level, then the $11,700 price is equivalent to $\$11{,}700/1.3$, or 9,000 purchasing power units. The monetary gain is $1,700 ($11,700 minus $10,000), but the gain in purchasing power units is only $*1,000 ($*9,000 minus $*8,000).

In countries that have experienced severe and prolonged inflation, companies have been allowed or even required to restate their assets to reflect the more recent and higher levels of purchase prices. The increment in the asset balances in such cases has not been reported as income, but depreciation thereafter has been based on these higher figures.

Individual companies in the United States, the Netherlands, and some other countries have made similar adjustments in their financial statements, but the practice has been slow to spread. The main reason for this has been the accountant's reluctance to agree that appraisals and price index numbers are objective, reliable, and verifiable enough to replace the historical cost figures with which he is familiar.

MANAGERIAL ACCOUNTING

Although published financial statements are the most widely visible outputs of business accounting systems and the ones with which the public is most concerned, they are only the tip of the iceberg. Most accounting data and most accounting reports are generated solely or mainly for the company's managers. Reports to management may be either summaries of past events, forecasts of the future, or a combination of the two. Preparation of these reports is the focus of managerial accounting.

The varied work of the managerial accountant can be classified into three broad functions: (1) cost finding, (2) budgetary planning and performance reporting, and (3) cost and profit analysis.

Cost finding. Cost finding is the process by which the company obtains estimates of the costs of producing a product, providing a service, performing a function, or operating a department. Some of these estimates are historical—how much did it cost?—while others are predictive of what it will cost in the future.

The most fully developed methods of cost finding are used to estimate the costs that have been incurred in a

factory to manufacture different products. The simplest of these methods is known as process costing. In this method, the accountant first accumulates the costs of each separate production operation or process for a specified period of time. The total of these costs is then restated as an average by dividing it by the total output of the process during the same period.

Process costing can be used whenever the output of individual processes is reasonably uniform or homogeneous, as in cement manufacturing, flour milling, and other relatively continuous production processes.

Job order costing

A second method, job order costing, is used when individual production centres or departments work on a variety of products rather than just one during a typical time period. Two categories of factory cost are recognized under this method: prime costs and factory overhead costs. Prime costs are those that can be traced directly to a specific batch, or job lot, of products. These are the direct labour and direct materials costs of production. Overhead costs, on the other hand, are those than can be traced only to departmental operations or to the factory as a whole and not to individual job orders. The salary of a departmental foreman is an example of an overhead cost.

Direct materials and direct labour costs are recorded directly on the job order cost sheets, one for each job. Because overhead costs cannot be traced to individual jobs, they are accumulated separately, with one set of overhead accounts for each factory department.

Although not traceable to individual jobs, overhead costs are generally assigned to them by means of burden rates; *i.e.*, the ratio of total overhead cost to total production volume for a given time period. A separate burden rate is usually calculated for each production department, and if the operations of a department are very varied, it is often subdivided into a set of more homogeneous cost centres, each with its own burden rate. Separate burden rates are sometimes even used for individual processing machines within a department if the machines differ widely in such factors as power consumption, maintenance cost, and depreciation.

Because output within a cost centre is not homogeneous, production volume must be measured by something other than the number of units of product, such as the number of machine hours or direct labour hours. Once the burden rate has been determined, a provision for overhead cost can be entered on each job order cost sheet on the basis of the number of direct labour hours or machine hours used on that job. For example, if the burden rate is $3.00 a machine hour and Job No. 7128 used 600 machine hours, then $1,800 would be shown as the overhead cost of this job.

Most burden rates are predetermined—that is, they represent the average planned overhead cost at some production volume. The main reason for this is that actual overhead cost averages depend on the total volume and efficiency of operations and not on any one job alone. The relevance of job order cost information will be impaired if these external fluctuations are allowed to change the amount of overhead cost assigned to a particular job.

The methods of cost finding described in the preceding paragraphs are known as full costing, or absorption costing, methods, in that the burden rates are intended to include provisions for all manufacturing costs. Both process and job order costing methods can also be adapted to

Variable costing

variable costing, or direct costing, in which only variable manufacturing costs are included in product cost. Variable costs are those that will be greater in total in the upper portions of the company's normal range of volumes than in the lower portion of this range. Total fixed costs, in contrast, are the same at all volume levels within the normal range.

Unit cost under variable costing represents the average variable cost of making the product. The main argument for the variable costing approach is that average variable cost is more relevant to most managerial decisions than average full cost. In deciding whether to manufacture goods in small or large lots, for example, management needs to estimate the cost of carrying different amounts of finished goods in inventory. (A large lot size leads to a larger average inventory.) More variable costs will have to be incurred to build up the inventory to a higher level; fixed manufacturing costs presumably will be unaffected.

Furthermore, when a management decision changes the company's fixed costs, the change is unlikely to be proportional to the change in volume; therefore, average fixed cost is seldom a valid basis for estimating the cost effects of such decisions. Variable costing eliminates the temptation to assume without question that average fixed cost can be used to estimate changes in total fixed cost.

Product cost estimates

Estimates of product costs can be built up in exactly the same way as historical averages. Once the route that the product will take through the factory is known, estimates of the amounts of materials, labour, and overhead required at each stage can be written down, totalled, and averaged.

Many systems go even farther than this. Estimates of the average costs of each type of material, each operation, and each product are prepared routinely and identified as standard costs. These standard cost figures are then readily available whenever estimates are needed and also serve as an important element in the company's performance reporting system, as described below.

Distribution cost analysis. Similar methods of cost finding can be used to determine or estimate the cost of providing services rather than physical goods. Most advertising agencies and consulting firms, for example, maintain some form of job cost records, either as a basis for billing their clients or as a means of estimating the profitability of individual job or accounts.

Estimates of the unit cost of distributing the company's products or of providing administrative and supporting services are more difficult to determine, however, and few companies attempt to derive unit costs in this area on a regular basis. Instead, estimates are prepared from time to time on the basis of special studies, mostly centring on observations of how employees spend their time during selected test periods. Providing these estimates is the task of distribution cost analysis.

Budgetary planning and performance reporting. The second major component of internal accounting systems for management's use is the company's budgetary planning and performance reporting system. This consists of two highly interrelated elements: (1) establishing budgetary plans and setting performance standards and (2) measuring actual results and reporting differences between actual performance and the plans.

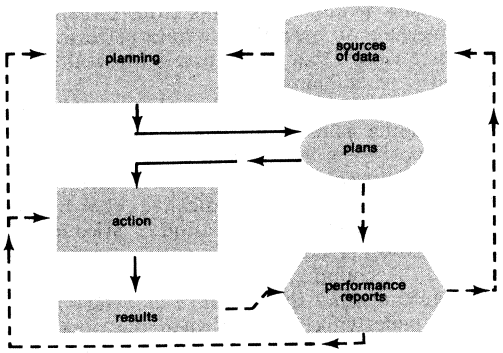

Figure 1: Budget planning and performance reporting.

The simplified diagram in Figure 1 illustrates the interrelationships between these two elements. Planning leads to plans, which then are translated into action. The results of these actions are compared with the plans and reported to management in comparative form. Management can then respond to substantial deviations from plan, either by taking corrective action, or if outside conditions differ from those predicated in the plans, by preparing revised plans.

Although plans can be either broad, strategic outlines of

the company's future, or schedules of the inputs and outputs associated with specific independent programs, most business plans are periodic plans—that is, they refer to company operations for a specified period of time. These periodic plans are summarized in a series of projected financial statements, or budgets.

The profit plan

The two principal budget statements are the profit plan and the cash forecast. The profit plan is an estimated income statement for the budget period. It summarizes the planned level of selling effort, reflected as selling expense, and the results of that effort, shown as sales revenue and the accompanying cost of goods sold. Separate profit plans are ordinarily prepared for each major segment of the company's operations.

The details underlying the profit plan are contained in departmental sales and cost budgets, each part identified with the executive or group responsible for carrying out that part. Figure 2 shows the essence of this relationship. The diagram in Figure 2, for example, shows that the company's profit plan is really the integrated product of the plans of its two major product divisions. The arrows connecting the two divisional plans represent the coordinative communications that tie them together on matters of mutual concern.

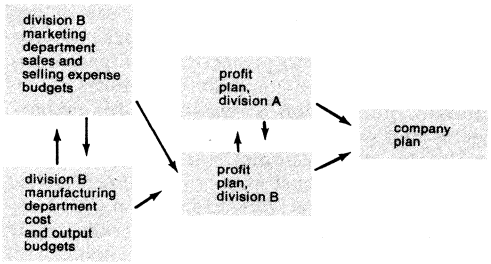

Figure 2: Relationship of company profit plan to responsibility structure.

The exhibit also goes one level farther down, showing that division B's profit plan is really a coordinated synthesis of the plans of the division's marketing and manufacturing departments. Arrows again emphasize the necessary coordination between the two. Each of these departmental plans, in turn, is a summary of the plans of the major offices, plants, or other units within the division. A complete representation of the company's profit plan would require an extension of the diagram to encompass every single responsibility centre in the entire company.

If standard costs have been established, they are shown in the factory cost budgets and in the standard cost of goods sold on the summary profit plans, with anticipated deviations, or variances, from standard cost budgeted separately. Many companies also prepare alternative budgets for operating volumes other than the volume anticipated for the period. A set of such alternative budgets is known as the flexible budget. The practice of flexible budgeting has been adopted widely by factory management to facilitate evaluation of cost performance at different volume levels and has also been extended to other elements of the profit plan.

The cash forecast

The second major component of the annual budgetary plan, the cash forecast or cash budget, summarizes the anticipated effects on cash of all of the firm's activities. It lists the anticipated cash payments, cash receipts, and the amount of cash on hand, month by month throughout the year. In most companies, responsibility for cash management rests mainly in the head office rather than at the divisional level. For this reason, divisional cash forecasts tend to be less important than divisional profit plans.

Company-wide cash forecasts, on the other hand, are just as important as company profit plans. Preliminary cash forecasts are used in deciding how much money will be made available for the payment of dividends, for the purchase or construction of buildings and equipment, and for other programs that do not pay for themselves immediately. The amount of short-term borrowing or short-term investment of temporarily idle funds is then generally geared to the requirements summarized in the final, adjusted forecast.

Other elements of the budgetary plan, in addition to the profit plan and the cash forecast, include capital expenditure budgets, manpower budgets, production budgets, and budgeted balance sheets. They all serve the same purpose: to help management decide upon a course of action and to serve as a point of reference against which to measure subsequent performance.

Planning is a management responsibility, not an accounting function. To plan is to decide, and only the manager has the authority to choose the direction the company is to take. Accounting personnel are nevertheless deeply involved in the planning process. First, they administer the budgetary planning system, establishing deadlines for the completion of each part of the process and seeing that these deadlines are met. Second, they analyze data and help management at various levels compare the estimated effects of different courses of action. Third, they are responsible for collating the tentative plans and proposals coming from the individual departments and divisions and then reviewing them for consistency and feasibility and sometimes for desirability as well. Finally, they must draw up the final plans and see that these plans are understood by the operating executives.

Once the budgetary plan has been adopted, accounting's next task is to prepare information on the results of company activities and make it available to management. The manager's main interest in this information centres on three questions: Have his own actions had the results he expected, and if not, why not? How successful have his subordinates been in managing the activities entrusted to them? What problems and opportunities seem to have arisen since the budgetary plan was prepared? For these purposes, the information must be comparative, relating actual results to the level of results that management regards as satisfactory. In each case, the standard for comparison is provided by the budgetary plan, adopted by the manager himself and accepted by his superiors.

Much of this information is contained in periodic financial reports. At the top management and divisional levels, the most important of these is the comparative income statement, one of which is illustrated in Table 5. This shows the profit planned for this period, the actual results, and the differences between the two. It also gives an explanation of some of the reasons for the difference between planned and actual income.

Table 5: Any Company, Inc.: Comparative Income Statement for the Month of October 19__
(in $000,000)

	actual	planned	difference
Divisional profit contribution			
Division A	$100	$120	$(20)
Division B	70	65	5
Division C	140	150	(10)
Total profit contribution	$310	$335	$(25)
Head office expenses	110	105	(5)
Net income before taxes	$200	$230	$(30)

Comments

(1) An industry-wide strike in customer factories caused a slowdown in division A deliveries, reducing profit by $24,000,000.

(2) Demand continued strong in division B, reflected in increased volume and a stronger price structure.

(3) Division C's unfavourable results were the result of production losses due to the model change and heavy introductory costs for the new line. These losses should be recovered by the end of the year.

(4) Salary increases account for most of the variance in head office expense. The methods department is seeking ways to offset this.

The report in this exhibit employs the widely used profit contribution format, in which divisional results reflect sales and expenses traceable to the individual divisions, with no deduction for head office expenses. Company net income is then obtained by deducting head office expenses as a lump sum from the total of the divisional profit contributions.

Measuring variances

A similar format can be used within the division, reporting the profit contribution of each of the division's product lines, with divisional headquarters expenses deducted at the bottom. By far the greatest number of reports, however, are cost or sales reports, mostly on a departmental basis. Departmental sales reports usually represent comparisons of actual sales with the volumes planned for the period. Departmental cost performance reports, in contrast, typically compare actual costs with standards or budgets that have been adjusted to correspond to the actual volume of work done during the period. This practice reflects a recognition that volume fluctuations generally originate outside the department and that the department head's responsibility is ordinarily to minimize cost while meeting the delivery schedules imposed on him by higher management.

For example, a factory department's output consists entirely of a single product, with a standard materials cost of $3 a unit and standard labour cost of $6. Materials cost represents three pounds of raw materials at $1 a pound; standard labour cost is two hours of labour at $3 an hour. Overhead costs in the department are budgeted at $10,000 a month plus $2 a unit. Under normal conditions, volume is 7,000 units a month, but during October 19___, only 6,000 units were produced. The cost standards for the month would be as follows:

materials
6,000 units × 3 lb per unit × $1.00 per lb = $18,000
labour
6,000 units × 2 hr per unit × $3.00 per hr = $36,000
overhead
6,000 units × $2.00 per unit + $10,000 = $22,000

The actual cost this month was $17,850 for materials (17,000 pounds at $1.05), $38,750 for labour (12,500 hours at $3.10 an hour), and $23,000 for overhead. A summary report would show the following:

	actual	standard	variance
materials	$17,850	$18,000	$150
labour	38,750	36,000	(2,750)
overhead	23,000	22,000	(1,000)
total	$79,600	$76,000	$(3,600)

These variances are usually analyzed further in attempt to identify the underlying causes. The labour variance, for example, can be seen as a result of both high wage rates ($3.10 instead of $3.00) and high labour usage (12,500 hours instead of 12,000). The factory accountant ordinarily would measure the effect of the rate change in the following way:

actual labour cost = 12,500 × $3.10 = (actual hours × actual wage rate)	$38,750
actual labour hours at standard wage rate = 12,500 × $3.00 =	37,500
labour rate variance	$(1,250)

The labour usage variance would then be obtained as follows:

actual labour hours × standard wage rate = 12,500 × $3.00	$37,500
standard labour cost (standard labour hours × standard wage rate) = 6,000 × 2 × $3.00	36,000
labour usage variance	$(1,500)

In most cases, the labour rate variance would not be reported to the department head, because it is not subject to his control.

Cost and profit analysis. The accountant shares with many others the task of analyzing cost and profit data to provide guidance in managerial decision making. Even if the analytical work is done largely by others, he has an interest in analytical methods because the systems he designs must collect data in forms suitable for analysis.

Managerial decisions are based on comparisons of the estimated future results of the alternative courses of action that the decision maker is choosing among. Recorded historical accounting data, in contrast, reflect conditions and experience of the past. Furthermore they are absolute, not comparative, in that they show the effects of one course of action but not whether these were better or worse than those that would have resulted from some other choice.

For decision making, therefore, historical accounting data must be examined, modified, and placed on a comparative basis. Even estimated data, such as budgets and standard costs, must be examined to see whether the estimates are still valid and relevant to managerial comparisons. To a large extent, this job of review and restatement is an accounting responsibility. Accordingly, a major part of the accountant's preparation for his profession is devoted to the study of methods and principles of analysis for managerial decision making.

OTHER PURPOSES OF ACCOUNTING SYSTEMS

Accounting systems are designed mainly to provide information that managers and outsiders can use in decision making. They also serve other purposes: to produce operating documents, to protect the company's assets, and to provide data for company tax returns.

Document preparation

The accounting organization is responsible for preparing documents that contain instructions for a variety of tasks, such as payment of customer bills or preparing employee payrolls. It also must prepare documents that serve what might be called private information purposes, such as the employee's own record of his salary and wages. Many of these documents also serve as sources of data for other accounting purposes, but they would have to be prepared even if no information reports were necessary. Measured by the number of people and the amount of time required, document preparation is one of accounting's biggest jobs.

Accounting systems must provide means of reducing the chance of losses of assets due to carelessness or dishonesty on the part of employees, suppliers, and customers. Asset protection devices are often very simple; for example, many restaurants use numbered meal checks so that waiters will not be able to submit one check to the customer and another, with a lower total, to the cashier. Other devices entail a partial duplication of effort or a division of tasks between two individuals to reduce the opportunity for unobserved thefts.

These are all part of the company's system of internal controls. Another important element in the internal control system is internal auditing. The task of the internal auditor is to see whether prescribed data handling and asset protection procedures are being followed. To accomplish this, he usually observes some of the work as it is being performed and examines a sample of past transactions for accuracy and fidelity to the system. He may insert a set of fictitious data into the system and see whether the resulting output meets a predetermined standard. This last technique is particularly useful in testing the validity of the programs that are used to process data through electronic computers.

Finally, the accounting system must provide data for use in the completion of the company's tax returns. This function is the concern of tax accounting. In some countries financial accounting must obey rules laid down for tax accounting by national tax laws and regulations, but no such requirement is imposed in the United States, and figures prepared for tax purposes often diverge from those submitted to shareholders and others. "Taxable income" is a legal concept rather than an accounting concept. Tax laws include incentives to encourage companies to do certain things and discourage them from doing others. Accordingly, what is "income" or "capital" to a tax agency may be far different from the accountant's measures of these same concepts.

Accra

Accra, capital of Ghana, is in population and area the largest city in the country. Architecturally and otherwise, it piquantly blends modern and traditional West African characteristics.

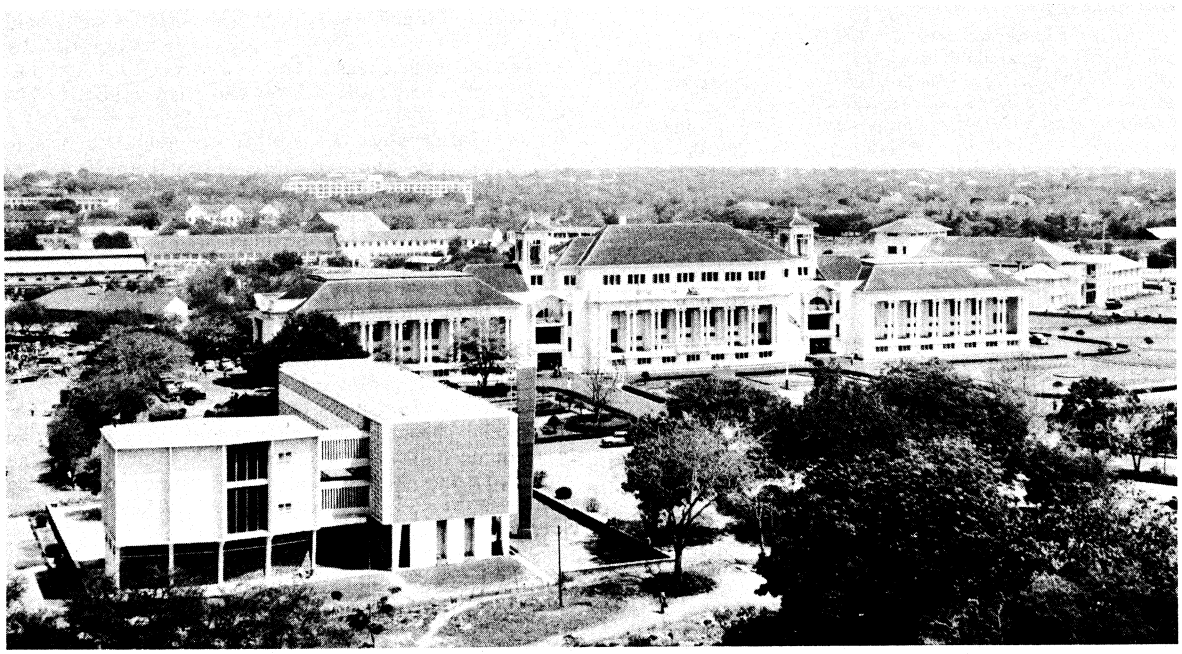
History. When the Portuguese first settled on the coast of what is now Ghana in 1482, the present site of Accra was occupied by several villages of the Ga tribe, ruled from a parent settlement, Ayaso or Ayawaso, located about 15 miles north. Subsequently, between 1650 and 1680 two forts and a castle were built by Europeans on promontories to seaward of the villages. These fortified trading posts were, from west to east, Ft. James (English), Ft. Crevecoeur (Dutch), and Christiansborg Castle (Danish). At about the same time as these European posts were being built, Ayaso was destroyed in a tribal war, and its population, together with that of the other major Ga towns on the Accra plains, was drawn to the coast by the prospect of profitable trade with the Europeans. As a result, three coastal villages—Osu (Christiansborg), Dutch Accra (later known as Ussher Town), and James Town—sprang up, becoming the nuclei of what was to be Accra. The name Accra itself is a corruption of the Akan word *nkran*. It refers to the black ants, which abound in the vicinity. It came to be applied to the inhabitants of this part of the Accra plains.

Two major factors accounted for the subsequent growth of Accra—firstly trade and secondly the transfer in 1877 of the capital of the British Gold Coast colony from Cape Coast to the village of Osu (Christiansborg). (The Danes and the Dutch had left in 1850 and 1872, respectively.) Accra was made the capital for three reasons. It was considered to be healthier, being close to the sanatorium at Aburi in the nearby Akwapim Mountains; it was a prosperous trading centre, and the surroundings were judged to be aesthetically pleasing. At this time James Town and Ussher Town formed a compact mass of buildings separated by narrow twisting lanes. Osu was another huddle of buildings, separated from the James Town–Ussher Town complex by a stretch of open country. It was also independent politically, with its own chief.

Population growth

In 1898 the Accra Municipal Council was formed to improve the town but could achieve little at first. The insanitary conditions that prevailed led to an outbreak of bubonic plague in 1907. Later, under the successful Ten Year (1920–30) Development Plan launched by Governor Gordon Guggisberg, Accra was systematically laid out. This and later development was accomplished by rapid population increase—from 60,726 in 1931, to 133,192 in 1948, to 337,828 in 1960, and then to about 634,000 in 1970.

Physical geography. Backed by the Accra Plains, the city's site is low-lying—elevation varies from 10 to 100 feet above sea level—and is flat or gently undulating. Inland the elevation increases gradually, and several hills stand out abruptly from the plain to the north of the town. On one of the hills, Legon, is the University of Ghana. Geologically, the flatness of the land is due to the weathering of underlying rocks followed by the deposition of clays, loose sand, and horizontally laid sandstones by the sea. The rocks have undergone much faulting. Topography and geological history thus pose problems for Accra. In many parts of the city the ground is not firm enough, because of the sands and clays, to provide an adequate natural foundation for buildings. Also, the land, being flat, floods readily, and its susceptibility to faulting is the cause of frequent earthquakes. The most violent recorded so far was in 1939.



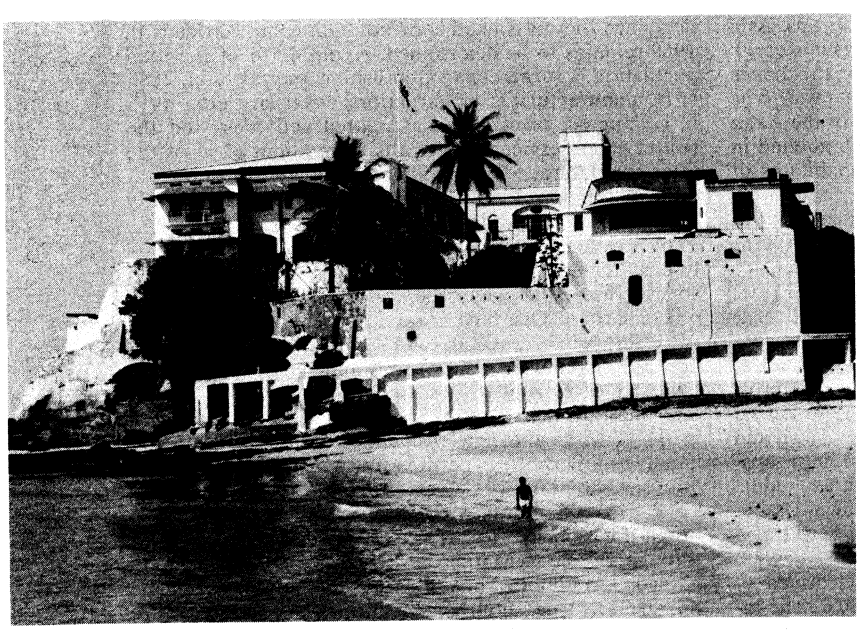
A seasonal river, the Odaw, flows through the city to enter the Korle Lagoon—the largest lagoon in the city—which forms the western boundary of James Town–Ussher Town. Elsewhere smaller seasonal streams enter the sea via lagoons. The most important river, however, is the Densu, close to the western boundary, the source of Accra's water supply. The Densu rises in the high rain forest region of the interior and is perennial.

Accra has a peculiarly low annual rainfall of about 29 inches. Except for this anomaly, the climate is typically equatorial, with monthly noon temperatures deviating little from the annual mean 84.5° F (29.2° C). Daily variations in temperature are slightly greater than the monthly variations. Relative humidities are lower than elsewhere on the coast, as a drier atmosphere attenuates the "stickiness" of the weather. Associated with this dry climate is a grassland vegetation dotted with clumps of bush. There is evidence that the vegetation was formerly more lush.

Accra is roughly 15 miles from west to east along the coast and 8½ miles at its widest north-south extent. Its population is mixed. Before 1969, when a number of African residents from other countries were deported, the local Ga formed roughly 40% and the Akan and Ewe immigrants together 38% of the total population. The rest were non-Ghanaian Nigerians and Togolese forming 40% and 30% respectively of the non-Ghanaian population. The extent of change in the ethnic composition since the mass exodus of non-Ghanaian Africans in 1969 remains to be determined. About 4.5% of the total population is rural, engaged in fishing and farming, 28% is in manufacturing, construction, electricity etc., 44% in commerce, transport, and related activities, and the rest in other services. Christians form about 62% of the total population, Muslims about 15%, and those in traditional religion 12%. The remaining 11% apparently do not profess any religion.

The people and the city. The population lives in clearly demarcated residential areas, where the architectural styles indicate the age of the buildings. For example, the oldest parts of Osu have a mixture of African buildings (single-story, rectangular, and gable roofed, and often grouped around a courtyard), and large two-storied buildings of European style with wide verandas on pillars, and rainwater storage tanks in walled-in courtyards in the rear. In the new residential areas, on the other hand, zoning policy permits only expensive modern houses to be built.

The area of uninterrupted settlement stretches in a broad arc, concave to the sea, from Labadi in the east through Tesano to Mamprobi-Chorkor in the west. Teshi, Nungua, Achimota, and other residential areas outside this arc are true suburbs. All the residential areas are being developed into neighbourhood units with markets, shops, police stations, elementary schools, clinics, cinemas, etc.



Public buildings of Accra. In the left foreground is the library, and in the centre and far right are the Supreme Court and Parliament buildings.
Ewing Galloway

Living conditions

There are marked variations in living conditions in different areas. At one extreme is Nima, the worst slum in Accra and the source of many social problems. Nima is overcrowded, and the population poorly housed, with densities reaching 400 persons an acre. In 1968 a mild outbreak of smallpox in the city originated there. Sabon Zongo, originally a quarter for northern Ghanaians only, is another such slum, with conditions little better than those in Nima. Other poor residential areas are former outlying villages—now suburbs—such as Okponglo and Odorkor, as well as those areas that were the original nuclei of the city. Ussher Town, for example, has population densities approaching those in Nima. At the other extreme are such well-to-do residential areas as the Ridge (built originally for Europeans and now occupied by Ghanaian senior civil servants), the Airport Residential Area, the Cantonments, and Tesano (where most of the houses are privately owned). There are also housing developments, of which some, like Ringway Estate and North Labone Estate, are designed for persons with high incomes, while others, such as Korle Gonno, Mamprobi, and Labadi, are more modest. Population densities in the wealthier areas average up to 10 persons per acre, and in the middle income areas average between 50 to 100 persons per acre.

The central business district, in which most of the multistoried buildings in the city are found, lies between James Town and Osu and has prolongations along Liberty Avenue and Kojo Thompson Road as far as Adabraka. Houses increase in frequency away from the core area. In the district are located the head offices of all of the large banks in the country (Bank of Ghana, Ghana Commercial Bank, Standard Bank of West Africa), the large trading firms (mostly foreign owned), the insurance agencies, the electricity corporation, the general post office, the large open markets to which most of the food supplies come, the Community Centre, the Supreme Court, and the Accra Central Library buildings.

(Left) Camera Press—Publix, (right) Authenticated News International

Half way between Ussher Town and Christiansborg is the administrative district, containing the government ministries and the offices of the Volta River Authority, as well as the City Council, which is directly responsible for the running of the city.

At Labadi, on Brewery Road, Ring Road West, and near the Korle Lagoon are the industrial estates, where vehicle assembly plants, workshops, and garment factories are located. The disposal of industrial waste does not cause serious pollution.

West of the Korle Lagoon from Ussher Town is Korle Bu General Hospital, the largest and best staffed in the country. (The protein deficiency disease, common in the tropics, known as kwashiorkor—a word meaning "golden boy" or "red boy" in the Ga language—was first given its distinctive name at Korle Bu in 1933.) It also houses the Ghana Medical School. Elsewhere, hospitals and polyclinics, both privately and state owned, are dispersed throughout the city. Similarly scattered are the numerous night clubs and hotels (the Ambassador, Continental, and Star hotels are the three largest), elementary and secondary schools, and churches. There are three cathedrals—Holy Spirit (Roman Catholic), Holy Trinity (Anglican), and Methodist. Close to the Holy Spirit Cathedral stand the national archives and the national museum. Also located in the city, and close to the Airport Residential Area, are the offices of the Council for Scientific and Industrial Research and the Ghana Academy of Arts and Sciences.

Recreational areas

Throughout the city are to be found many large open spaces, including undeveloped areas, cemeteries, car and lorry parks, landscape parks, gardens, and football parks. The football stadium and the race course are both close to the government ministries. Also nearby is Black Star Square, in which stands Independence Arch, used for ceremonial parades.

Accra is well paved. Its most important streets radiate inland from the central business district and are connected to one another by Ring Road. In each part of the city the streets form a clear pattern (usually concentric or gridiron). Public transport along them is provided by City Council buses (the bus service was inaugurated in 1927) but buses are so few that greater reliance is placed on privately owned taxis and passenger motor vehicles known locally as "tro-tro" (from "tro," the Ga word for threepence, which was once the fare).

A focus for converging roads, Accra is also connected directly by rail to Kumasi, as well as to the new port city of Tema, 17 miles to the east, which has taken over Accra's port function. Accra is a terminus of the internal air service and has Ghana's only international airport, Kotoka International Airport. Also located in Accra are the Ghana Broadcasting System (Radio Ghana) studios, the headquarters of all radio and television services, and the offices of the principal newspapers.

Acid–Base Reactions and Equilibria

Acids are chemical compounds that show, in water solution, a sharp taste, a corrosive action on metals, and the ability to turn certain blue vegetable dyes red. Bases are chemical compounds that, in solution, are soapy to the touch and turn red vegetable dyes blue. When mixed, acids and bases neutralize one another and produce salts, substances with a salty taste and none of the characteristic properties of either acids or bases.

Early ideas about acids and bases

The idea that some substances are acids, whereas others are bases, is almost as old as chemistry; and the terms acid, base, and salt occur very early in the writings of the medieval alchemists. Acids were probably the first of these to be recognized, apparently because of their sour taste. The English word acid, the French *acide*, the German *Säure*, and the Russian *kislota* are all derived from words meaning sour (Latin *acidus*, German *sauer*, Old Norse *sūur*, and Russian *kisly*). Other properties associated at an early date with acids were their solvent, or corrosive, action; their effect on vegetable dyes; and their effervescence when applied to chalk (production of bubbles of carbon dioxide gas). Bases (or alkalies) were characterized mainly by their ability to neutralize acids and form salts, the latter being typified rather loosely as crystalline substances soluble in water and having a saline taste.

In spite of their imprecise nature, these ideas served to correlate a considerable range of qualitative observations; and many of the commonest chemical materials that early chemists encountered could be classified as acids (hydrochloric, sulfuric, nitric, and carbonic acids), bases (soda, potash, lime, ammonia) or salts (common salt, salammoniac, saltpetre, alum, borax). The absence of any apparent physical basis for the phenomena concerned made it difficult to make quantitative progress in understanding acid–base behaviour, but the ability of a fixed quantity of acid to neutralize a fixed quantity of base was one of the earliest examples of chemical equivalence: the idea that a certain measure of one substance is in some chemical sense equal to a different amount of a second substance. In addition, it was found quite early that one acid could be displaced from a salt with another acid, and this made it possible to arrange acids in an approximate order of strength. It also soon became clear that many of these displacements could take place in either direction according to experimental conditions. This phenomenon suggested that acid–base reactions are reversible—that is, that the products of the reaction can interact to regenerate the starting material. It also introduced the concept of equilibrium to acid–base chemistry—this concept states that reversible chemical reactions reach a point of balance, or equilibrium, at which the starting materials and the products are each regenerated by one of the two reactions as rapidly as they are consumed by the other.

Apart from their theoretical interest, acids and bases play a large part in industrial chemistry and in everyday life. Sulfuric acid and sodium hydroxide are among the products of chemical industry manufactured in largest amount, and a large percentage of chemical processes involve acids or bases as reactants or as catalysts. Almost every biological chemical process is closely bound up with acid–base equilibria in the cell, or in the organism as a whole, and the acidity or alkalinity of the soil and water are of great importance for the plants or animals living in them. Both the ideas and the terminology of acid–base chemistry have permeated daily life, and the term salt is especially common.

THEORETICAL APPROACHES TO THE DEFINITION OF ACIDS AND BASES

Definitions in terms of hydrogen and hydroxide ions. The first attempt at a theoretical interpretation of acid behaviour was made by the French chemist Antoine-Laurent Lavoisier at the end of the 18th century. Lavoisier supposed that all acids must contain oxygen, and this idea was incorporated in the names used for this element in the various languages; the English oxygen, from the Greek *oxys* (sour) and *genna* (production); the German *Sauerstoff*, literally acid material; and the Russian *kislorod*, from *kislota* (acid). Following the discovery that hydrochloric acid contained no oxygen, the English chemist Sir Humphry Davy in about 1815 first recognized that the key element in acids was hydrogen. Not all substances that contain hydrogen, however, are acids, and the first really satisfactory definition of an acid was given by the German chemist Justus von Liebig in 1838. According to Liebig, an acid is a compound containing hydrogen in a form in which it can be replaced by a metal. This definition held the field for about 50 years and is still considered essentially correct, though somewhat outmoded. At the time of Liebig's proposal, bases were still regarded solely as substances that neutralized acids with the production of salts, and nothing was known about the constitutional features of bases that enabled them to do this.

The oxygen theory of acids

Hydrogen and hydroxide ion definitions of acids and bases

The whole subject of acid-base chemistry acquired a new look and a quantitative aspect with the advent of the electrolytic dissociation theory propounded by the German chemist Wilhelm Ostwald and the Swedish chemist Svante August Arrhenius (both Nobel laureates) in the 1880s. The principal feature of this theory is that certain compounds, called electrolytes, dissociate in solution to give ions—atoms bearing positive and negative charges resulting from the transfer of electrons from one atom to another of different kind. With the development of this theory it was realized that acids are merely those hydrogen compounds that give rise to hydrogen ions (H^+) in aqueous solution. It was also realized at that time that there is a correspondence between the degree of acidity of a solution (as shown by effects on vegetable dyes and other properties) and the concentration of hydrogen ions in the solution. Correspondingly, basic (or alkaline) properties could then be associated with the presence of hydroxide ions (OH^-) in aqueous solution, and the neutralization of acids by bases could be expiained in terms of the reaction of these two ions to give the neutral molecule water ($H^+ + OH^- \rightarrow H_2O$.) This led naturally to the following simple definitions: Acids and bases are substances that give rise, respectively, to hydrogen and hydroxide ions in aqueous solution. This definition was generally accepted for the next 30 or 40 years. In purely qualitative terms, it does not offer many advantages over Liebig's definition of acids, but it does provide a satisfactory definition for bases.

Nevertheless, there is a great advantage in the definition of acids and bases in terms of hydrogen and hydroxide ions and this advantage lies in its quantitative aspects. Because the concentrations of hydrogen and hydroxide ions in solution can be measured, notably by determining the electrical conductivity of the solution (its ability to carry an electrical current), a quantitative measure of the acidity or alkalinity of the solution is provided. Moreover, the equations developed to express the relationships between the various components of reversible reactions can be applied to acid and base dissociations to give definite values, called dissociation constants. These constants can be used to characterize the relative strengths (degrees of dissociation) of acids and bases and, for this reason, supersede earlier semiquantitative estimates of acid or base strength. As a result of this approach, a satisfactory quantitative description was given at an early date of a large mass of experimental observations, a description that remains essentially unaffected by later developments in definitions of acid–base reactions.

The success of these quantitative developments, however, unfortunately helped to conceal some ambiguities and logical inconsistencies in the qualitative definitions of acids and bases in terms of the production of hydrogen and hydroxide ions, respectively. For example, it was not clear whether a substance like anhydrous hydrogen chloride, which would not conduct electricity, should be regarded as an acid, or whether it should be considered an acid only after it had come in contact with water. A modified definition of bases also seemed to be required that would be applicable to nonaqueous solutions, in which the anion (negatively charged ion) produced is not the hydroxide ion, as is the case in water, but varies from solvent to solvent, the methoxide ion (CH_3O^-) acting as the basic anion in methanol (CH_3OH), for example, and the amide ion (NH_2^-) playing the same role in liquid ammonia (NH_3). Even with acids the solvent is involved, since there is much evidence to show that the so-called hydrogen ion in solution does not exist as H^+, but always contains at least one molecule of solvent, as H_3O^+ in water, $CH_3OH_2^+$ in methanol, and NH_4^+ in liquid ammonia. These considerations led to the development of definitions of acids and bases that depended on the solvent (see below). In spite of this change, however, the difficulty still remained that typical acid–base properties, such as neutralization, indicator (vegetable-dye) effects, and catalysis, often took place in solvents such as benzene or chloroform in which free ions could barely be detected at all (by conductivity measurements). Even for aqueous solutions a particular ambiguity arises in the definition of bases, some of which (for example, metallic hydroxides) contain a hydroxyl group, whereas others (such as amines) do not. The latter produce hydroxide ions in solution by reacting with water molecules.

The Brønsted–Lowry acid–base definition. In order to resolve the various difficulties in the hydrogen–hydroxide ion definitions of acids and bases, a new, more generalized definition was proposed in 1923 almost simultaneously by the Danish chemist Johannes Nicolaus Brønsted and the English chemist Thomas Martin Lowry. Although the pursuit of exact verbal definitions of qualitative concepts is usually not profitable in physical science, the Brønsted–Lowry definition of acids and bases has had far-reaching consequences in the understanding of a wide range of phenomena and in the stimulation of much experimental work. The definition is as follows: an acid is a species having a tendency to lose a proton, and a base is a species having a tendency to gain a proton. The term proton means the species H^+ (the nucleus of the hydrogen atom) rather than the actual hydrogen ions that occur in various solutions; the definition is thus independent of the solvent. The use of the word species rather than substance or molecule implies that the terms acid and base are not restricted to uncharged molecules, but apply also to positively or negatively charged ions. This extension is one of the important features of the Brønsted–Lowry definition. It can be summarized by the equation $A \rightleftarrows B + H^+$ in which A and B together are a conjugate acid–base pair. In such a pair A must obviously have one more positive charge (or one less negative charge) than B, but there is no other restriction on the sign or magnitude of the charges. Several examples of conjugate acid–base pairs are given in Table 1.

Proton definition of acids and bases

Table 1: Examples of Conjugate Acid-Base Pairs

acid	base
Acetic acid, CH_3CO_2H	acetate ion, $CH_3CO_2^-$
Bisulfate ion, HSO_4^-	sulfate ion, SO_4^{2-}
Ammonium ion, NH_4^+	ammonia, NH_3
Ammonia, NH_3	amide ion, NH_2^-
Water, H_2O	hydroxide ion, OH^-
Hydronium (oxonium) ion, H_3O^+	water, H_2O

A number of points about the Brønsted–Lowry definition should be emphasized:

1. As mentioned above, this definition is independent of the solvent. The ions derived from the solvent (H_3O^+ and OH^- in water, and NH_4^+ and NH_2^- in liquid ammonia) are not accorded any special status, but appear as examples of acids or bases in terms of the general definition. On the other hand, of course, they will be particularly important species for reactions in the solvent to which they relate.

2. In addition to the familar molecular acids, two classes of ionic acids emerge from the new definition. The first comprises anions derived from acids containing more than one acidic hydrogen; *e.g.*, the bisulfate ion (HSO_4^-, as in Table 1) and primary and secondary phosphate ions ($H_2PO_4^-$ and HPO_4^{2-}) derived from phosphoric acid (H_3PO_4). The second and more interesting class consists of positively charged ions (cations), such as the ammonium ion (NH_4^+), which can be derived by the addition of a proton to a molecular base, in this case ammonia (NH_3). The hydronium ion (H_3O^+), which is the hydrogen ion in aqueous solution, also belongs to this class. The charge of these ionic acids, of course, always must be balanced by ions of opposite charges, but these oppositely charged ions usually are irrelevant to the acid–base properties of the system. For example, if sodium bisulfate ($Na^+HSO_4^-$) or ammonium chloride ($NH_4^+Cl^-$) is used as an acid, the sodium ion (Na^+) and the chloride ion (Cl^-) contribute nothing to the acidic properties and could equally well be replaced by other ions, such as potassium (K^+) and perchlorate (ClO_4^-), respectively.

3. Molecules such as ammonia and organic amines are bases by virtue of their tendency to accept a proton. With metallic hydroxides such as sodium hydroxide, on the other hand, the basic properties are due to the hydroxide ion itself, the sodium ion serving merely to preserve electrical

neutrality. Moreover, not only the hydroxide ion, but also the anions of other weak acids (for example the acetate ion) must be classed as bases because of their tendency to reform the acid by accepting a proton. Formally, the anion of any acid might be regarded as a base, but for the anion of a very strong acid (the chloride ion, for example) the tendency to accept a proton is so weak that its basic properties are insignificant and it is inappropriate to describe it as a base. Similarly, all hydrogen compounds could formally be defined as acids, but in many of them (for example, most hydrocarbons, such as methane, CH_4) the tendency to lose a proton is so small that the term acid would not normally be applied to them.

Amphoteric substance

4. Some species, including molecules as well as ions, possess both acidic and basic properties; such materials are said to be amphoteric. As shown in Table 1, both water and ammonia are amphoteric, a situation that can be represented by the schemes H_3O^+–H_2O–OH^- and NH_4^+–NH_3–NH_2^-. Another example is the secondary phosphate ion, HPO_4^{2-}, which can either lose or accept a proton, according to the following equations: $HPO_4^{2-} \rightleftarrows PO_4^{3-} + H^+$ and $HPO_4^{2-} + H^+ \rightleftarrows H_2PO_4^-$. The amphoteric properties of water are particularly important in determining its properties as a solvent for acid–base reactions.

5. The equation $A \rightleftarrows B + H^+$, used in the Brønsted–Lowry definition, does not represent a reaction that can be observed in practice, since the free proton, H^+, can be observed only in gaseous systems at low pressures. In solution, the proton always is attached to some other species, commonly a solvent molecule. Thus in water the ion H_3O^+ consists of a proton bound to a water molecule. For this reason all observable acid–base reactions in solution are combined in pairs, with the result that they are of the form $A_1 + B_2 \rightleftarrows B_1 + A_2$. The fact that the process $A \rightleftarrows B + H^+$ cannot be observed does not imply any serious inadequacy of the definition. A similar situation exists with the definitions of oxidizing and reducing agents, which are defined respectively as species having a tendency to gain or lose electrons, even though one of these reactions never occurs alone and free electrons are never detected in solution (any more than free protons are).

Alternative acid–base definitions. Although the Brønsted–Lowry concept of acids and bases as donors and acceptors of protons is still the most generally accepted one, other definitions are often encountered. Certain of these are adapted for special situations only, but the most important of these other definitions is in some respects more general than the Brønsted–Lowry definition. This definition was first proposed by the U.S. chemist Gilbert N. Lewis in 1923.

The Lewis definition of acids and bases

According to Lewis, an acid is a species that can accept an electron pair from a base with the formation of a chemical bond composed of a shared electron pair (covalent bond). This classification includes as bases the same species covered by the Brønsted–Lowry definition, since a molecule or ion that can accept a proton does so because it has one or more unshared pairs of electrons, and therefore it also can combine with electron acceptors other than the proton. On the other hand, the typical Lewis acids need not (and usually do not) contain protons, being species with outer electron shells that are capable of expansion, such as boron trifluoride (BF_3), sulfur trioxide (SO_3), and silver ion (Ag^+). Lewis originally based his ideas on the experimental fact that these nonprotonic acids often exhibit the properties regarded as typical of acids, such as neutralization of bases, action on indicators, and catalysis. Such substances often are electron acceptors, but this is not always the case; carbon dioxide (CO_2) and nitrogen pentoxide (N_2O_5), for example, contain completed octets of electrons and, according to usual valence theory, cannot accept any more. In addition, hydrogen-containing substances that have always been regarded as acids, acetic acid, for example, are not obviously electron acceptors, being rather adducts of the proton (a true Lewis acid) and a base such as the acetate ion. They can only be brought logically into the Lewis scheme by appealing to the fact that the reaction between a proton acid, which may be designated as XH, and a base, denoted by B, passes through an intermediate hydrogen-bonded state, X-H . . . B (in which the dotted line indicates a hydrogen-bond, a relatively weak secondary attractive force).

Numerous lengthy polemical exchanges have taken place regarding the relative merits of the Brønsted–Lowry and Lewis definitions of acids and bases. The difference is essentially one of nomenclature and has little scientific content. In the remainder of this article the term acid will be used to denote a proton donor (following the Brønsted–Lowry terminology) whereas the term Lewis acid will be employed exclusively to refer to electron-pair acceptors. This choice is based partly upon the logical difficulties mentioned in the last paragraph, and partly on the fact (see below) that the quantitative description of acid–base reactions is much simpler when it is confined to proton acids. This terminology also represents the commonest usage of the terms.

The definition of Lewis acids and bases in terms of the gain or loss of electrons should not be confused with the definition of oxidizing and reducing agents in similar terms. In oxidation–reduction reactions one or more electrons is transferred completely from the reducing agent to the oxidizing agent, whereas in a Lewis acid-base reaction an electron pair on the base is used to form a covalent link with the acid.

Certain other acid–base definitions have been based upon reactions occurring in specific solvent systems. For proton acids in amphoteric solvents these are equivalent to the Brønsted–Lowry definition. It is sometimes convenient to have general terms for the cation and anion derived from the solvent molecule by the addition and removal of a proton, respectively. The terms lyonium and lyate ions are occasionally used in this way. In water, the lyonium and lyate ions are H_3O^+ and OH^-; in ethanol, they are $C_2H_5OH_2^+$ and $C_2H_5O^-$; and in liquid ammonia, NH_4^+ and NH_2^-. For a given solvent, an acid can then be defined as a substance that increases the lyonium ion concentration (and correspondingly decreases the lyate ion concentration), whereas a base increases the lyate ion concentration (and decreases the lyonium ion concentration). This kind of definition, to be sure, really does not add anything to the concept of acids and bases as proton donors and proton acceptors.

Generalized solvent definitions

The idea that an acid is a solute that gives rise to cations characteristic of the solvent, and a base is a solute that gives rise to anions characteristic of the solvent, has sometimes been extended to solvents where no protons are involved at all, for example, liquid sulfur dioxide, SO_2. In this example, the solvent is supposed to ionize according to the equation $2SO_2 \rightleftarrows SO^{2+} + SO_3^{2-}$. Thionyl chloride, regarded as $SO^{2+} + 2Cl^-$, then can be considered an acid, and potassium sulfite, $2K^+ + SO_3^{2-}$, a base. The species SO^{2+} and SO_3^{2-} can certainly be regarded as Lewis acids and bases, but it is doubtful that they exist to any appreciable extent in liquid sulfur dioxide, a situation that makes the discussion somewhat artificial. Although this view of acids and bases has been useful in stimulating work in unusual types of solvent (for example in carbonyl chloride, selenium oxychloride, antimony trichloride, and hydrogen cyanide) it has not met with general acceptance.

ACID–BASE REACTIONS

Proton-transfer reactions. As already mentioned, the reaction expressed by the Brønsted–Lowry definition, $A \rightleftarrows B + H^+$, does not actually occur in any solution processes. This is because H^+, the bare proton, has an enormous tendency to add to almost all chemical species and cannot exist in any detectable concentrations except in a high vacuum. Apart from any specific chemical interaction, the very small size of the proton (about 10^{-15} metres) means that it exerts an extremely powerful electric field, which will polarize and therefore attract any molecule or ion it comes into contact with. It has been estimated that the dissociation of 19 grams of the hydronium ion H_3O^+ to give 1 gram of protons and 18 grams of water would require the expenditure of about 1,200,000 joules (290,000 calories) of energy, and thus it is an extremely unlikely process indeed.

Combined pairs of acid–base reactions

Typical acid–base reactions may be thought of as the combination of two reaction schemes $A_1 \rightleftarrows B_1 + H^+$ and $H^+ + B_2 \rightleftarrows A_2$, leading to the combined form: $A_1 + B_2 \rightleftarrows B_1 + A_2$. This represents a proton-transfer reaction from A_1 to B_2, producing B_1 and A_2. A large number of reactions in solution, often referred to under a variety of names, can be represented in this way. This is illustrated by the following examples, in each of which the species are written in the order A_1, B_2, B_1, A_2.

Dissociation of molecular acids in water. In this instance, water acts as a base. The equation for the dissociation of acetic acid, for example, is as follows: $CH_3CO_2H + H_2O \rightleftarrows CH_3CO_2^- + H_3O^+$.

Dissociation of bases in water. In this case, the water molecule acts as an acid and adds a proton to the base. An example, using ammonia as the base, is $H_2O + NH_3 \rightleftarrows OH^- + NH_4^+$. Older formulations would have written the left-hand side of the equation as ammonium hydroxide, NH_4OH, but it is not now believed that this species exists, except as a weak, hydrogen-bonded complex.

Dissociation of acids and bases in nonaqueous solvents. These situations are entirely analogous to the comparable reactions in water. For example, the dissociation of acetic acid in methanol may be written as $CH_3CO_2H + CH_3OH \rightleftarrows CH_3CO_2^- + CH_3OH_2^+$, and the dissociation of ammonia in the same solvent as $CH_3OH + NH_3 \rightleftarrows CH_3O^- + NH_4^+$.

Self-dissociation of amphoteric solvents. In this case, one solvent molecule acts as an acid, and the other as a base. Self-dissociation of water and liquid ammonia may be given as examples:

$$H_2O + H_2O \rightleftarrows OH^- + H_3O^+$$
$$NH_3 + NH_3 \rightleftarrows NH_2^- + NH_4^+.$$

Neutralization. For a strong acid and a strong base in water, the neutralization reaction is between hydrogen and hydroxide ions; *i.e.*, $H_3O^+ + OH^- \rightleftarrows H_2O$. For a weak acid and a weak base neutralization is more appropriately considered to involve direct proton transfer from the acid to the base. For example, the neutralization of acetic acid by ammonia may be written as $CH_3CO_2H + NH_3 \rightarrow CH_3CO_2^- + NH_4^+$. This equation does not involve the solvent; it therefore also represents the process of neutralization in an inert solvent, such as benzene, or in the complete absence of a solvent. (If one of the reactants is present in large excess, the reaction is more appropriately described as the dissociation of acetic acid in liquid ammonia, or of ammonia in glacial acetic acid.)

Acidic and basic salt solutions

Hydrolysis of salts. Many salts give aqueous solutions with acidic or basic properties. This is termed hydrolysis, and the explanation of hydrolysis reactions in classical acid–base terms was somewhat involved. In terms of the Brønsted–Lowry concept, however, hydrolysis appears to be a natural consequence of the acidic properties of cations derived from weak bases and the basic properties of anions derived from weak acids. For example, hydrolysis of aqueous solutions of ammonium chloride and of sodium acetate is represented by the following equations:

$$(Cl^-) + NH_4^+ + H_2O \rightleftarrows (Cl^-) + NH_3 + H_3O^+$$
$$(Na^+) + H_2O + CH_3CO_2^- \rightleftarrows (Na^+) + OH^- + CH_3CO_2H$$

The sodium and chloride ions take no part in the reaction and could equally well be omitted from the equations.

The acidity of the solution represented by the first equation is due to the presence of the hydronium ion (H_3O^+) and the basicity of the second comes from the hydroxide ion (OH^-). The reverse reactions simply represent, respectively, the neutralization of aqueous ammonia by a strong acid and of aqueous acetic acid by a strong base.

A superficially different type of hydrolysis occurs in aqueous solutions of salts of some metals, especially those giving multiply charged cations. For example, aluminum, ferric, and chromic salts all give aqueous solutions that are acidic. This behaviour also can be interpreted in terms of proton-transfer reactions if it is remembered that the ions involved are strongly hydrated in solution. In a solution of an aluminum salt, for instance, a proton is transferred from one of the water molecules in the hydration shell to a molecule of solvent water. The resulting hydronium ion (H_3O^+) accounts for the acidity of the solution:

$$Al(H_2O)_6^{3+} + H_2O \rightleftarrows Al(H_2O)_5OH^{2+} + H_3O^+.$$

Formation of adducts

Reactions of Lewis acids. In the reaction of a Lewis acid with a base the essential process is the formation of an adduct in which the two species are joined by a covalent bond; proton transfers are not normally involved. If both the Lewis acid and base are uncharged, the resulting bond is termed semipolar or coordinate, as in the reaction of boron trifluoride with ammonia.

$$\underset{\text{acid}}{BF_3} + \underset{\text{base}}{NH_3} \rightarrow \underset{\text{adduct.}}{F_3\bar{B}\text{–}\overset{+}{N}H_3}$$

Frequently, however, either or both species bears a charge (most commonly a positive charge on the acid or a negative charge on the base), and the location of charges within the adduct often depends upon the theoretical interpretation of the valences involved. Examples of such reactions are:

$$\underset{\text{silver ion}}{Ag^+} + \underset{\text{ammonia}}{2NH_3} \rightarrow \underset{\text{adduct}}{[Ag(NH_3)_2]^+}$$
$$\underset{\text{boron trifluoride}}{BF_3} + \underset{\text{hydroxide ion}}{OH^-} \rightarrow \underset{\text{adduct}}{[BF_3(OH)]^-}$$
$$\underset{\text{cadmium ion}}{Cd^{2+}} + \underset{\text{cyanide ion}}{4CN^-} \rightarrow \underset{\text{adduct.}}{[Cd(CN)_4]^{2-}}$$

In another common type of process, one acid, or base, in an adduct is replaced by another:

$$\underset{\text{adduct (1)}}{Cl_4\bar{S}n\text{–}\overset{+}{N}H_3} + \underset{\text{acid (2)}}{BF_3} \rightarrow \underset{\text{adduct (2)}}{F_3\bar{B}\text{–}\overset{+}{N}H_3} + \underset{\text{acid (1)}}{SnCl_4}$$
$$\underset{\text{adduct (1)}}{Al(H_2O)_6^{3+}} + \underset{\text{base (2)}}{6F^-} \rightarrow \underset{\text{adduct (2)}}{AlF_6^{3-}} + \underset{\text{base (1).}}{6H_2O}$$

In fact, reactions such as the simple adduct formations above often are formulated more correctly as replacements. For example, if the reaction of boron trifluoride with ammonia is carried out in ether as a solvent, it becomes a replacement reaction:

$$(C_2H_5)_2\overset{+}{O}\text{–}\bar{B}F_3 + NH_3 \rightarrow F_3\bar{B}\text{–}\overset{+}{N}H_3 + (C_2H_5)_2O.$$

Similarly, the reaction of silver ions with ammonia in aqueous solution is better written as a replacement reaction:

$$Ag(H_2O)_2^+ + 2NH_3 \rightarrow Ag(NH_3)_2^+ + 2H_2O.$$

Furthermore, if most covalent molecules are regarded as adducts of (often hypothetical) Lewis acids and bases, an enormous number of reactions can be formulated in the same way. To take a single example, the reaction of methyl chloride with hydroxide ion to give methanol and chloride ion (usually written as $CH_3Cl + OH^- \rightarrow CH_3OH + Cl^-$) can be reformulated as replacement of a base in a Lewis acid–base adduct, as follows: (adduct of CH_3^+ and Cl^-) + OH^- → (adduct of CH_3^+ and OH^-) + Cl^-. Opinions differ as to the usefulness of this extremely generalized extension of the Lewis acid–base-adduct concept.

Reactions of anhydrous oxides

The reactions of anhydrous oxides (usually solid or molten) to give salts may be regarded as examples of Lewis acid–base-adduct formation. For example, in the reaction of calcium oxide with silica to give calcium silicate, the calcium ions play no essential part in the process, which may be considered therefore to be adduct formation between silica as the acid and oxide ion as the base:

$$\underset{\text{acid}}{SiO_2} + \underset{\text{base}}{O^{2-}} \rightarrow \underset{\text{adduct.}}{SiO_3^{2-}}$$

A great deal of the chemistry of molten-oxide systems can be represented in this way, or in terms of the replacement of one acid by another in an adduct.

Acid–base catalysis. Acids (including Lewis acids) and bases act as powerful catalysts for a great variety of chemical reactions, in the laboratory, in industry, and in processes occurring in nature. Historically, catalytic action was regarded as one of the essential characteristics of acids, and the parallel occurrence of catalytic action and electrical conductivity was one of the compelling pieces of evidence in establishing the theory of electrolytic dissociation as the basis of acid–base behaviour at the end of the 19th century.

Acid–base catalysis was originally thought of in terms of

a mysterious influence of the acid or base, but it is now generally believed to involve an actual acid–base reaction between the catalyst and the reacting substance, termed the substrate, with the catalyst being regenerated at a later stage of the reaction. Moreover, knowledge of reaction mechanisms is now sufficient to suggest detailed sequences of reactions for many acid- or base-catalysis reactions, most of which sequences are at least plausible and in many instances are well established.

Regeneration of the catalyst

In most acid–base reactions the addition or removal of a proton does not bring about any drastic change in the structure of the molecule, or in its stability or reactivity. It is a characteristic of reactions catalyzed by acids or bases, however, that the addition or removal of a proton either makes the substrate unstable, so that it decomposes or rearranges, or that it causes the substrate to become reactive toward some other species present in the system. In cases of rearrangement, the regeneration of the catalyst often involves the removal or addition of a proton at a site other than that at which the initial addition or removal took place. It is not necessary that the substrate in an acid- or base-catalyzed reaction should itself have marked acid–base properties, since even a very small extent of initial acid–base reaction may be enough to bring about the subsequent change.

Instances of acid–base catalysis are numerous indeed; a few examples are given here, as follows:

Isomerization of olefins, acid-catalyzed. Unsaturated compounds frequently rearrange reversibly under the influence of acids to give products in which the double bond occurs in a new location. The interconversion of 2-butene and 1-butene is shown here:

$$CH_3CH=CHCH_3 + H_3O^+ \rightleftarrows CH_3CH_2\overset{+}{C}HCH_3 + H_2O$$
$$CH_3CH_2\overset{+}{C}HCH_3 + H_2O \rightleftarrows CH_3CH_2CH=CH_2 + H_3O^+.$$

Reversible dehydration of alcohols, acid-catalyzed. Under the influence of acids, alcohols generally undergo loss of water to give olefinic products. The dehydration of ethanol to ethylene occurs as follows:

$$CH_3CH_2OH + H_3O^+ \rightleftarrows CH_3CH_2OH_2^+ + H_2O$$
$$CH_3CH_2OH_2^+ \rightleftarrows CH_3CH_2^+ + H_2O \rightleftarrows CH_2=CH_2 + H_3O^+.$$

Keto–enol tautomerism, acid- and base-catalyzed. Acids and bases both bring about the establishment of an equilibrium between ketones (or aldehydes) and their enol forms, which consist of a hydroxyl group directly attached to a doubly bonded carbon atom. (–C(OH)=C–). The interconversion between the two forms is called keto–enol tautomerism. The reaction cannot always be observed directly, since the enol form may not reach measurable concentrations, even at equilibrium, but the highly active enol may be detected by its reaction with various reagents, notably the halogens (bromine, for example). Keto–enol tautomerism of acetone can be brought about by acid or base catalysis, as follows:

$$CH_3\overset{\overset{O}{\|}}{C}CH_3 + H_3O^+ \rightleftarrows CH_3\overset{\overset{+OH}{|}}{C}CH_3 + H_2O \rightleftarrows$$

keto form

$$CH_3C(OH)=CH_2 + H_3O^+$$

enol form

$$CH_3\overset{\overset{O}{\|}}{C}CH_3 + OH^- \rightleftarrows CH_3\overset{\overset{O^-}{|}}{C}=CH_2 + H_2O \rightleftarrows$$

keto form

$$CH_3C(OH)=CH_2 + OH^-$$

enol form

Aldol condensation, base-catalyzed. Self-condensation of aldehydes, the so-called aldol condensation, occurs readily, when catalyzed by bases, to give β-hydroxyaldehydes. The prototype of this reaction is the conversion of acetaldehyde to β-hydroxybutyraldehyde, or aldol. The first step of this reaction is the production of an enolate ion (as in formation of the keto–enol tautomeric mixture), but this anion then reacts with a second molecule of acetaldehyde to give the product as shown below:

$$CH_3CHO + OH^- \rightleftarrows [CH_2CHO]^- + H_2O$$
$$CH_3CHO + [CH_2CHO]^- \rightleftarrows CH_3CH(O^-)CH_2CHO$$
$$CH_3CH(O^-)CH_2CHO + H_2O \rightleftarrows \underset{\text{aldol}}{CH_3CHOHCH_2CHO} + OH^-$$

Importance of acid–base catalysis

These examples illustrate the importance of acid–base catalysis in organic reactions. The equations have been written in terms of H_3O^+ and OH^- as the acid and base catalysts, respectively, and these are certainly the most important catalysts in aqueous solution. For many of these reactions (especially isomerization of olefins and dehydration of alcohols), there is ample evidence that other acids or bases also can act as catalysts. This behaviour is known as general acid–base catalysis. It appears particularly clearly in inert solvents such as benzene, in which catalysis by molecular acids and bases is frequently observed despite the absence of detectable quantities of ions derived from the solvent. Acidic groups, such as sulfonic acid ($-SO_3H$) and carboxylic acid groups ($-CO_2H$), attached to a solid molecular framework (as in some ion exchange resins) also act as heterogeneous catalysts for many chemical reactions.

The above examples show that proton-transfer processes can play a specific part in reaction mechanisms and, in these and similar instances, it is doubtful whether any uncatalyzed or spontaneous reaction of the same type can take place. Apparent evidence to the contrary can usually be explained by catalysis by solvent molecules or by adventitious acidic or basic impurities.

Lewis-acid catalysis

Lewis acids can exert a catalytic effect in two different ways. In the first of these they interact with hydrogen-containing compounds present in the system to assist the release of a proton to the substrate. For example, the polymerization of olefins by Lewis acids, such as boron trifluoride (BF_3), aluminum chloride ($AlCl_3$), and titanium tetrachloride ($TiCl_4$), is believed to be caused by their interaction with proton acids (for example, traces of water) and the olefin to give a carbonium ion, which then reacts further with more olefin:

$$BF_3 + H_2O + CHR=CHR' \rightarrow CH_2R\text{–}\overset{+}{C}HR' + [BF_3OH]^-$$
$$CH_2R\text{–}\overset{+}{C}HR' + CHR=CHR' \rightarrow CH_2RCHR'CHR\overset{+}{C}HR', \text{ etc.}$$

In the second mode of action, the Lewis acid acts directly on the substrate, and by withdrawing electrons converts it into a reactive form. A typical example is the action of catalysts like aluminum chloride on alkyl halides to produce carbonium ions: $RCl + AlCl_3 \rightarrow R^+ + [AlCl_4]^-$. The carbonium ion can then react further with other substances, for example, aromatic hydrocarbons. The same type of catalysis probably occurs with many solid oxide catalysts (for example, aluminosilicates), although it is often difficult to decide whether the catalytic action of these materials is due to centres with a deficiency of electrons or to acidic hydroxyl groups.

QUANTITATIVE ASPECTS OF ACID–BASE EQUILIBRIA

General considerations. Certain general principles apply to any solvent with both acidic and basic properties, for example, water, alcohols, ammonia, amines, and acetic acid. Denoting the solvent molecule by SH, it can give rise to the ions SH_2^+ and S^-, sometimes called lyonium and lyate ions, respectively (see above). In the pure solvent these are the only ions present, and they must be present in equal concentrations to preserve electrical neutrality. The equilibrium involved, therefore, is as follows: $2SH \rightleftarrows SH_2^+ + S^-$. The equilibrium constant (K_s') for this reaction (the mathematical quantity that expresses the relationships between the concentrations of the various species present at equilibrium) would normally be given by the equation $K_s' = [SH_2^+][S^-]/[SH]^2$, in which the square brackets denote the concentrations of the species within the brackets. In a given solvent, however, the concentration of the

Equilibrium constants

solvent, [SH], is a large and constant quantity, and it is therefore usual to eliminate this term and express the self-dissociation of the solvent by the equation $K_s = [SH_2^+][S^-]$. In this equation, K_s is termed the ion product or the auto-protolysis constant of the solvent. The concentrations are usually expressed in moles per litre, a mole being the molecular weight of the compound in grams. Since a solvent that is a good proton donor is normally a poor proton acceptor, and vice versa, the degree of ionization is generally low and K_s is usually a small quantity. It is about 10^{-14} for water at ordinary temperatures, and one of the largest K_s values known is 1.7×10^{-4} for 100 percent sulfuric acid. The above equation applies not only to the pure solvent, but also (with the same value of K_s) to any dilute solutions of acids, bases, or salts in the solvent in question. In these solutions $[SH_2^+]$ and $[S^-]$ need not be equal, since the condition of electrical neutrality involves the concentration of other ions as well, and it is obvious from the equation that a high value of $[SH_2^+]$ must imply a low value of $[S^-]$, and vice versa.

If an acid A is added to the solvent SH it will be at least partly converted into the conjugate base B according to the reaction $A + SH \rightleftarrows B + SH_2^+$, which would be characterized formally by an equilibrium constant $[B][SH_2^+]/[A][SH]$. Again, however, it is usual to omit the term for the constant concentration of the solvent, [SH], from this expression, and to define a constant K_a by the equation

$$\frac{[B][SH_2^+]}{[A]} = K_a.$$

Dissociation constants

K_a is known as the dissociation constant of the acid A in the solvent SH. Any acid–base reaction $A_1 + B_2 \rightleftarrows B_1 + A_2$ will proceed from left to right almost completely if A_1 is a much stronger acid than A_2. It is a natural extension of this idea to use the equilibrium constant as a measure of the strength of A_1 relative to A_2. The dissociation constant is thus (apart from the constant factor [SH], which has been omitted) a measure of the acid strength of A relative to that of the lyonium ion SH_2^+.

In some instances reaction goes so completely from left to right that it is not possible to measure the equilibrium constant. A is said then to be a strong acid in the solvent SH; similarly, acids with readily measurable dissociation constants (in practice less than about 0.1) are known as weak acids.

Similar considerations apply to solutions of bases. The reaction involved in this case is $SH + B \rightleftarrows S^- + A$ and the equilibrium constant K_b defined by

$$\frac{[S^-][A]}{[B]} = K_b$$

is termed the dissociation constant of the base B. Apart from the omitted constant factor [SH], K_b represents the basic strength of B relative to that of the lyate ion S^-. Bases are termed strong and weak in the same way that acids are.

The values of K_a and K_b for a conjugate acid–base pair A–B in a given solvent are not independent, since consideration of the dissociation constants of the solvent, acid, and base show that $K_aK_b = [SH_2^+][S^-] = K_s$ in which K_s is the ion product of the solvent. It is therefore unnecessary to specify both K_a and K_b, and it has become common practice to characterize an acid–base pair by K_a only, which may be termed the acidity constant of A–B in the solvent SH. If the value of K_b is required it is readily obtained from K_a and K_s. Since readily accessible values of K_a are always much less than unity, it is often convenient to introduce a quantity pK_a, sometimes called the acidity exponent, and defined by the relation $pK_a = -\log_{10} K_a$. Values of pK_a are generally of a more convenient magnitude.

Acidity exponent

The above expressions for the various equilibrium constants depend only on the concentrations of the species concerned, which are tacitly assumed to exist in solution independently of one another. This is not always the case, and in exact treatments of these equilibria two modifications are frequently necessary. In the first place, some or all of the reacting species are ions and, because of the electrical forces between them, the law expressing their concentrations at equilibrium is not always valid. Corrections may be applied by multiplying the concentrations by certain factors called activity coefficients, the values of which can be calculated theoretically or derived from other measurements. Furthermore, ions of opposite charge may attract one another so strongly that they no longer exist independently, but are partly present as ion pairs, thus altering the forms of the equilibrium equations. For many purposes, however, the simple equations given here are adequate, especially with regard to reactions in aqueous solutions.

Acid–base equilibria in aqueous solutions. Since aqueous solutions are of particular importance in the laboratory and in the physiology of animals and plants, it is appropriate to consider them separately. The ion product of water, $K_w = [H_3O^+][OH^-]$, has the value 1.0×10^{-14} mole^2 litre^{-2} at 25° C, but it is strongly temperature dependent, becoming 1.0×10^{-15} at 0° C and 7×10^{-13} at 100° C. In principle the value of K_w can be determined by measuring the electrical conductance of very pure water, in which $[H_3O^+] = [OH^-] = 10^{-7}$ at 25° C, but in practice it is derived from other measurements, for example, measurements of the degree of hydrolysis of salts.

Ion product of water

For an uncharged acid, such as acetic, the dissociation constant is given by the following expression:

$$\frac{[CH_3CO_2^-][H_3O^+]}{[CH_3CO_2H]} = K_a.$$

For this example (acetic acid) K_a has the value 1.76×10^{-5} at 25° C. It is often convenient to express the dissociation constant in terms of the degree of dissociation of the acid. This quantity, which is represented in equations by the Greek letter alpha, α, is equal to the fraction of the acid that appears in dissociated form—in this case as the ions $CH_3CO_2^-$ and H_3O^+. If the initial concentration of acid is designated by c, then the concentrations of the ions are each equal to αc, that is $[H_3O^+] = [CH_3CO_2^-] = \alpha c$, and the concentration of undissociated acid is equal to $c(1 - \alpha)$, or $[CH_3CO_2H] = c(1 - \alpha)$.

Substituting these expressions into the equation giving the value of the dissociation constant gives the following result: $\frac{\alpha^2 c}{1 - \alpha} = K_a$. From this equation it can be inferred that the degree of dissociation (α) increases with decreasing concentration (c). For small degrees of dissociation ($\alpha << 1$) the equation becomes $\alpha = \frac{K_a^{\frac{1}{2}}}{c^{\frac{1}{2}}}$ whereas at sufficiently low concentrations ($c << 1$) α tends to unity ($\alpha \rightarrow 1$).

Discussions exactly analogous to this apply to a number of other acid–base equilibria, for example, (1) the dissociation of ammonia in water, (2) the hydrolysis of ammonium salts, and (3) the hydrolysis of an acetate.

(1) $H_2O + NH_3 \rightleftarrows OH^- + NH_4^+$
(2) $NH_4^+ + H_2O \rightleftarrows NH_3 + H_3O^+$
(3) $H_2O + CH_3CO_2^- \rightleftarrows OH^- + CH_3CO_2H$

For reaction (1) α is the degree of dissociation of ammonia, and the dissociation constant is K_b, the basic dissociation constant. In reaction (2), the hydrolysis of an ammonium salt (for example, ammonium chloride), α would be termed the degree of hydrolysis and K the hydrolysis constant. In terms of the general definition of acids and bases, however, K could equally be called the acidity constant for the acid–base pair NH_4^+–NH_3, and this is a more rational way of describing the process. Finally, reaction (3) represents the hydrolysis of an acetate (for example, sodium acetate); the resulting equilibrium constant is termed the hydrolysis constant and can be seen to equal K_w/K_a, where K_w is the ion product of water and K_a the acidity constant for the acid–base pair CH_3CO_2H – $CH_3CO_2^-$; *i.e.*, the dissociation constant of acetic acid. The investigation of equilibria such as this is, in fact, one of the methods for determining the value of K_w (see above).

Dissociations in water

The equilibria considered so far arise when one component of an acid–base pair is dissolved in water—if necessary, along with an ion, such as Na^+ or Cl^-, having negligible acid–base properties. The direct consequence of this is that the two new species produced (for example, those on the right-hand sides of the equations [1–3] above) have equal

concentrations (αc), and hence the previously given equation $K = \frac{\alpha^2 c}{1 - \alpha}$ is applicable.

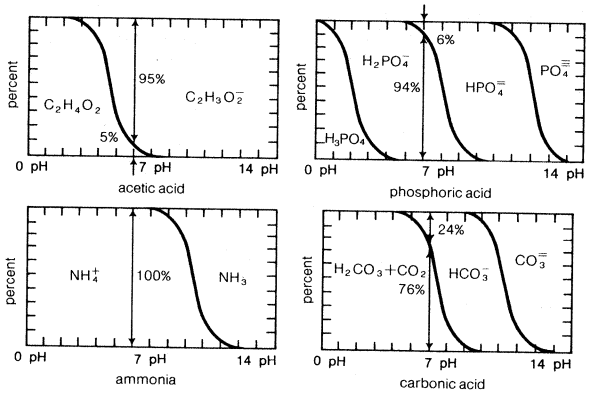
Buffered solutions

A solution of a more generally useful type can be obtained by deliberately varying the proportions of acid and base present; such a solution is called a buffered solution or, somewhat more colloquially, a buffer. A buffered solution containing various concentrations of acetic acid and acetate ion, for example, can be prepared by mixing solutions of acetic acid and sodium acetate, by partially neutralizing a solution of acetic acid with sodium hydroxide, or by adding less than one equivalent of a strong acid to a solution of sodium acetate. Similarly, a buffer based on the pair $NH_4^+ - NH_3$ can be prepared by mixing solutions of ammonia and an ammonium salt, by partially neutralizing a solution of ammonia with a strong acid, or by adding less than one equivalent of sodium hydroxide to a solution of an ammonium salt. The hydrogen ion concentration in a buffer solution is, of course, still given by the usual equation, which is conveniently written as

$$[H_3O^+] = K_a \frac{[A]}{[B]}.$$

Hydrogen-ion concentration and *p*H

Since hydrogen ion concentrations are usually less than unity, and cover an extremely wide range, it is often convenient to use instead the negative logarithm of the actual concentration, a figure that varies usually only in the range 1–13. This figure is termed the *p*H, and its definition is expressed by the equation $pH = -\log_{10}[H_3O^+]$. For example, in pure water $[H_3O^+] = 1 \times 10^{-7}$, with the result that the $pH = 7.0$. The same term can be applied to alkaline solutions; thus in 0.1 molar sodium hydroxide $[OH^-] = 0.1$, $[H_3O^+] = K_w/[OH^-] = 1 \times 10^{-14}/0.1 = 10^{-13}$, $pH = 13.0$.



Applying the concept of *p*H to buffered solutions gives the following equation: $pH = pK_a - \log_{10}\frac{[A]}{[B]}$ in which $\frac{[A]}{[B]}$, known as the buffer ratio, can be calculated from the way in which the solution is prepared. According to this equation, the *p*H of the buffered solution depends only on the pK_a of the acid and on the buffer ratio. Most particularly it does not depend on the actual concentrations of A and B. Therefore, the *p*H of a buffered solution is little affected by dilution of the solution. It is also insensitive to the addition of acid or alkali, provided that the amounts added are much smaller than both [A] and [B]. This so-called buffering action will be impaired if either [A] or [B] becomes too small; hence, buffer ratios must not deviate too far from unity, and the effective buffering range of a given acid–base system is roughly from $pH = pK_a + 1$ to $pH = pK_a - 1$, corresponding to buffer ratios from 0.1 to 10.

Buffer action

The figure shows the relation between *p*H and composition for a number of commonly used buffer systems. Effective buffer action is confined to the central, steep portion of each curve, where the *p*H is least sensitive to the composition. The figure shows that an acid bearing several acidic hydrogens, such as phosphoric acid, can be used to prepare buffer solutions in several different *p*H ranges. Buffer action plays an important part in controlling the *p*H of many biological fluids; for example, the *p*H of the blood is controlled at about 7.4 by the carbonic acid–bicarbonate system shown in the figure. Buffers are widely used to control the *p*H in chemical or biological experiments. For the latter, the system $H_2PO_4^- - HPO_4^{2-}$ is particularly useful, being effective in the physiological *p*H range, 6–8.

The same principles can be applied for the quantitative treatment of systems containing larger numbers of acid–base pairs; for example, in an aqueous solution of ammonium acetate, the following acid–base pairs must be considered: $NH_4^+ - NH_3$, $CH_3CO_2H - CH_3CO_2^-$, $H_3O - H_2O$, and $H_2O - OH^-$. The situation is much more complicated in many solutions that are important in industry or in nature, but it is always possible to make a complete prediction of the state of the system in terms of the acidity constants K_a of each acid–base pair (provided, of course, that reactions other than proton transfers do not interfere).

Acid–base equilibria in non-aqueous solvents. Although acid–base properties have been investigated most thoroughly in aqueous solutions, partly because of their practical importance, water is in many respects an abnormal solvent. In particular, it has a higher dielectric constant (a measure of the ability of the medium to reduce the force between two electric charges) than most other liquids, and it is able itself to act either as an acid or as a base. The behaviour of acids and bases in several other solvents will be described briefly here.

Relation between *p*H and composition for a number of commonly used buffer systems.
From N. J. Bjerrum, *Inorganic Chemistry* (1936); Heinemann Educational Books Ltd.

Effects of solvent on dissociation

The effect of the solvent on the dissociation of acids or bases depends largely upon the basic or acidic properties of the solvent, respectively. Since many acid–base reactions involve an increase or decrease in the number of ions, they are also influenced by the dielectric constant of the solvent, for a higher dielectric constant favours the formation of ions. Finally, the specific solvation (or close association with the solvent) of particular ions (excluding the solvation of the proton to give SH_2^+, which is already included in the basicity of the solvent) may be important. It is usually not easy to separate these three effects and, in particular, the effects of dielectric constant and solvation merge into one another. These points are illustrated with examples of several of the more important solvents. In this discussion the solvents are classified as amphoteric (both acidic and basic), acidic (in which the acidic properties are much more prominent than the basic), basic (in which the reverse is true), and aprotic (in which both acidic and basic properties are almost entirely absent). Finally, concentrated aqueous acids are mentioned as an example, and a particularly important one, of mixed solvents.

Amphoteric solvents. The most important nonaqueous solvents of this class are the lower alcohols methanol and ethanol. They resemble water in their acid–base properties but, because of their lower dielectric constants, facilitate processes producing ions to a much smaller extent. In particular, the ion products of these solvents are much smaller ($K_s = 10^{-17}$ for CH_3OH and 10^{-19} for C_2H_5OH, compared with 10^{-14} for water), and the dissociation constants of molecular acids and bases are uniformly lower than in water by four to five powers of ten. Nitric acid, for example, which is almost completely dissociated in water (K_a about 20), has $K_a = 2.5 \times 10^{-4}$ in methanol. On the other hand, the equilibrium constants of processes such as $NH_4^+ + ROH \rightleftarrows NH_3 + ROH_2^+$ and $CH_3CO_2^- + ROH \rightleftarrows CH_3CO_2H + RO^-$ are similar in all three solvents, since they do not involve any change in the number of ions.

Sulfuric acid as solvent

Acidic solvents. The most important strongly acidic solvent is sulfuric acid, which is able to protonate a wide variety of compounds containing oxygen or nitrogen. Thus, water, alcohols, ethers, ketones, nitro compounds, and sulfones all act as bases in sulfuric acid. This solvent must also possess some basic properties, because its ionic product is high ($[H_3SO_4^+][HSO_4^-] = 1.7 \times 10^{-4}$), but the basicity of the solvent is obscured normally by its very high acidity. For example, carboxylic acids behave as strong bases in sulfuric acid, reacting almost completely according to the equation $RCO_2H + H_2SO_4 \rightarrow RCO_2H_2^+ + HSO_4^-$. Many substances undergo reactions in sulfuric acid that are more complicated than simple proton transfers, often

yielding species important because of their chemical reactivity. Thus, some alcohols produce carbonium ions in sulfuric acid; with triphenylcarbinol, for example, the reaction is $(C_6H_5)_3COH + 2H_2SO_4 \rightarrow (C_6H_5)_3C^+ + H_3O^+ + 2HSO_4^-$. Nitric acid gives the nitronium ion, NO_2^+, according to the equation $(HNO_3 + 2H_2SO_4 \rightarrow NO_2^+ + H_3O^+ + 2HSO_4^-)$. This ion frequently is the active agent in the nitration of organic compounds. Hydrogen fluoride has solvent properties resembling those of sulfuric acid, but is less acidic and has negligible basic properties.

Acetic acid is another acidic solvent that has been extensively studied. Because of its low dielectric constant, ions exist in it largely in the form of ion pairs, and more complex associates are frequently formed. For this reason a quantitative interpretation of acid–base equilibria in acetic acid is often difficult, but some general conclusions can be drawn. In particular, it can be seen that all substances more basic in water solution than aniline react completely with acetic acid according to the equation $B + CH_3CO_2H \rightarrow BH^+ + CH_3CO_2^-$. All such bases therefore give solutions with indistinguishable acid–base properties; this is often referred to as a levelling effect of the solvent. The converse is true for acids; for example, the strong mineral acids, nitric, hydrochloric, sulfuric, hydrobromic, and perchloric (HNO_3, HCl, H_2SO_4, HBr, and $HClO_4$) are "levelled" in aqueous solution by complete conversion to the hydronium ion, but in acetic acid they are differentiated as weak acids with strengths in the approximate ratio 1:9:30:160:400.

Basic solvents. The only basic solvent that has been investigated in any detail is liquid ammonia, which has the very low ion product $[NH_4^+][NH_2^-] = 10^{-33}$. As might be expected, this solvent has a marked levelling effect upon acids; thus, for example, acetic, benzoic, nitric, and hydrochloric acids all give solutions with identical acidic properties, due to the ion NH_4^+—although, of course, in water they behave very differently.

Aprotic solvents. Strictly aprotic solvents include the hydrocarbons and their halogen derivatives, which undergo no reaction with added acids or bases. Acid–base equilibrium in these solvents can be investigated only when a second acid–base system is added; the usual reaction $A_1 + B_2 \rightleftarrows B_1 + A_2$ then takes place. Most such investigations have employed an indicator as one of the reacting systems, but the results are often difficult to interpret because of association of both ions and molecules in these media of low dielectric constant.

The term aprotic has been extended recently to include solvents that are unable to lose a proton, although they may have weakly basic properties. Some of these aprotic solvents have high dielectric constants (for example, N, N-dimethylformamide, dimethyl sulfoxide, and nitrobenzene) and are good solvents for a variety of substances. They have a powerful differentiating effect on the properties of acids and bases. In particular, basic anions are poorly solvated in these solvents, and thus behave as very strong bases; for example, it has been estimated that sodium methoxide dissolved in dimethyl sulfoxide gives a solution 10^9 times as basic as in methanol.

Concentrated aqueous acids. Dilute solutions of strong acids, for example, hydrochloric, sulfuric, and perchloric (HCl, H_2SO_4, $HClO_4$), in water behave essentially as solutions of the ion H_3O^+, and their acidity increases in proportion to their concentration. At concentrations greater than about one molar (that is, containing one mole of acid per litre of solution), however, the acidity, as measured by action on indicators or by catalytic ability, increases much more rapidly than the concentration. For example, a 10 molar solution of any strong acid is about 1,000 times as acidic as a 1 molar solution. This behaviour is undoubtedly largely due to the depletion of water with increasing concentration of acid; the hydronium ion, H_3O^+, is known to have a strong tendency to further hydration, probably mainly to the ion $H_3O^+(H_2O)_3$ (*i.e.*, $H_9O_4^+$), and a decrease in water content increases the proton-donating power of the solution. The acidity of these concentrated solutions is commonly measured by the acidity function, H_o, a quantity measured by the effect of the solvent on a basic indicator I. It is defined by $H_o + pK_{IH^+} - \log_{10}[IH^+]/[I]$ and becomes equal to the *p*H in dilute solution. The acidity function H_o is often found to be independent of the nature of the indicator and to give an approximate measure of the catalytic power of the acid solution. Sulfuric acid–water mixtures ranging from 10 to 100 percent sulfuric acid have H_o values between −0.3 and −11.1, corresponding to an acidity range of nearly 11 powers of ten.

Acidity function

Acid–base equilibria involving Lewis acids. Much less information is available about Lewis acid–base equilibria than about ordinary acid–base equilibria, but it is clear that the situation is less simple for the former than for the latter. When a given Lewis acid reacts with a series of similarly constituted bases the equilibrium constants often vary in parallel with the conventional basic strengths. This is the case when a zinc halide, ZnX_2, for example, reacts with a series of amines. In general, however, it is not possible to arrange Lewis acids and bases in a unique order that will predict the extent to which a given pair will react. Thus, although the hydroxide ion (OH^-) is always a much stronger base than ammonia (NH_3) in reactions with proton acids, in reactions with the Lewis acid Ag^+, the complex $Ag(NH_3)_2^+$ is fairly stable, whereas AgOH is completely dissociated. Similarly, for some metal cations complex formation increases in the order fluoride < chloride <bromide < iodide, whereas for other metal cations the order is the reverse of this.

This kind of behaviour has led to a classification of Lewis acids and bases into "hard" and "soft" categories; as a rule, hard acids react preferentially with hard bases and, similarly, soft acids react with soft bases. The terms hard and soft are chosen to suggest that the atomic structures associated with hard acids and bases are rigid and impenetrable, whereas those associated with soft acids and bases are more readily deformable. Hard acids include: the proton; sodium, calcium, and, aluminum ions; and carbonium ions. The soft acids include: cuprous, silver, mercurous, and the halogen cations. Typical soft bases are iodide, thiocyanate, sulfide, and triphenylphosphine; whereas hard bases include hydroxide, fluoride, and many oxyanions. The dividing line between the hard and soft categories is not a sharp one, and its theoretical interpretation is obscure. Nevertheless, a surprising amount of factual information can be coordinated on the basis of preferential reactions of hard acids with hard bases and soft acids with soft bases.

Hard and soft acids and bases

The effect of molecular structure on acid–base equilibria. Regularities and trends in the properties of the elements are best understood in terms of the periodic table, an orderly pattern seen when the elements are arranged in order of increasing atomic number. Comparing the hydrides of the various elements in the table reveals appreciable acidity only among those of the elements on the right-hand side of the table, especially the halogen elements—fluorine, chlorine, bromine, and iodine. This generalization is borne out when the elements across the first period of the table are examined in order; as the right-hand side of the table is approached the elements encountered are carbon, nitrogen, oxygen, and fluorine. The hydrides of these elements show increasing acidity. Methane, CH_4, a hydride of carbon, has no detectable acidic properties, and the pK_a decreases sharply in the series ammonia (NH_3) 35; water (H_2O), 16; and hydrogen fluoride (HF), 4. In any given group of the periodic table, the acidity of the hydrides increases as the group is descended. For example, the two groups at the right-hand side of the table include, respectively, and in descending order, the elements oxygen, sulfur, selenium, and tellurium; and fluorine, chlorine, bromine, and iodine. The pK_a's of the hydrides of the first group are as follows: water (H_2O), 16; hydrogen sulfide (H_2S), 7; hydrogen selenide (H_2Se), 4; and hydrogen telluride (H_2Te), 3. Similarly, hydrogen fluoride (HF) is a weak acid, whereas hydrogen chloride (HCl), hydrogen bromide (HBr), and hydrogen iodide (HI) are all completely dissociated (are strong acids) in aqueous solution. These trends are due to variations in bond strength, electronegativity (attractive power of the atomic

nucleus for electrons), and ionic solvation energy, of which the first is the most important. When a hydride is able to lose two or more protons, the loss of the second is always more difficult because of the increased negative charge on the base—*e.g.*, $H_2S - HS^-$ (pK 7), $HS^- - S^{2-}$ (pK 15); similarly, $NH_4^+ - NH_3$ (pK 9.5), $NH_3 - NH_2^-$ (pK 35).

A simple rule applies to the strengths of the oxyacids, which can be given the general formula $XO_n(OH)_m$, in which X is any nonmetal. In these compounds, the pK decreases with increasing n, but does not depend significantly upon m. When n = 0 (*e.g.*, ClOH, $Si(OH)_4$), pK_a is between 8 and 11; n = 1 (*e.g.*, HNO_2, H_2SO_3) gives pK_a 2–4; whereas with n = 2 or 3 (*e.g.*, H_2SO_4, $HClO_4$), the acids are completely dissociated in water ($pK_a < 0$). These regularities are probably attributable to the sharing of the negative charge of the anion between n + 1 equivalent oxygen atoms; the more extensive the charge spread, the lower is the energy of the anion and hence the stronger the acid.

Strengths of oxyacids

The most important groups of organic acids are the alcohols (including the phenols) and the carboxylic acids. The simple alcohols are very weak acids (pK 16–19); the phenols are considerably stronger ($pK \sim 10$); and the carboxylic acids stronger still ($pK \sim 5$). The strength of the carboxylic acids is due to the sharing of the negative charge between two equivalent oxygen atoms in the ion RCO_2^-. The most important organic bases are the amines, RNH_2, R_2NH, or R_3N. Most of these are stronger bases than ammonia; *i.e.*, their cations are weaker acids than the ammonium ion.

The effect of substituents on the acid–base properties of organic molecules has been very extensively studied and is one of the main methods of investigating the nature of the electron displacements produced by substitution in these molecules. The simplest classification is into electron-attracting substituents (halogens, carbonyl, nitro, and positively charged groups) and electron-repelling groups (alkyl groups, negatively charged groups). The electron-attracting groups make acids stronger and bases weaker, whereas electron-repelling groups have the opposite effects. There are, however, often more specific electronic effects, especially in aromatic and unsaturated compounds, for which special explanations are needed.

THE EXPERIMENTAL STUDY OF ACID–BASE REACTIONS AND EQUILIBRIA

The determination of dissociation constants in aqueous solution. The classical method for determining the dissociation constant of an acid or a base is to measure the electrical conductivity of solutions of varying concentrations. From these the degree of dissociation (α, see above) can be determined and K_a calculated from the equation

Measurements of electrical conductivity

$$K_a = \frac{\alpha^2 c}{1 - \alpha}.$$

This method is unsuitable for acids with pK less than 2 because α is then close to unity and the value $1 - \alpha$ is therefore subject to error. It also is unsuitable for acids of $pK > 7$, because impurities in the solvent may affect the conductivity or displace the dissociation equilibrium.

It is often preferable to use a more specific method for determining the concentration of one of the species in the scheme $A + H_2O \rightleftarrows B + H_3O^+$. For example, a hydrogen electrode (or more commonly a glass electrode, which responds in the same way) together with a reference electrode, commonly the calomel electrode, serves to measure the actual hydrogen ion concentration, or the pH, of the solution. If E is the electromotive force (in volts) observed by the electrode, the equation giving the pH is as follows:

$$E = E_o + 0.059 \log_{10} [H_3O^+] = E_o - 0.059\ pH.$$

In this equation, the value of E_o depends on the nature of the reference electrode and is usually obtained by calibration with a solution of known pH. Measurements can be made on aqueous solutions of the acid, in which case $[B] = [H_3O^+]$, but it is better to use a series of buffer solutions with known ratios [A]/[B], since these are less sensitive to the presence of impurities. Such a series is obtained by successive additions of alkali to a solution of the acid (or of a strong acid to a solution of the base) and the procedure is then often termed a pH titration.

If A and B have different optical properties—for example, if they differ in colour or in the absorption of ultraviolet light—this property can be used to measure the ratio [A]/[B], commonly by using an instrument called a spectrophotometer. Since $[H_3O^+]$ must also be known, the commonest procedure is to measure [A]/[B] in a solution made by adding a small quantity of A or B to a standard buffer solution. If A and B do not have convenient optical properties—as is commonly the case—an indicator; that is, an acid–base system that does show a difference in colour in changing from A to B, is used. If a small quantity of indicator A_I–B_I, with acidity constant K_I, is added to a buffer solution A–B, it is easily shown that the following relation holds:

$$K_A = K_I \frac{[B]}{[A]} \cdot \frac{[A_I]}{[B_I]},$$

in which $[A_I]/[B_I]$ is measured spectrophotometrically, and all the other quantities on the right hand side of the equation are known.

If accurate values of K are required, it is necessary in all the above methods to take into account the effect of interionic forces upon the equation and the quantities measured. This factor can induce a considerable degree of complexity into the problem.

Selected values of acidity constants. Table 2 contains acidity constants for selected substances. These are listed as acids or bases according to the nature of the uncharged species, but in each case the value given is (pK_a) for the acid form (pK_a and pK_b for a conjugate acid–base pair being related by the equation

$$pK_a + pK_b = pK_w = 14.00$$

for aqueous solutions at 25° C). For instances in which several values of pK_a are given, these relate to successive dissociations; *e.g.*, for phosphoric acid they correspond to dissociations of H_3PO_4, $H_2PO_4^-$, and HPO_4^{2-}. All values given refer to aqueous solutions at or near 25° C; parentheses indicate values that have been estimated indirectly, or are uncertain for other reasons.

Table 2: pK_a's of Representative Acids and Bases

	pK_a		pK_a
Inorganic acids		**Carboxylic acids**	
Boric acid	9.1 (20° C)	Formic	3.75 (20° C)
Hypochlorous acid	7.53 (18° C)	Acetic	4.75
Hydrogen sulfide	7.0, 11.9 (18° C)	Chloroacetic	2.85
Carbonic acid	6.4, 10.3	Dichloroacetic	1.48
Phosphoric acid	2.1, 7.2, 12.8	Trichloroacetic	0.70
Sulfurous acid	1.8, 6.9 (18° C)	Oxalic	1.23, 4.19
Nitric acid	−1.6	Malonic	2.83, 5.69
Sulfuric acid	(−3), 1.9	Benzoic	4.19
Hydrogen chloride	(−7)	**Nitrogen bases**	
Perchloric acid	(−8)	Methylamine	10.66
Inorganic bases		Dimethylamine	10.73
Ammonia	9.25	Trimethylamine	9.81
Hydrazine	−0.9, 8.23 (20° C)	Piperidine	11.12
Hydroxylamine	6.03 (20° C)	Aniline	4.63
Alcohols and phenols		Pyridine	5.25
Methanol	15.5	Quinoline	4.90 (20° C)
Trifluoroethanol	12.37	Pyrrole	−0.27
Phenol	9.89		
o-Nitrophenol	7.17		
m-Nitrophenol	8.28		
p-Nitrophenol	7.15		
o-Chlorophenol	8.49		
m-Chlorophenol	8.85		
p-Chlorophenol	9.18		
Picric acid	0.38

ANDRUSSOW, *Dissociation Constants of Organic Acids in Aqueous Solution* (1961); and D.D. PERRIN, *Dissociation Constants of Organic Bases in Aqueous Solution* (1965).

(R.P.B.)

Acoustical Engineering

Acoustical engineering is the field of engineering concerned with the control of sound and noise in the environment and with the provision of good hearing conditions in buildings. Although there has been concern about noise and hearing from early times, modern pioneering work in the field started about 1900. Since then, a considerable body of knowledge has developed, making it possible to solve a wide variety of acoustical problems in advance of construction.

Acoustics often has been regarded as a science dealing only with hearing conditions in auditoriums, but there are other aspects of the environment in which it plays an important role. Every office building, airport terminal, hospital, and even the private house has sound and noise-control problems. If these problems are not recognized and dealt with during the design of the structure, they must be corrected later.

Acoustical engineering is also concerned with the control of noise from external sources, such as transportation systems. In a building near an airport, heavier construction is usually employed, special precautions must be taken with windows, and the building must be sealed and air-conditioned.

The nature of sound. A sound source produces pressure variations in the air, compressions and rarefactions moving outward from the source in a progressive, spherical wave at a speed of about 1,100 feet (335 metres) per second. In free space, the energy intensity in the wave decreases as the distance from the source increases. For each doubling of distance between source and receiver, the perceived loudness of the sound decreases about one third. Sound waves indoors are reflected many times by the enclosing surfaces, the intensity (except near the source) remaining more or less uniform throughout a room. The sound wave carries energy from the source to the ear or other receiver.

The table shows the enormous range of intensity of sounds to which the ear is exposed. Using a threshold value of one arbitrary unit for a sound so faint that it can just be detected, the loudest sound heard is 1,000,000,000,000 times that volume. A more convenient means of expressing this vast range has been developed by using the unit known as the decibel. The number of decibels between two intensity levels is obtained by taking ten times the logarithm of the ratio of the intensities. Although the tolerable range is great, the absolute energy of sound is small, an average voice having only about $\frac{1}{1,000,000}$ of the energy needed to operate an ordinary electric lamp (see also SOUND).

Intensity of Sound

type of noise	units	decibels
Airplane engine nearby	1,000,000,000,000	120
	100,000,000,000	110
Airplane cabin (normal flight)	10,000,000,000	100
Heavy traffic, pneumatic drill	1,000,000,000	90
	100,000,000	80
Noisy office, telephone conversation, ordinary traffic	10,000,000	70
	1,000,000	60
Average office	100,000	50
Ordinary conversation	10,000	40
Quiet home, quiet conversation	1,000	30
	100	20
Rustle of leaves, whisper	10	10
	1	0

The decibel sound rating

Criteria for sound-control design. The amount of sound energy that reaches the listener depends on the paths by which the sound has travelled, on the distance from the source, the power of the source, and the nature of such intervening barriers as walls, doors, windows, and sound-absorbing ducts. Whether the acoustical engineer's objective is to make it possible to hear more or less, the characteristics of the source, of the path, and of the receiver must be considered.

Qualities that characterize a desirable acoustic environment vary widely, depending on how the space is to be used, how particular the users are, and how the specific space involved relates to other parts of the building. A library reading room, for example, should be free of distraction. This objective can be achieved either by keeping the reading room silent or by providing a moderate, continuous, background sound level of unobtrusive, unrecognizable character, sometimes called white noise. Because the background sound hides or masks the minor noises that are unavoidable, the second approach is considered more realistic. In a large business office, a higher degree of background noise might be acceptable, up to a point at which it interfered with conferences and telephone conversations. In general, people usually tolerate a noise conveying no information better than they do one that tells them something, and an expected noise is usually more tolerable than an unexpected one of the same magnitude.

Tolerable noise levels

The acoustical character of a space is as important as the amount of sound generated in it or transmitted into it. If a room is finished in hard, sound-reflecting materials, sounds in the room not only persist but seem to come from all directions.

There are optimum ranges for the reverberant character of occupied spaces. An aid to the acoustical engineer is the fact that the acoustical character does not need to be uniform throughout a building; on the contrary, variations may provide a pleasant contrast, from a large, reverberant, monumental space to a smaller, quieter, more intimate space in which communication is easy.

CONTROL OF NOISE

Outdoors. The most effective method of noise control outdoors is to separate the source and receiver in space, but because this is not always feasible, some type of barrier is often introduced. Walls and earth banks can be used to control many types of outdoor noise, but the effectiveness of any barrier depends on how well it cuts off the line-of-sight path between source and receiver. A wall to control traffic noise, for example, can be effective at ground level, provided it is near either the source or the receiver, but a low wall constructed in front of a multistory apartment house will do nothing to control noise for those above the level of the wall. Trees and shrubs have little effect.

Indoors. When a sound wave strikes a sizable obstacle such as a wall or ceiling, part of it is reflected, part of it is absorbed, and part of it is transmitted to some adjoining space. The relative magnitudes of these three parts of the original sound are determined by the physical properties of the obstacle. A hard-surfaced, dense plaster reflects a great deal of the sound that strikes it, while a soft surface such as a heavy carpet absorbs most sound and reflects little. Absorption and reflection are important only in connection with the space in which the sound originates. More often the problem is the portion of the sound that is transmitted to an adjoining space. Although the mechanisms governing sound absorption and sound isolation are complex, they must be understood in order to predict the resulting acoustical environment in a finished building.

Sound absorption. Useful sound absorption is provided by porous materials such as carpets, draperies.

glass-fibre blankets, clothing, and the many specially made, sound-absorbing materials. An essential property of a sound-absorbing material is that it have a porous structure into which the molecules in the air carrying sound energy can dissipate, thus losing energy in the form of heat. Sound energy so dissipated is never recovered as sound. Because it is essential that the interstices of sound-absorbing materials be intercommunicating, a closed-cell foam material is not a good sound absorber. Porous sound-absorbing materials may sometimes be faced with hard-surfaced, refinishable perforated panels, wood strips, or the like, but these facings must be so designed that the sound can penetrate into the porous material behind the facings. In general, the solid parts of the facing material should not be larger than two or three inches (five to eight centimetres) and the openings between these elements to the sound-absorbing material should represent 10–25 percent of the area.

Sound-absorbing materials

When sound-absorbing materials are placed within a room, the reflection of energy is greatly reduced and the sound dies away rapidly instead of being reflected many times by the enclosing surfaces. When the sound dies away quickly, the room has what is called a short reverberation time. If surfaces are highly reflective and sound continues to reflect from surface to surface with almost no loss, the room has a long reverberation time. The "feel" or quality of a space as sensed by the occupants is determined largely by the amount and type of sound-absorbing finish.

When a room has a short reverberation time, sounds seem to come from their point of origin rather than from everywhere, surrounding the listener with many reflections. There is actually some reduction in the level of sound from a source in such a "dead" room when contrasted with a hard, reverberant, sound-reflecting "live" room. A nonreverberant space seems more comfortable, and speech communication is easier because the jumble of successive sounds is absent. The proper use of sound-absorbing finishes can improve the quality of almost any space in which a number of people must work, live, or play together. Large open-plan offices and schools work satisfactorily only when both the floor and ceiling are covered with a sound-absorbing finish.

Dead and live rooms

Sound-absorbing ceilings can be very useful for noise control in factories, but the source of the noise must also be considered. Since a sound-absorbing ceiling affects only the noise level in the overall space, it has no effect on the level of sound reaching the ear of a worker near a noisy machine. In areas where noise is less intense, as in restaurants and college dining halls, a sound-absorbing ceiling is more effective. The potential of sound-absorbing materials in private residences has been largely neglected. A sound-absorbing ceiling in a dining room, for example, can reduce the din at a dinner party (whether the room is carpeted or not) to a pleasant level that permits conversation at ordinary voice level. The kitchen, with its customarily hard finishes, can also be a more pleasant space in which to work if it has a sound-absorbing ceiling.

Sound-absorbing materials are used as linings for air ducts to reduce the transmission of sound from room to room and from the fan. Also, mufflers for internal combustion engines incorporate either resonant or dissipative sound-absorbing materials to reduce the noise transmitted with the exhaust gases.

Sound isolation. While sound-absorbing treatments are useful in the control of the character of occupied spaces and in reducing the magnitude of noise in an enclosure, they are useless as noise barriers. A curtain hung in a doorway or over a wall provides no improvement in sound isolation. Acoustic tiles nailed to the underside of floor joints do not improve the isolation between the living room and a downstairs playroom.

The sound isolation provided by a barrier such as a wall, floor, ceiling, or window, is determined almost entirely by its weight or inertia. Since a sound wave consists of the back-and-forth oscillating motion of molecules in the air, these moving particles, when they encounter an obstacle, tend to make the obstacle oscillate slightly. If the obstacle has a great deal of weight or inertia, it resists this attempt at being moved, but if it is relatively lightweight it may move quite easily. When the obstacle is moved by action of the sound wave on one side, it radiates a new sound wave on the other side. This new sound wave is the transmitted sound, the sound heard in the adjoining space. The sound energy is transmitted from one side of the partition to the other by the direct motion of the partition. The heavier the construction, the less sound gets through. A great deal less sound can be heard through an eight-inch brick wall, for example, than through a lightweight plasterboard partition.

Any construction must be completely airtight if it is to be useful as a sound isolator. An opening in a barrier (such as an open door) transmits much more sound energy than an area of wall of equal size. A wall of porous concrete block or construction with loose joints allows sound energy to be transmitted through the leaks and cracks. Doors and windows work at their best as sound barriers only when they are tightly weatherstripped. Probably the most difficult problem in modern building construction is to make airtight connections between the many dry, prefabricated elements that form the enclosure and subdivision of buildings. Every service penetration for piping, every shrinkage crack, and, in fact, any leaks at all seriously limit the ultimate performance of noise-isolating construction.

Since it is often impractical to use extremely heavy construction for walls and partitions in buildings, two separated elements, instead of a single heavy unit, are sometimes employed. Two layers of glass, for example, separated by a space of about six inches (15 centimetres), can be as effective as a heavy masonry wall. A double window of this sort is a good isolator provided it is completely weatherstripped. Ordinary sealed double glass, with an air space of 0.5 inch (1.25 centimetres) or less, is not really a double construction from the acoustical point of view, because the air space is too small to permit independent motion of the two pieces of glass. Double plaster walls, using separate framing for each face, are often used for party walls between apartments. This construction can be very effective, but its acoustical effect is seriously impaired by back-to-back convenience outlets or penetrations for heating pipes or plumbing.

Sound-isolating construction

Background noise. The amount of acoustical privacy between two spaces is related to the background noise level as well as to the sound isolation provided by the construction. Architects have often been surprised to find that a partition type that worked well in a city office building was far from satisfactory in a quieter location. In such cases, a small amount of white noise may be added to the ambient noise level.

Background noise should be bland, unnoticeable, and continuous. Steady traffic noise of the city or the characteristic sounds of many types of air diffusers are the kinds of background noise that people expect in a typical modern building. When there are no partitions, the background noise becomes even more important in determining privacy. A large, elegant, but sparsely filled dining room is often so quiet that patrons must speak in low tones to preserve privacy, while with a moderate level of conversation throughout an ordinary restaurant, good privacy can be had at comfortable voice levels.

Structure-borne noise and vibrations. Sound is also transmitted in a building when the structure sustains a direct impact or when a vibrating object is in rigid contact with it. The structure then radiates sound energy into the air. For this reason a neighbour's doorbell, if fastened directly to a common wall between apartments, can often be heard as loudly in one apartment as the other. The sound of movements from the floor above is a familiar structure-borne sound, as is the noise from a rigidly attached appliance, or from the great variety of mechanical devices that fill modern buildings. As is the case with airborne sound, the heavier the construction the less sound of impact and vibration is transmitted.

Combined with massive construction is the need for resilient isolation. The noise of a footfall overhead is considerably reduced when the floor is covered by heavy

Resilient isolation

carpeting. Footsteps can be made almost inaudible if, during construction, an additional layer of concrete or a wood floor is "floated" on special resilient pads on top of the basic structural floor. A doorbell on a resilient mounting is inaudible in a neighbour's apartment. A garbage grinder, attached to the sink through a rubber collar, is relatively quiet. Water pipes and drains, isolated from walls and floors with resilient materials, perform their functions with little noise. Fans and compressors, mounted so that they are free to vibrate on springs or rubber mountings, create little noise, although in the absence of such mountings, the whole structure acts as a sounding board for these devices.

Not only must moving equipment be properly mounted, but it must also be connected to necessary electrical and plumbing services through flexible connectors. Any rigid ties to the structure of the building nullify the value of resilient mountings.

CRITERIA FOR GOOD HEARING CONDITIONS

Good hearing conditions for an audience listening to speech or music, whether in an auditorium, courtroom, church, outdoor theatre, or living room, depend on four basic conditions. The space must be quiet, the sounds to be heard must have adequate loudness, there must be a good distribution of sound, and the sounds must be properly blended, with adequate separation for good articulation of music or speech.

Absence of noise. Perhaps the single most important factor in providing good hearing conditions is the absence of any interfering noise. Background noise that can be useful in providing privacy and freedom from distraction in the office or apartment has no place in the room in which there is serious listening to speech or music. Not only must the air-handling system be inaudible, but there must be no noise transmitted from other spaces in the building or from outside.

Adequate loudness and distribution. Obviously, the sounds to be heard should be loud enough and should be uniformly distributed. People sitting in the front of a room should not be subjected to greater volumes of sound than those in the rear. Hot spots, where the sound is too loud, and dead spots, where the sound is too faint, can be as unsatisfactory as seats in which everything is heard twice due to delayed echoes. Adequate loudness and good distribution of sound are determined largely by the shape and surface finish of the room.

Figure 1A illustrates how sound is distributed when an audience is seated on level ground outdoors. In a free field, a sound wave decreases in intensity by a factor equal to the square of the distance from the source. As the sound wave grazes the heads and clothing of the sound-absorptive audience, however, there are additional losses. People seated far back in such an audience receive less sound energy not only because they are far away from the sound source but because some of it is absorbed by the people in front of them. In such a seating area, loudness and distribution requirements are poorly met.

The ancient Greeks and Romans solved the problem by placing audiences on steep hillsides, which resulted not only in much better sight lines but in significantly smaller losses by absorption of the intervening audience (Figure 1B). Good sight lines almost always mean good hearing lines. An alternative to the steep hillside is to raise the source of sound high above the audience, but this is not usually convenient. A more satisfactory indoor arrangement is to let the ceiling of the room act as a sound mirror, bringing reflected sound down on top of the audience to reinforce the direct sound (Figure 2). In

Sound mirror

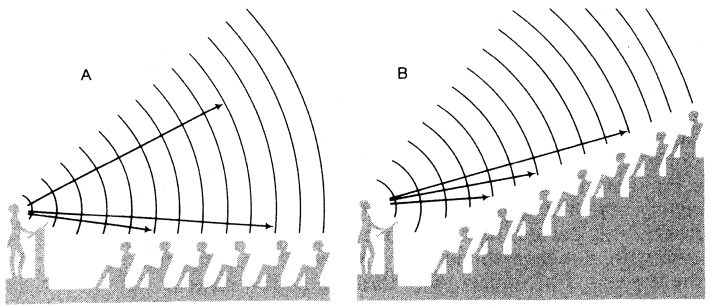

Figure 1: (A) Distribution of sound when audience is seated on ground level outdoors. (B) Distribution of sound in an outdoor theatre of the classical Greek design.

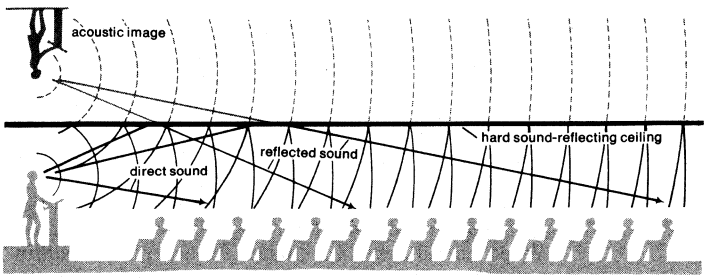

Figure 2: Distribution of sound in a well-constructed auditorium.

many auditoriums more sound energy is received from the ceiling and other reflectors in the room than directly from the source of sound itself. The ceiling is the most important surface in the room in assuring adequate loudness and good sound distribution. A ceiling in any room that must have good hearing conditions for an audience must always be hard and sound-reflecting, not sound-absorbing. This principle is often overlooked; in fact many auditoriums and other buildings for audience use have been deliberately but mistakenly equipped with sound-absorbing ceilings. Such use of sound-absorbing material inevitably produces bad hearing conditions because the room has been deprived of its most useful sound reflector. Sound-absorbing material is useful in rear wall surfaces to control echo and reverberation.

An equally important function of the sound-reflective ceiling is the mixing of sounds that emanate from various parts of a large performing group; *e.g.*, a congregation in a church or an orchestra or a chorus on a stage. Whenever people perform together, it is essential that all members of the group hear each other. An orchestra cannot perform satisfactorily in a conventional stagehouse surrounded by velour draperies, because the various instrumentalists cannot hear each other. Some type of overhead reflector must be used.

If a listener is to receive sound energy by reflection from the ceiling, he must be seated directly under the ceiling; seats in a deep underbalcony area are usually the poorest in the house. The undersurface of such a balcony should always slope upward toward the front, with a sufficient opening to permit the rearmost seats a line of sight to part of the ceiling.

The reflections from ceiling and wall surfaces useful to the listener in improving loudness, clarity, and articulation must arrive at the listener's ear not more than about 30 milliseconds (thousandths of a second) after the initial sound reaches him. This means that the sound will have travelled over a path not more than about 30 feet (nine metres) greater than the distance between source and listener. Reflections delayed longer than this tend to detract from clarity and add confusion. If a reflection is delayed longer than about 70 milliseconds, it begins to be audible as a separate sound or echo.

To provide the members of the audience in the front half of the orchestra, or main floor, of an auditorium with these early reflections, the ceiling near the performing area cannot be more than 30 or 35 feet (nine or 11 metres) above the floor. Ceiling heights of 60 or 70 feet (20 metres) subject much of the main-floor audience to poor sound quality and lack of clarity. In the balconies and toward the rear of the main floor, reflections with a small time delay are received, even if the ceiling is rather high.

BLENDING AND SEPARATION: REVERBERATION TIME

Equal in importance to a quiet listening area and uniformly distributed, sufficiently loud sound is the blend-

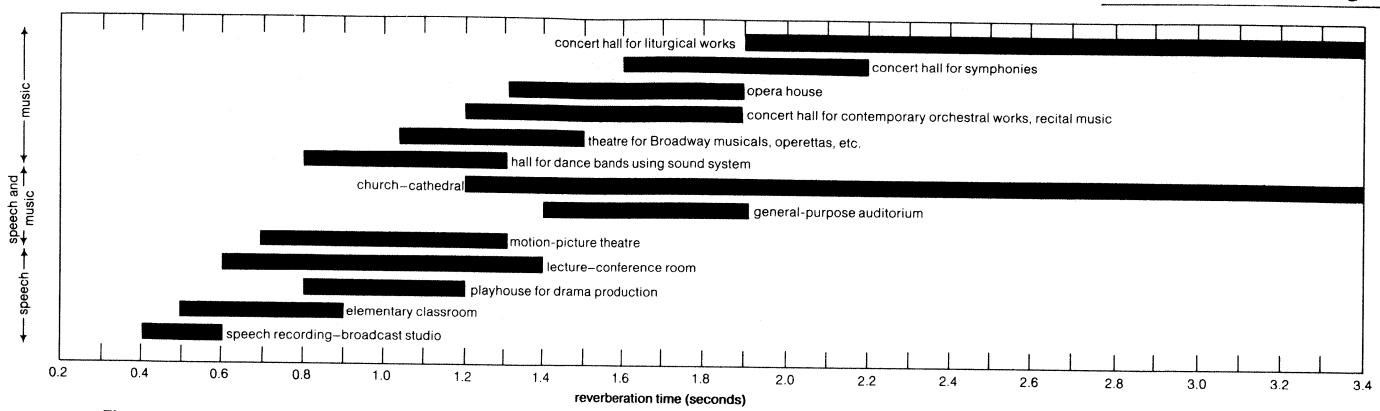

Figure 3: Optimum reverberation time for various types of facilities.

ing of sounds to ensure full quality without excessive muddling. This blending process is called reverberation. The reverberation time in a room is arbitrarily defined as the time required for the sound to decrease to $\frac{1}{1,000,000}$ of its original intensity (or by 60 decibels) after the source is cut off.

Reverberation time is determined by the volume of the room and by the sound-absorbing properties of the finishes, furnishings, and people in the room. The greater the volume, the greater the reverberation time. The greater the area of sound-absorbing finishes, however, the less the reverberation time. In many theatres and auditoriums the audience is the principal absorber of sound. For this reason fabric-upholstered seats that absorb sound in the same way as the audience does are employed to minimize the variation in the reverberation time with a varying audience size. With hard seats, special fabric coverings are sometimes placed over the seats when the theatre is used empty for rehearsals.

In general, a relatively long reverberation time is needed for a sufficient blending of musical sounds but a shorter one is needed for the proper understanding of speech. Over the years, experienced listeners have listened to the sound quality in a large number of auditoriums and have correlated their likes and dislikes with actually measured reverberation time (see Figure 3). Even though a space has a reverberation time lying within the optimum range for a particular function, it does not necessarily follow that it will be an excellent space unless all other conditions for good hearing are satisfied.

Balancing early and reverberant energy

The requirement that reflections of sound reach the ears of the listener not more than about 30 milliseconds after the original signal determines the height of ceiling reflectors. A matter not well understood until recently has been the importance of balancing very carefully the amount of early sound (original signal plus early reflection) with the energy that reaches the ear in the reverberant field (after many reflections around the room). If there is too much early sound, the effect is too articulate and "dry". On the other hand, if there is too much reverberant energy, the effect is fuzzy, or "wet."

The optimum ratio between the early and the reverberant energy varies with the uses of the space. The overhead reflecting surface may take the form of a solid, reflecting canopy, or perhaps the reflecting surface may be made of many panels. The important point is that some early energy be reflected to the ears of the listeners and be balanced with the reverberant sound.

Older halls, noted for good sound quality, often lack such reflecting surfaces. Many have heavily ornamented wall and ceiling surfaces that scatter a great deal of energy back to the listeners, some of it early enough to be useful in improving articulation and clarity.

SOUND AMPLIFICATION

In many situations, adequate loudness and good distribution of sound can only be obtained by reinforcement of the natural transmission from source to listener by means of a sound-amplifying system. In large sports arenas, in airport terminal buildings, and other noisy locations, it is almost always necessary to provide reinforcement. Even in auditoriums where strong-voiced speakers can be heard clearly, the weaker voices must be amplified, and also recorded material or motion picture sound must often be amplified.

Loudspeaker systems

There are two principal types of sound amplification systems: central and distributed. In general, the most realistic amplification is obtained when a directional loudspeaker is placed not more than about 25 feet (eight metres) above the sound source. To the audience, the amplified sound seems to come from the same direction as the original source. Loudspeakers at each side of a platform give much poorer results, with a complete lack of directional realism. High-quality loudspeaker systems, however, are usually quite large, and so are not always easy to place above centre of the stage.

When it is not necessary to associate the amplified sound with the original source, as in an airport terminal, a distributed system of loudspeakers can be used. These must all be operated at a low level so that each listener hears only the loudspeaker near him. This type of system operates much like downlighting. The room is covered with small "pools" of sound. In some auditoriums in which it is impossible to locate a central loudspeaker above the live source of sound, a distributed system of loudspeakers can be used, either in the ceiling if it is low enough, or in the backs of seats. The realism of such a system can be greatly improved if time delay is introduced to allow the amplified sound to reach the listeners slightly later than the original sound.

A line source or column loudspeaker is often used to give greater directionality than can be obtained with a direct-radiator cone speaker. These units must be placed as carefully as any other type of loudspeaker and do not necessarily improve all situations.

Loudspeaker systems are often used unnecessarily. A well-designed hall or theatre seating 300 or 400 people almost never requires one. In auditoriums seating more than 500 a sound-reinforcing system is usually provided, though not always needed, and in larger halls it is frequently desirable to provide some reinforcement of natural sounds. In any case, the sound system must be carefully integrated with the design of the room and with the arrangement of the audience.

Acre

A state (*estado*) of the northern region of the Republic of Brazil, Acre covers the southwesternmost part of Brazil's Hiléia (Hylea), the forest zone of the Amazon River basin. Bounded north by Amazonas state (*estado*), it has western and southern frontiers with Peru and southeastern with Bolivia. With an area of 58,915 square miles (152,589 square kilometres), it had a population of about 220,000 in 1970. The capital is Rio Branco on the Rio Acre in the eastern part of the state. The state's name is derived from that of the Rio Acre, which seems to be of Indian origin. Covered by tropical rainforest, Acre produces the highest quality rubber in Brazil.

History. Portuguese explorers, making their way through the immense Amazon forest from the Atlantic estuary of the Amazon River, did not reach Acre before the middle decades of the 18th century, when there were no settled inhabitants but only roving bands of Indians. Under the Brazilian Empire, more expeditions began to penetrate the territory in the 1850s and 1860s; and although the whole area was ceded by Brazil to Bolivia in 1867 (by the Treaty of Ayacucho), the rubber boom of the following decades attracted more and more immigrants from northeastern Brazil. On July 4, 1899, during a local revolution, an independent Republic of Acre was proclaimed by Luís Gálvez Rodríguez, a Spanish adventurer, but this regime was short-lived. After further vicissitudes, in which a Brazilian immigrant, José Plácido de Castro, played the most active role, negotiations sponsored by Brazil's foreign minister culminated in 1903 in the Treaty of Petropólis, whereby Acre was reincorporated with Brazil. The frontier with Peru was agreed upon in 1909. Organized at first as a territory of Brazil, Acre achieved statehood in June 1962.

The Bolivian interregnum

Physical geography. With an average altitude of 600 feet (183 metres) above sea level, the land slopes gently down toward the Amazonian Plain from the higher ground in the west and in the south. The soils are sediments laid down within the past 65 million years (Cenozoic Era). An average annual temperature of 77° F (25° C) and an annual rainfall of 79–98 inches (2,000–2,500 millimetres) makes the climate warm and humid. The forest is traversed by numerous headstreams of two of the Amazon's major tributaries, the Juruá and the Purus. The principal trees of the forest are *Hevea brasiliensis* and *Bertholletia excelsa*, yielding rubber and Brazil nuts, respectively. The indigenous fauna include peccaries (piglike hoofed animals), red deer, capybaras (a rodent with no tail and partly webbed feet), agoutis (short-haired, short-eared, rabbitlike rodents), and tapirs (a large hoofed quadruped).

Population. The local Indian tribes are few and small, most of Acre's population consisting of immigrants, or descendants of immigrants, from northeastern Brazil. About 80 percent of the people live on the rivers and tracks that give access to the raw materials of the forests; the remainder live in the towns. The largest city, Rio Branco, had a population of 35,000 in 1970; other major towns are Cruzeiro do Sul, Sena Madureira, Tarauacá, and Feijó. The common language is Portuguese, the predominant religion Roman Catholicism. Amoebic dysentery, malaria, and leprosy are the most distressing endemic diseases.

Administration. According to the law of 1962, the system of internal government is determined by a state legislative assembly. There are 16 seats in the assembly occupied by nine state and seven federal representatives; elections are held every four years. There is also a state governor, elected for a five-year term.

Economy. Acre's chief natural resource is rubber, which constitutes 80 percent of the state's exports. The indigenous rubber tree yields the best rubber of all Amazonia, and Acre is Brazil's leading producer of that commodity, its annual output of 10,000 to 15,000 tons amounting to about one-third of the national total. Each tree can yield a yearly average of 4.4 pounds (2 kilograms), the highest yield obtainable from natural forest trees, and a single worker can extract 3,300 pounds (1,500 kilograms) per annum.

Rubber

Brazil nuts are the next most important natural product of the forest. About 4,000 to 8,000 tons are exported every year.

Agriculture, which is only of the subsistence type, is concerned with short-cycle crops, chiefly manioc, corn, and beans. Zebus (humped oxen) are being raised on the open-range system, but this activity is still at an early stage; pigs and chickens are bred quite widely. Though hunting and fishing contribute an important element to the people's diet, the state depends upon imports for most of its consumption. It exports practically all its marketable produce.

Transportation. Development has been held back by the high cost of production and by difficulties of transport. Rivers are the main channels of communication. Rio Branco is connected with Manaus, capital of Amazonas, by the Rio Acre-Purus-Amazon linkage and with Brasília—the federal capital—by a land highway; there are also air services connecting Rio Branco with both places. Belem, in Pará state, and Manaus are Acre's chief external markets.

(J.C.M.C.)

Acting

Whether on the stage, in films, or in television, acting is generally agreed to be a matter less of mimicry, exhibitionism, or imitation than of the ability to react to imaginary stimuli. Its essential elements remain the twin requisites enunciated in the 18th century by French actor François-Joseph Talma: "unusual sensitivity and extraordinary intelligence." The intelligence he refers to comes not from book learning but from the ability to understand the workings of the human personality.

The essential problems in acting—those of whether the actor actually "feels" or merely imitates, of whether he should speak naturally or rhetorically, and of what actually constitutes being natural—are as old as theatre itself. They are concerned not merely with "realistic" acting, which arose in the theatre in the 19th century, but with the nature of the acting process itself.

Such problems acquired increased urgency in recent times, in which an immense investment of time, effort, and money is required for a dramatic production in the commercial theatre, motion pictures, or television; often the viability of such a production depends on the actor's ability to revivify states of high emotion on command, with complete plausibility and without being overwhelmed by other aspects of production. In a film, for example, because of technical problems, the actor sometimes must re-enact a scene a dozen times—each time striving for perfection—and then proceed to an unrelated scene, from some other part of the story, demanding an entirely different attitude from him. In such circumstances the training of an actor is not a luxury but a necessity.

Yet, in an otherwise excellent contemporary handbook of the theatre, the editor apologized for the absence of a section on the actor, which subject, he said, had been assigned to one who, though practically and theoretically conversant with acting, finally acknowledged that he could offer no recipes to the professional nor could he find any logical foundation with which to begin. As early as the middle of the 18th century, the German critic and dramatist Gotthold Ephraim Lessing had already drawn attention to this difficulty. "We have actors but no art of acting." It remains as true today as when stated by George Henry Lewes in his excellent *On Actors and the Art of Acting* (1875):

> I have heard those for whose opinions in other directions my respect is great, utter judgments on this subject which proved that they had not even a suspicion of what the art of acting really is.

Difficulty of definition

Efforts to define the nature of an art or craft usually are based upon the masterpieces of that field. Without that necessary reference point, vague speculations and generalizations—without proof of validity—are likely. In the visual, musical, and literary arts, this foundation exists; the work of the great masters of the past and the present serves not only to elucidate the art but also to create standards to emulate. It is difficult to imagine what the present state of comprehension of music would be if only the music of today were available, and the achievements of Monteverdi, Bach, Beethoven, and Mozart had to be known only by hearsay. Yet, this is precisely the situation that exists in acting. The actor, in the words of the 19th-century American actor Lawrence Barrett, "is forever carving a statue of snow." That is why the understanding of acting has not equalled the appreciation of it and why the actor's creative process has defied comprehension.

Despite these problems, an attempt is made in this article to analyze the art of acting and discuss the techniques that have been found useful in helping actors to develop their art. No attempt is made here to present a "history of acting," because, as has been suggested, there is virtually no record of it apart from the literature on the history of theatre. There is much of interest on acting in other articles on the history of theatre, such as THEATRE, WESTERN and DANCE AND THEATRE, EAST ASIAN. The subject of acting also receives attention in the articles THEATRE, ART OF and DIRECTING, and, in the medium of films, MOTION PICTURES, ART OF.

THEORIES OF TRADITIONS

The actor as creative artist and interpreter

Throughout the history of theatre, continual confusion has been expressed over the question of whether the actor is a creative artist or simply an interpreter. Since the actor's performance is usually based on the play, and the dramatist is conceded to be a creative artist, it is sometimes concluded that the actor must be only an interpretive artist. Some modern exponents of the actor's creativity have indirectly accepted this view and have turned, therefore, to nonverbal theatre. But others deny that this recourse to primitivism is necessary in order to make acting a creative art. When composers like Schubert or Schumann create musical settings for the poems of Heine or Goethe, their music does not lose its essentially creative nature. Verdi used Shakespeare's Othello and Falstaff for his great operas, but his music is no less creative for that. When an artist uses the work of another artist in the same medium, that may properly be called noncreative imitation: the original artist has already solved the basic problems of execution, and his pattern is simply followed by the imitator. Such a work can be considered merely an exercise in skill (or in execution). An artist in one medium who uses an art work of another medium as subject matter, however, must solve all the problems posed by his own medium—a creative achievement. It is therefore quite proper to speak of a character as if he were the actor's creation—of John Gielgud's "Hamlet," for example, or John Barrymore's or Johnston Forbes-Robertson's. Because a medium offers the potential for creativity, of course, not all of its practitioners are necessarily creative: there are imitative artists in every medium. But acting can only be understood after it is first recognized as a creative medium demanding a creative act. In "The Art of Acting" the American drama teacher Brander Matthews remarked,

> The actor needs to have under control not only his gestures and his tones, but all other means of stimulating sensibility and these should be ready for use at all times, wholly independent of the words of the text.

In the same work he quoted with approval the words of the great 19th-century Italian tragedian Ernesto Rossi that a "great actor is independent of the poet, because the supreme essence of feeling does not reside in prose or in verse, but in the accent with which it is delivered." And even Denis Diderot, the French philosopher of the 18th century whose famous *The Paradox of Acting* (written 1773–78; published 1830) is dealt with below and who was himself a dramatist, stated:

> even with the clearest, the most precise, the most forceful of writers, words are no more, and never can be more, than symbols, indicating a thought, a feeling or an idea; symbols which need action, gesture, intonation, and a whole context of circumstances, to give them full significance.

If the art of acting is regarded as merely interpretive, the external elements of the actor's skill tend to be emphasized, but, when acting is recognized as a creative art, it leads inevitably to a search for the deeper resources that stimulate the actor's imagination and sensitivity. This search presents difficult problems. The actor must learn to train and to control the most sensitive material available to any craftsman: the living organism of a human being in all of its manifestations—mental, physical, and emotional. The actor is at once the piano and the pianist.

Acting should not be confused with pantomime, which is a form of external movements and gestures that represents an object or an event but not its symbolic significance. Similarly, the actor is not to be mistaken for an imitator. Many of the best imitators are unable to act in their own person or to create a character that is an extension of themselves rather than an imitation of someone else. Again acting should not be confused with make-believe, which functions only as a form of self-expression. It is not exhibitionism: a faculty for showing off or entertaining at parties is not the same as the talent demanded of the actor—the ability to put oneself into another character, to create a nonexistent event and perform it to its logical fulfillment, to repeat this performance not only when he is in a favourable mood but also at specified times and places, regardless of his own feelings on each occasion—in other words, the ability to create and to respond to imaginary objects and circumstances.

Genuine and feigned emotion. The most famous instance of supposed acting in ancient Greece was that of the actor Polus performing in the *Electra* of Sophocles, at Athens. The plot requires Electra to carry an urn supposed to contain the ashes of Orestes and lament and bewail the fate she believed had overtaken him. Accordingly, Polus, clad in the mourning garb of Electra, took from the tomb the ashes and urn of his own son (who had recently died), embraced them as if they were those of Orestes, and rendered not the appearance or imitation of sorrow but genuine grief and unfeigned lamentation. Rather than acting, this was in fact real grief being expressed.

From antiquity, rival traditions of acting can be discerned—one stressing the externals of voice, speech, and gesture and the other looking to the actual emotional processes of the actor. Aristotle defined acting as "the right management of the voice to express the various emotions," and this primacy of the voice as the actor's outstanding medium has been widely accepted. "Dramatic ability," he said further, "is a natural gift, and can hardly be taught. The principles of good diction can be so taught." Aristotle did not fall into the common mistake of thinking that acting is only good diction; rather, he simply recognized that diction, unlike acting, can be taught; he was well aware of something more than diction in acting but he knew no way of training it. He saw good acting resulting either from a great natural quickness of parts or an enthusiasm allied to madness. "By the first of these, we mold ourselves with facility to the imitation of every form; by the other, transported out of ourselves, we become what we imagine."

If the voice and diction were the essential elements in acting, it would have much in common with oratory, but in actuality the actor is not an orator. The orator speaks in his own character and his intention is to impress and persuade the audience; he may need some of the qualifications of the actor, but many actors are poor orators. The emphasis in oratory is on the skillful use of the voice, and many great actors do not possess impressive vocal instruments. When the great tragedian Edmund Kean appeared for the first time in London in the early 19th century, the critic William Hazlitt, who welcomed him enthusiastically, wished him well and hoped he would soon recover from his cold. He later realized that it was Kean's

natural timbre. Other leading actors, such as Albert Bassermann and Giovanni Grasso, have suffered from asthma and still conveyed a powerful temperament and maintained their vocal expressiveness.

The dichotomy noted in ancient Greece persisted through ancient Roman theatre and into modern times. On the one hand, there was a recognition of the need for the actor to be affected by the sensations he wishes to arouse in others; on the other hand, a need was also seen for a precise system of expression—the peculiar look, tone, and gesture appropriate to every emotion of the mind.

Beginning of modern acting

Modern acting began with the commedia dell'arte. These Italian comedies companies, the earliest mention of which is in 1545, rapidly achieved extraordinary popularity. Until then, acting was an amateur occupation. The actor was limited simply to illustrating the text by means of a narrow scheme of gesture and rhetorical speech. But in the commedia dell'arte the actor used only an outline, a plot; he improvised the play, giving free rein to the actor's art, developing his own characters or masks that he repeated in each play. Each character became an extension of the actor's own personality but elastic enough to respond to innumerable dramatic situations; thus, these actors began to develop the distinctive stage character of the theatre, whereas previously the emphasis had been on the literary aspect of theatre (see also COMMEDIA DELL' ARTE). Since this demanded high skill, the actors joined into companies. The actor became professional. By doing so, he stimulated the development of modern drama. The essential requisite for the drama is its performance. The dramatist's creation finds its fulfillment not in the writer's study but on the stage. This fulfillment can best be achieved through the contribution of the professional actor.

Nonetheless, actors continued to learn by doing. Their schools were professional companies; their classroom, the stage; their teachers, the audience and their fellow players. Schools of dramatic art, isolated from theatres or companies, are a relative innovation and are still unknown in several European countries.

Diderot's "Paradox of Acting." The most significant statement on acting is Diderot's *Paradox of Acting*. Because of its polemic brilliance, it remains the most widely known essay on acting. It has found little acceptance within the profession, though its famous paradox—that in order to move the audience the actor must himself remain unmoved—is still highly regarded.

Regardless of the untenable solutions it proposes, Diderot's essay contains an excellent description of the actor's problem. What bothered Diderot was the unsolved problem of how the actor, if he were full, really full, of feeling, could play the same part twice running with the same spirit and success. Full of fire at the first performance, he would be worn out and cold as marble at the third. Diderot confirmed his view by noting "the unequal acting of players who play from the heart. Their playing is alternately strong and feeble, fiery and cold, dull and sublime." This was the case with the actress who in her day was the outstanding example of emotional acting. "She comes on the stage without knowing what she is going to say; half the time she does not know what she is saying; but she has one sublime moment." Diderot knew that actors do feel and experience; he knew the nature of inspiration. But he also knew that some actors refused to recognize the need for craft, for training.

Diderot asked how the actor, if he is himself while he is playing, is to stop being himself: how he is to catch just the point at which he is to stay his hand? Diderot demanded unity in a performance; he demanded respect for the author's concept, and he understood the difficulty of repeating a performance. He demanded a definite course to the passion—a beginning, a middle, and an end. In Diderot's day, however, the problem of developing a technique for creating inspiration in the actor remained unsolved. The theoretic formulation had already been stated as well as it ever could be by the actor Talma:

> I call sensibility that faculty of exaltation which agitates an actor, takes possession of his senses, shakes even his very soul, and enables him to enter into the worst tragic situations, and the most terrible of the passions as if they were his own. The intelligence which accompanies sensibility judges the impressions which the latter has made us feel: it selects, arranges them, and subjects them to calculation.

The difficulty of solving the problem is illustrated by the work of the 19th-century French teacher François Delsarte, whose influence was widespread not only in France but also in the United States. Delsarte became dissatisfied with routine acting techniques. He observed their mechanical and stultifying character and realized that under the stress of natural instinct or emotion, the body assumes appropriate attitudes and gestures quite different from those described by his teachers. But when he attempted to formulate laws of speech and gesture, on the basis of years of diligent observation and study, he created a series of elaborate pictoral descriptions that were just as mechanical as those he originally criticized. Knowledge of affective behaviour had not advanced far enough to serve as an aid in solving the problem of the actor: there was still too little understanding of human behaviour, of the relation between the conscious and unconscious, and of the role of the senses.

Delsarte's laws of speech and gesture

Stanislavsky's contribution. It is in this context that the enormous contribution in the early 20th century of the great Russian actor and theorist Konstantin Stanislavsky can be appreciated. Stanislavsky was not an aesthetician but was primarily concerned with the problem of developing a workable technique. He applied himself to the very problems that Diderot and others had believed insoluble: the recapture and repetition of moments of spontaneity or inspiration, which could not be controlled and repeated at will even by many of the greatest actors. Stanislavsky dedicated himself to the central problem of how to stimulate the actor's creativity. Even early in his career, while watching performances by great actors, he had felt that all of them had something in common, something he encountered only in greatly talented actors. In his later work, as director of the Moscow Art Theatre, he often experienced those flashes of intuition or inspiration that stimulate the imagination and turn something that one understands with the mind into an emotional reality and experience. Stanislavsky described such a moment occurring at a low point in the rehearsals for Anton Chekhov's drama *Three Sisters*, when "the actors stopped in the middle of the play, ceased to act, seeing no sense in their work." Suddenly something incomprehensible happened: an accidental sound, of someone nervously scratching his fingernails on the bench on which he sat, reminded Stanislavsky of a scratching mouse, setting off an entire sequence of previously unconscious memories that put the work at hand into a new spiritual context.

Later, in examining many parts he had played, especially that of Dr. Stockmann in Henrik Ibsen's *An Enemy of the People*, a role he felt was better suited to him than any other in his repertoire, he became aware of how much his characterizations had been based unconsciously on his memories. With the passing of time, however, the memories and the feelings aroused by them were lost, and he began to repeat mechanically the fixed appurtenances of the role—the movements of the muscles, the mimetics of the face, eyes, arms, and body, and the physical signs of absent emotion. This led him to the perception that creativeness on the stage demands a condition which he called "the creative mood." To the genius on the stage, this condition almost always comes of itself, and less talented people receive it less often. Although everyone on the stage receives the creative mood sometimes, none seemed able to control it with their own will.

The role of the creative mood

Stanislavsky's description of the problem thus far had reached the point at which all previous examinations had stopped. By going further and inquiring into technical means for controlling the creative mood, Stanislavsky laid the foundation for the modern approach to the actor's problem. Stanislavsky had no intention of creating inspiration by artificial means; rather, he wanted to learn how to create favourable conditions for the appearance of inspiration by means of the will. He emphasized that

this problem could be evaded: other artists may create whenever they are of a mind or feel inspired, but "the artist of the stage must be the master of his own inspiration and must know how to call it forth when it is announced on the poster of the theatre." If he is unable to find a conscious path to unconscious creativeness, the actor is forced to rely on the superficial aspects of scenic craft and theatrical cliches.

Stanislavsky believed that the problem could be solved through advanced psychology, especially the concept of "affective memory" described by the French psychologist Théodule Ribot in the 1890s. Although there has been confusion and misunderstanding about it, and its very existence has been questioned, the concept of affective memory is of prime importance for the understanding of how spontaneous and emotional experiences occur and can be repeated on the stage.

Affective memory is a reliving of past experiences—likes and dislikes—when an analogous situation recurs. Something that has brought pain is anticipated with dislike the second time. This dislike, which is felt immediately, rather than remembered, is like a residue of previous appraisals. Affective memory may be linked directly to the memory of a traumatic experience, as the same situation or a similar one recurs, or to an experience that bears little apparent relation to the original, if the memory has been repressed. Of course, an experience need not necessarily be traumatic to leave an affective memory. The concept of affective memory has found a place in several schools of psychology, including the Freudian and the Pavlovian, though different explanations have been offered.

The concept embraces both sense memory and emotional memory. The latter term was used by Stanislavsky in his later work to refer to the experiences of an intense and explosive nature that are so necessary for the most dramatic moments in the theatre. The concept of affective memory is essential to an understanding of how the actor functions and the faculties that have to be trained to develop his talent. It is his unusually sensitive affective memory that enables the actor to respond to events that must be imagined on the stage and to repeat performances. This point was stressed by Stanislavsky's great pupil Yevgeny Vakhtangov, who emphasized that literal emotion—emotion that derives from the presence of an object that actually stimulates it—cannot be controlled and cannot be relied upon to provide the level of response that is required in every performance.

The use of affective memory is not limited only to acting. Wordsworth defined poetry as originating from "emotion recollected in tranquility." Marcel Proust, in a long passage in *Swann's Way*, brilliantly described the working of affective memory and illustrated precisely the way in which it can be recalled. Instances of its presence can be multiplied from all the arts—literary, visual, or musical. But, though in the other arts it can function unconsciously, the actor must learn to use it consciously to satisfy the unique conditions under which he must create.

Stanislavsky's "Method"

The "Method" is the name by which the totality of Stanislavsky's ideas have become most widely known. The Method represents a development of his procedures based not only on his writings but also on his actual achievement in his major productions. It includes the work of Vakhtangov, who demonstrated that Stanislavsky's ideas apply to the essential problems of the actor in any style and not only the realistic style most often associated with them. The Method became widely known in mid-20th century largely through the work in films of actors such as Marlon Brando, Rod Steiger, and Geraldine Page, who had studied at the Actors Studio in New York City. These actors made a powerful impression and showed a remarkable ability to bridge the gap between stage, screen, and television to an extent that aroused excitement and interest in the rest of the world. So strong was the fusion of performer and role that many of the traits of the character were confused with those of the actor, which led to serious misunderstanding. But at mid-20th century an American style of acting was being born.

Later developments. The post-Stanislavsky period has been influenced chiefly by the ideas of Antonin Artaud, Bertolt Brecht, and Jerzy Grotowski (who pointed out that the other two were more concerned with aesthetics than with methods). Artaud, a French avant-gardist director and actor, exerted an enormous posthumous influence on contemporary theatre through his writings. In them he proclaimed the "theatre of cruelty," which is based on the extreme development of gesture and sensory responses by the actors so that they can communicate with the audience at a more profound psychological level than is possible through words. Artaud's ideas achieved international attention through the productions of Peter Brook and the Royal Shakespeare Company, especially *The Persecution and Assassination of Jean-Paul Marat as Performed by the Inmates of Charenton under the Direction of the Marquis de Sade*, which called for emotional states verging on hysteria from most of the cast during each performance.

The ideas of Artaud, Brecht, and Grotowski

Contrary to the opinion of many, however, Artaud thought of the theatre not as a psychological but as a plastic and physical domain and of the actor as an "athlete of the heart." For every feeling, every mental action, and every leap of human emotion, there is a corresponding breath that is appropriate to it. It has been pointed out by Grotowski, however, that if Artaud's principles are analyzed in a practical way, "they lead to stereotypes: a particular type of movement to exteriorize a particular type of emotion. In the end, this leads to cliches."

Through his plays and the remarkable productions of the Berliner Ensemble in East Berlin in the 1950s, which represent the most important contribution to theatre of the post-Stanislavsky period, Bertolt Brecht generated ideas about acting that have received wide prominence and have usually been counterposed to those of Stanislavsky. Whereas in Stanislavsky-inspired productions the actors often seem to be exaggerating their individuality, Brecht's characters struck many observers as existing primarily as representatives of a class—in some cases self-effacing to the point of dehumanization. Brecht himself, however, denied that his ideas were opposed to Stanislavsky's. He drew attention to the relatively quiet style of acting that sometimes struck visitors to the Berliner Ensemble. Brecht called his approach epic realism. He stressed that the stage of a realistic theatre must be peopled by live, three-dimensional, self-contradictory people, with all their passions, unconsidered utterances, and actions. The actor has to be able to create such people. Brecht mentioned some of the procedures of Stanislavsky he felt indebted to—the creation of the given circumstances that motivate the beginning of an event, the emphasis on creating the activity of the day that helps to define the actor's behaviour, and the individualizing of the characters that make up a mass. And he warns that "we shall get empty, superficial, formalistic, mechanical acting if in our technical training we forget for a moment that it is the actor's duty to portray living people."

Brecht's epic realism

A contemporary Polish director, Jerzy Grotowski, made the most thorough effort to rediscover the elements of the actor's art. Although he credited Stanislavsky with having posed the most important questions, he was not satisfied either with Stanislavsky, who let natural impulses dominate, or with Brecht, who was too much concerned, Grotowski felt, with the construction of the role. To Grotowski, the actor is a man who works in public with his body, offering it publicly. The work with the actor's instrument consists of physical, plastic, and vocal training to guide him toward the right kind of concentration, to commit himself totally, and to achieve a state of "trance." The actors concentrate on the search for "signs," which express through sound and movement those impulses that waver on the borderline between dream and reality. By means of such signs, the actor's own psychoanalytic language of sounds and gestures is constructed, in the same way as a great poet creates his own language.

The actors of Grotowski's troupe are superbly trained physically and vocally, and they commit themselves to their task with total energy. They have been accused,

however, of conveying too little human emotion. Grotowski's criticism that Artaud's work leads to cliches has also been made of his own work. There is little evidence in it of the level of acting observed in the work of great actors.

THE ACTOR'S QUALIFICATIONS AND TRAINING

In view of the diversity of approaches to the actor's problems, it would seem difficult to arrive at any useful generalizations that are valid for all of them. Even among theatre groups that approach the production of a play from a fixed style or a fixed scale of expression, as in Japanese kabuki and classic Oriental theatre generally, the same basic concerns are apparent. The following is an attempt to set down an approach that has proven successful in a variety of professional procedures.

Looks and personality

The qualifications of the actor are generally thought to be a good physique, a retentive memory, an alert brain, a clear, resonant voice with good articulation, and controlled breathing. While looks and the even more important element of personality are undoubtedly factors, their characteristics are difficult to determine; they are usually recognized after the actor has become successful rather than before. Many actors do not possess them offstage but seem to ignite them as soon as they begin to perform. The modern mediums of the cinema and TV have intensified the importance of these external elements, continually searching for actors resembling those who have already achieved success, without helping to clarify these qualities. Yet the central element of the actor's talent, as differentiated from his means, is a special sensibility ("fire," "enthusiasm," "spirit," in the words of 18th-century theoreticians), an ability to respond to imaginary stimuli and situations, which makes it possible for him to enter into the experience and emotions of the character he is to represent. These elements have always been recognized as distinguishing the great actor but were assumed to be beyond the reach of the ordinary actor; they were regarded as elements "born in him" and not susceptible to training. This is precisely the area of the modern training of the actor.

The first stage in the training of the actor's control of his physical, mental, and psychical resources is the ability to relax. Because this ability seems to have little to do with the final achievements in acting, it is often disregarded, but it is basic to any expenditure of will and energy on his part. In a state of physical or mental tension, or both, the actor cannot think, the commands he gives himself are not transmitted, sensation is stifled, and expression is inhibited. The process of relaxation serves to clear the actor of the unnecessary pressures that he has accumulated before the moment of acting begins, to free him of blocks or interferences that may inhibit sensory responses. Physical and mental energies are comparatively easy to train, but sensory control is much more difficult. Relaxation is not a static state or effort. Often in the initial stages of training the actor is subject to strong eruptions of unconscious impulses. He must learn to continue the relaxation, to force his will to maintain his effort on the action of the nerves and the muscles. Relaxation is connected with the exercise of the actor's will.

The role of concentration

The converse of relaxation is concentration. Everything the actor does demands concentration. His training proceeds by work with imaginary objects: working with real objects often leads to pantomimic or to physical imitation, but the actor may begin with them in order to learn how to respond with his entire organism and to apply such responses to his work with imaginary objects—the real medium of the stage—as he would to real ones. This capacity to respond to stimuli that come not from outward reality but from the promptings of one's own imagination may be seen to some extent in every human being; something akin to it is found in psychology in the study of conditioned reflexes, of automatic and spontaneous reactions, and of behaviour patterns. In heightening the sensory awareness and stimulating the senses to respond more strongly in life, the actor acquires the ability to recreate any object, sensation, or experience in the imagination. Here the concept of affective memory, already discussed, plays a fundamental role.

The French actor Talma has already been quoted as stressing the actor's need for an "excess of sensibility, always more lively, more rapid, and more powerful." But he has also properly pointed out that

> his intelligence must always be on the watch, and acting in concert with his sensibility, regulate its movements and effects: for he cannot, like the painter and the poet, efface what he does. To form a great actor the union of sensibility and intelligence is required.

In strengthening his concentration, the actor uses not only will but also a process of self-awareness by which he observes what is happening and trains his instrument to respond to his commands. The very process of concentration and of commitment and involvement must include awareness. The more the actor learns to master concentration, the more aware he becomes.

The actor's sense of truth

An additional factor is the development of the actor's sense of truth—a faculty particularly stressed by Stanislavsky. The growth of self-awareness is useless if it is not accompanied by a correct evaluation of what is true and what is false. If the actor must rely on outside judgment and remain dependent on it, he may become insecure and lose his spontaneity and responsiveness. His mastery of inner relaxation and concentration helps him achieve a combination of spontaneity, commitment, and awareness. Thus, the actor's involvement and his awareness, rather than being in opposition to each other, are in accord.

The actor's sense of truth is also involved in another major area of the actor's training—his work with actions (the way he behaves physically on the stage), sometimes called the "business" of the actor. Some idea must supply an incentive or intention to pull together what could otherwise be a series of disconnected and unrelated physical deeds. Some purpose, some aim must motivate the actor's will and energy. Any performance thus may be seen as a series of actions—as the score of the play—which must be carried out not simply physically but logically and truthfully. They must accomplish their purpose anew each night at every performance rather than merely repeating the external movements.

To develop spontaneity, to train himself to behave logically and truthfully, and to listen and respond to his partner, the actor practices improvisation—dramatizing contrived situations without a script. Improvisation is of enormous importance in the process of training and also of performance. It teaches the actor to speak rather than to read his lines, and it breaks his unconscious adherence to conventional theatrical patterns of behaviour. It forces him to use his senses and often to discover not only the logic but also the significance of a scene. It compels the actor to work creatively and prevents him from reverting to skillful but mechanical repetition.

By means of exercises that may be remote from the actual roles he plays—such as the "song and dance" (in which a song is rendered in various ways, each conveying strongly a particular feeling about it) or, conversely, the spoken "inner monologue" (in which the actor recalls an important personal experience in minute detail) or others—the actor not only intensifies his capacity for experience, but also frees his blocked, or inhibited, impulses. He is enabled to deal with his own subjection to automatic habitual forms of behaviour and mannerisms and to acquire new means of expression, corresponding to the true nature and strength of his impulse. He is thus enabled to develop a much larger scale of expression than the customary casual means of behaviour in life permit.

Voice and body training

The basic means of the actor, which have traditionally served as the primary area of his training, are voice and body gesture. The methods used to train these tools of the actor derive from other fields, such as from the training of the singer's voice and of some forms of dance and pantomime. These contain many useful exercises for the strengthening of the respective muscles of the voice and body. But the singer's voice must retain its beauty and its musical quality regardless of the circumstances involved, and the dancer's body must always wind up in a formally acceptable attitude; and their respective training is so de-

signed. Their needs are quite different from the needs of the actor. His voice must be flexible and expressive of all situations and experiences. It must be able to deliver a "poor" voice or a vulgar, rough, angry, or harsh voice. It must vary as much as the events to be created. His attitudes must be those of the character—of a human who may be ill at ease, slovenly, awkward, debilitated, or natural—giving no indication that it is being accomplished by a skilled craftsman. The technical accomplishment in the singer and in the dancer may represent a large part of what is appreciated in their performances; but in the actor, the very fact of the accomplishment must remain hidden. Technical accomplishment should go unnoticed by the audience.

For this reason, many actors have expressed dissatisfaction with the accepted methods for training the actor's voice, speech, and body. In this respect, the work of Grotowski and of producing units throughout the world that have been influenced by him have demonstrated new possibilities. The skill of the actors in such groups has been generally admired, and their work could serve as a basis for training the actor. Relaxation, concentration, work on objects, sense memory, emotional memory, action and improvisation, and the training of voice and body constitute the actor's work on himself. Work with objects and sense memory are as fundamental to his art as are daily finger exercises to a pianist.

THE ACTOR'S APPROACH TO HIS ROLE

Stanislavsky suggested that the actor, in approaching his work on a scene, ask himself four questions: (1) who he is (character), (2) where he is (place), (3) what he is doing there (action and intention), and (4) what happened before he came there (given circumstances). The answers to these questions provide the actor with the necessary background for his performance, helping him to create the scene. In approaching the play in its entirety, the actor must subject his role to more intense analysis: he must search for the spine, or the kernel, of the play as well as its division into separate sections or units of actions. He must discern the beats of the play (*i.e.*, the smallest units of dramatic action into which each role can be divided) as well as the rhythms of the play as a whole, and he must determine what adjustments must be made in his performance for each of the other characters. For some plays an additional element is necessary: the overall mood, or pervading texture, that surrounds the play or out of which the play stems. The attempt to determine it, however, may lead to an excess of verbal and mental gymnastics that are of little actual value, unless the actors have been trained in the proper procedures. The actors must act out the elements involved in the analysis in order to receive any concrete benefit from it; otherwise it may remain superficial or merely intellectual.

Collaboration with the director

Another area deserving attention is the rehearsal process. This is primarily the time in which the director's conception of the play must be harmonized with those of the actors; it is of immense importance that the actor approach the rehearsal in a creative frame of mind, ready to enlarge both his own and his colleagues' interpretations. Without a logical sequence of rehearsals, the actor's creativity cannot be properly stimulated. Without an understanding of the psychology of the rehearsal procedure, much of the work of the actor and the director may be defeated in production. There are, for example, significant possibilities in the reading rehearsal, in which the actors, usually seated in a circle, read aloud from the script and discuss its meanings as they proceed through it. There is enormous value in improvisation, when it is understood and used correctly. The relation between the individual actor and the ensemble is welded during the rehearsals, and they are the proper time to encourage the actor to begin to develop his movements to block the scene, to memorize his lines.

Styles of performance. In an effort to bring new life to plays of the past and present and to advance the imaginative possibilities of theatre, there has been a rediscovery of style in the 20th century. Style is the attribute of any complete achievement; it is not, as is often assumed by laymen, merely the manners and customs of a particular period. Such manners may be more strikingly elegant compared with those of the present, but they remain only manners. The Elizabethan form of theatre had conflicting styles within it, judging from a description of them in *Hamlet*, and so did the Greek and the French classical theatre. Even in the Japanese Kabuki and Nō theatre there have been conflicts of styles like those in Western theatre.

Style is not, as is sometimes assumed, the opposite of realism. Neither is it necessarily characterized by an expansiveness or broadness in acting. Style is the angle from which reality is observed. It is an attribute of all creative activity—not just of period or classic plays. The search for the specific content and reality of a play leads to style. The search for style in itself or in the traditions of the past often leads to empty forms.

Just as style should not be identified with a particular period, neither should it be associated with specific playwrights. Such terms as a Shakespearean or a Chekhovian style actually refer to the theatrical conventions traditionally associated with those dramas—a rhetorical and "larger than life" manner in the first and a static "mood" in the latter. These elements are little related to style; otherwise great Shakespearian and Chekhovian productions could be re-created generation after generation in precisely the same way. The fact is that those dramas must be continually re-created from the new views of each emerging generation. Even the performances of Jean Racine's dramas re-created in the correct manner of French classical theatre do not attain great success in France. It is possible that more might be achieved by an interpretation of Racine along Chekhovian lines: the use of methods associated with the productions of Chekhov combined with a fresh understanding of Racine's character development might revise the opinion that his plays are excessively wordy at the expense of reality. This criticism was also levelled against Chekhov before Stanislavsky's Moscow Art Theatre demonstrated the inner logic of his plays.

Highly regarded theatrical performances

The most highly regarded performances in theatrical history were achieved by creating believable characters behaving logically and truthfully. The actors often used means that were criticized as being vulgar—either too naturalistic or too realistic—because they broke the formal patterns of poetic speech. These actors demonstrated little reliance on the formal elements that traditionally have been supposed to characterize style. French actors, who have been considered exemplars of this traditional notion of style, have not excelled in Shakespeare; this perhaps is an indication of the defects inherent in an approach based on the external concept of style.

The term style is often used incorrectly in reference to the theatrical conditions that simulate the original concept, structure, and dynamics of a play. The rediscovery in the 20th century of the Shakespearean stage, for example, led to a new quickness and fluidity, a nearly cinematic technique, in presenting Shakespeare's plays, but these techniques should not be interpreted as the original and therefore correct style of production. Shakespeare continues to be presented in a vast range of styles.

Plays that entail interaction between actor and audience also present no unique problems to the actor. The audience is treated with the same conviction and reality as if it were another presence in the drama, as if it were simply another character.

Acting in different media. The fundamentals of the actor's art remain the same no matter how bizarre the dramatic context: the actors may be abstractions, for example, as in Stanislavsky's 1908 production of Maurice Maeterlinck's allegorical fantasy *The Bluebird;* they may play a band of actors producing a play, which they then proceed to perform in a vivid theatrical fashion, as in Vakhtangov's production of *The Dybbuk*, a play about an evil spirit, by S. Ansky; they may imagine themselves into a satiric extravaganza, as in experiments by the Group Theatre (a major U.S. troupe of the 1930s, working on the basis of Stanislavsky's ideas) based on the satirical pictures of George Grosz, (1931); or they assume the

distorted attitudes appropriate to an expressionist world, as in the classic horror film *The Cabinet of Dr. Caligari* (1919).

Acting in motion pictures and television

The growth of motion pictures, especially the rise of the "talkies," beginning in 1927, greatly affected acting, as theatre talent was diverted from the stage. The requirements of acting in motion pictures, television, theatre, and opera are basically the same, although some of the techniques are different. It is possible to put strips of film together and create a performance that never was actually given. The performance is created by the director rather than by the actor. There have been performers in motion pictures who were thus completely products of the camera and contributed little from an acting point of view, depending rather on their physical charms and personality. Others, however, were authentic actors, who developed a style perfectly suited to the medium; Charlie Chaplin, for example, ranks as one of the greatest actors of all time in any medium.

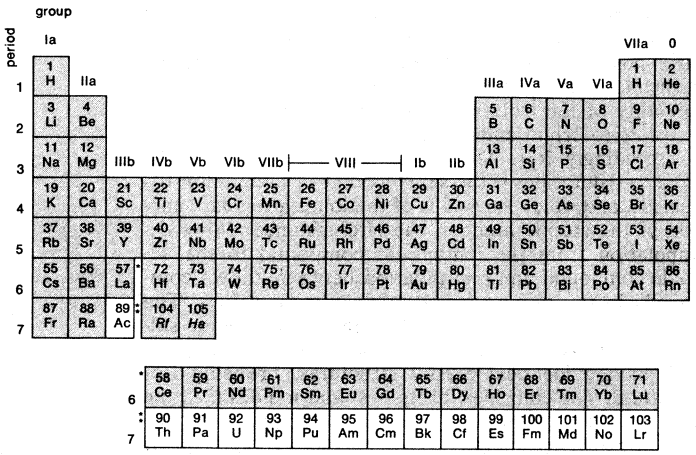
Despite the technical demands that are unique to each medium, the properly trained actor moves easily from one medium to another without any diminution of his talent. Those who have been trained in the rhetorical and theatrical gesture approach, as many British and French actors have been, sometimes find difficulty in making the transition to films. The theatre tends to diminish action and voice, requiring a heightened intensity to project across the footlights. The camera, however, exaggerates action and emotion. Moreover, some actors find it difficult to perform scenes out of sequence, as is usually done in films, and for other actors the closeup can be intimidating. But the fact is that actors training for films usually use the same exercises as theatrical actors—working with imaginary objects and partners, performing appropriate physical and psychological tasks, and others. Moreover, most of the foremost actors in mid-20th century, such as Sir Laurence Olivier, Jean-Louis Barrault, and Katharine Hepburn, have been outstanding in both film and theatre.

The contemporary theatre is characterized by many plays that demand more dynamic and more imaginative physical actions of the actors than previously and that utilize a diversity of audio-visual effects and multimedia devices. Under the need to fulfill these demands, acting could easily revert to its old-fashioned externalized forms. In addition, the development of repertory theatres in the United States, England, and elsewhere, with their eclectic repertoires and their combinations of contemporary and classic plays, often leads to a search for meretricious "style" rather than for genuine content. These new pitfalls may be avoided, however, in much the same way as those that faced the actor in previous epochs, by understanding of the true fundamentals of the art of acting.

BIBLIOGRAPHY. The literature on actors and acting is overwhelming. Most of it is of little value. Significant are the statements of actors or theatre practitioners that must form the basis of our understanding. The best anthology in any language with useful notes and bibliography is TOBY COLE and H.K. CHINOY (eds.), *Actors on Acting: The Theories, Techniques, and Practices of the Great Actors of All Times As Told in Their Own Words*, rev. ed. (1970). The most valuable statements are those of Luigi Riccoboni, F.J. Talma, and William Gillette. Some of these are reprinted complete in *Papers on Acting*, ed. by BRANDER MATTHEWS (1958), which also includes the polemic between Henry Irving and C. Coquelin. A useful introduction to the literature is EDWIN DUERR, *The Length and Depth of Acting* (1962), flawed by the common inability to relate theory to practice. The famous essay by Diderot, in translation, *The Paradox of Acting*, is printed with WILLIAM ARCHER'S reply in *Masks or Faces* (1957). From the critical point of view the essay by PIERRE REMOND DE SAINTE-ALBINE, *Le Comédien* (1747; Eng. trans., *The Actor*, 1750 and 1755, reprinted 1969 with additional anecdotes of Garrick and other English actors), is still valuable. Important contributions are G.H. LEWES, *On Actors and the Art of Acting*, (1957); G.B. SHAW, *Our Theatres in the Nineties*, 3 vol. (1932); STARK YOUNG, *The Flower in Drama* (1923) and *Glamour* (1925). Basic to modern understanding are the works of STANISLAVSKY: *An Actor Prepares* (1936, reprinted 1956), *Building a Character* (1949), *Creating a Role* (1961). The English versions are well translated and edited by ELIZABETH REYNOLDS HAPGOOD. Complete versions with the useful notes of the Russian editions are available in German translation and are essential for serious study. A handy though somewhat superficial description based on secondary sources of the background surrounding his endeavour is CHRISTINE EDWARDS, *The Stanislavsky Heritage* (1965). Useful also are ROBERT LEWIS, *Method or Madness?* (1958); the essay by LEE STRASBERG on "Acting and the Training of the Actor," in JOHN GASSNER, *Producing the Play* (1941; rev. ed., 1953); ROBERT HETHMON (ed.), *Strasberg at the Actors Studio* (1965); RICHARD BOLESLAVSKI, *Acting: The First Six Lessons* (1949, reprinted 1962); and TOBY COLE, *Acting: A Handbook of the Stanislavski Method* (1955). For a proper appreciation of Stanislavsky's approach, the work of his pupil E.B. VAKHTANGOV is essential. A brilliant description is in NIKOLAI GORCHAKOV, *The Vakhtangov School of Stage Art* (1961; orig. pub. in Russian, 1957). The last period of Stanislavsky's work is unfortunately not available in English but is described in the German translation of WASSILI TOPORKOW, *K.S. Stanislawski bei der Probe* (1952). Recent contributions on acting are JERZY GROTOWSKI, *Toward a Poor Theatre* (1968); ANTONIN ARTAUD, *Le Théâtre et son double* (1938; Eng. trans., *The Theater and Its Double*, 1958); JOHN WILLETT (trans.), *Brecht on Theatre* (1964); MICHEL SAINT-DENIS, *Theatre: The Rediscovery of Style* (1960); VIOLA SPOLIN, *Improvisation for the Theater* (1963); and MICHAEL CHEKHOV, *To the Actor* (1953). The relation of music to theatrical declamation is touched on by ROMAIN ROLLAND in his essay on "Lully's Recitative and Racine's Declamation" in *Some Musicians of Former Days* (1915). Another important viewpoint relating the actor to his environment is F.S. BOAS, "Edmund Kean in His Heroic Parts," in *From Richardson to Pinero* (1936). This approach has recently been attempted on a larger scale in J.W. DONAHUE, *Dramatic Character in the English Romantic Age* (1970). No history of acting can be written without a knowledge of what acting consists of and the creative processes involved. German students have in many specialized studies and dissertations tried to formulate methods for studying the actor's work by examining critical descriptions, stage directions, and iconographical material. A bibliography is available in HANS KNUDSEN, *Methodik der Theaterwissenschaft* (1971).

(Le.S.)

Actinide Elements and Their Compounds



The actinide elements constitute a group of 15 consecutive elements in the periodic table from actinium, symbol Ac, with atomic number 89, to lawrencium, symbol Lr, and atomic number 103. As a group they are significant largely because of their radioactivity. Although several members of the group, including uranium (the most familiar), occur naturally, most are man-made. Both uranium and plutonium have been used in atomic bombs for their explosive power and currently are being employed in atomic-generating plants for the production of electrical power.

PROPERTIES OF THE ACTINIDES AS A GROUP

General comparisons. The properties of all of the actinide elements are quite similar because of the similarity of the arrangements of electrons around the nuclei of their atoms. In any atom the total number of electrically negative electrons equals the number of positively charged protons in the nucleus, thus keeping the atom as a whole electrically neutral. The periodic table is a catalogue of the elements so arranged that the atoms of any one element have one more proton that those of the element immediately before it in the succession. This means that the atom of each successive element must have one more electron to balance the one additional proton and keep the atom neutral (see ATOMIC STRUCTURE). The increasing number of electrons are arranged around the nucleus in concentric shells and subshells. These shells are identified by ascending numbers counting outward from the nucleus, 1, 2, 3, etc. The subshells, called orbitals, are identified by shell number and a letter (*s*, or *p*, or *d*, etc.). Each electron has a specific energy that is defined in terms of four energy quantum numbers. In a general discussion, however, it is enough to identify an electron as 1*s*, or 3*p*, or 5*d*, etc. There is a limit to the number of electrons that any shell may contain, and no atom may have more than eight electrons in its outermost shell. Such an octet arrangement is extremely stable, and the next element in the series must begin a new shell outside the octet. This means that shells that can contain a

maximum of more than eight electrons become filled later as inside shells. In the heaviest atoms, three such incomplete inner shells exist. The chemical properties, and many of the physical properties, of the elements depend almost wholly on the activity of the electrons in the outermost shell. Thus, similar configurations of the outermost shell in different elements give those elements similar properties. Electrons from inner shells may also participate in chemical activity, but their behaviour is of considerably lesser importance. All the electrons that may be active in chemical bonds are called valence electrons.

Atomic structure. The actinide elements follow one another in the seventh series of the periodic table (see the Figure). Each has 86 electrons arranged as in the atoms

Actinide elements in the periodic table of the elements.

of the noble gas radon (which precedes actinium by several spaces in the table), with three more electrons that may be positioned in the 6*d* and 7*s* orbitals (the seventh shell is outermost), and with additional electrons packing into inside orbitals. Specifically, the series is formed by the insertion of one more electron for each successive new element into an underlying 5*f* orbital. The valence electrons, however, are found mainly in the 6*d* and 7*s* orbitals. Thus, the chief difference among the atoms of the elements of the series is the single additional electron deep within the electron cloud; but the fact is that, because of its position in the 5th shell, this distinguishing electron actually affects the chemical properties of the actinides only in a relatively minor way; 5*f* electrons are not involved in the formation of chemical bonds with other atoms.

As is usual with the elements of any group, there are a number of exceptions to these generalities, particularly in the lower members of the series; but for most of these elements, the concept of a series of nearly identical actinide elements is a useful guide for predicting their chemical and physical properties.

Like all elements, each actinide has its own particular atomic number, equal to the number of protons in the nucleus and, consequently, to the number of electrons; at the same time the atoms of an element are capable of existing in a number of forms (isotopes), each of which has a different number of neutrons in its nucleus and hence a different atomic mass. Although isotopes of a given element behave alike chemically, they may have different stabilities in relation to radioactive decay, which is a property of the nucleus. No element beyond bismuth in the periodic classification—*i.e.*, no element that has an atomic number greater than 83—has any stable isotopes; radioactive isotopes of every element in the table can be produced in the laboratory. The actinides are unusual in forming a series of 15 elements having no stable isotopes; every actinide isotope undergoes radioactive decay, and, as a result, only a few of the lighter, more stable members of the series (such as thorium and uranium) are found in nature. The half-life, or the precise time required for one-half of any amount of a particular isotope to disappear due to radioactive decay, is a measure of the stability of that isotope. The naturally occurring isotopes in the actinide series have long half-lives, of the order of billions of years.

Usefulness. The practical significance of the actinides arises from the fissionability, or potential for splitting, of certain of their isotopes. When an atomic nucleus breaks apart, or undergoes fission, a far more disruptive process than ordinary radioactive decay, enormous amounts of energy are liberated. This energy can be allowed to generate an atomic explosion, or it can be controlled and used as a fuel to generate heat for the production of electrical power. Nuclear processes for power production give off no smoke, smog, or noxious gases, as conventional coal- or gas-fueled plants do. Nuclear power plants, however, do yield waste heat that may be considered as thermal pollution, and they also yield useless and dangerous radioactive wastes which, although they are pollutants, may be less undesirable than those from fossil-fuel generators. For this and other reasons, such as economy of operation, there is a potential for an enormous electrical energy production inherent in atomic energy generating technologies, and, since the actinide elements are the only known fissionable materials, the practical impact of their availability is great. The isotope of uranium with the atomic number 92 and mass 235, written as uranium-235 or, in chemical symbols, as ^{235}U, is present to the extent of only 0.7 percent in ordinary uranium, but it is a necessary fissionable material in the operation of an atomic reactor using natural uranium. Other fissionable isotopes of great importance are uranium-233, plutonium-239, and plutonium-241.

Nuclear fission

Fissionable plutonium isotopes are formed as by-products of fission in reactors using uranium; when neutrons are added to uranium-238, which is not itself fissionable, it is converted to the fissionable isotope plutonium-239. Thorium, also, is potentially of great economic value, because one of its isotopes, thorium-232, can be converted into the fissionable isotope uranium-233 in an atomic breeder reactor (*i.e.*, one that produces more fissionable material than it consumes), thus increasing by many times available supplies of fissionable materials. Since thorium is about three times more plentiful than uranium, the potential use of this element to produce atomic energy is significant.

The heavier actinides, those beyond plutonium in the periodic table, are of interest principally to research scientists, though they have some practical uses as sources of thermoelectric heat and neutrons. They are employed to some extent in cancer therapy.

Actinium, thorium, protactinium, and uranium are the only actinide elements found in nature to any significant extent. The remaining actinide elements are all manmade by bombarding naturally occurring actinides with neutrons or with heavy ions (charged particles) in particle accelerators (such as cyclotrons). The actinides beyond uranium do not occur in nature (except, in some cases, in trace amounts), since the stability of their isotopes decreases with increase in atomic number and whatever quantities may be produced decay too fast to accumulate. The half-life of uranium-238, the most stable uranium isotope, is 4.5×10^9 years. Plutonium-239 has a half-life of 24,400 years and is produced in reactors in ton amounts; but nobelium and lawrencium, elements 102 and 103, with half-lives of seconds, are produced a few atoms at a time. The first of these synthetic actinide elements to be discovered (1940) was neptunium, symbol Np, atomic number 93, which was prepared by bombardment of uranium metal with neutrons (see TRANSURANIUM ELEMENTS).

Chemical properties. The chemistry of any element can be understood best in terms of atomic structure and its effect on the formation of chemical bonds. Three general types of chemical bonds can be formed: ionic, in which valence electrons are shifted from the less to the more electronegative atom, producing oppositely charged ions, which then associate by virtue of their mutual attraction; covalent, in which a pair of electrons is shared by each atom; and metallic, in which the arrangement of

atoms allows the valence electrons to move about in the structure. These bonded atoms may be represented in several ways for purposes of chemical discussion; as molecular formula, structural formula, general formula, etc. In each case, an atom is signified by the symbol of the element, followed by a subscript that indicates the actual number of those atoms in the bonded structure. For example, water molecules are combinations of two hydrogen atoms and one oxygen atom; the molecular formula for water is H_2O. Hydrogen peroxide, with two oxygen atoms and two hydrogen atoms, has the formula H_2O_2. In a general formula, representative letters for groups of elements are used instead of the symbols for actual elements, and the letter *n* is used instead of a number when the numbers of atoms in the molecule are defined in terms of ratios. For example, any one alkali metal combines with any one halogen atom; therefore, the general formula for alkali halides is MX, M representing lithium, sodium, potassium, etc., and X representing fluorine, chlorine, bromine, etc.

There are two series of elements (actinide and lanthanide) in the periodic table (see the Figure) in which added electrons (with increasing atomic number) go into internal *f* orbitals, where they are partially buried and consequently not chemically active. These two series occur in Group IIIb of the table; because the outer, or valence, electrons of these elements are much the same, the chemical properties of the elements in the two series tend to resemble one another closely. A great deal is known about the lanthanides, all but one of which occur in nature as stable isotopes and, therefore, predictions about the chemistry of the actinides, some of which can be prepared only in minute quantities, can be made with some success by comparing their electron structures with those of the lanthanides. In the lanthanide series of elements, with atomic numbers from 57 to 71, and found in the periodic table directly above the actinides, each added electron goes into the *f* orbital of the fourth shell; these orbitals are designated as 4*f*. In the actinide elements, the added electrons also go into an *f* orbital in a similar manner, but in the fifth shell, instead. Electrons with larger quantum numbers generally are farther from the nucleus than those with smaller quantum numbers, and are therefore usually less strongly held by it. As expected, then, electrons in the 5*f* orbitals, being farther from the nucleus, are much less tightly bound than are those in 4*f* orbitals and, in fact, sometimes are active enough to take part in chemical reactions. The result is that the actinide elements, in which the 5*f* orbitals are being filled, have more variable valences (number of electrons available for chemical bonds) than do the lanthanides, in which the 4*f* orbitals are being filled.

Similar lanthanide and actinide series

The similarities between many lanthanide and actinide compounds are striking and offer a useful comparison. Under certain conditions, for example, actinium, americium, curium, and berkelium metals have the same crystal structure, as do many of the lanthanides. It is not yet known whether californium or einsteinium, the only other actinide elements with sufficiently stable isotopes for chemical work, have the same structure. Several of the lighter actinide elements from thorium through plutonium have different and unusual metallic structures, presumably due to the mixing of 5*f* and 6*d* orbitals in their atoms, some electrons entering unfilled 6*d* orbitals rather than the expected 5*f* orbitals.

The actinides generally show multiple oxidation states. When an element combines with others to form a compound, the number of electrons of its atom that are, or can be, involved in the bonds of that particular compound is called the oxidation state of the element. An element may have more than one possible oxidation state, and these are designated by the number of electrons involved, and by a plus or minus sign to indicate the role they play. Compounds of americium and californium with an oxidation state of +2 are known; there are reasons for expecting the existence of this state in some of the elements heavier than californium. For example, spectroscopic evidence for einsteinium(II) in the presence of the fluoride ion has been obtained. (Roman numerals following the name or symbol of an element are used to designate the oxidation state of the element.) Divalent actinides (that is, actinides in the +2 oxidation state) form compounds with nearly the same properties as those of the divalent lanthanides and, accordingly, iodides, bromides, and chlorides of divalent americium and californium have been found to be stable. If X symbolizes the nonactinide and M symbolizes the actinide element, then the general formula for these compounds would be one atom of actinide and two atoms of nonactinide: MX_2.

The +2 oxidation state

Great similarities in chemical behaviour are found in the actinides of oxidation state +3, from actinium to einsteinium; furthermore, they are much like the lanthanides of the same oxidation state. The crystal types and many physical properties of these trivalent actinides are dependent more on the size of the +3 ion (an atom that has given up three electrons and has become an ion with three positive charges, symbolized as Ac^{+3}, etc.) of the particular element that is involved. For instance, the solubility of the trifluorides formed by actinides with a +3 state (thorium and protactinium have no such state) is exceedingly low. The crystal-structure type for the actinide trifluorides is the same as that of lanthanum trifluoride, and, since the radius of the ion is a regular function of the atomic number, the circumstance allows extrapolation from the lanthanum compound to the actinide compound and interpolation between known compounds in the series to determine missing values. The hydroxides, phosphates, oxalates, and alkali double sulfates of the actinides are also insoluble, with many of each having identical crystal structures, or being isostructural. The chlorides, bromides, and iodides (*i.e.*, the halides) of the actinides are, for the most part, isostructural for any one halide, and the structure type can be predicted from a knowledge of the ionic radius. The solubility of these halides in water is generally great. The +3 oxides of actinides are also isostructural, with the general formula M_2O_3, in which M is any of the actinide elements; they form cubic (or hexagonal) crystals, and the sizes of the molecules are thus easily predictable. Generally, then, the chemistry of the actinides in the +3 oxidation state is similar, with the differences mainly due to ionic size. As a consequence of these similarities, separations of the elements and of their components are frequently difficult, necessitating the use of methods in which very slight physical differences of the atoms or ions serve to separate the chemically almost identical materials. Two methods are ion-exchange reactions, in which differences in ions and bonding are used to effect separation and solvent extraction, in which specific solvents are used to dissolve and withdraw from the mixture the desired element or its compound.

The +3 oxidation state

Actinides in the +4 oxidation state also are much alike (and also resemble the +4 lanthanides). The +4 actinides, thorium, protactinium, uranium, neptunium, plutonium, berkelium, and, to a lesser extent, americium and curium, are sufficiently stable to undergo chemical reactions in water solutions. Crystallized compounds in the +4 state exist for thorium, protactinium, uranium, neptunium, plutonium, americium, curium, berkelium, and californium. The oxides and many complex fluorides are known for all of these elements. The dioxides are all isostructural, as are the tetrafluorides. Most of these actinide compounds can be prepared in a dry state by igniting the metal itself, or one of its other compounds, in an atmosphere of oxygen or of fluorine. Some tetrachlorides, bromides, and iodides are known for thorium, uranium, and neptunium. The ease with which they can be formed decreases with increasing atomic number. Berkelium(IV) appears to be sufficiently stable to allow the preparation of the tetrachloride. Hydroxides of a number of these elements in the +4 state also are known; they are of very low solubility, as are the fluorides, oxalates, and phosphates. Again, many physical properties of the tetrafluorides are influenced more by ionic size than by atomic number, and isostructurality of these actinide and lanthanide compounds is the rule rather than the exception.

The +4 oxidation state

The similarities exhibited by the lanthanide and actinide compounds in the +3 and +4 oxidation states, as well as in some cases by the free elements, can be very useful. A great many individual differences, however, do arise. These are due, in part, to mixing of the orbitals (some electrons moving into *d* rather than *f* orbitals) and, in part, to the relative degrees of binding of the *f* electrons.

Special properties. *Chemical.* The metals thorium, protactinium, uranium, neptunium, and plutonium are for the most part different from one another. Uranium, neptunium, and plutonium have extremely dense metallic forms. Neptunium, for example, with a density of 20.45 grams per cubic centimetre when crystallized into the orthorhombic crystal form, is one of the densest metals known to man. A possible explanation for the fact that these metals show a number of different crystal forms is that the electrons in the 5*f* orbitals mix with those in the 6*d* orbitals and consequently form a number of hybrid electronic states of nearly the same energy. Beginning with americium, however, the electron energy levels seem to be sufficiently separated so that mixing does not occur.

The other main differences shown by the actinides is that some possess the +5, +6, and +7 oxidation states (no lanthanide element exceeds the +4 state). It appears that the 5*f* electrons of the actinides, being far enough from the positively charged nucleus, permit increasingly easier removal and consequent formation of higher oxidation states. The element protactinium shows the +5 state; uranium, neptunium, and americium exhibit the +5 and +6 states; only neptunium and plutonium have the +7 state.

There are two types of chemical reactions for the +5 and +6 states. If M symbolizes any actinide, and O, as usual, symbolizes oxygen, then the ions found both in aqueous (water) solution and in solids prepared from solution are represented by the general formulas MO_2^+ (meaning a molecule consisting of one atom of M with two of oxygen, the whole having a single positive charge) and MO_2^{2+}. In nonaqueous solution, and in solids prepared from them, compounds of M that do not contain oxygen are known. With the halogens (X being a general designation for a halogen—fluorine, chlorine, bromine, or iodine), compounds are known that can be represented as MX_5 (meaning a molecule consisting of one atom of an actinide with five atoms of a halide) and MX_6, as well as complexes of the type having the molecular formulas MX_6^-, MX_7^{2-}, and MX_8^{3-} for the +5 states, and MX_7^- and MX_8^{2-} for the +6 states. Neptunium(VII) and plutonium (VII) have been prepared in basic solution, and certain oxygenated ions (of the type represented by MO_5^{3-}) as well as a few solid compounds, have been identified with the same oxidation state. Complex oxides with alkali metals in which these two elements have the +7 state also have been prepared.

Physiological. All the actinide elements are heavy metals and, as such, are toxic, just as lead is toxic—relatively large amounts ingested over a long period cause serious illness. But, with the exception of the long-lived thorium and uranium isotopes, the real danger with the actinide elements lies in the radioactive properties of these elements. They are emitters of tissue-destroying and cancer-producing rays (alpha, beta, or gamma; see RADIOACTIVITY). Furthermore, the chemistry of many of these elements is such that, once ingested, they tend to remain in the body almost indefinitely. Several, such as plutonium and americium, migrate to the bone marrow, where their radiation interferes with the production of red blood cells. As a consequence, workers using these elements are required to take elaborate precautions to prevent ingestion. Less than one-millionth of a gram can be fatal.

Radioactive decay series

Nuclear. All of the actinide elements are unstable toward radioactive decay; the reason that actinium, thorium, protactinium, and uranium are found in nature at all is because some of their isotopes are unusually stable and others are being formed constantly by decay of the long-lived isotopes. It is convenient to divide the naturally occurring isotopes into families based on the relationships of their atomic masses to each other. The mass numbers of all isotopes of the so-called thorium series, for instance, turn out to be multiples of four, and the series is known as the 4n series. In the uranium series, masses have been shown to be such that they are represented by 4n + 2; and in the actinium series, by 4n + 3. Not found in nature to any significant extent, but which can be artificially produced by man, is the neptunium, or 4n + 1 series, named for its longest-lived member, neptunium-237.

In the various radioactive decay processes, several "rays" are emitted, the term ray being a holdover from the time when all of these emissions were thought to be rays. They are: (1) electrons, called beta particles to indicate their origin in radioactive decay, and designated as negative beta, or β^-, particles; (2) helium nuclei, called alpha particles and designated as α particles, or as helium with a plus two charge, He^{+2}; (3) gamma rays, which are electromagnetic waves of very high frequency, designated as γ rays; (4) positrons, which are positively charged electrons and are designated as positive beta, or β^+, particles. Finally, an orbital electron in a radioactive atom may be captured by the nucleus and taken into it. This radioactive event is called K-capture. Except for the emission of gamma rays, each of these processes leads to an isotope of a different element; that is, to a substance with a different atomic number. The emission of an alpha particle leads to a change in atomic weight as well, because this emission has significant mass. The changes occur in sequence, each decay process leading to still another unstable element, until a region of stable isotopes of the elements lead and bismuth is reached.

The most important nuclear reactions, however, involve the capture of neutrons by an actinide nucleus, followed by splitting, or fission, of that nucleus into two unequal parts, with the liberation of enormous quantities of energy plus two or more extra neutrons. Atomic reactors and atomic bombs depend upon the chain reaction set up by this process: the resulting neutrons react further, inducing more fission reactions, which produce more neutrons, which lead to still more fission reactions, with the result that, without control, a great deal of energy is liberated very quickly.

One gram of burning coal yields fewer than 10,000 calories of heat. The fission of one gram of uranium-235 produces 2×10^{10} calories, or about 2,000,000 times as much energy. With adequate control the energy can be released in useful form.

The most important actinide by far, because of its fissionability, is uranium, which has several isotopes. Natural uranium consists mostly of uranium-238, a nonfissionable isotope; uranium-235 occurs to the extent of only seven-tenths of one percent; and there are even smaller amounts of uranium-234.

Fissionable isotopes

The fissionable isotope uranium-235 is the valuable substance that causes the chain reactions with neutrons. Methods that separate isotopes by virtue of their different masses are used to eliminate the unwanted isotopes in the naturally occurring mixture of uranium ores and thus enrich natural uranium with respect to uranium-235. Such enriched uranium was used in the first atomic bomb exploded over Japan.

Two other fissionable actinide isotopes are important and undoubtedly will be more so in the future. The first is the isotope plutonium-239 prepared by neutron bombardment of uranium-238. First, uranium-239 is formed by neutron capture; this isotope then undergoes negative beta decay, giving neptunium-239, which in turn reacts by negative beta decay to give plutonium-239. Plutonium-239 thus is formed as a by-product in uranium piles in which uranium-238 is exposed to neutrons; it can be used in place of uranium-235 in atomic weapons or in reactions. The second fissionable isotope is potentially even more important, because it is produced from the element thorium, of which there are enormous reserves on Earth. When the isotope thorium-232 is bombarded by neutrons, one of which it captures, it is converted to thorium-233. This substance decays by

beta emission to protactinium-233, which again emits a beta particle to give uranium-233, also a fissionable isotope of uranium. Since uranium is a relatively scarce element, development of atomic power on a large scale is expected to deplete rapidly the uranium that can be produced economically. The use of thorium thus could extend the supplies of fissionable material by about threefold, and the use of plutonium as well could more than double it. Breeder power reactors are designed so that very few neutrons are lost through the surface or from absorption by impurities, and more fissionable material (either uranium-233 or plutonium-239) is produced than is consumed. Should such breeder reactors be made practicable, never-ending supplies of fissionable isotopes would be available.

Thermoelectric power generators

Although no other fissionable isotopes of the actinides occur in significant amount, there are practical uses of the nonfissionable isotopes due to the amounts of heat they produce by nuclear decay. For special power sources that require great dependability, thermoelectric generators using these isotopes can be considered. Alpha-emitting isotopes with radioactive half-lives in the range of several months to 100 years or more are suitable candidates. (Beta- or gamma-emitting isotopes require too much shielding to be usable.) Curium-244, which has a half-life of 17.6 years, produces 2.9 watts of heat per gram. Another isotope, plutonium-238, produces 0.57 watts per gram and has the much longer half-life of 86 years. Such power sources have been planted on the Moon to provide electrical energy for transmitting messages back to Earth. Plutonium-238 also is being considered for use as a power source for artificial hearts; it already has been implanted in the human body to power a heart pacemaker, which is not expected to need replacement for at least ten years.

COMPOUNDS OF THE INDIVIDUAL ACTINIDE ELEMENTS

Actinium. Actinium, atomic number 89, exhibits only a single oxidation state of plus three, and the compounds formed are the hydroxide, oxalate, fluoride, phosphate, sulfide, oxide, and the double sulfate salt with any one of the alkali metals, all of slight solubility. The other halides and oxyhalides also have been prepared. Because even the stablest isotope of actinium, actinium-227, decays to elements that are strongly radioactive (thorium-227 and francium-223), comparatively few chemical studies of actinium have been made.

Thorium. Thorium, atomic number 90, has two 6*d* and two 7*s* electrons outside the radon electron core; it readily loses these four electrons when it is dissolved or when it combines with other atoms. Thus, +4 is its only oxidation state. Although compounds have been prepared in which thorium atoms and iodine atoms are present in the ratios of 1:2 and 1:3, these are not ionic compounds but semiconducting substances consisting of thorium(IV), iodine, and electrons (see SEMICONDUCTORS AND INSULATORS, THEORY OF). Similar compounds of thorium with nitrogen, sulfur, selenium, carbon, and other elements are also known.

The chemistry of thorium(IV) is that of the thorium ion, Th^{4+}. Insoluble oxides, peroxides, hydroxides, fluorides, phosphates, and oxalates are known. All of the halides have been prepared by conventional techniques, and, with the exception of thorium fluoride, ThF_4, all are soluble in dilute acids. Many double fluoride salts of the alkali and alkaline-earth metals with thorium have been prepared, and a very complicated series of such complex compounds with many different crystalline forms is known.

Thorium metal can be alloyed with relatively few other elements because its atomic diameter, 3.6 Å (1 Å, or angstrom unit, equals 10^{-10} metre), is too large for it to fit into their crystalline structures. It does form intermetallic compounds with aluminum, beryllium, cobalt, copper, iron, magnesium, manganese, mercury, nickel, zinc, and certain other elements.

The compound of thorium produced in largest quantity is the nitrate, which has the formula $Th(NO_3)_4 \cdot xH_2O$, in which x may have various values. The production of mantles for incandescent gas lighting formerly consumed large amounts of this compound; when cotton impregnated with thorium nitrate is burned, the nitrate is converted into thorium dioxide, which emits a brilliant white light upon heating by a gas flame. The addition of a small proportion of thorium sulfate to the nitrate improves the mechanical strength of the dioxide; small proportions of cerium salts increase the brightness of the light produced.

Thorium dioxide, often called thoria, is the thorium compound commonly employed as a nuclear energy source in breeder reactors (see above *Usefulness;* see also NUCLEAR REACTOR). Dispersion of a small amount of thoria in nickel renders that metal unusually resistant to corrosion even at temperatures as high as 2,400° F.

A few organometallic compounds of thorium, such as the cyclopentadienyl derivative, are known, as are many coordination compounds (*q.v.*) with negatively charged organic ions, including those formed from ethylenediaminetetraacetic acid, 2,4-pentanedione, and the arsenic-containing dyestuff thorin. Although the thorium atom itself does not impart visible colour to its compounds, many of its organic coordination compounds are highly coloured, a fact that is utilized in analytical procedures for the detection and determination of thorium.

Protactinium. Protactinium, atomic number 91, has five electrons added to the radon electron structure. It could therefore have +3, +4, or +5 oxidation states. Experimentally, it is found that protactinium(V) is the stable species, although protactinium(IV) occurs under mild reducing conditions. Protactinium(III) is exceedingly difficult to obtain, and there is, in fact, reason to suppose it cannot exist at all.

Because of the high electrical charge of pentavalent protactinium, the ion Pa^{5+} does not exist as an individual particle; stable solutions of the element in this oxidation state, however, can be prepared in the presence of strong acids containing ions such as chloride, fluoride, sulfate, or nitrate, which are called ligands when they bond to the metal atom in a specific way (ligands donate electron pairs in forming covalent bonds; see COORDINATION COMPOUNDS). In the absence of such ions, which convert it into comparatively simple species, protactinium forms very insoluble, intractable macromolecules or polymers, in which repeating structural units are linked together in long chains. Complex protactinium fluorides have been tentatively identified in aqueous solutions containing fluoride ions, and compounds containing these complex ions have been isolated. All of the halides of protactinium(V) have been synthesized, as have the well-known pentoxide (molecular formula Pa_2O_5) and a stable oxyfluoride (Pa_2OF_8). Numerous complex compounds of the protactinium halides with the halides of the alkali and alkaline-earth metals also have been made.

The conversion of compounds of protactinium(V) to those of protactinium(IV) is relatively easy; the processes are examples of chemical reduction (see OXIDATION-REDUCTION REACTIONS). Tetravalent protactinium behaves as a normal +4 actinide. Its compounds, which are similar to those known for thorium, are formed by the reactions of hydrogen gas with solid compounds of protactinium(V) at 400° C (750° F). The dioxide (with a molecular formula of PaO_2), all of the tetrahalides, and a number of complex compounds have been prepared and identified.

Alloys of protactinium

Several alloys of protactinium, particularly those with uranium, have been prepared and studied. Little work has been done on organometallic compounds of protactinium, but there is every reason to believe that they will prove accessible.

Uranium. Uranium, atomic number 92, has six electrons added to the radon electron core. As might be expected, therefore, it has +3, +4, +5, and +6 oxidation states. The +3 state is easily oxidized to the +4 state. In aqueous solution, this uranium(IV) is further oxidized by oxygen in the air to uranium(VI), uranium(V) being unstable.

Uranium forms the compounds that would be expected for an element having the +3, +4, +5, and +6 oxidation states. It forms series of halides corresponding to

the general formulas (X representing any halide) UX_3 (meaning a molecule consisting of one atom of uranium and three atoms of a halogen), UX_4, UX_5, and UX_6, as well as complexes of these with alkali metal halides. The compounds of the +3 state are stable only as dry compounds; in water solution they are oxidized to the +4 state. The uranium(IV) compounds behave as predicted; *i.e.*, the hydroxide and fluoride are insoluble, and extensive hydrolysis of them occurs in dilute acid solutions. Many compounds of uranium(V) that do not contain oxygen are known, and are stable in the absence of water or oxygen. All halides of uranium(V), except the iodide, are known, as are many complexes with alkali metals. The same two classes of ions are found with uranium(VI). In water, the uranyl ion, UO_2^{2+}, occurs, and compounds containing this ion, such as sodium uranyl acetate (used in analytical chemistry), are known. In basic solution, complex uranates containing up to seven uranium atoms per molecule are formed. In the absence of oxygen or water the fluoride of uranium(VI), the hexafluoride, is stable and is used in the commercially important gaseous diffusion process for the enrichment of uranium-235 in ordinary uranium. Uranium hexachloride also has been prepared, but the hexabromide and hexaiodide are unknown.

The hydride of uranium is a well-defined compound used as a generator of pure hydrogen; when heated to 432° C, hydrogen is given off at a pressure of one atmosphere. The uranium–oxygen system is complicated; uranium oxides having compositions represented by the formulas UO_2, U_3O_8, and UO_3 are known, in addition to others that have less simple formulas. Oxides of many other metals react with uranium or with its oxides, forming compounds containing oxygen, uranium, and the other metal; for example, calcium oxide, CaO, combines with uranium trioxide, UO_3, to produce calcium uranate(VI), $CaUO_4$. There are three nitrides of uranium, having the formulas UN, U_2N_3, and UN_2; the same atomic ratios are found in compounds of the uranium–sulfur system and also in the uranium–carbon system. Uranium carbides are particularly useful as fuels in nuclear reactors that operate at elevated temperatures. Uranium forms a large number of coloured complexes with organic compounds; certain of these are used for colorimetric analysis of small amounts of uranium. Many alloys of uranium have been prepared and characterized. Numerous organometallic compounds have been reported, such as the cyclopentadienyl derivative. Literally hundreds of uranium compounds have been prepared and studied, chiefly because of the use of the element as a nuclear fuel.

Neptunium. Neptunium, atomic number 93, has the radon electron core plus seven outer electrons. There is some uncertainty about the existence of *5f* electrons in elemental neptunium, but their presence in the various compounds of neptunium(III), neptunium(IV), neptunium(V), and neptunium(VI) has been demonstrated. Neptunium in aqueous solution exists as ions in the +3 and +4 states and as oxygenated ions in the +5 and +6 states. The +3 state is unstable in air, being oxidized to the +4 state. It is, however, much more stable than is the +3 state of uranium. The trend towards greater stability for the lower oxidation states with increasing atomic number is noticeable throughout the actinide series. Although the uranyl(VI) ion is the most stable of the uranium ions, the neptunium(V) ion is the stable ion of neptunium in aqueous solution. In addition to the oxygen-containing neptunyl(V) and neptunyl(VI) ions, NpO_2^+ and NpO_2^{2+}, nonoxygenated neptunium(V) and neptunium(VI) compounds are known in the solid state. In particular, neptunium(V) exists in complex ions having the formulas NpF_6^-, NpF_7^{2-}, and NpF_8^{3-}, and neptunium(VI) is present in the neutral molecules of the compound neptunium hexafluoride, NpF_6. All these chemical species have close analogues in the chemistry of uranium. Whereas uranium(VI) has no electrons left beyond the radon core, neptunium(VI) has one. This electron can be removed in basic solution to form neptunium(VII).

Compounds containing neptunium(III) are made most easily by dry reactions, since in solution it is rapidly air-oxidized to neptunium(IV). Neptunium(III) forms compounds typical of the trivalent state; all of the halides are known, as well as a complex salt of potassium with neptunium(III) fluoride. Neptunium(III) fluoride is insoluble in dilute acid. Neptunium in the +4 state is a typical tetravalent actinide, stable in the absence of oxidizing agents and forming the expected compounds. The tetrafluoride, chloride, and bromide of neptunium(IV) are known, but the decreasing stability of the higher oxidation states with increasing atomic number is shown by the lack of existence of the iodide. Oxygenated ions are known both in solution and in numerous solid compounds. As is true of uranium, nonoxygenated compounds of neptunium(V) and neptunium(VI) have been prepared. Salts of alkali metals and complex anions with fluorine exist. Neptunium(VII) forms a few moderately insoluble compounds in basic solution, but not much information about them is available. Complex oxides containing neptunium(VII) and alkali metal ions have been prepared.

A hydride of neptunium is known. The neptunium–oxygen system is complicated in the same way that the uranium–oxygen system is. Carbides, phosphides, nitrides, and silicides also are known. A number of organoneptunium compounds have been prepared. Alloy systems have been studied, and the existence of a number of intermetallic compounds has been reported.

Plutonium. Plutonium, atomic number 94, has the electron core of radon plus eight outer electrons. The amazing number of complex forms of the metal is thought to be due to a mixing of *5f* and *6d* orbitals, which have nearly the same energy. In its compounds, plutonium has been shown beyond any doubt to contain *5f* electrons. Well-characterized oxidation states of +3, +4, +5, +6, and +7 exist, with numerous compounds of these known. The decreasing stability of actinide elements of higher oxidation states with increasing atomic number is again evident; plutonium(IV) is the stable state in aqueous solution. Like uranium and neptunium, plutonium forms oxygenated plutonyl ions as well as fluoride complex ions. Plutonyl(V) is unstable in solution. Plutonium(VI) fluoride is known; it resembles the fluorides of neptunium(VI) and uranium(VI) in its physical properties, although it is less stable. Plutonium(VII) has been shown to exist in strongly basic solution; it is considerably less stable than is neptunium(VII).

Plutonium(III) forms compounds typical of a +3 actinide. Although it is air-oxidized to plutonium(IV), many mild reducing agents stabilize the +3 state, thereby allowing the preparation of many compounds of this oxidation state. Plutonium(IV) is the stable state in aqueous solution, and its compounds can conveniently be prepared from solution. Plutonium(V) has been prepared as an alkali metal–fluoride complex, although plutonium(V) fluoride itself is unknown. In aqueous solution only relatively mild oxidation is necessary to prepare the plutonyl(VI) ion. Only two compounds of plutonium(VII) have been prepared from solution (with barium and strontium). Complex oxides of the alkali metals and plutonium(VII) also have been prepared.

Two hydrides of plutonium are known. Plutonium(IV) forms the oxide of highest oxidation number, which again reflects the lowered stability of higher oxidation states with increasing atomic number. Other oxides are known, and a number of oxides of plutonium and other metals have been reported. Carbides, silicides, nitrides, phosphides, sulfides, and similar compounds also have been prepared.

A considerable number of organic plutonium compounds are known. There are many intermetallic compounds of plutonium with beryllium, aluminum, manganese, iron, cobalt, nickel, and other metals. The intermetallic compounds formed by plutonium differ from those of the other actinides because the structures of plutonium metal are different.

Americium. Americium, atomic number 95, has the radon electron core plus nine outer electrons, seven of which are in the *5f* shell. The stable valence state in solu-

tion is americium(III), in which there are six *5f* electrons, analogous to the lanthanide element, europium. By analogy with europium, americium might be expected to have a stable +2 oxidation state, and solid compounds with halogens, such as americium(II) iodide, AmI_2, and americium(II) bromide, $AmBr_2$, are known. In addition to solutions of americium(III), solutions and solid compounds of americium(IV), (V), and (VI) are known. For the +5 and +6 states, however, only two ions have been found. There is no evidence for the existence of americium(VII) in basic solutions; it appears to be much less stable than either neptunium(VII) or plutonium(VII), and no solid compounds of americium(VII) have been made.

Americium(III) forms typical +3 actinide compounds; insoluble hydroxides and fluorides can be prepared from its stable solutions. The only known halide of americium(IV) is the fluoride. An americium(IV) hydroxide also has been made. Several oxides have been prepared. A few salts of americium(V), such as the carbonates, fluorides, and oxalates have been made. For the +6 state, oxides and sodium americyl acetate have been reported. No compound of americium(V) or (VI) has been prepared that is not in the form of the oxygenated ion.

Americium forms a hydride. A few other compounds, such as sulfides, phosphides, and carbides, have been reported, but there has been much less study of americium chemistry than that of the preceding actinides, due in part to the rarity of americium.

Curium. Curium, atomic number 96, has the radon electron core plus ten outer electrons, seven of which are *5f* electrons. Thus, the *5f* orbital is half filled in this element, as the *4f* orbital is in gadolinium.

This electronic configuration is especially stable, and only curium(III) might be expected to exist, as does only gadolinium(III). In fact, however, curium(IV) can be prepared. This is considered to be further evidence that *5f* electrons are more loosely held than are *4f* electrons. No oxidation states higher than curium(IV) are known. Curium(IV) is a strong oxidizing agent.

Almost all of the known chemistry is that of a typical +3 actinide. Curium(III) is the stable state in solution. All of the halides have been prepared, as have hydroxides, fluorides, phosphates, and other compounds. The only two binary compounds of curium(IV) are the tetrafluoride and the dioxide.

A lower oxide is known; it melts at about 2,000° C and may be useful as a thermoelectric-power source. A number of double fluoride salts of alkali metals and curium(IV) have been prepared. The study of curium chemistry is complicated by the short half-lives of the available isotopes, 5 months for curium-242 and 17.6 years for curium-244, and by the rarity of the element.

Berkelium. Berkelium, atomic number 97, has the radon electron core plus 11 outer electrons, eight of which are *5f* orbital electrons, one more than that of the half-filled shell of curium. Berkelium might be expected to have a +3 state and, due to the stability of the half-filled shell, might also be expected to lose one more electron to form a +4 state. In fact, both +3 and +4 states are found. The upper state is a quite strong oxidizing agent, but it is sufficiently stable to occur both in solution and in the solid state. All of the berkelium(III) halides have been synthesized, but the only berkelium(IV) halide known is the tetrafluoride. Without doubt, a number of complex fluorides with alkali metals can be prepared. Both the sesquioxide and the dioxide have been identified. The chemical behaviour of berkelium is that of a typical actinide capable of existing in +3 and +4 oxidation states.

Californium. Californium, atomic number 98, has the radon core plus 12 electrons, ten of which are *5f* electrons. In solution, californium(III) is the only oxidation state found. Californium(IV) fluoride, however, has been prepared by the use of fluorine, and oxygen under high pressure has furnished the dioxide; these are the only californium(IV) compounds known. A few californium(III) compounds have been studied, such as the trichloride, the oxychloride, and the trioxide. Apparently californium(III) and californium(IV) behave as typical actinides in the +3 and +4 oxidation states. Compounds containing californium(II) that had been prepared by the early 1970s included the iodide, CfI_2, and the bromide, $CfBr_2$.

Einsteinium. Einsteinium, atomic number 99, has the radon electron core plus 13 electrons; 11 of these are in the *5f* orbital. Very little of its chemistry has been explored, but evidence points to the existence of einsteinium(III) as the stable state, both in solution and in solids. The trichloride and the oxychloride have been reported. The alpha particles emitted by the isotope einsteinium-253 available for these studies tear the crystals apart so that no X-ray diffraction lines are obtained at room temperature. It was found necessary to heat the crystals to about 400° C so that the disruption was healed continuously by crystallization processes before meaningful data could be obtained. The oxide of Es(III), Es_2O_3, has been prepared and identified by electron diffraction. Einsteinium(II) was shown by spectroscopic means to be present within a crystal of calcium fluoride. There is some evidence that einsteinium(II) can be prepared from aqueous solution as amalgams with alkali metals. There is no evidence for einsteinium(IV) or higher states, but, as of the early 1970s, little research in this direction had been carried out.

Fermium. Fermium, atomic number 100, has 14 outer electrons, of which 12 are in the *5f* orbital. The order in which fermium comes off an ion-exchange column is the best proof of the existence of fermium(III). The lanthanide and actinide elements are routinely separated by this procedure, and the order in which they are separated depends in part on their oxidation states. No compounds of the element have been made. There is evidence for the existence of fermium(II) based on alkali metal-amalgam reductions in solution. No other chemistry is known, and, due to the element's rarity, little more is expected to be known soon.

Mendelevium. Mendelevium, atomic number 101, possesses 13 electrons in the *5f* orbital, one less than the completed shell. The chemical knowledge of mendelevium is based almost entirely on its behaviour in ion exchange separations, in which it acts as a typical +3 actinide. Sodium amalgam reduction experiments suggest a quite stable +2 state, which can be prepared rather easily from the +3 state. There are no known compounds of mendelevium, and due to the short half-lives of the isotopes, none can be identified.

Nobelium. Nobelium, atomic number 102, has a completed *5f* orbital containing 14 electrons. Even less of its chemistry is known than that of mendelevium. Two oxidation states, +2 and +3, have been shown to exist. Nobelium(II) is believed to be the stable state in solution—in the absence of any but the strongest oxidizing agents. That this should be the only actinide element with an extremely stable divalent state is quite in line with the trend toward increasing stability of lower valence states with increasing atomic number. The lanthanide analogue of nobelium, ytterbium, also forms a stable +2 state.

Lawrencium. Lawrencium, atomic number 103, is the last of the actinide elements; it has a completed *5f* orbital containing 14 electrons. Its known isotopes are so unstable that the chemical behaviour of lawrencium is largely conjectural; its ion-exchange behaviour suggests that it is a typical +3 actinide. Different valence states may exist in solid compounds, but probably not in solution.

Acton, Lord

An English moralist and historian who, though Catholic by tradition and inclination, was deeply opposed to the doctrine of papal infallibility as formulated by the Vatican Council of 1870, John Emerich Edward Dalberg Acton propounded an austerely liberal philosophy, in which was, nevertheless, present an awareness of the threats to liberty contained in state and society.

By courtesy of the National Portrait Gallery, London

Acton, oil painting by Franz von Lenbach (1836–1904). In the National Portrait Gallery, London.

A stern critic of nationalism, his liberalism was rooted in Christianity. "I fully admit that political Rights proceed directly from religious duties, and hold this to be the true basis of Liberalism." For him, conscience was the fount of freedom, and its claims were superior to those of the state. "The nation is responsible to Heaven for the acts of the State." If democracy could not restrain itself, liberty would be lost. The test of a country's freedom was the amount of security enjoyed by minorities. For Acton, in his judgment of politics as of history, morality was fundamental. He was the great modern philosopher of resistance to the evil state.

Civilized, cosmopolitan, rich, learned, and widely connected, he is remembered as much for his few historical writings as for his prescient concern with the problems of political morality.

Acton was born in Naples on January 10, 1834, the only son of Sir Ferdinand Richard Edward Acton (1801–37) by his marriage to Marie Louise Pelline von Dalberg, heiress to a very respectable German title.

In 1840 his widowed mother married Lord Leveson, the future Lord Granville and Liberal foreign secretary, an alliance that brought Acton early into the intimate circle of the great Whigs. Educated at Oscott College, Warwickshire, he went to Munich to study under the German Catholic Church historian Johann Joseph Ignaz von Döllinger, who grounded him in the new German methods of historical research.

Early training in historical research

Having spent much time in the United States and Europe, he returned to England, settled at the family seat in Aldenham, Shropshire, and was elected to the House of Commons for Carlow, Shropshire, in 1859. In the same year he became editor, following John Henry Newman, of the Roman Catholic monthly the *Rambler*, but this experience was unfortunate. He himself believed that a rigorously scientific history would ultimately strengthen the church and that Christian doctrine would be harmonized with the findings of history. When Pius IX indicated that it was wrong, though not heretical, to reject the opinion of the Roman congregations, Acton did not dispute the Pope's authority but held that it condemned the intellectual independence of his journal (by then called the *Home and Foreign Review*) and so laid down the editorship in 1864. Though he was no upholder of the papacy's temporal power and was ready to denounce its unfortunate effects on the course of history, he was firmly attached to Catholicism: unlike Döllinger, he remained faithful to the Catholic Church after 1870. He regarded "communion with Rome as dearer than life."

His parliamentary career had ended in 1865—he was an almost silent member—but his friendship with William Gladstone, the Liberal leader and prime minister, was of great consequence for the minds of both men. The poet and educationist Matthew Arnold used to say that "Gladstone influences all around him but Acton; it is Acton who influences Gladstone." He claimed, in fact, to be the author of the Home Rule policy for Ireland.

Acton was raised to the peerage on Gladstone's recommendation in 1869, and in 1892 Gladstone repaid his services as adviser by having him made a lord-in-waiting to Queen Victoria.

In 1865 he married Marie von Arco-Valley, daughter of a Bavarian count, by whom he was to have one son and three daughters.

After 1870 Acton wrote little, his only notable publications being a masterly essay in the *Quarterly Review* (January 1878) on "Democracy in Europe"; two lectures delivered at Bridgnorth in 1877 on *The History of Freedom in Antiquity* and *The History of Freedom in Christianity* (both published in 1907)—these last the only tangible portions put together by him of his long-projected "History of Liberty"—and an essay on modern German historians in the first number of the *English Historical Review*, which he helped to found (1886). In 1895, on the death of Sir John Seeley, the prime minister Lord Rosebery had him appointed to the regius professorship of modern history at Cambridge. His inaugural *Lecture on the Study of History* (published in 1895) made a great impression in the university, and his influence on historical study was felt. He delivered two valuable courses of lectures, on the French Revolution and on modern history, but it was in private that the influence of his teaching was most marked.

His influence as a lecturer in history

In 1899 and 1900 he devoted much of his energy to coordinating the project of *The Cambridge Modern History*, a monument of objective, detailed, collaborative scholarship.

His efforts to secure, direct, and coordinate contributors for the project exhausted him. Suffering from the effects of a paralytic stroke that he had suffered in 1901, Acton withdrew to a Bavarian property belonging to his wife's family at Tegernsee. He died there on June 19, 1902.

His life, as stated in his own words, "is the story of a man who started in life believing himself a sincere Catholic and a sincere Liberal; who therefore renounced everything in Catholicism which was not compatible with Liberty and everything in Politics not compatible with Catholicism."

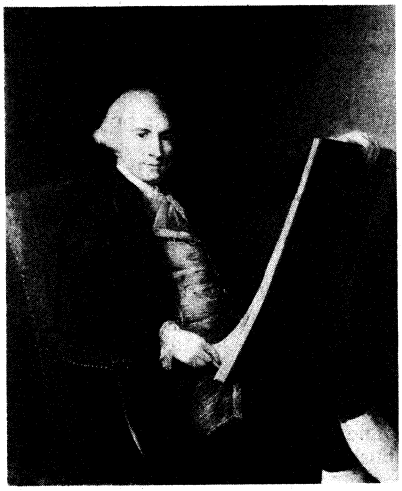
Adam, Robert



One of the greatest British architects of the 18th century and the originator of the delicate neoclassical Adam style of decoration, Robert Adam was born at Kirkcaldy, Fifeshire, Scotland, on July 3, 1728, the second son of William Adam, the foremost Scottish architect of his time. William, who as Master Mason to the Ordnance in North Britain supervised the design of military buildings, also designed numerous country houses in a conservative Palladian style—the modified classic Roman style that was originally developed by the 16th-century architect Andrea Palladio.

Early life

The Adam children grew up in the cultured atmosphere

of a propertied and well-connected 18th-century family. Shortly after Robert's birth, the family moved to Edinburgh, where, at the age of six, he entered the Edinburgh High School. In 1743 he enrolled at Edinburgh College (now University of Edinburgh), but in 1745 he abandoned his studies and the following year entered his father's offices as an apprentice and assistant.

By courtesy of the National Portrait Gallery, London

Adam, oil painting by an unknown artist. In the National Portrait Gallery, London.

William Adam died in 1748, and his post as Master Mason to the Board of Ordnance passed to his eldest son, John, who took Robert into partnership; and in the succeeding few years both benefitted from the lucrative contracts that resulted from the appointment. Besides building Ft. George in the Moray Firth near Inverness, the Adam brothers were also engaged on another important assignment—the completion of the interior of the Earl of Hopetoun's house. In their interiors, the brothers introduced into Scotland a new, lighter, almost Rococo, style of decoration. The other important private commission of these years was Dumfries House, Ayrshire, for Lord Dumfries.

European influences

In 1754 Robert, who by then considered himself to be worth £5,000, was invited to accompany the Honourable Charles Hope, the Earl's younger brother, to Italy. He thus had the opportunity to realize the dream he had been saving for since his father's death, and, just as important, he had the social advantages of travelling with the brother of an earl. He was as much concerned with meeting young noblemen abroad as with acquiring more architectural knowledge from a study of the monuments of Roman antiquity. The letters he wrote to his family during his years abroad give a picture of Robert as a madly ambitious young man, an arrogant social climber, and yet still a dedicated artist.

He met Charles Hope in Brussels, and together they proceeded to Paris, where Robert fitted himself out in the latest fashions and set out to "lay in a stock of good acquaintance that may be of use to me hereafter." After fewer than three weeks in Paris, they set off for Italy by way of the south of France, visiting en route the Roman sites of Nîmes, Arles, the Pont du Gard, and Montpellier. They reached Genoa early in January 1755 and proceeded to Florence via Leghorn. Arriving at the end of the month, they were immediately caught up in the social whirl for which Robert had hoped.

While he was in Florence Robert made the acquaintance of a man who was to have an important professional influence upon him. This man was the talented young French architect and draftsman Charles-Louis Clérisseau, who agreed to accompany him on his tour as instructor and draftsman. Clérisseau had been a student at the French Academy in Rome but had left in 1754 after a dispute with its director. As a result of his friendship with Clérisseau, Robert came in contact with avant-garde architectural theory in Rome. "I hope," he wrote, "to have my ideas greatly enlarged and my taste formed upon the solid foundation of genuine antiquity." Clérisseau agreed to

> serve [him] as an antiquarian . . . teach [him] perspective and drawing . . . [and] give [him] copies of all [Clérisseau's] studies of the antique, bas-reliefs and other ornaments . . . .

Adam left Florence in February 1755 and travelled to Rome, where he had to decide whether to devote himself to elegant society or to architecture

> If I am known in Rome to be an architect, if I am seen drawing or with a pencil in my hand, I cannot enter into genteel company who will not admit an artist or, if they do admit him, will very probably rub affronts on him in order to prevent his appearing at their card-playing, balls and concerts.

He had to decide: "Shall I lose Hope and my introduction to the great, or shall I lose Clérisseau and my taste for the grand?"

He quarrelled with Hope, and the two separated. Taking rooms for himself and Clérisseau, Robert settled down to serious study, visiting, sketching, and measuring the monuments of antiquity. Among the important figures he met in Rome were the art collector Cardinal Albani and the engraver Giambattista Piranesi, who dedicated an engraving and a book to him.

In May 1757 Adam and Clérisseau left Rome and travelled to Dalmatia via Venice to visit the ruins of Diocletian's palace at Spalatro (Split). Adam felt he

> could not help considering my knowledge of Architecture as imperfect, unless I should be able to add the observation of a private edifice of the Ancients to my study of their public works.

They spent five weeks at Spalatro, preparing the drawings that were eventually to be published in 1764 as the *Ruins of the Palace of the Emperor Diocletian at Spalatro in Dalmatia.*

Having nearly exhausted his money and anxious to return to England, Robert had to forgo the pleasures of further expeditions to Greece and Egypt. He returned to London in January 1758, his head full of details of Roman antiquities. The current Palladian style was losing its appeal, and the public was ready for a new architectural style. Adam lost no time in making his reputation, and by the mid 1760s he had, with the help of his younger brother James, who joined him in London in 1763, created and fully developed the Adam style. That style, which he and James later claimed had "brought about, in this country . . . a kind of revolution in the whole system of this useful and elegant art," was marked by a then new lightness and freedom in the use of the classical elements of architecture. In the Royal Society of Arts building (1772–74), for instance, Adam combined an Ionic pilaster—a rectangular column with scroll-like ornaments projecting from a wall—with a Doric entablature —the upper section of a wall designed in the oldest, simplest Greek style, a liberty a Palladian would never have dared take. This new style consisted basically of a fresh combination of many architectural elements. The various influences included the Palladianism of Lord Burlington and William Kent, both architects; the movement and vigour of the architecture of Sir John Vanbrugh; contemporary French influence, discernible particularly in details, planning, and furniture design; Roman archaeological influences; and the influence of Italian Renaissance decoration, particularly the fanciful ornamentation of the 16th century. Adam's genius was thus a result not of isolated influences but of the synthesis of various lines of development. The Adam style was essentially a decorative style, and it is as a designer of interiors that Adam is chiefly remembered. He gave meticulous attention to every part of each room, from the carpets to the most unobtrusive decoration.

The Adam style

Robert's first important work in London was the Admiralty Screen (1758). Through the influence of Lord Bute, a friend of the King, he was appointed Architect of the King's Works in November 1761 along with Sir William Chambers, his principal architectural rival. By the early 1760s he had many domestic commissions; almost without exception these consisted of the completion

First work in London

or redecoration of earlier houses. It was ironic that despite his fame and ability Adam was rarely called upon to build completely new houses, nor was he to realize his grandiose ideas for public buildings until the very end of his life.

The first Adam interiors at Hatchlands, Surrey (1758–61), and Shardeloes, Buckinghamshire (1759–61), were still near-Palladian in style. But by 1761 his mature style was beginning to develop, and important commissions from this time include Harewood, Yorkshire; Croome Court, Worcestershire; Kedleston Hall, Derbyshire; Bowood, Wiltshire; and Osterley Park, Middlesex. In 1762 he was employed to redesign the interior of Syon House, Middlesex.

Robert produced an important plan that proposed filling an old centre court with a vast domed pantheon-like hall; it was never executed, however. The entrance hall of Syon, based on a basilica—a rectangular building divided into three areas by two rows of columns—with its half-domed ends, is one of the most significant Neoclassical interiors in England.

Other houses from this early phase include the first completely new house, Mersham-le-Hatch, Kent (1762–72); Lansdowne House, Berkeley Square, London (1762–68); Luton Hoo, Bedfordshire (1766–75); Newby Hall, Yorkshire (*c.*1767–85); and Kenwood, London (1767–68).

The south front of Kedleston Hall provides an example of Adam's exterior treatment. His theme of a triumphal arch as the exterior expressions of the great domed interior hall is the first use of this particular Roman form in domestic architecture. The double portico (an open space created by a roof held up by columns) at Osterley Park, derived from the Portico of Octavia, Rome, is a similar Neoclassical motif.

In 1768 Robert and James Adam leased a site on the Thames for a speculative development to be known as the Adelphi (it was almost totally destroyed in 1936). They invested a large sum on embanking the site and building several terraces of houses (1768–72) in which the Adam interior style of slim pilasters supporting a shallow frieze and cornice—the middle and uppermost sections of an entablature—was brought out of doors. It was, however, a financial disaster. In 1773 they again speculated unsuccessfully in a group of stuccoed terraces in Portland Place, London.

The Adams built three major London houses in the early 1770s, which were superb examples of their mature style—No. 20, St. James's Square for Sir Watkin Williams-Wynn (1772–74); No. 20, Portman Square for the Countess of Home (1775–77; now the Courtauld Institute of Art); and Derby House in Grosvenor Square for the Earl of Derby (1773–74; demolished 1862).

In 1773 they published the first volume of *The Works in Architecture of Robert and James Adam.* A second volume followed in 1779, a third was published posthumously in 1822. In the preface to the first volume they explain their idea of "movement," an essential aspect of the Adam style:

> *Movement* is meant to express, the rise and fall, the advance and recess, with other diversity of form, in the different parts of a building, so as to add greatly to the picturesque of the composition.

By 1780 Robert Adam's popularity was beginning to decline, and Horace Walpole, after visiting the architect Henry Holland's new Carlton House, wrote, "How sick one shall be, after this chaste palace, of Mr. Adam's gingerbread and sippets of embroidery."

Neo-Gothic work

Robert Adam designed and built a number of romantic Neo-Gothic castles, mostly dating from the 1780s, in Scotland. The most important of the castles is Culzean, Ayrshire, for the earls of Cassilis (1777–90). Another important work in the Gothic style was the interior at Alnwick Castle, Northumberland (*c.* 1770–80; destroyed in the 19th century).

Toward the end of his life, Robert built the Register House, Edinburgh (1772–92), in which he at last realized the conception of a monumental domed hall within a square, envisaged at Syon some years earlier; and in 1789 he designed the University of Edinburgh, whose entrance front is perhaps his most successful exterior. At Fitzroy Square, London (1790), and Charlotte Square, Edinburgh (1791), he experimented for the last time with the introduction of movement into street architecture.

As a designer of furniture, Adam played a leading role. The furniture style he evolved, popularized by the cabinetmaker George Hepplewhite, was always meant to harmonize with the rest of the interiors. In this field, too, he was prolific, turning his hand to everything from organ cases and sedan chairs to saltcellars and door fittings. It is one of the outstanding features of an Adam interior that everything, even the smallest detail, was part of the unified scheme created by the architect.

Robert Adam died on March 3, 1792, and was buried in Westminster Abbey. The bulk of the nearly 9,000 drawings he left were purchased by the architect Sir John Soane in 1833 and are now in the Soane Museum, London.

MAJOR WORKS

PUBLIC BUILDINGS: Screen wall to the Admiralty, London (1760; mutilated 1827, since restored); Gunton Church, Norfolk (1769); Pulteney Bridge, Bath, Somerset (1769–74); Chandos House, Portland Place, London (1770–71); Royal Society of Arts, London (1772–74); Register House, Edinburgh (1772–92); Mistley Church, Essex (1776; demolished except for twin towers, 1870); Portland Place, London (1776–*c.* 1780; partly rebuilt or demolished).

COUNTRY HOUSES: Shardeloes, Buckinghamshire, portico, interior decorations, and stables (1759–61); Harewood House, Yorkshire, modified John Carr's designs and designed the interiors (1759–71; house much altered, 1843–50); Osterley Park, Middlesex, remodelling of interior (1761–80); Syon House, Middlesex, remodelling of interior (1762–69); Mersham-le-Hatch, Kent (1762–72); Kedleston Hall, Derbyshire (*c.* 1765–70); Luton Hoo, Bedfordshire (1766–75; altered *c.* 1816; reconstructed after a fire in 1843); Nostell Priory, Yorkshire, redecoration (1766–85); Kenwood House, Hampstead, London, remodelling (1767–68); Newby Hall, Yorkshire, added porch and wings and remodelled library (*c.* 1767–85); Saltram House, Devon, decoration (1768 and 1779); Culzean Castle, Ayrshire (1777–90).

TOWN HOUSES: Lansdowne House, Berkeley Square, London (1762–68); Adelphi Buildings, Strand, London (1768–72, demolished); 20, St. James's Square, London (1772–74); Derby House, Grosvenor Square, London (1773–74, demolished); Home House, 20, Portman Square, London (1775–77).

WRITINGS: *Ruins of the Palace of the Emperor Diocletian at Spalatro in Dalmatia* (1764); *The Works in Architecture of Robert and James Adam,* 3 vol. (1773–1822).

BIBLIOGRAPHY. A.T. BOLTON, *The Architecture of Robert and James Adam,* 2 vol. (1922), the standard work on the subject, with comprehensive lists of works and many illustrations; JOHN FLEMING, *Robert Adam and His Circle* (1962), an excellent biographical work based on original letters; EILEEN HARRIS, *The Furniture of Robert Adam* (1963), the best and most complete account of Adam's activity as a furniture designer; DAMIE STILLMAN, *The Decorative Work of Robert Adam* (1966), an account of Adam's work in the field of interior decoration, well-illustrated with original drawings; DOREEN YARWOOD, *Robert Adam* (1970), a popular and often incorrect recent biography concentrating on Adam the man rather than the artist.

(S.Mi.)

Adams, Henry

An American historian, novelist, and man of letters, Henry Adams is the author of one of the outstanding autobiographies in Western literature and a towering figure in 19th-century American intellectual history. Belonging to a patrician family of statesmen and scholars, he felt out of place amid the modern egalitarian and technological forces that were transforming Western society at the end of the 19th century.

Henry Brooks Adams, born in Boston on February 16, 1838, was the product of that city's Brahmin class, a cultured elite that traced its lineage to Puritan New England. He was the great-grandson of John Adams and the grandson of John Quincy Adams. The Adams family tradition of leadership was carried on by his father, Charles Francis Adams (1807–86), a diplomat, historian, and congressman. His younger brother, Brooks (1848–

Henry Adams.

1927), was also a historian; his older brother, Charles Francis, Jr. (1835–1915), was an author and railroad executive. Through his mother, Abigail Brown Brooks, Adams was related to one of the most distinguished and wealthiest families in Boston. Tradition ingrained a deep sense of morality in Adams. He never escaped his heritage and often spoke of himself as a child of the 17th and 18th centuries who was forced to come to terms with the new world of the 20th century.

Adams was graduated from Harvard in 1858 and, in typical patrician fashion, embarked upon a grand tour of Europe in search of amusement and a vocation. Anticipating a career as an attorney, he spent the winter of 1859 attending lectures in civil law at the University of Berlin. With the outbreak of the U.S. Civil War in 1861, Pres. Abraham Lincoln appointed Adams' father minister to England. Henry, age 23, accompanied him to London, acting as his private secretary until 1868.

Career as a correspondent

Returning to the United States, Adams travelled to Washington, D.C., as a newspaper correspondent for *The Nation* and other leading journals. He plunged into the capital's social and political life, anxious to begin the reconstruction of a nation shattered by war. He called for civil service reform and retention of the gold standard. Adams wrote numerous essays exposing political corruption and warning against the growing power of economic monopolies, particularly railroads. These articles were published in *Chapters of Erie and Other Essays* (1871). The mediocrity of the nation's "statesmen" constantly irritated him. Adams liked to repeat Pres. Ulysses S. Grant's remark that Venice would be a fine city if it were drained.

Adams continued his reformist activities as editor of the *North American Review* (1870–76). Moreover, he participated in the Liberal Republican movement. This group of insurgents, repelled by partisanship and the scandals of the Grant administration, bolted the Republican Party in 1872 and nominated the Democrat Horace Greeley for president. Their crusade soon foundered. Adams grew disillusioned with a world he characterized as devoid of principle. He was disgusted with demagogic politicians and a society in which all became "servant[s] of the powerhouse." Americans, he wrote, "had no time for thought; they saw, and could see, nothing beyond their day's work; their attitude to the universe outside them was that of the deep-sea fish." His anonymously published novel *Democracy, an American Novel* (1880) reflected his loss of faith. The heroine, Madeleine Lee, like Adams himself, becomes an intimate of Washington's political circles. As confidante of a Midwestern senator, Madeleine is introduced to the democratic process. She meets the President and other figures who are equally vacuous. After her contact with the power brokers, Madeleine concluded: "Democracy has shaken my nerves to pieces."

In 1870 Charles W. Eliot, president of Harvard College, appointed Adams professor of medieval history. He was the first American to employ the seminar method in teaching history. In 1877 he resigned to edit the papers of Thomas Jefferson's treasury secretary, Albert Gallatin. Pursuing his interest in U.S. history, Adams completed two biographies, *The Life of Albert Gallatin* (1879) and *John Randolph* (1882). He continued to delve into the nation's early national period, hoping to understand the nature of an evolving American democracy. This study culminated in his nine-volume *History of the United States of America* during the administrations of Jefferson and Madison (1889–91), a scholarly work that received immediate acclaim. In this work he explored the dilemma of governing an egalitarian society in a political world in which the predominant tendency was to aggrandize power. In 1884 Adams wrote another novel, *Esther*. Published under a pseudonym, *Esther* dealt with the relationship between religion and modern science, a theme that engaged Adams throughout his life.

His nine-volume history of the United States

Adams was stunned when, in 1885, his wife of 13 years, Marian Hooper, committed suicide. Distraught, he arranged for the sculpture of a mysterious, cloaked woman to be placed upon her grave. The union had produced no children, and Adams never remarried. After his wife's death, Adams began a period of restless wandering. He travelled the globe from the South Sea islands to the Middle East. Gradually the circuit narrowed to winters in Washington and summers in Paris.

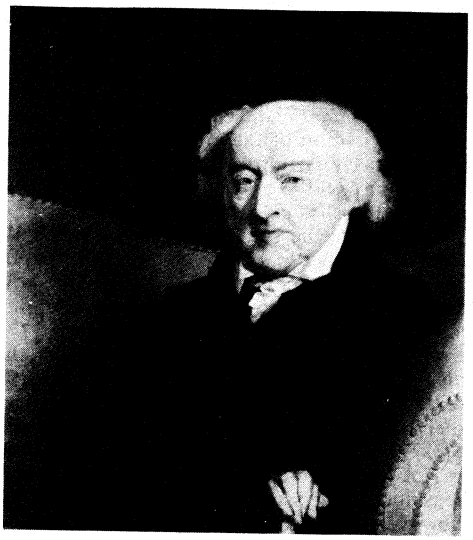
Though Adams referred to his existence during this period as that of a "cave-dweller," his life was quite the opposite. From the 1870s until his last years, intellectuals gravitated to his home to discuss art, science, politics, and literature. Among them were the British diplomat Sir Cecil Arthur Spring-Rice, the architect Henry Hobson Richardson, and Sen. Henry Cabot Lodge. His closest friends were the geologist Clarence King and the painter John La Farge. Adams, King, and La Farge were inseparable. Their letters remain a rich source of information on everything from gossip to the most current trends of thought.

While in France, Adams pushed further into the recesses of history in search of "a fixed point . . . from which he might measure motion down to his own time." That point became medieval Christendom in the 13th century. In *Mont-Saint-Michel and Chartres* (printed privately, 1904; published, 1913) he described the medieval world view as reflected in its cathedrals. These buildings, he believed, expressed "an emotion, the deepest man ever felt—the struggle of his own littleness to grasp the infinite." Adams' attraction to the Middle Ages lay in the era's ideological unity; a coherence expressed in Catholicism and symbolized by the Virgin Mary.

The autobiography

The Education of Henry Adams (printed privately, 1907) was a companion volume to *Chartres*. The *Education* remains Adams' best known work and one of the most distinguished of all autobiographies. In contrast to *Chartres*, the *Education* centred upon the 20th-century universe of multiplicity, particularly the exploding world of science and technology. In opposition to the medieval Virgin, Adams saw a new godhead—the dynamo—symbol of modern history's anarchic energies. The *Education* recorded his failure to understand the centrifugal forces of contemporary life. The book traced Adams' confrontations with reality as he moved from the custom-bound world of his birth into the modern, existential universe in which certainties had vanished. The *Education* was published posthumously in 1918.

Neither history nor education provided an answer for Henry Adams. Individuals, he believed, could not face reality; to endure, one adopts illusions. His attempt to draw lines of continuity from the 13th to the 20th centuries ended in futility. "All he could prove," Adams concluded, "was change."



In 1908 Adams edited the letters and diary of his friend John Hay, secretary of state from 1898 to 1905. His last book, *The Life of George Cabot Lodge*, was published in 1911. In two speculative essays, "Rule of Phase Applied to History" (1909) and *Letter to American Teachers*

of History (1910), Adams calculated the demise of the world. Basing his theory on a scientific law, the dissipation of energy, he described civilization as having retrogressed through four stages: the religious, mechanical, electrical, and ethereal. The cataclysm, he prophesied, would occur in 1921. How literally Adams intended his prediction remains a point of dispute.

In 1912, at the age of 74, Adams suffered a stroke. His haunting fear of senility became real for a short time. For three months he lay partially paralyzed, his mind hovering between reason and delirium. He recovered sufficiently, however, to travel to Europe once again. On March 27, 1918, Adams died in his sleep in his Washington home and, according to his wish, was buried next to his wife in an unmarked grave. In 1919 he was posthumously awarded a Pulitzer Prize for the *Education*.

Assessment

Adams is noted for an ironic literary style coupled with a detached, often bitter, tone. These characteristics have led some critics to view him as an irascible misfit. They contend that his fascination with the Middle Ages and his continuous emphasis upon failure were masks behind which he hid a misanthropic alienation from the world. More sympathetic commentators see Adams as a romantic figure who sought meaning in the chaos and violence of the 20th century. As Adams described it, he was in pursuit of ". . . a world that sensitive and timid natures could regard without a shudder."

BIBLIOGRAPHY. HENRY ADAMS, *The Degradation of the Democratic Dogma* (1919, reprinted 1969), a collection of Adams' theoretical essays with a lengthy introduction by his brother Brooks; "The Great Secession Winter 1860–1861," *Proceedings*, Massachusetts Historical Society, 43:656–687 (1909–10), an essay, written during the secession crisis of 1860–61 but not published for 50 years, which analyzed the political developments that led to the Civil War; *Essays in Anglo-Saxon Law* (1876), a collection of studies in early British history written by Adams and his seminar students; *Historical Essays* (1891), a reprint of articles Adams had previously published in various journals; and introductions to *Documents Relating to New England Federalism* (1877), which shed light on the politics of the early national period; WORTHINGTON CHAUNCEY FORD (ed.), *A Cycle of Adams Letters, 1861–1865*, 2 vol. (1920, reprinted in 1 vol. 1969), *Letters of Henry Adams, 1858–1891* (1930, reprinted 1969), and *Letters of Henry Adams, 1892–1918* (1938, reprinted 1969), all contain a rich selection of Adams' letters; ERNEST SAMUELS, *The Young Henry Adams* (1948), *Henry Adams: The Middle Years* (1958), and *Henry Adams: The Major Phase* (1964), the most comprehensive and distinguished biography of Adams; J.C. LEVENSON, *The Mind and Art of Henry Adams* (1957), an unexcelled interpretative work centring upon both the man and his writings; WILLIAM H. JORDY, *Henry Adams: Scientific Historian* (1952), focussed upon Adams' scientific approach and his quest for a historical synthesis; MELVIN LYON, *Symbol and Idea in Henry Adams* (1970), an examination of the problem of illusion and reality, which Adams often expressed through symbols, as seen in his six major works; VERN WAGNER, *The Suspension of Henry Adams: A Study of Manner and Matter* (1969), a discussion of Adams' writing style as an example of unique literary artistry; FREDERIC COPLE JAHER, *Doubters and Dissenters: Cataclysmic Thought in America, 1885–1918* (1964), a critical study of Adams, seeing him as a displaced Brahmin afloat in an industrialized world he was helpless to understand.

(C.McH.)

Adams, John

The first vice president and the second president of the United States, John Adams played a major role in the entire Revolutionary movement—as an aggressive delegate from Massachusetts to the Continental Congress from 1774 to 1778, as a learned advisor and drafter of new state constitutions after 1776, and as a blunt but effective diplomat who helped the 13 American Continental Colonies to secure peace and independence from Britain in 1783. Elevated to high political office in later years, he remained a nonpolitical politician, who remained blind to the relevance of political parties or to any kind of opposition. In his opinion, only the proper organization of government through a system of checks and balances could prevent tyranny, which he identified with the "democracy" of the French Revolution. His belief in his own political rectitude and his love of books, if not his robust love of husbandry, were inherited by his eldest son, John Quincy Adams, who became the sixth president of the U. S.

Youth. John Adams was born on October 30, 1735 (new style), the eldest of three sons of Deacon John Adams, a farmer and selectman, and Susanna Boylston of Braintree, Massachusetts. There he grew up, relishing all the outdoor joys of boyhood, and was educated for college. After graduating in 1755 from Harvard, he studied law in Worcester from 1756 to 1758 in the office of James Putnam, a sophisticated and learned man, in whose household he lived while teaching in the local grammar school. Having returned to Braintree in 1758 and been admitted to the Boston bar, Adams in 1764 married Abigail Smith, a minister's daughter of neighbouring Weymouth who had important family connections that were to benefit his practice.

Intelligent, vivacious, and witty, Abigail composed brilliant letters that together with an uninhibited diary kept by Adams reveal the earthy culture of the New England countryside of the late 18th century and its avidity for manners and learning. In this remarkably self-revealing diary, Adams exhibits a notable talent for the delineation of character in others. A bundle of contradictions himself, he was sometimes outspoken to the point of rudeness, but at other times, scholarly and urbane; irascible, jealous, and suspicious, he was also often playful and tender.

Career as a lawyer in Braintree

As a young lawyer Adams was not only proud of his learning but apparently ambitious of seeing himself in print. In this he succeeded in 1763 by making contributions simultaneously to different newspapers, so that, as has been remarked, "he was carrying on a dialogue with himself in the two leading Boston papers." This was at the time when "sides" were beginning to be formed in Massachusetts politics, the radical wing of colonial opposition to British measures being led by James Otis, Jr., a popular leader at the bar. Adams had long admired Otis, particularly his eloquent defense of the rights of the colonists in the Writs of Assistance case (1761), in which he argued the unconstitutionality of any writ that entitled customhouse officers to search colonists' homes for smuggled goods without specific evidence. Adams remembered this issue in his old age as the one that signalled the opening of the contest with Britain. Doubtless his recollection of the incident was somewhat dramatized, but it inspired him with zeal for the cause of the patriots, and there can be no doubt about his own vigorous and learned participation in the crisis four years later over the Stamp Act, a British revenue law that required publications and documents in the American colonies to bear a stamp. Although he opposed the riots associated with

the act, he regarded it as illegal because the colonists had not consented to it. This argument resulted in his famous articles in the *Boston Gazette*, beginning in August 1765, which were reprinted in London in 1768 as *A Dissertation On the Canon and Feudal Law*. The *Dissertation* argued that the opposition of the New England colonies to the Stamp Act was a part of the protest of New World individualism against Old World collective authority. In 1768 Adams moved his family from Braintree to Boston, where he proudly wore the robes of a barrister recently introduced into the practice of the Superior Court by Chief Justice Thomas Hutchinson (1711–80), later governor of Massachusetts, a man for whom Adams, somewhat paradoxically, bore the utmost dislike. In 1770 Adams courageously participated in the defense of the British soldiers accused of murder in the so-called Boston Massacre. Attempting to maintain order and to enforce the Townshend Acts, which imposed import duties on glass, lead, tea, paper, and paint, the soldiers became involved in a riot that resulted in the deaths of five persons. Public sentiment was strongly against the accused. The trial, however, resulted in the acquittal of the commanding officer and most of the soldiers.

Adams' public career received a temporary setback in 1771. His law practice had recently been enlarged to the point where he had to hire two clerks, but, suffering a brief relapse in health and spirits, he moved back to Braintree and made a long horseback trip "to take the waters" at Stafford Springs. Apparently much improved, he returned to Boston in 1772 to earn a living for his growing family, a girl born in 1765 and his first son, John Quincy, in 1767. His private interests, however, were soon again being sacrificed to public ends, for he was elected to serve in the Massachusetts House of Representatives.

Continental Congress. In August 1774, Adams journeyed to Philadelphia with the Massachusetts delegation to the First Continental Congress, the first federal legislature of the 13 American colonies. Entries in his diary give a rare insight into the composition of that memorable body, which clearly yielded to the radicals in giving first place to grievances rather than to plans for reconciliation with Britain. Here, Adams served as an outspoken but shrewd member for three stormy years. Meantime, in early 1775 he published letters in the *Boston Gazette* under the pseudonym Novanglus, which were rebuttals to letters by the Loyalist writer Daniel Leonard, or "Massachusettensis." Novanglus, not unlike Thomas Jefferson in his "Summary View" of the previous year, emphasized an advanced stage in revolutionary thought: that the colonies having always been outside the realm had never properly been subject to imperial control by Parliament.

Only the personal tie with the sovereign now remained, and this Adams proceeded to sever. In the Second Continental Congress, in June 1775, he nominated George Washington of Virginia to be commander in chief of the almost nonexistent army, a move that he hoped would gain Virginia's support for the Revolutionary policies. A year later, he seconded the resolution of Richard Henry Lee of Virginia "that these United Colonies are, and of a right ought to be, free and independent States" and on June 11, 1776, was appointed to serve on a committee to draft a declaration of independence. Written primarily by Thomas Jefferson, the Declaration was defended on the floor of Congress primarily by Adams. Meanwhile, he had had altercations with some of the more conciliatory members of that body, notably with John Dickinson of Delaware, whom he had described in an imprudent letter, captured and gleefully published by the British, as a "piddling genius." His dislike of hesitant congressmen was accompanied by mixed feelings about a newly arrived journalist, Thomas Paine, the Englishman, whose "Common Sense" nevertheless hastened the cause of independence that Adams strongly favoured in 1776. At a time of general confusion, Adams' *Thoughts On Government* were circulated by several of his colleagues for use throughout the colonies in the making of new constitutions. The *Thoughts* embodied for the first time Adams' conviction that the principal functions of government must be separated in order to prevent tyranny.

Defense of the Declaration of Independence

Revolutionary politics. Between 1776 and 1778, Adams divided his time in promoting the Revolutionary cause in his hometown and state and in serving on numerous congressional committees, including one to create a navy and one to review foreign affairs. The Revolutionaries had begun to hope that they could improve their position by involving France with its old enemy, Britain. Late in 1777, Adams was named by Congress to serve with Benjamin Franklin as a joint commissioner to France, replacing Silas Deane, an original American commissioner whose loyalty to the Revolutionary cause had been called into question. Adams sailed on a continental frigate in February, together with his eldest son, 11-year-old John Quincy Adams. In France, he learned that Franklin had already successfully concluded a French alliance, and later in the year, when the joint American commission in France was dissolved, he returned home, leaving Franklin in sole charge. He arrived in America in the summer of 1779, in time to play a major role in the drafting of the most famous of all Revolutionary state constitutions—that of Massachusetts in 1780—along lines that he considered the proper divisions of functions: "that it may be a government of laws and not of men." He reacquainted himself with congressional politics and again found himself the questionable beneficiary of the old quarrel over Deane. Appointed one of the commissioners to negotiate commercial treaties and to make peace with Great Britain, it was clear that Adams' friends in Congress were noticeably not of the "pro-French" faction but advocates of the blunt, frank school of "shirt-sleeve" diplomacy.

Role in the French alliance

Once again he had to set out on a long and perilous journey overseas, again taking John Quincy with him and a younger son, Charles, and again leaving his wife to run the farm at Braintree. It was a major separation in the lives of the Adamses, not to be healed until six years later when Abigail and her 18-year-old daughter sailed to rejoin the family at Auteuil, near Paris. This was after Adams, together with John Jay, one of the peace commissioners appointed by Congress, and Franklin, had helped bring about a final peace with Britain—on favourable terms and in ways not entirely relished by the French allies—and had negotiated several badly needed congressional loans in Holland. In 1785 he was made the first United States minister to the Court of St. James and moved with his family to England.

Foreign service. In middle age John Adams thus entered into what may be called the second major phase of his life, a career in foreign service in which his son and grandson were also one day to win distinction. The transformation of the simple Braintree lawyer into an envoy capable of dealing with experienced European diplomats was, however, less astonishing than it seems. Although his long years of foreign residence were later to influence American public opinion to the effect that the "Duke of Braintree" had become an aristocrat, such vilification was always basically political. John Adams the envoy was essentially the same blunt New Englander he had always been, and what he principally learned abroad between 1778 and 1788 seems to have been to distrust French politics of the Old Régime (preceding the French Revolution of 1789) and the morals of Europeans, generally; neither idea was wholly new.

While minister to Great Britain, and a year before he returned to America, Adams published his *Defence of the Constitutions of Government of the United States of America* (1787), expressing himself strongly along what some people considered to be "aristocratic" lines—as in the suggestion that "the rich, the well-born and the able" would have to compose the upper chamber of a republic if it were to survive. The work was filled with learned and frequently unacknowledged extracts from an awesome range of writers on government and human nature. Yet despite all its pretentiousness, it merely emphasized ideas held by Adams since 1776 at least—that all branches of government should be separated and that the legislature itself should be two-chambered. It was a schol-

ar's view, based more or less upon what the French political philosopher Montesquieu had once understood to be the make-up of the British government and its system of checks and balances. The political reputation of the *Defence* became an important factor in explaining some of the political difficulties experienced by John Adams in later years. More importantly, the first volume of the *Defence* had arrived in America in time to influence the members of the Philadelphia Convention had they so desired. Offended by the aristocratic tone of the work, many electors, in 1789, failed to cast their votes for Adams. While George Washington received the vote of every elector and was thus elected president, Adams received only 34 out of 69, the second largest number, and was thus declared vice president.

Vice presidency

Vice presidency and presidency. The differences of opinion among the members of the new government over the policies to be pursued resulted in the formation of two well-defined political groups: the Federalists—the conservative faction led by Alexander Hamilton, which advocated a strong, centralized government and favoured industry, landowners, and merchants—and the Democratic-Republicans, led by Thomas Jefferson, who emphasized personal liberty and limited powers for the federal government. Adams had been a supporter of the new Federal plan for a republic from the very first, and although he was less conservative than many others in the party, he became one of the leading Federalists. As vice president, moreover, he was to think of himself, somewhat pompously it is true, as a lightning rod for the whole national experiment. He even fancied himself at one time as a "whipping boy" for some of Hamilton's measures, although his agrarian nature eventually rebelled against the consequence of those policies. The newspaper publication of his *Discourses on Davila* alienated Hamilton, who criticized the work for fear it might bring the federal experiment into disrepute, while Jefferson, on the other hand, thought it verged on promulgating a hereditary monarchy and aristocracy. This alleged predilection for a "mix'd monarchy" later influenced opposition to Adams as a Federalist.

It was no doubt symptomatic of a certain unpopularity of Adams that he could secure only about half of the electoral votes possible in the elections of 1789 and 1792. His eight years under Washington were politically insignificant—as indeed he termed the office of vice president itself—although as presiding officer in the Senate, "His Rotundity" (as his detractors called him) invariably voted in a Federalist direction when breaking ties. Not until 1796, when he was selected by a congressional caucus to succeed Washington, did opposition in his own party become apparent. The fact that he received only a few more electoral votes than Jefferson was due in part to the number of votes cast for another Federalist, Thomas Pinckney of South Carolina, the recently successful envoy to Spain and a favourite with party leaders. Thus, Adams began his term as president with deep suspicions, not only about Jefferson but about Hamilton and his followers. Nevertheless, he kept the cabinet of Washington more or less intact until 1800, despite the fact that several of its members relied upon the advice of Hamilton, Washington's brilliant secretary of the treasury, who was now trying to rehabilitate his fortunes in law practice in New York. The retention of most members of Washington's cabinet was a serious mistake that was partly due to Adams' continuing inability to grasp the significance of "parties." He proudly thought of himself like Washington, as a leader of the whole nation.

Election to the presidency

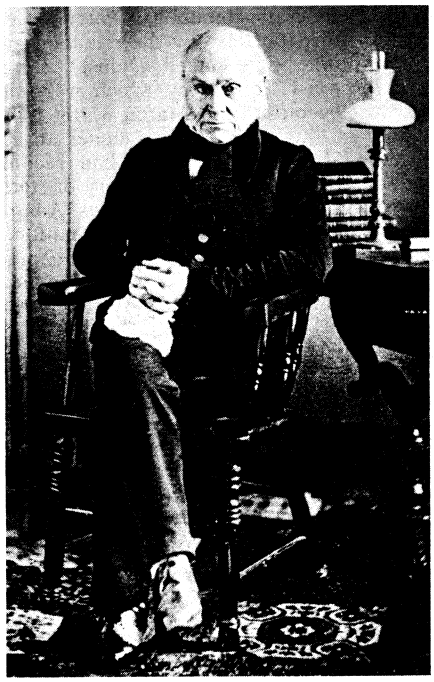
The Adams administration went from crisis to crisis, for the French Revolutionists were threatening to create a new imperium in Europe, and in America they were stirring up their numerous admirers. Adams had been appalled by the nature of this new revolutionary upheaval from the very beginning, so different, as he saw it, from what had happened in America. Together with his son John Quincy he had taken up the gauntlet seemingly thrown down by Jefferson in 1791, when the latter had endorsed the publication in America of Tom Paine's "Rights of Man," which defended the French Revolution. But if Adams was angered by his Francophile critics, Abigail was outraged, for criticism of her husband was to her little less than treason. Adams did not originate the Alien and Sedition Acts in 1798, which were designed to restrict the activities of friends of Revolutionary France who either hoped to come to America or were already there, but he did sign them into law, and doubtless with Abigail's hearty concurrence. Hating militarism, he decided in 1799 not to go to war with France but to reopen negotiations—after military preparations had been started by Hamilton with the support of the more warlike Federalists. This decision drew the sting from the extremists, many of whom now saw Adams himself as the true enemy. Adams seems to have been more friendly to moderate Federalists than he himself realized. More popular than his own party, he was defeated for re-election in 1800 not only by the strategy of the opposition, the Democratic-Republican Party led by Jefferson and Aaron Burr, but also by the reluctant endorsement of Hamilton who retaliated against Adams' conciliatory policy toward France, by which war was averted. In office to the bitter end, March 3, 1801, he signed in a number of "midnight judges," under an act reforming the national judiciary that he had recommended, having already appointed his secretary of state, John Marshall of Virginia, as chief justice. Thus, Adams attempted to keep Federalists in control of the national judiciary, at least, and he hurried away from the capital without bothering to greet Thomas Jefferson, the new president. He was to remember his critics with great bitterness.

Signing of the Alien and Sedition Acts

Retirement at Quincy. Adams retired to Quincy and lived on into a vigorous and combative old age, composing parts of an "Autobiography" on three different occasions and in varying moods; writing innumerable letters to set people straight about the American Revolution; heaping coals of fire on the head of his neighbour and former friend, Mercy Otis Warren, for the misinformation allegedly conveyed in her *History* of the American Revolution; rejoicing in the size of his manure pile; enjoying his tankard of hard cider each morning before breakfast; and glorying in the diplomatic success and political eminence of his son, John Quincy Adams. Even after Abigail's death in 1818, he strove to maintain an active life, taking long walks in the countryside, dictating to dutiful nieces, and enjoying the role of a senior citizen become a sage.

Gilbert Stuart's portrait of Adams in his 89th year shows him in characteristically bold mood but shrunken frame, obviously in need of teeth, his palsied fingers transparently thin. His last great joy was the elevation of his son to the presidency in 1825. He died on July 4, 1826, just 50 years after the formal Declaration of Independence, on the same day and only a few hours after the death of Thomas Jefferson, the one-time friend and collaborator who had become his political enemy only to become reconciled and friendly again late in life. He lies buried, next to Abigail, in the Stone Temple in downtown Quincy, about halfway between his humble place of birth and the Adams Mansion.

BIBLIOGRAPHY. PAGE SMITH, *John Adams*, 2 vol. (1962), is an exhaustive modern account, enriched with details from the microfilm of the recently opened Adams Family Papers. For broad interpretation, an older biography, GILBERT CHINARD, *Honest John Adams* (1933), is charming and still useful. C.D. BOWEN, *John Adams and the American Revolution* (1950), is a novelized and highly readable story of the early years. The Adams Family Papers have provided the raw material for the modern edition of the *Diary and Autobiography of John Adams*, ed. by L.H. BUTTERFIELD *et al.*, 4 vol. (1961), supplemented by *The Earliest Diary of John Adams* (1966). These bring up-to-date the 19th-century edition by CHARLES FRANCIS ADAMS of his grandfather's major writings, *The Works of John Adams, Second President of the United States: With a Life of the Author*, 10 vol. (1850–56). The opening portions of the *Life* in this edition were written by John Adams' son, John Quincy Adams, the 6th president. It should be noted that both the *Diary* and the *Autobiography* contain virtually nothing on John Adams' later career as vice president and president; his "second life" after retirement to Quincy in 1801 is even more neglected. The original



sketch of Adams by EDWARD CHANNING in older editions of the *Encyclopædia Britannica* is still worthwhile, simply because Channing wrote it.

(R.A.E.)

Adams, John Quincy

Adams, John Quincy, eldest son of Pres. John Adams and sixth president of the United States, had two notable careers: first as one of America's greatest diplomats and second as outstanding champion of the antislavery cause in the House of Representatives during the last 16 years of his long life. Between these two careers was the period of his presidency of the United States, from 1825 to 1829.

John Quincy Adams, daguerreotype by A.S. Southworth and J.J. Hawes.

Early life. Adams was born on July 11, 1767, in that part of Braintree that is now Quincy, Massachusetts. He entered the world at the same time his maternal great-grandfather, John Quincy, for many years a prominent member of the Massachusetts legislature, was leaving it; hence his name. He grew up as a child of the American Revolution. He watched the Battle of Bunker Hill from Penn's Hill and heard the cannons roar across the Back Bay. His patriot father, at that time a delegate to the Continental Congress, and his patriot mother, one of the intellectual women of those times, had a strong molding influence on his education after the war had deprived Braintree of its only schoolmaster. In 1778 and again in 1780 the boy accompanied his father to Europe. He studied at a private school in Paris in 1778–79 and at the University of Leiden in 1780. Thus, at an early age he acquired an excellent knowledge of the French language and a smattering of Dutch. In 1780, also, he began to keep regularly the diary that forms so conspicuous a record of the doings of himself and his contemporaries through the next 60 years of American history.

Early influences

Early diplomatic and political career. In 1781, at the age of 14, he accompanied Francis Dana, United States envoy to Russia, as his private secretary and interpreter of French. Dana, after lingering for more than a year in St. Petersburg, was not received by the Russian government; and in 1782 Adams, returning by way of Scandinavia, Hanover, and the Netherlands, joined his father in Paris. There he acted, in an informal way, as an additional secretary to the American commissioners in the negotiation of the treaty of peace that concluded the American Revolution. Instead of remaining in London with his father, who had been appointed United States minister to the Court of St. James, he chose to return to Massachusetts, where he graduated from Harvard College in 1787. He then read law at Newburyport under the tutelage of Theophilus Parsons, and in 1790 he was admitted to the bar in Boston. While struggling for a practice, he wrote a series of articles for the newspapers in which he controverted some of the doctrines in Thomas Paine's "Rights of Man." In another later series he ably supported the neutrality policy of George Washington's administration as it faced the war that broke out between France and England in 1793. These articles were brought to President Washington's attention and resulted in Adams' appointment as U.S. minister to the Netherlands in May 1794.

Diplomatic posts

The Hague was then the best diplomatic listening post in Europe for the war of the first coalition against Revolutionary France. Young Adams' official dispatches to the Secretary of State and his informal letters to his father, who was now the vice president, kept the government well informed of the diplomatic activities and wars of the distressed Continent and the danger of becoming involved in the European vortex. These letters were also read by President Washington: some of Adams' phrases, in fact, appeared in Washington's "Farewell Address" of 1796. During the absence of the regular minister at London, Thomas Pinckney, Adams transacted public business with the British Foreign Office relating to exchange of ratifications of the Jay Treaty of 1794 between the United States and Great Britain. In 1796 Washington, who came to regard young Adams as the ablest officer in the foreign service, appointed him minister to Portugal, but before his departure his father John Adams became president and changed the young diplomat's destination to Prussia.

John Quincy Adams was married in London in 1797, on the eve of his departure for Berlin, to Louisa Catherine Johnson (1775–1852), daughter of the United States consul Joshua Johnson, a Marylander by birth, and his wife, Katherine Nuth, an Englishwoman.

While in Berlin, Adams negotiated (1799) a treaty of amity and commerce with Prussia. Recalled from Berlin by President Adams after the election of Thomas Jefferson to the presidency in 1800, the younger Adams reached Boston in 1801 and the next year was elected to the Massachusetts Senate. In 1803 the Massachusetts legislature elected him as a member of the Senate of the United States.

Up to this time John Quincy Adams was regarded as belonging to the Federalist Party, but he found its general policy displeasing. He was frowned upon as the son of his father by the followers of Alexander Hamilton and by reactionary groups, and he soon found himself practically powerless as an unpopular member of an unpopular minority. Actually he was not then, and indeed never was, a strict party man; all through his life, ever aspiring to higher public service, he considered himself a "man of my whole country." Adams arrived in Washington too late to vote for ratification of the treaty for the purchase of Louisiana, opposed by the other Federalist senators, but he voted for the appropriations to carry it into effect and announced that he would have voted for the purchase treaty itself. Nevertheless, he joined his Federalist colleagues in voting against a bill to enable the President to place officials of his own appointment in control of the newly acquired territory; such a bill, Adams vainly protested, overstepped the constitutional powers of the presidency, violated the right of self-government, and imposed taxation without representation. In December 1807 he supported President Jefferson's suggestion of an embargo prohibiting all foreign commerce (an attempt to gain British recognition of American rights) and vigorously urged instant action, saying: "The President has recommended the measure on his high responsibility. I would not consider, I would not deliberate; I would act!" Within five hours the Senate had passed the embargo bill and sent it to the House of Representatives. Support of this measure, hated by the

Break with the Federalists

Federalists and unpopular in New England because it stifled the region's economy, cost Adams his seat in the Senate. His successor was chosen on June 3, 1808, several months before the usual time of electing a senator for the next term, and five days later Adams resigned. In the same year he attended the Republican congressional caucus, which nominated James Madison for the presidency, and thus allied himself with that party. From 1806 to 1809 Adams was Boylston professor of rhetoric and oratory at Harvard College.

In 1809 President Madison sent Adams to Russia to represent the United States at the court of the tsars. He arrived at St. Petersburg at the psychological moment when the Tsar had made up his mind to break with Napoleon. Adams therefore met with a favourable reception and a disposition to further the interests of American commerce in every possible way. From this vantage point he watched and reported Napoleon's invasion of Russia and the final disastrous retreat and dissolution of France's *grande armée*. On the outbreak of the war between the United States and England in 1812, he was still at St. Petersburg. That September the Russian government suggested that the Tsar was willing to act as mediator between the two belligerents. Madison precipitately accepted this proposition and sent Albert Gallatin and James Bayard to act as commissioners with Adams, but England would have nothing to do with it. In August 1814, however, these gentlemen, with Henry Clay and Jonathan Russell, began negotiations with English commissioners that resulted in the signing of the Treaty of Ghent on December 24 of that year. Adams then visited Paris, where he witnessed the return of Napoleon from Elba, and next went to London, where, with Clay and Gallatin, he negotiated (1815) a "Convention to Regulate Commerce and Navigation." Soon afterward he became U.S. minister to Great Britain, as his father had been before him, and as his son, Charles Francis Adams, was to be after him. After accomplishing little in London, he returned to the United States in the summer of 1817 to become secretary of state in the Cabinet of Pres. James Monroe. This appointment was primarily because of his diplomatic experience but also because of the President's desire to have a sectionally well-balanced Cabinet in what came to be known as the Era of Good Feeling.

Secretary of state

As secretary of state Adams played the leading part in the acquisition of Florida. Ever since the acquisition of Louisiana, successive administrations had sought to include at least a part of Florida in that purchase. In 1819, after long negotiations, Adams succeeded in getting the Spanish minister to agree to a treaty in which Spain would abandon all claims to territory east of the Mississippi, the United States would relinquish all claim to what is now Texas, and a boundary of the United States would be drawn (for the first time) from the Atlantic to the Pacific Ocean. This Transcontinental Treaty was perhaps the greatest victory ever won by a single man in the diplomatic history of the United States. Adams himself was responsible for the idea of extending the country's northern boundary westward from the Rocky Mountains to the Pacific—considered a stroke of diplomatic genius. To use his own word, it marked a triumphant "epocha" in U.S. continental expansion. Before the Spanish government ratified the Transcontinental Treaty in 1819, however, Mexico (including Texas) had thrown off allegiance to the mother country, and the United States had occupied Florida by force of arms. As secretary of state, Adams was also responsible for conclusion of the treaty of 1818 with Great Britain, laying down the northern boundary of the United States from the Lake of the Woods to the Rocky Mountains along the line of 49° north latitude. Years later, as a member of the House of Representatives he supported 49° north latitude as the boundary of Oregon from the Rocky Mountains to the Pacific Ocean: "I want that country for our Western pioneers." Polk's Oregon treaty of 1846 drew that boundary along the line of 49°. The Monroe Doctrine rightly bears the name of the president who in 1823 assumed the responsibility for its promulgation, but it was the work of John Quincy Adams more than of any other single man.

Presidency and feud with Jackson. As President Monroe's second term drew to a close in 1824, there was a lack of good feeling among his official advisers, three of whom—Secretary of State John Quincy Adams, Secretary of War John C. Calhoun, and Secretary of the Treasury William H. Crawford—aspired to succeed him in his high office. Henry Clay, speaker of the house, and Gen. Andrew Jackson were also candidates. Calhoun was nominated for the vice presidency. Of the other four, Jackson received 99 electoral votes for the presidency, Adams 84, Crawford 41, and Clay 37; because no one had a majority, the decision was made by the House of Representatives, which was confined in its choice to the three candidates who had received the largest number of votes. Clay, who had for years assumed a censorious attitude toward Jackson, cast his influence for Adams, whose election was thereby secured on the first ballot. A few days later Adams offered Clay the office of secretary of state, which was accepted. The charge of "bargain and corruption" followed, and the feud thus created between Adams and Jackson greatly influenced the history of the United States.

The election of 1824

Up to this point Adams' career had been almost uniformly successful, but his presidency (1825–29), during which the country prospered, was in most respects a political failure because of the virulent opposition of the Jacksonians. In 1828 Jackson was elected president over Adams. It was during Jackson's administration that irreconcilable differences developed between the followers of Adams and the followers of Jackson, the former becoming known as the National Republicans, who, with the Anti-Masons, were the precursors of the Whigs. In 1829 Adams retired to private life in the town of Quincy, but only for a brief period; in 1830, supported largely by members of the Anti-Mason movement (a political force formed initially in opposition to Freemasonry), he was elected a member of the national House of Representatives. When it was suggested to him that his acceptance of this position would degrade a former president, Adams replied that no person could be degraded by serving the people as a representative in Congress or, he added, as a selectman of his town. He served in the House of Representatives from 1831 until his death, in 1848. But he had not abandoned his hopes for a re-election to the presidency—whether as nominee of the Anti-Masonic Party (in which he was very active as long as that party had political possibilities) or of the National Republican Party or of a union of both or even of the later Whig Party—always in his own mind as a "man of the whole nation." Gradually, these hopes faded.

Second career in Congress. His long second career in Congress was at least as important as his earlier career as a diplomat. Throughout, he was conspicuous as an opponent of the expansion of slavery and was at heart an Abolitionist, though he never became one in the political sense of the word. In 1839 he presented to the House of Representatives a resolution for a constitutional amendment providing that every child born in the United States after July 4, 1842, should be born free; that, with the exception of Florida, no new state should be admitted into the Union with slavery; and that neither slavery nor the slave trade should exist in the District of Columbia after July 4, 1845. The "gag rules," a resolution passed by Southern members of Congress against all discussion of slavery in the House of Representatives, effectively blocked any discussion of Adams' proposed amendment. His prolonged fight for the repeal of the gag rules and for the right of petition to Congress for the mitigation or abolition of slavery was one of the most dramatic contests in the history of Congress. These petitions, from individuals and groups of individuals from all over the northern states, were increasingly sent to Adams, and he dutifully presented them. Adams contended that the gag rules were a direct violation of the First Amendment to the federal Constitution, and he refused to be silenced on the question, fighting indomitably for repeal, in spite of the bitter denunciation of his opponents. Each year the num-

Opposition to slavery

ber of antislavery petitions received and presented by him grew in great numbers. Perhaps the climax was in 1837 when Adams presented a petition from 22 slaves and, threatened by his opponents with censure, defended himself with remarkable keenness and ability. At each session the majority against him decreased until, in 1844, his motion to repeal the then standing 21st (gag) rule of the House was carried by a vote of 108 to 80, and his long battle was over.

Another spectacular contribution of Adams to the antislavery cause was his championing of the cause of the Africans of the slave ship "Amistad"—slaves who had mutinied and escaped from their Spanish owners off the coast of Cuba and brought the slave ship into United States waters near Long Island. Adams defended these Negroes as freemen before the Supreme Court in 1841 against efforts of the administration of Pres. Martin Van Buren to return them to their masters and to inevitable death. Adams won their freedom.

As a member of Congress—in fact, throughout his life—Adams was a constant supporter of improvement of the arts and sciences and the diffusion of knowledge; and he did much to conserve the bequest of James Smithson (an eccentric Englishman) to the United States and to create and endow the Smithsonian Institution with the money from Smithson's estate.

Adams' death

Perhaps the most dramatic event in Adams' life was its end. On February 21, 1848, in the act of protesting an honorary grant of swords by Congress to the generals who had won what Adams considered a "most unrighteous war" with Mexico, he suffered a cerebral stroke, fell unconscious to the floor of the House, and died two days later in the capitol building. His obsequies in Washington and in his native Massachusetts assumed the character of a countrywide pageant of mourning.

Personality. Few men in American public life have possessed more independence, more public spirit, and more ability than did Adams; but throughout his political career he was handicapped by a certain personal reserve and austerity and coolness of manner, which prevented him from appealing to the imaginations and affections of the people. He had few intimate friends, and not many men in American history have been regarded, during the period of their lifetime, with so much hostility or attacked with so much rancour by their political opponents.

MORSE, *John Quincy Adams* (1883; new ed., 1899); DEXTER PERKINS, "John Quincy Adams," in *American Secretaries of State and Their Diplomacy*, vol. 4 (1928, reprinted 1963); BENNETT CHAMP CLARK, *John Quincy Adams, "Old Man Eloquent"* (1932). Two basic volumes by SAMUEL FLAGG BEMIS, *John Quincy Adams and the Foundations of American Foreign Policy* (1949) and *John Quincy Adams and the Union* (1956), utilized the fabulous archives of the Adams family, now in the possession of the Massachusetts Historical Society and in the process of voluminous publication, and a wealth of other official and private collections.

(S.F.Be.)

Adams, Samuel

A radical champion of revolution and a skillful politician and polemicist, Samuel Adams did more than any other American to arouse opposition against English rule in the Colonies. He was born in Boston, Massachusetts, on Sept. 27, 1722, a second cousin of John Adams, second president of the United States. He graduated from Harvard College in 1740, briefly studied law, and failed in several business ventures. As a tax collector in Boston, he neglected to collect the public levies and to keep proper accounts, thus exposing himself to suit.

Although unsuccessful in conducting personal or public business, Adams took an active and influential part in local politics. By the time the English Parliament passed the Sugar Act (1764) taxing molasses for revenue, Adams was a powerful figure in the opposition to British authority in the Colonies. He denounced the act, being one of the first of the colonials to cry out against taxation without representation. He played an important part in instigating the Stamp Act riots in Boston that were directed against the new requirement to pay taxes on all legal and commercial documents, newspapers, and college diplomas.

Samuel Adams, oil portrait by John Singleton Copley, *c.* 1770-72. In the Museum of Fine Arts, Boston.

By courtesy of the Museum of Fine Arts, Boston, deposited by the City of Boston

His influence was soon second only to James Otis, the lawyer and politician who gained prominence by his resistance to the revenue acts. Elected to the lower house of the Massachusetts general court from Boston, Adams served in that body until 1774, after 1766 as its clerk. In 1769 Adams assumed the leadership of the Massachusetts radicals. There is some reason to believe that he had committed himself to American independence a year earlier. John Adams may have erred in ascribing this extreme stand to his cousin at so early a time, but certainly Samuel Adams was one of the first American leaders to deny Parliament's authority over the Colonies; and he was also one of the first—certainly by 1774—to establish independence as the proper goal.

Commitment to American independence

John Adams described his cousin as a plain, modest, and virtuous man. But in addition, Samuel Adams was a propagandist who was not overscrupulous in his attacks upon British officials and policies, and a passionate politician as well. In innumerable newspaper letters and essays over various signatures, he described British measures and the behaviour of royal governors, judges, and customs men in the darkest colours. He was a master of organization, arranging for the election of men who agreed with him, procuring committees that would act as he wished, and securing the passage of resolutions that he desired.

During the crisis over the Townshend duties (1767–70), the new import taxes on previously duty-free products proposed by cabinet minister Charles Townshend, Adams was unable to persuade the Massachusetts colonists to take extreme steps, partly because of the moderating influence of Otis. The British troops sent to Boston in 1768, however, offered a fine target for this propaganda, and Adams saw to it that they were portrayed in the colonial newspapers as brutal soldiery oppressing inoffensive citizens and assailing their wives and daughters. He was one of the leaders in the town meeting that demanded and secured the removal of the troops from Boston after some British soldiers fired into a mob and killed five Americans. When news came that the Townshend duties, except for that on tea, had been repealed, his following dwindled. Nevertheless, during the years 1770–73, when other colonial leaders were inactive, Adams persistently revived old issues and found new ones; he was responsible for the foundation (1772) of the committee of correspondence of Boston that kept in contact with similar bodies

Foundation of committee of correspondence

in other towns, in whose establishment he also had a hand. These committees later became effective instruments in the fight against the British.

The passage by Parliament of the Tea Act of 1773, which granted the East India Company a monopoly on tea sales in the Colonies, gave Adams ample opportunity to exercise his remarkable talents. Although he did not participate in the Boston Tea Party, he was undoubtedly one of its planners. He was again a leading figure in the opposition of Massachusetts to the execution of the Intolerable (Coercive) Acts passed by the British Parliament in retaliation for the dumping of tea in Boston Harbor; and as a member of the First Continental Congress, which spoke for the 13 Colonies, he insisted that the delegates take a vigorous stand against Britain. A member of the provincial congress of Massachusetts in 1774–75, he participated in making preparations for warfare should Britain resort to arms. When the British troops marched out of Boston to Concord, Adams and the president of the Continental Congress, John Hancock, were staying in a farmhouse near the line of march; and it has been said that the arrest of the two men was one of the purposes of the expedition. But the troops made no effort to find them, and British orders called only for destruction of military supplies gathered at Concord. When Gen. Thomas Gage issued an offer of pardon to the rebels some weeks later, however, he excepted Adams and Hancock.

Member of Continental Congress

As a member of the Continental Congress, in which he served as a delegate until 1781, Adams was less conspicuous than he was in town meetings and the Massachusetts legislature, for the congress contained many men as able as he. He and John Adams were among the first to call for a final separation from Britain, both signed the Declaration of Independence, and both exerted considerable influence in the congress.

Adams was a member of the convention that framed the Massachusetts constitution of 1780 and also sat in the convention of his state that ratified the Federal Constitution. He was at first an anti-Federalist who opposed the ratification of the Constitution for fear that it would vest too much power in the federal government but finally abandoned his opposition when the Federalists promised to support a number of future amendments, including a bill of rights. He was defeated in the first congressional election. Returning to political power as a follower of Hancock, he was lieutenant governor of Massachusetts from 1789 to 1793 and governor from 1794 to 1797. When parties developed on a national scale, he affiliated himself with the Democratic Republicans, the forerunner of the Democratic Party. After being defeated as a presidential elector favouring Thomas Jefferson in the election of 1796, he retired to private life. He died on Oct. 2, 1803.

BIBLIOGRAPHY. The best biography of Samuel Adams is JOHN C. MILLER, *Sam Adams: Pioneer in Propaganda* (1936). There are several others: WILLIAM V. WELLS, *The Life and Public Services of Samuel Adams*, 3 vol. (1865); JAMES K. HOSMER, *Samuel Adams* (1885); RALPH V. HARLOW, *Samuel Adams: Promoter of the American Revolution* (1923); and STEWART BEACH, *Samuel Adams: The Fateful Years, 1764–1776* (1965). Many of Samuel Adams' writings have been lost or destroyed, but a substantial collection of them, edited by HARRY A. CUSHING, *The Writings of Samuel Adams*, 4 vol., was published in 1904–08.

(J.R.Al.)

Addis Ababa

Addis Ababa, the capital city of Ethiopia, is located at the country's geographical centre. Situated at an altitude of 8,000 feet above sea level, it is the highest city in Africa. Its municipal boundaries enclose more than 90 square miles of forested hills and valleys, among which the city has grown in chaotic fashion. The fast-growing population of about 960,000 reflects the city's importance as a symbol of modernity in a largely poor and underdeveloped country.

As well as being the seat of government, Addis Ababa is also the centre of Ethiopia's economic activity. It is the main distribution centre for agricultural and consumer goods and houses much of the country's fledgling industry. Although isolated from the world before World War II, since the 1960s it has become the diplomatic centre for black Africa.

History. Only since the late 19th century has Addis Ababa been the capital of the Ethiopian state. Its immediate predecessor, Entoto, was situated on a high tableland and was found to be unsatisfactory because of extreme cold and an acute shortage of firewood. The empress Taitu, wife of Emperor Menelik II (reigned 1889–1913), persuaded the Emperor to build a house near the hot springs at the foot of the tableland and to grant land in the area to members of the nobility. The city was thus founded in 1887 and was named Addis Ababa ("new flower") by the Empress.

Founding of the city

In its first years the city was more like a military encampment than a town. The central focus was the Emperor's palace, which was surrounded by the dwellings of his troops and of his innumerable retainers. The rest of the town reflected a similar pattern; the residences of the nobility were widely scattered, and each was surrounded by dwellings of troops and retainers.

As the population increased, the capital increasingly experienced a shortage of firewood. In 1905 several varieties of the fast-growing eucalyptus tree were imported from Australia; the trees spread and provided a forest cover for the city. In 1917 the construction of the railway between Addis Ababa and the French Somaliland port of Djibouti connected the landlocked city to the Indian Ocean. At the time of the coming of the Italians in 1935, the population of Addis Ababa was estimated at more than 100,000. It had by that time some of the features of a modern town, including a few hospitals and schools, a power and water supply, a police force, and a rudimentary system of paved roads.

Addis Ababa was the capital of Italian East Africa from 1935 to 1941. The Italians attempted to turn it into a colonial town with strictly segregated residential areas. They introduced the concept of zoning and built a new native market, still known as the Mercato (Italian: "market"). Modern stone houses were built during this period, particularly in the areas of European residence, and many roads were paved. Other innovations included the large water reservoir at Gefarsa to the west and the hydroelectric station at Akaki to the south.

There were only limited changes in Addis Ababa between 1941 and 1960, but development has been impressive since then. Nearly half of the housing units in Addis Ababa in 1970 were built during the 1960s, as were a number of high-rise office and apartment buildings, luxurious residential villas, and low-cost housing projects. The road system and the water and power supply systems were also expanded in order to serve the growing city.

The contemporary city. Addis Ababa is located on the wide Shewan Plateau, which is crossed by several streams, including the Kebena, Kechene, Kurtume, and Akaki rivers. The lower slopes of the Entoto Hills form the northern limit of the city. The rugged site slopes generally southward, and altitudes vary from 8,500 to 7,200 feet within a distance of about six miles.

The only unusual feature in the otherwise ideal climate is the annual average rainfall of 49 inches, which comes in violent thundershowers mostly in April, July, and August. The temperature varies between a minimum monthly average of 59° F (15° C) in December and a maximum average of 66° F (19° C) in May, with a comfortable annual average temperature of 61° F (16° C).

The climate is favourable for a wide range of plant life. There are extensive eucalyptus groves in and around the city, as well as trees natural to the area such as certain species of acacia and fir. Vegetables, cereals, and livestock, raised in the surrounding region, help to feed the growing population. Wildlife consists mainly of the many hyenas and wild dogs that often venture far into the city at night, scavenging for refuse.

The inadequate sewage system presents significant sanitation problems. The city's streams are badly polluted, but serious air pollution is only a potential threat.

The municipal boundaries of Addis Ababa enclose 92 square miles (238 square kilometres), but in the early 1970s only about one-third of this area was built-up. Opportunities for further expansion are ample, except to the north, where the Entoto Hills are an effective barrier.

Principal zones of the city

Because of unplanned growth, zoning is diffuse, but there are general concentrations of function. The governmental and educational section begins at Asfa Wossen Street and ends at Meskel Square, running south through the centre of the city. Along this route are found three campuses of the university, several schools, the National Museum, six governmental ministries, several palaces, the houses of Parliament, and Africa Hall.

The industrial zone in the far south extends chiefly along the road leading to the town of Debre Zeit and reaches beyond the municipal boundaries. There is also a small concentration of factories to the south of Mexico Square in the southwest.

The commercial zone has two focuses—the Mercato, located in the west, and the Piazza (officially, de Gaulle Square), in the centre of town. The Mercato is reputed to be one of the largest indigenous markets in Africa and attracts buyers and sellers from a 50-mile radius on Saturdays. In the Piazza and adjoining areas are the more expensive European-style shopping centres. Smaller markets and shopping areas are scattered everywhere.

The purely residential areas of expensive homes and villas are situated along the road to the new airport in the southeast and to the south and west of the old airport in the southwest.

Unplanned growth has led to the haphazard development of the road network. Only a few roads are large enough to accommodate the growing volume of traffic. The major roads are paved, but these are mostly in the commercial areas. Access by car to many homes—where it exists at all—is down tortuous cobblestone streets or along muddy dirt roads. Only the main arteries have official street names, and there are no numbered addresses because of the chaotic, twisted street pattern. Public transport is provided by a fleet of about 150 buses that run along the main roads.

Addis Ababa is the hub of the country's transportation network. The five road outlets connect the city to provincial capitals; the only railway is that running to Djibouti. There are air connections to about 40 domestic airports, as well as scheduled international flights to Europe, to India, and to other African cities.

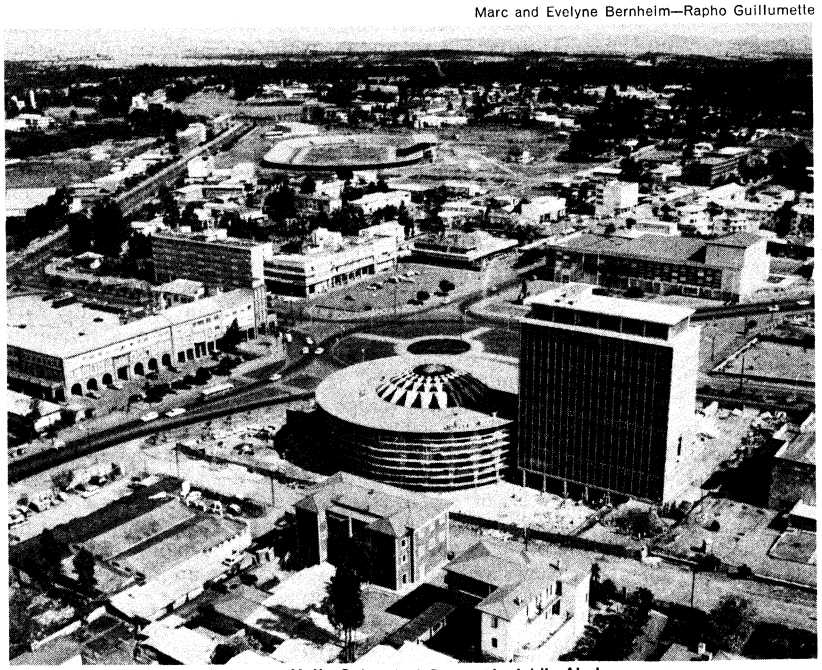
With more than 46,000 motor vehicles registered in Addis Ababa in the early 1970s, as well as many vehicles coming from out of town, traffic was congested. The problem was also complicated by heavy pedestrian and domestic-animal traffic in some parts of the city.

The city's population

The total city population in the early 1970s was about 960,000. The most populous administrative districts were Teklehaimanot and Mekakelegna, in the centre of town, and Bole, in the south. The densest population occurred in the Arada, Teklehaimanot, and Mekakelegna districts. The average population density was about 10,000 persons per square mile.

There is a slight excess of males over females in the relatively young population, of which 40 percent is less than 15 years of age. Ethnic composition is highly varied; the most numerous group is the Amharas, who constitute well over half of the population. The Gallas make up about one-fifth of the total inhabitants; the rest consist of Gurages, Hareris, Tigres, Walamos (Wollamos), Somalis, Dorses, and other groups. There is also a significant foreign community, consisting mainly of Arabs, Italians, Greeks, and Armenians. The largest religious group is composed of the adherents of the Ethiopian Orthodox Church. There is a large Muslim community, and there are also adherents of other Christian denominations.

About two-thirds of the population live in housing units that average about three persons to one room. Of these units, about one-fourth are owned by their occupiers, and the remainder are rented; a few are occupied either rent-free or in exchange for services rendered. Only about 7 percent of the housing units have piped water. About half, however, have access to piped water within a distance of 80 feet; others are near a river or well.



In 1967 about 40 percent of the housing units consisted of permanent structures made of durable materials such as stone, bricks, concrete, tiles, or mud and wood. The remainder were constructed of locally available materials and had roofs of thatch or of corrugated iron.

The economy. Addis Ababa contains about 60 percent of the industries and about 50 percent of the industrial workers of Ethiopia. The variety of consumer products manufactured for the local market includes textiles, shoes, food, beverages, wood products, plastics, and chemical products. Most of the country's service industries are also located in the city. Industry, however, employs no more than 3 percent of the total city population.

Larger industries are mostly government-owned; smaller industries and larger retail outlets are generally owned and operated by aliens. Arabs are gradually losing control of the small retail business to Ethiopians.

The bulk of the export and import trade of Ethiopia is channelled through Addis Ababa on its way to or from

Marc and Evelyne Bernheim—Rapho Guillumette

Commercial Bank of Ethiopia, on Haile Selassie I Square in Addis Ababa.

the ports of Djibouti, on the Gulf of Aden, or Aseb (Assab), on the Red Sea. The city is also the collection and distribution centre for much of the country's internal trade. Banking and insurance services are concentrated in Addis Ababa, and there is a small but growing stock exchange.

As the country's industrial, commercial, and administrative centre, Addis Ababa contributes a major proportion of the country's gross domestic product. Per capita income in the city is several times higher than that in the nation as a whole; it attracts a constant flow of unskilled labour from the countryside, which has resulted in an increasing amount of unemployment in the city.

Administration and social conditions. Addis Ababa is the centre of all governmental activity. The 14 government ministries are located in the city, as are the houses of Parliament, the imperial palaces, and nearly all of the autonomous governmental agencies. Several international organizations have their headquarters in Addis Ababa, the most important of which are the Organization of African Unity and the United Nations Economic Commission for Africa (located in Africa Hall).

City government

According to the city charter of 1954, all legislative power is vested in an elective 20-member municipal council that may enact local legislation, adopt budgets, and determine policies. Two council members are elected from each of the city's 10 districts for two-year terms. Executive power rests in the mayor, or *kantiba*, who is appointed directly by the emperor and is the ex officio president of the municipal council. The Ministry of Interior has general supervisory powers over the mayor and the council.

The city is divided into ten administrative districts, or *weredawoch*. These are Teklehaimanot, Arada, and Mekakelegna districts, in the centre; Gefarsa, Gulele, and Entoto districts, to the north; Lideta and Bole districts, to the south; Yekka district, to the east; and Keranio district, to the west.

The water supply was augmented in 1970 by the construction of a dam over the Legedadi River, about 15 miles east of the city. The Legedadi reservoir, with a capacity of about 1,400,000,000 cubic feet, and the reservoir on the Akaki River, with a capacity of over 200,000,000 cubic feet, are together expected to supply sufficient water to meet current and future demands. Electric power for the city and the industrial ribbon to the south comes chiefly from the two hydroelectric plants on the Awash River. The plants have a combined installed generating capacity of about 75,000 kilowatts.

In 1970 Addis Ababa had more than 50 medical clinics and 13 hospitals, with a total capacity of more than 2,500 beds. Excluding military medical personnel, there were about 170 doctors and about 300 trained nurses. Nearly all the medical services in the city are either supported or heavily subsidized by the state. The city is relatively healthy and is free from malaria. Other infectious and parasitic diseases such as amoebic dysentery and infectious hepatitis, however, have a high occurrence.

There are six police stations and a large police force. The rate of major crimes is relatively low for a city of comparable size, and no organized crime is known to exist. Pocket picking and robbery, however, are prevalent, and most of the larger households employ watchmen. The three fire stations are well equipped, and firemen also provide miscellaneous rescue services.

Educational services

In the early 1970s the government operated more than 30 elementary, 25 junior secondary, and more than 10 senior secondary schools. In addition, there were schools on all three levels operated by private individuals, by missions, or by the foreign communities. In-service vocational training was offered by private and government institutions, and many schools also offered evening classes. The total school population, numbering about 120,000 in 1970, included about 74 percent of the school-age children.

Haile Selassie I University was established in Addis Ababa in 1961. Eight of its ten faculties are located in the city on four campuses with a student body of more than 4,000 and a faculty numbering nearly 600. A junior college for the training of teachers was established in 1969.

Cultural life. The traditional custodians of culture in Ethiopia have been religious institutions, but the promotion of contemporary cultural life is mostly in the hands of secular institutions. The Department of Fine Arts of the Ministry of Education operates the National School of Music and the art school, while the Antiquities Administration runs the National Library and the National Museum. The university has the Museum of the Institute of Ethiopian Studies, which is primarily anthropological in emphasis. The government-supported patriotic association (Hager Fikir Mahber) and the Haile Selassie I Theatre have popular folklore troupes and theatre groups. Art, Amharic literature, and Ethiopian studies are supported by the Haile Selassie I Prize Trust, which awards annual prizes.

The mass media

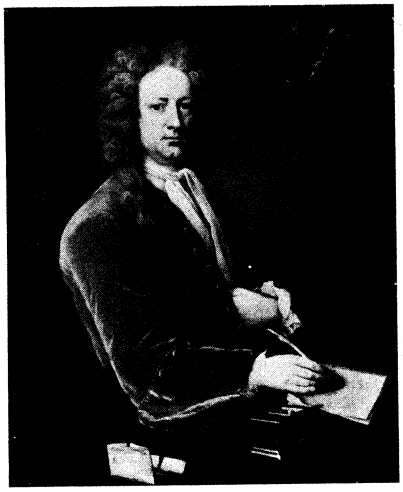
A government-owned radio station, with medium-wave service for the Addis Ababa region and shortwave service for the rest of the nation, broadcasts news and information, primarily in Amharic and English. Music programs are primarily Ethiopian, but they include a substantial amount of Western popular music. There has been some experimentation with educational programs designed for use in schools. A powerful private radio station, owned by the Lutheran World Federation, also operates from Addis Ababa and beams basically religious broadcasts in several languages to African and Asian countries. There is a government television station catering to the Addis Ababa region as far south as Asella; it broadcasts daily for about four hours in Amharic and English.

The two major daily newspapers in Addis Ababa—the *Addis Zemen* ("New Era") in Amharic and *The Ethiopian Herald* in English—are published by the Ministry of Information. The ministry also publishes two Amharic weeklies—*Ye-zareitu Ityopia* ("Ethiopia of Today") and *Ye-sport fana* ("The Light of Sports")—one Amharic monthly, *Menen*, and one illustrated English quarterly, *The Ethiopian Mirror*. The most popular newspaper is the Amharic fortnightly *Polisenna Ermejjaw* ("Police and Progress"), which is published by the police force and relies heavily on crime reporting.

Formally designated recreational areas are limited, but open spaces suitable for recreational purposes abound within and around the built-up areas. A small zoo of the imperial lions is located in a park near the university. The more affluent members of the population have access to the lake region, which is a short drive to the south; resorts in that area provide facilities for boating, water-skiing, bathing, and bird-watching.

The most popular spectator sport is soccer, which is played at the Haile Selassie I Stadium. Basketball, volleyball, and other sports are also played, chiefly by school teams. Facilities are available at private clubs and hotels for golf, polo, tennis, and swimming.

BIBLIOGRAPHY. The most extensive work on the city for the period up to 1960 is EDOUARD BERLAN, *Addis-Abeba: la plus haute ville d'Afrique* (1963). No comprehensive work exists in English, but a number of useful articles have appeared in the *Ethiopia Observer;* see especially MARTIN JOHNSON, "Addis Ababa from the Air," and RICHARD PANKHURST, "The Foundation and Growth of Addis Ababa to 1935," both in vol. 6, no. 1 (1962). An account of the indigenous market place is given in MAURICE DE YOUNG, "An African Emporium: The Addis Ababa Markato," *Journal of Ethiopian Studies*, vol. 5, no. 2 (1967). Much practical information on the city is given in the municipality's *Pocket Guide of Addis Ababa* (1964); and a good map of the city is edition 3 of the Mapping and Geography Institute (MGI) of Ethiopia (1964).



(A.Dem.)

Addison, Joseph

Essayist, poet, dramatist, and statesman, Joseph Addison successfully combined two careers in his short life. As a writer he produced one of the great tragedies of the 18th century in *Cato* and brought to perfection the art of the periodical essay in his journal, *The Spectator*. As a civil servant he became an influential supporter of the Whigs (who sought to further the constitutional prin-

ciples established by the Revolution of 1688) in a number of government posts, finally becoming secretary of state under George I. He achieved early fame as a writer of Latin and English verse, but it was his poem on the battle of Blenheim that brought him to the attention of the Whig leaders and paved the way to government employment and literary fame. Dr. Johnson's praise of *The Spectator* as a model of prose style established Addison as one of the most universally admired and influential masters of prose in the language.

In the National Portrait Gallery, London.

Youth and early career. Addison was born in Milston, Wiltshire, on May 1, 1672, the eldest son of the Rev. Lancelot Addison, later archdeacon of Coventry and dean of Lichfield. After schooling in Amesbury and Salisbury and at Lichfield Grammar School, he was enrolled at the age of 14 in the Charterhouse in London. Here began his lifelong friendship with Richard Steele, who later became his literary collaborator. Both went on to Oxford, where Addison matriculated at Queen's College in May 1687. Through distinction in Latin verse he won election as Demy to Magdalen College on July 30, 1689, and took the degree of M.A. on February 14, 1693. At Magdalen he spent ten years as tutor in preparation for a career as a scholar and man of letters. In 1695 *A Poem to his Majesty* (William III), with a dedication to Lord Keeper Somers, the influential Whig statesman, brought favourable notice not only from Somers but also Charles Montague (later earl of Halifax), who saw in Addison a writer whose services were of potential use to the crown. A treasury grant offered opportunity for travel and preparation for government service. Much of his Latin verse had been published in the second volume of *Musarum Anglicanarum Analecta* (1699), which Addison himself edited. He had also attained distinction by contributing the preface to Virgil's *Georgics*, in John Dryden's great translation of 1697.

European influences on Addison

The European tour (1699–1704) enabled Addison not only to become acquainted with English diplomats abroad but also to meet contemporary European men of letters and to observe at first hand the background of the Latin poets. His letters from Paris record visits to such celebrities as the literary critic Boileau, who was the most famous poet of his day, and to Nicolas Malebranche, the French philosopher, as well as his impressions of French drama and opera. He spent the year 1701 in leisurely travel in Italy, viewing ancient ruins, mountains, and rivers, as well as statues, paintings, and medals, against the background of Horace and Virgil, Claudian and Silius Italicus, who were to figure in his *Remarks on several Parts of Italy* (1705). "A Letter from Italy" (1704), a poetic epistle to Lord Halifax, records his delight in surveying these "poetic fields." The prose *Remarks*, addressed to Lord Somers, reveals not only his interest in the arts but also a true Whig's hatred of despotic power and the concentration of wealth in the papal treasury, contrasted with the widespread poverty of the people. From Italy Addison crossed the Alps at Mont Cenis into Switzerland, where, in Geneva, he learned in March 1702 of the death of William III and the consequent loss of power of his two chief patrons, Somers and Halifax. Instead of returning to England, therefore, he remained in Switzerland through the summer and then made an extended tour to Vienna, Dresden, Hanover (for a visit to the electress Sophia, the mother of the future King George I of England), and Hamburg, finally reaching Holland. There he lingered nearly a year, with visits to such men of letters as Pierre Bayle and contacts with Englishmen in Amsterdam, including the publisher Jacob Tonson (who was then in Holland arranging for the first English publication of Bayle's great *Dictionary*), before returning to England in 1704.

Government service. In London Addison renewed his friendship with Somers and Halifax and other members of the Kit-Cat Club, founded by Tonson as an association of prominent Whig leaders and literary figures of the day—among them Steele, William Congreve, Sir John Vanbrugh, and Sir Samuel Garth. In August of this year London was electrified by the news of the Duke of Marlborough's sweeping victory over the French at Blenheim, and Addison was approached by government leaders to write a poem worthy of the great occasion. Even before the final draft was completed, Addison was appointed commissioner of appeals in excise, a sinecure left vacant by the death of John Locke. *The Campaign*, addressed to Marlborough, was published on December 14 (though dated 1705), the very day the Duke returned in triumph to London. By its rejection of conventional classical imagery (what Dr. Johnson called its "rational and manly contempt of fiction") and its effective portrayal of Marlborough's military genius, it was an immediate success, and three editions were sold before the year's end. It perfectly expressed the nation's great hour of victory.

Years as undersecretary. The Whig success in the election of May 1705, which saw the return of Somers and Halifax to the Privy Council, brought Addison increased financial security in an appointment as undersecretary to the secretary of state for southern affairs, a position of considerable administrative importance, with an income of over £500 a year. With an office at the Cockpit (the government offices in Whitehall), Addison found himself in a busy and lucrative post, involving correspondence with diplomats abroad and a variety of business at home. Early in 1706 he accompanied Halifax to the court of Hanover to discuss details of the Act of Settlement, providing for the Hanoverian succession upon the death of Queen Anne; here and in Holland contacts were renewed with Bayle, the German philosopher Leibniz, and other men of letters. Addison's retention in a new, more powerful Whig administration in the autumn of 1706 reflected his further rise in government service.

Collaboration with Steele

At this time he began to see much of Steele, helping him write *The Tender Husband* (1705), for which he also provided a prologue; when the play was published it carried a dedication to Addison in honour of "an inviolable friendship." In practical ways Addison also assisted Steele with substantial loans and the appointment as editor of the official London *Gazette*. Moreover, as undersecretary, Addison frequently supplied him with material for the paper. He lodged with Steele during the summer of 1707, until the latter's marriage in September, when Addison moved to larger quarters.

As a challenge to the popularity of Italian opera, Addison chose to write an opera in English centred on the legend of "fair Rosamond" and set in Woodstock Park, site of Marlborough's Blenheim Palace. For the music he engaged Thomas Clayton, composer of *Arsinoe, Queen of Cyprus*—an unfortunate choice as it turned out; when *Rosamond* was staged at Drury Lane (March 4, 1707), it ran for only three nights. The libretto itself was well constructed and the lyrics light and effective. Later in the century, with new music by Thomas Augustine Arne, it in fact proved very popular.

Duties in Ireland. In 1708 Addison was elected to Parliament for Lostwithiel in Cornwall and later in the same year was made secretary to the Earl of Wharton, the new lord lieutenant of Ireland. Addison's post was in effect that of secretary of state for Irish affairs, with a revenue of some £2,000 a year. In addition to routine duties as Irish secretary, he was responsible to the crown for much official policy in Ireland, where such delicate matters as the Test Act, the laws against Roman Catholics, and the settlement of the Protestant palatines required a tactful and firm hand. He was elected a member of the Irish Parliament taking his seat as representative for Cavan on May 15, 1709. He also interested himself in the preservation and arrangement of the Irish public records, purchasing the office of keeper of the records in Bermingham's Tower, which he developed into a responsible office with an annual salary of £400.

Addison served as Irish secretary for the two years during which Wharton was lord lieutenant, residing in Dublin Castle from April to September 1709 and from May to August 1710, spending the winter months in England. It was during his term as Irish secretary that his friend Steele began publishing *The Tatler*, which appeared three times a week under the pseudonym of Isaac Bickerstaff. The first number appeared on April 12, 1709, while Addison was still in England, but according to his first biographer (Thomas Tickell), it was not until the appearance of No. 6 (on April 23) that Addison recognized an observation on Virgil that he himself had made to Steele and knew him to be "Isaac Bickerstaff." It seems unlikely, however, that Steele should have kept the project a secret from Addison, since the two were close friends and had virtually collaborated on the *Gazette*. At any rate, while still in Ireland, Addison began contributing to the new periodical. Back in London in September 1709, he supplied most of the essays during the winter of 1709–10 before returning to Ireland in May.

Publication of *The Tatler*

Years of Tory dominance. The year 1710 was marked by the overturn of the Whigs from power and a substantial Tory victory at the polls. Although Addison easily retained his seat in the Commons—this time for Malmesbury in Wiltshire—his old and powerful patrons were again out of favour, and for the first time since his appointment as undersecretary in 1705, Addison found himself without employment. He was thus able to devote even more time to literary activity and to cultivation of personal friendships not only with Steele and other Kit-Cats but, for a short period, with Jonathan Swift—until Swift's shift of allegiance to the rising Tory leaders resulted in estrangement. Addison continued contributing to the final numbers of *The Tatler*, which Steele finally brought to a close on January 2, 1711.

Thanks to Addison's help *The Tatler* was an undoubted success, although it had met with criticism because of Steele's attacks on the new Tory government. By the end of 1710 Steele had enough material for a collected edition of *The Tatler;* thereupon, he and Addison decided to make a fresh start with a new periodical. *The Spectator*, appearing six days a week, from March 1, 1711, to December 6, 1712, offered a wide range of material to its readers, from discussion of the latest fashions to serious disquisitions on criticism and morality, including Addison's weekly papers on *Paradise Lost* and the series on the "pleasures of the imagination." The members of the Spectator Club, whose speculations the new paper professed to publish, were (besides Mr. Spectator himself) Sir Roger de Coverley, an eccentric and old-fashioned country squire; Captain Sentry, a retired army officer; Sir Andrew Freeport, a merchant "of great eminence in the City"; a member of the Inner Temple and frequenter of playhouses; Will Honeycomb, an elderly beau who fancied himself knowledgeable in the ways of women; and finally, a grave and learned clergyman. In bringing learning "out of closets and libraries, schools and colleges, to dwell in clubs and assemblies, at tea-tables, and in coffee-houses," *The Spectator* was eminently successful—as shown by the great variety of letters from readers and the steadily increasing number of advertisements printed. Over 3,000 copies were published daily, and the 555 numbers were then collected into seven volumes. Two years later (from June 18 to December 20, 1714) Addison published 80 additional numbers, with the help of two assistants, and these were later reprinted as volume eight.

Subject matter of *The Spectator*

Addison's other notable literary production, while in the political wilderness during the years of Tory dominance, was his tragedy *Cato*. Performed at Drury Lane on April 14, 1713, the play was a resounding success—largely, no doubt, because of the political overtones that both parties read into the play. To the Whigs Cato seemed the resolute defender of liberty against French tyranny; while the Tories were able to interpret the domineering Caesar as a kind of Roman Marlborough whose military victories were a threat to English liberties. The play enjoyed an unusual run of 20 performances in April and May 1713, eight editions were sold within the year, and it continued to be performed, read, and quoted throughout the century.

Success of *Cato*

Later years. With the death of Queen Anne on August 1, 1714, and the accession of George I, Addison's political fortunes rose. He was appointed secretary to the regents (who governed until the arrival of the new monarch from Hanover) and in April 1717 was made secretary of state. Ill health, however, prevented his taking a very active part in government affairs, and he resigned the office the following year. Meanwhile, he had married the dowager Countess of Warwick and spent the remaining years of his life in comparative affluence at Holland House in Kensington. A series of political essays, *The Free-Holder, or Political Essays*, was published from December 23, 1715, to June 29, 1716, and his comedy *The Drummer* was produced at Drury Lane on March 10, 1716. The dispute over Lord Sunderland's bill for restricting the peerage, in which Addison and Steele took opposing sides, unfortunately estranged the two friends during the last year of Addison's life. He died on June 17, 1719, and was buried in Westminster Abbey, near the grave of his old patron and friend Lord Halifax.

MAJOR WORKS

POEMS: "A Letter from Italy" in Dryden's fifth miscellany (1704); *The Campaign* (1705); Latin verse in vol. 2 of *Musarum Anglicanarum Analecta*, ed. by Addison (1699).

DRAMATIC WORKS: *Rosamond: An Opera* (1707); *Cato: A Tragedy* (1713); *The Drummer; or, the Haunted-House, a Comedy* (1716).

PERIODICAL ESSAYS: *The Tatler* (1709–11), about 42 numbers; *The Whig Examiner* (1710), all 5 numbers; *The Spectator* (1711–12), 251 numbers; *The Guardian* (1713), 53 numbers; *The Lover* (1714), 2 numbers; *The Reader* (1714), 2 numbers; *The Spectator*, 2nd series (1714), 25 numbers; *The Free-Holder, or Political Essays* (1715–16), all 55 numbers; *The Old Whig* (1719), both numbers.

OTHER PROSE WORKS: *Remarks on Several Parts of Italy* (1705); *The Present State of the War* (1708); *The Late Tryal and Conviction of Count Tariff* (1713).

BIBLIOGRAPHY. Addison's works were published with a life by THOMAS TICKELL, 4 vol. (1721; reprinted 1730, 1741, 1804); and by JOHN BASKERVILLE (1761); edited with notes by RICHARD HURD, 6 vol. (1811); and in Bohn's British Classics, 6 vol. (1854–56, frequently reprinted); and by G.W. GREENE, 6 vol. (1856). The standard modern edition of the *Miscellaneous Works* (poems, plays, and prose, omitting the periodical essays) is by A.C. GUTHKELCH, 2 vol. (1914). Addison's *Letters* were edited by WALTER GRAHAM (1941). The definitive edition of *The Spectator* is by DONALD F. BOND, 5 vol. (1965), who has also edited *Critical Essays from the Spectator* (1970). The standard biography is PETER SMITHERS, *The Life of Joseph Addison*, 2nd ed. (1968).

(D.F.B.)

Aden, Gulf of

The Gulf of Aden is the deepwater basin that forms a natural sea link between the Red Sea and the Arabian Sea. Named after the seaport of Aden, in Yemen (Aden), at its western end, the gulf is situated between the coasts of Arabia and the "horn" of Africa. To the west, it narrows into the Gulf of Tadjoura; its eastern geographic limits are defined by the meridian of Cape Guardafui (51°16′ E). In oceanographic and geologic terms, however, it extends to the eastern limits of the continental

shelf beyond the Kuria Muria Islands to the north and the island of Socotra to the south, covering an area of some 205,000 square miles (530,000 square kilometres). Its total length, measured from east-northeast to west-southwest, is 920 miles, and its mean width, measured from north-northeast to south-southwest is 300 miles.

The Sheba Ridge

Submarine relief. The dominant relief feature is the Sheba Ridge, an extension of the ridge system of the Indian Ocean, which extends along the middle of the gulf. The rough topography of the ridge includes a well-defined median valley that is continually offset by faults running approximately northeast to southwest. The largest of these faults forms the Alula-Fartak Trench, in which is found the gulf's maximum recorded depth of 17,586 feet (5,360 metres). The Sheba Ridge is flanked on both sides by sediment-filled basins that reach depths of 13,000 feet at the mouth of the gulf. To the west, the ridge gives way to a relatively shallow east–west-trending valley known as the Tadjoura Trench.

Geology. The main factor in the gulf's geologic formation is the spreading of the sea floor away from the Sheba Ridge axis. The African and Arabian continents split initially along the present continental margins either in the late Eocene Epoch (38,000,000 to 54,000,000 years ago) or else in the Oligocene Epoch (26,000,000 to 38,000,000 years ago). They have since drifted apart in a direction parallel to the gulf's faults.

The gulf is underlain by an oceanic crust, and the Sheba Ridge is characterized by shallow earthquake activity, high heat flow, fresh lavas, and a thin or absent sedimentary cover. The evolution of the gulf is also linked with the geological evolution of the East African Rift Valley and of the Red Sea.

Bottom deposits. Sediment thicknesses increase away from the Sheba Ridge toward the continental shelf, especially in the region south of the Wādī Ḥaḍramawt (a seasonal river that drains into the gulf from the Arabian Peninsula), where a thickness of about one mile is found. Brown, green, and gray muds—characteristic of materials originating on land—predominate near the coasts. The basins are filled mainly with material from the coastal margins, eroded by turbid water currents, while sediments formed in deep water far from land predominate on the Sheba Ridge. A slight amount of wind-blown material is also present.

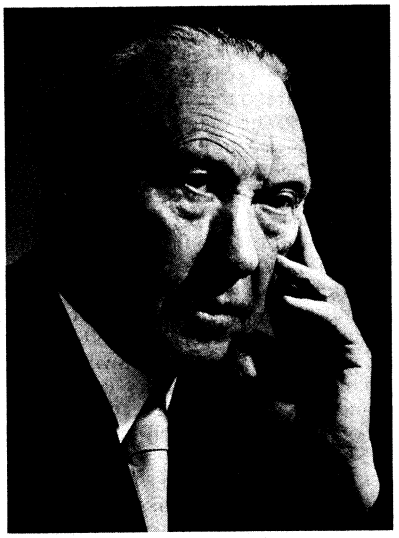
Currents, temperature, and salinity. The intensive exchange of water between the Red Sea, the Gulf of Aden, and the Arabian Sea, as well as strong evaporation and monsoon (rain-bearing) winds that constitute part of the air flow, all assist in the formation of a complex water structure. The surface layer is highly saline, and eddies complicate its flow pattern. During the northeast monsoon from November to March, the surface temperature is fairly uniform—between 77° and 82° F (25° and 28° C). During the stronger southwest monsoon from May to September, however, horizontal temperature gradients develop, with temperatures ranging from 77° to 88° F (25° to 31° C). In the subsurface layer, at depths of from 300 to 2,000 feet, slightly less saline water flows from the Arabian Sea and passes into the Red Sea through the straits of Bab el-Mandeb. This flow is reversed below 2,500 feet in a highly saline layer that originates in the Red Sea. A low temperature and salinity layer occurs at depths of from 3,000 to 6,000 feet down to the bottom in the east but only in the depressions to the west.

Marine life. Marine life is rich in both the quantity and the variety of its species. Seasonally variable upwelling of waters in the coastal zone provides the surface layer with a considerable supply of nutrient elements, which produce an abundant growth of plankton. Sardines and mackerel abound in these areas of upwelling. The main open-sea fish are dolphin, tuna, billfish, and sharks. Whales are frequently sighted. The gulf provides a breeding ground for sea turtles, and rock lobster are abundant.

Species of fish

Fisheries. Despite a lack of large-scale commercial fishing facilities, the coastline supports many isolated fishing towns and villages. Local fishing takes place close to the shore; sardines, tuna, kingfish, and mackerel make up the bulk of the annual catches. Crayfish and sharks are also fished locally, while survey ships have occasionally pulled in exceptional catches of fish.

Prospects for the future. Future development of the gulf is difficult to predict because it has been little studied. Except for the fisheries, little is known of its resources. Full development of the fishing industry is contingent upon a better understanding of the considerable seasonal, annual, and regional variations in the movements of fish populations.



BIBLIOGRAPHY. The morphology, geology, and geophysics of the gulf and its surrounding areas are comprehensively covered in various articles in the *Phil. Trans. R. Soc.*, Series A, vol. 267, no. 1181 (1970), which also contains up-to-date bathymetric and magnetic charts of the gulf itself. The hydrological structure of the water mass is described by V.A. KHIMITSA in *Oceanology*, 8:318–322 (1968); while its physical and chemical properties are covered in the *University of California, Institute of Marine Resources Report, I.M.R. Reference 67–12* (1967). Biology is not covered by any standard text but fishery data is reported in the *Commercial Fisheries Review* (monthly).

(M.T.J.)

Adenauer, Konrad

First chancellor of the Federal Republic of Germany, Konrad Adenauer presided over the reconstruction of the western part of Germany after World War II. During his tenure of office (1949–63), West Germany regained its sovereignty, re-armed, and won a respected place in the affairs of Europe.

©Karsh—Rapho Guillumette

Adenauer.

Konrad Adenauer was born on January 5, 1876, the son of a Cologne civil servant. He grew up in a Roman Catholic family of simple means in which frugality, fulfillment of duty, and religious dedication were stressed. He studied jurisprudence and political science at the Universities of Freiburg, Munich, and Bonn. In 1906 he was elected to the Cologne City Council and, in 1917, during World War I, was chosen *Oberbürgermeister*, or lord mayor, of the city. From 1920 he served as a member of the Staatsrat (the central organ representing the diets of the Prussian provinces) and in 1928 was elected its speaker. Politically, he belonged to the Centre Party, which in Cologne was long the leading political force. The largest part of German Catholicism became politically entrenched in it. The conflict between Bismarck and the Vatican had caused the state and German Catholicism to become critically and widely separated. In the Rhineland at that time, Catholicism was submerged in the reservations of the German states, which had come under Prussian rule only in the 19th century.

Mayor of Cologne

Such influences and moods were shared with Adenauer, but they do not explain why he never seized on the opportunities offered by the Central Party to play a forma-

tive role in German politics in the Weimar Republic between 1919 and 1933. Nevertheless, under the Weimar Republic Adenauer's career remained confined to local politics; his inner aloofness and his alienation from the leading men of his own party might have contributed to this. During the Nazi regime he was twice imprisoned.

At the end of World War II, Adenauer returned to his birthplace. The Allied military authorities called him back to his old office, but, before he could begin his task of rebuilding the beautiful, old, bomb-shattered city, Adenauer was dismissed by Sir John Barraclough, British military governor of the North Rhine area, who found him politically incompetent. This second fall from power did not cause Adenauer to withdraw from public life. On the contrary, it released him for his real mission.

Even before the end of the war, a new political party was being formed—the German Christian Democratic Union (CDU)—in which Catholics and Protestants buried their long-standing differences to present a common front against Nazism and to promote Christian principles in government. This movement sprang from the insights of many that the old parties of the civil camp were obsolete and were in their death throes and that the Catholics and the Protestants must unite. This was something new for Germany, which for centuries following the Reformation had created a climate in which the two communities encountered each other often polemically or at a respectful distance. Adenauer was now able to play an important role in the formation of the new party, and in 1946 he became its chairman. He had always had a sharp eye for the possibilities and necessities of political tactics. The CDU began expanding in the four zones of the Allied occupation. As the Soviet Union began increasingly to obstruct the Allied Control Council, the Western Allies decided to give their three occupation zones a federal–state organization. Adenauer became president of the Parlamentarischer Rat (Parliamentary Council), the task of which was to work out a provisional constitution for the intended Federal Republic. The first Bundestag elections took place in August 1949. The CDU won with a narrow majority over the opposition Social Democratic Party (SPD), and Adenauer was appointed chancellor.

Chancellor

As a result of his upbringing and education, Adenauer was always opposed to Socialist ideas. He rejected the notion of an egalitarian mass society, arguing that it would not allow legitimate leadership to emerge. His leading political theme was individualism under the rule of law. He was imbued with the conviction that the state must guarantee its citizens optimal room for independent intellectual and economic development, as well as absolute protection under the law. In these views Adenauer reflected the Roman Catholic social teachings of Pope Leo XIII.

The political platform of the CDU, however, went beyond Adenauer's ideas; it advocated some programs of a Socialist nature. In the controversies that resulted from his party's social program, Adenauer restrained himself—both as chairman of the party and as a government official—from interference. Such restraint was not entirely in keeping with his nature and position.

But Konrad Adenauer was not a politician with merely private interests; he was quite pragmatic in his approach. He was willing to compromise on domestic programs with which he philosophically disagreed so that he could promote the unity of the country and give West Germany an important place in the European community.

Foreign policy

Indeed, the focus of his interest throughout his career lay in foreign affairs. He viewed the expansion of Communist rule into the heart of Europe as a direct threat to the West and its values. He had no faith in the possibility of peaceful coexistence with the Communist world and felt the need for tough opposition to any aggressive military threats from the Communist bloc. He considered as irreconcilable the principal differences between individualistic rule of law and totalitarian dictatorship and between humanistic–Christian teachings and Communist social regimentation. He therefore became a strong advocate of the politics of containment. He was not, however, an opponent of the relaxation of tensions. Under the circumstances, he felt that a policy of appeasement was utterly illusory, if not traitorous. Except for the period during which Nikita S. Khrushchev was in power in the Soviet Union, Adenauer believed the Communist bloc to be a direct military threat that could only be held in check by superior deterrent forces. As a result, he energetically supported German contributions to the North Atlantic Treaty Organization (NATO) and its nuclear arsenal, and he would have preferred the development of a European defense community. He saw in its creation one of the most promising instruments for imparting to Europe a new order and character. A prerequisite for this defense community was the reconciliation of Germany with its neighbours, especially France, and Adenauer worked for this with all his strength.

During Adenauer's chancellorship his opponents demanded that Germany be neutralized and placed in a position of non-alignment between the Eastern and Western blocs. But Adenauer and his party won all major elections because they declared that the risks to security in such a policy would be intolerable. Behind this position was a decision made by the CDU and its party leaders to guide Germany out of its historically vulnerable position between East and West by making the nation an intrinsic part of a united Europe.

To the end of his life, Adenauer was reproached, unfairly, for not having seriously desired the reunification of Germany, but he believed that it was impossible to come to terms with the Soviet Union. In addition, he had made his decision to bring German policies into close alignment with those of the West.

In 1963 Adenauer turned over the chancellorship to Ludwig Erhard, who claimed much credit for the "miracle" of Germany's economic recovery after the war.

There were no political reasons for his decision to step down from office; rather, it was his belief that at age 88—after 14 years in national government—he had grown too old to lead the nation. Thereafter, he began to write his memoirs. Nevertheless, he continued as chairman of the CDU until March 1966.

Personal characteristics

That Adenauer was able to hold his demanding office into the ninth decade of his life bespeaks his excellent physical, mental, and spiritual constitution, his first class staff, and loyal party. Equally important—and in many instances even more important—were the congenial relations he enjoyed with the American and European statesmen, particularly U.S. secretary of state John Foster Dulles and French president Charles de Gaulle. Adenauer's open and undisguised warmth toward these statesmen belies the charge that he was a cold and suspicious individual. He was merely a sober man of great sensibility who despised wishful thinking, which he held to be especially dangerous for Germany. His use of language served him in his political goals, for it was sharpened to be intelligible and convincing to the common man; and its simplicity emphasized his authority.

In his personal life, Adenauer was unpretentious and extremely disciplined. His family was gathered around him, and he was its patriarch. He was married twice and was twice widowed. He ate little, detested smoking, and loved to work in his large garden. He cultivated a deepened appreciation for painting, and several works of old masters adorned the walls of his own home as well as his official residence—the Schaumburg Palace. As a rule, his day began early and ended late, for he required little sleep.

Konrad Adenauer died on April 19, 1967. Among the friends and opponents of the past who visited West Germany to pay a last farewell were the leaders of the United States and France, as well as many other heads of state, including David Ben-Gurion of Israel.

(1965–68), his autobiography encompassing the years 1945 to 1963; RUDOLF MORSEY and KONRAD REPGEN (eds.), *Adenauer-Studien*, vol. 1 (1971), contributions by four German historians and political scientists on the politics and personality of Adenauer; PAUL WEYMAR, *Konrad Adenauer* (1955), an authorized popular biography that provides the best description of his life.

(Eu.G.)

Adhesives

Adhesives are substances capable of holding materials together by surface attachment. Egyptian carvings dating back 3,300 years depict the gluing of a thin piece of veneer to what appears to be a plank of sycamore. Papyrus, an early, nonwoven fabric, has the fibres of reed-like plants bonded together with flour paste. Bitumen, tree pitches, and beeswax were used as sealants (protective coatings) and adhesives in ancient and medieval times. The gold leaf of illuminated manuscripts was bonded to paper by egg white, and wooden objects were bonded with glues from fish, horn, and cheese.

In the 19th century rubber- and pyroxylin-cements were introduced, but decisive advances in adhesives technology awaited the 20th century, during which natural adhesives have been improved and many synthetics have come from the laboratories. Adhesives are now essential components of plywood, automobiles, shoes, furniture, cartons, nonwoven fabrics, and a host of other products. While the natural products such as hide glue, starch and dextrin, casein, and natural gums are still important from the standpoint of cost, the synthetics have largely taken over the adhesives industry both as modifiers of natural materials and, more importantly, as high-strength, moisture-resistant additives capable of being produced in many readily usable forms.

The rapid growth of the aircraft and aerospace industries has had a profound impact on adhesives technology. The demand for a high degree of structural strength coupled with resistance to fatigue and severe environmental conditions has led to the development of high-performance materials, counterparts of which have found their way into many industrial and domestic applications.

Polymeric materials

Virtually all synthetic adhesives and certain of the natural materials are polymeric. A polymer is a substance composed of giant molecules formed by the union of from two to hundreds of thousands of simple molecules. The simple molecules that will undergo such a change are known as monomers and their union is called polymerization. The monomer molecules may be all alike, or there may be two or more varieties of monomer involved in the formation of a single polymer. Ethylene molecules can be united with themselves to form a monopolymer or homopolymer such as polyethylene. Copolymers involving a wide variety of monomer types may be formed; the synthetic rubber SBR (styrene-butadiene rubber) which is based on styrene and butadiene monomers, is one example of a relatively simple copolymer. Many polymeric materials offer the high degree of strength, and often flexibility, necessary in many adhesives applications.

A few of the more important advantages of adhesive bonding include: (1) rapid, economical joining, (2) a means of providing a new structural or composite unit, (3) more uniform distribution of stress, (4) a means for obtaining surfaces free of holes or protuberances or with unusual contours, (5) a method of forming joints sealed against moisture, and (6) an important means for minimizing potential points of corrosion so often evident in mechanical joining or even in welded metal components.

Some recent developments in adhesives and bonding include delayed-tack adhesives that after hardening can be reactivated for controlled periods of time by heating; conductive adhesives for use in thermal or electrical applications; anaerobic adhesives that set in the absence of air; hot-melt applied adhesives capable of reactivation with water; high-heat-resistant products without embrittlement tendency at very low temperatures; encapsulated adhesives activated by pressure; adhesives capable of electrodeposition on complex metal shapes; improved surgical adhesives; and adhesives for the construction, garment, and plumbing industries.

In the early 1970s adhesives were proliferating in applications and growing steadily in total volume. Synthetic resin products were increasing. Worldwide adhesive production reached 7,500,000,000 pounds (3,400,000,000 kilograms) in 1970, and promised to reach 14,000,000,000 pounds (6,300,000,000 kilograms) by 1980.

Adhesive types. Adhesives in current use may be classified into a number of groups.

Thermoplastic adhesives. Under normal temperature conditions these materials are capable of supplying the strength needed for a variety of uses and can be softened, or resoftened, by heating. They reharden on cooling without undergoing any chemical change.

Thermosetting adhesives. These polymers are used in higher demand structural applications and have the ability to form a permanently solid, heat-resistant material by cross linking, that is, the joining of long-chain polymers to each other by lateral linking.

Contact adhesives or cements. These usually are based on solvent solutions of neoprene, a relatively crystalline elastomer, and are in common use for installing hard-surfaced, counter-top laminates. Contact cements are so named because they usually are applied to both surfaces to be bonded. Following evaporation of the solvent component, the two surfaces may be joined to form a strong bond with a high resistance to shearing (sliding) forces.

Hot-melt adhesives. Products of this type contain no solvent or dispersant. Resins on which they are based are fusible as well as adhesive in character. These adhesives are applied in a molten state and, on cooling, form rigid, strong bonds. Their principal use is in packaging and lamination.

Pressure-sensitive adhesives. Materials of this group usually are used on such products as masking or mending tapes or as backings for some strippable wall coverings. Not high-strength materials, these are today generally based on synthetic elastomeric components.

Remoistenable adhesives. This group of adhesives includes the products commonly used for sealing envelopes, applying stamps or labels, or as adhesives for cartons or package-sealing tapes. Products of this type are applied from solution or dispersion and allowed to dry. The adhesive characteristic of the base material is reactivated by the application of water.

Adhesive forms. Adhesives exist in a variety of forms that include: (1) solutions in water or other solvent; (2) dispersions or emulsions, in which minute drops of liquid are dispersed in a solvent; (3) preformed sheets or tapes, sometimes reinforced with a woven or nonwoven carrier for the adhesive; (4) hot melts, where no solvent is required and the material forms a strong bond on cooling; and (5) monomeric, which polymerize rapidly in place to form a strong bond.

Theory of adhesion. During the 1960s studies were undertaken to provide a better understanding of adhesion. This work has been concerned largely with familiar physical-chemical phenomena, but a new broader theory of adhesion called the adsorption theory has emerged and is steadily gaining in favour. This theory holds that adhesives stick primarily because of intimate intermolecular contact; thus, if any two materials are placed close enough together presumably they will adhere. If this theory is true, adhesion requires no chemical bond and no mechanical dovetailing. Proponents point to a universal intermolecular force that holds the solid matter of the world together, and suggest that adhesion is a matter of physical adsorption, an attraction mechanism inherent in any surface.

The adsorption theory of adhesion contradicts the popular notion that adhesives must be sticky or tacky substances. Any material is potentially adhesive, for example, water. Water can make close molecular contact with a material; it fails to hold merely because its shear strength is low, and it evaporates. Copper can be an adhesive, but it can only be used to join materials capable of withstanding its high melting temperature. Even polyethylene, which is slippery and difficult to wet, potentially is a good adhesive if handled properly.

To best achieve the extensive and intimate contact required for adhesion, surfaces must be clean, and one of the materials must be fluid during some phase of the bonding process. For best results, the adhesive must not only be fluid, it must also spread, flowing into surface crevices rather than bridging over them.

Adhesives must either be used in a thin layer or have high cohesive strength, that is, the adhesive material itself must be strong when it sets to prevent failure of the bond during use. Maximum bond strength may be obtained by loading the adhesive joint in a preferential direction; thus, best performance with a large bond area is obtained when loading is "in shear," that is, when the loading pressure pulls the adhesive surface across the bonded surface. If the pull is "in tension," that is, pulling the adhesive directly away from the bonded surface, the stress on the adhesive is much greater.

NATURAL ADHESIVES

Natural adhesives are primarily of animal or vegetable origin. Sodium silicate (water glass) is virtually the only inorganic natural product important as an adhesive. It is also the only nonpolymeric adhesive material used in significant volume. Though the demand for natural products has declined in the second half of the 20th century, certain of these continue to be used in considerable volume, particularly in the wood and paper fields. The more important natural products are described below:

Collagen

Animal glue. The term animal glue usually is confined to glues prepared from mammalian collagen, the principal protein constituent of skin, bone, and sinew. Other types of glue obtained from animal sources are usually referred to according to the material from which they are derived, for example, casein glue. Soybean glue, in spite of its vegetable origin, is usually included in this broad category because of its protein nature.

When treated with acids, alkalies, or hot water, the insoluble protein collagen slowly becomes soluble. If the original protein is pure and the conversion process is mild, the high molecular weight product is called gelatin and may be used for edible or photographic products. The lower molecular weight material produced by more vigorous processing is normally less pure and darker in colour and is called animal glue.

Animal glue traditionally has been used in wood joining, book bindery, sandpaper manufacture, heavy gummed tapes, and similar applications. In spite of its advantage of high initial tack (stickiness), much animal glue has been modified by or entirely replaced with synthetic products.

Casein glue. This product is made by dissolving casein, a protein obtained from milk, in an aqueous alkaline solvent. The degree and type of alkali influences product behaviour. In wood bonding, casein glues generally are superior to true animal glues in moisture resistance and aging characteristics. Casein also is used to improve adhering characteristics of paints and coatings.

Blood albumen glue. Glue of this type can be made from either fresh slaughterhouse blood or dried soluble blood powder to which water has been added. Addition of alkali to albumen-water mixtures improves adhesive properties. A considerable quantity of glue products from blood is used in the plywood industry.

Vegetable adhesives. Vegetable adhesives are those that are soluble or dispersible in water and are produced or extracted from natural sources by relatively simple processes. Other adhesives of vegetable origin, such as rubber cements, nitrocellulose, and ethyl cellulose lacquer cements are extracted or produced from plant sources; but these are not water soluble or water dispersible and are not usually called vegetable adhesives.

Vegetable adhesives are obtained from plant sources throughout the world. Starches (and dextrins), which constitute the principal source of adhesives of this type, may be extracted by commercial means from corn, wheat, potatoes, or rice. Their major uses are in corrugated board, packaging, and as a wallpaper adhesive.

Natural gums

Substances known as natural gums extracted from their natural sources also are used as adhesives. Agar, a marine-plant colloid (suspension of extremely minute particles), is extracted by hot water and subsequently frozen for purification. Algin is obtained by digesting seaweed in alkali and precipitating either the calcium salt or alginic acid. Gum arabic is harvested from acacia trees artificially wounded to cause the gum to exude. Chitin, although produced principally from the skeletal material of invertebrates, is loosely classified as vegetable. Synthetically produced carbohydrate adhesives are made from dextrans, in turn produced by the fermentation of sucrose. Most gums are used chiefly in water-remoistenable products.

SYNTHETIC RESIN ADHESIVES

Adhesives based on synthetic resins excel in versatility and performance. A wide range of base polymers may be synthesized for adhesive and other uses in a constant supply of uniform products. Synthetic resins can be modified in many ways and are often combined to obtain the best characteristics for a particular application. Synthetic adhesives may be divided into two main categories: thermoplastic, and thermosetting. A third category, which sometimes straddles the two, is the class of rubber- or elastomer-based materials (see also PLASTICS AND RESINS).

Thermoplastic resin adhesives. A number of different resins may serve as thermoplastic adhesives and may be used in the form of solutions, dispersions, or solids.

Vinyl resins. The vinyl resins, all of which contain a vinyl ($CH_2 = CH-$) group in their molecules, comprise the largest class of thermoplastic adhesives. Many modifications are available; the adhesive bonds may be formed either by fusing with heat or by evaporation of solvent. Vinyl acetate, obtained by the reaction of acetylene, a gaseous hydrocarbon, and acetic acid, the chief acid of vinegar, with a suitable catalyst, can be polymerized to form the white emulsions or water dispersions often sold for household use and consumed industrially in large quantities for bonding wood and paper products.

Other polyvinyl resins are used in laminating shatterproof glass, in bonding plastic sheet to metals, in various construction applications, and in bonding upholstery materials to furniture frames.

Styrene, synthesized from ethyl benzene, may be polymerized to form polystyrene, which is used either in solution or aqueous dispersion to bond plastic tile to wood, plaster, or concrete materials.

Acrylates, resins derived from acrylic acid, a liquid organic acid that polymerizes readily, are displacing rubber and rosin in pressure-sensitive adhesive tapes.

The cyanoacrylates, monomers that polymerize spontaneously in place, form excellent bonds almost instantly to a variety of surfaces. Materials of this group have been used as tissue adhesives in surgical procedures.

Cellulose derivatives. Certain esters and ethers, compounds derived from cellulose, a complex carbohydrate that comprises the main part of plant cell walls and yields many fibrous products, have been used extensively as adhesives.

Cellulose acetate and cellulose nitrate are dissolved in solvents to form quick-drying, general-purpose, household adhesives; they are excellent for wood and paper and are resistant to moisture, but their adhesion to metal and glass is poor. Nitrocellulose was used to bond some of the early nonstitched footwear, but its use for this purpose is now limited.

Other thermoplastics. Polyamides, chemically similar to nylon, or modifications of them are used as hot-melt adhesives, as are rosin, rosin derivatives, ethylene, and vinyl acetate copolymers. Many other thermoplastic polymers also can be adapted for particular hot-melt applications.

Infusible and insoluble bonds

Thermosetting resin adhesives. Thermosetting adhesives are based on synthetic resins that, on hardening, or curing, undergo an irreversible chemical and physical change to become substantially infusible and insoluble. The type of chemical reaction responsible for the change varies with the resin type. Generally, thermosetting adhesives retain their strength better at elevated temperatures than do the thermoplastic adhesives. The number of resins in this category presently in use or potentially useful is large. Some of the major classes are listed below:

Urea–formaldehyde resins. Urea (a nitrogenous compound, the chief solid constituent of the urine of mam-

mals, synthesized from carbon dioxide and ammonia) and formaldehyde (a colourless, irritating gaseous compound made by oxidation of gaseous hydrocarbons) are made to undergo a condensation reaction, that is, a chemical change in which they combine, eliminating water and forming a polymer. The polymer molecules can be further cross-linked to form bonds that are resistant to moisture and heat. These urea–formaldehyde resins are in common use in the plywood industry.

Melamines. Melamine, an alkaline, white, crystalline, organic compound, reacts with formaldehyde in a way analogous to that of urea. The melamine and formaldehyde form a hard, clear, water-and-heat resistant product that is commonly used in bonding industrial and decorative laminates for door liners and counter tops.

Phenol–formaldehyde adhesives. Phenol, a poisonous crystalline organic acid, on condensation with formaldehyde, forms a phenolic resin that was one of the first thermosetting adhesives produced. It has been used in plywood, in structural and decorative laminates, in conventional glues, in adhesives for high-strength aircraft structural uses, and in other adhesive formulations to obtain additional resistance to water or heat, or to contribute hardness and rigidity.

Resorcinol–formaldehyde adhesives. Resorcinol, a crystalline phenol, reacts with formaldehyde to form a glue capable of setting without heat like the less costly phenolic resin, but unlike the phenolic glue that cures, or sets, under acid conditions, the resorcinol–formaldehyde adhesive cures under neutral or near neutral conditions. Resorcinol–formaldehyde adhesives are valuable in producing water-and-weather resistant wood bonds for structural and marine applications.

Epoxy resin adhesives. Epoxies are usually furnished in two parts, a resin containing an epoxide group (an oxygen atom joined to two other atoms that are already connected with each other), and a catalyst consisting of an amine or other compound that acts as a curing agent. These two parts are mixed together just before use, and hardening is rapid. Epoxies that are designed to harden at room temperature must be used within a short time after mixing, known as the pot life, often a half hour or less. Epoxies that need to be cured at elevated temperatures may be kept for days or even months at room temperature before they harden, but will harden quickly when heated. Epoxies may be formulated to form a hard, or a slightly flexible bond. Extremely strong bonds may be obtained that are resistant to moisture and high temperatures. Both porous and nonporous materials, including metals, may be bonded together with excellent adhesion. Since epoxies harden by chemical action and are made without solvents, they shrink very slightly on hardening; this quality adapts them for use on poorly fitted joints or where a considerable buildup is required. Their excellence as electrical insulators makes them useful in electronics and aircraft industries. Epoxy resins are used as surface coatings, and as laminating adhesives in making plastic tanks and pipes. They are used in formulations along with other adhesive types, for example those based on phenolics. There is an extremely large potential number of resins containing reactive epoxide groups.

Polyimide resins. Polyimide resins are polymers usually consisting of aromatic nuclei coupled by repeating imide linkages formed by condensation of a diacid or a diamine. These recently developed products are being used increasingly as binders for glass- or graphite-fibre-reinforced composite structures. High priced and relatively difficult to handle, these adhesives in the early 1970s were used only in applications where extreme resistance to heat is required along with good mechanical properties and chemical resistance. In these specialized applications, the polyimides tend to replace the more conventional epoxy, phenolic, and polyester adhesives.

Polyester resins. Polyester resins are polymers whose molecules contain many ester groups (–COO–). Esters are organic compounds analogous to salts in inorganic chemistry. These adhesives are used as binders for glass fibres in the formation of structural panels for luggage, boats, automobile bodies, and machine housings. Like other thermosetting resins, the polyesters harden by chemical action rather than by loss of solvent or dispersant.

Rigid or flexible bonds

Polyurethane-based adhesives. Polyurethanes are polymers containing repeating units of urethane structures which are a reaction product of di- or polyisocyanates with compounds containing active hydrogen. Polyurethanes also form many flexible and rigid foams, and coatings of many uses. Soluble polyurethane elastomers may be used as adhesives. Room-temperature curing is possible, but heat cures give superior bond strengths. Products can be formulated from starting components to yield a wide range of flexibility or rigidity. Polyurethanes have been used in bonding other rubberlike materials and also in laminating fabrics and foams in the garment industry.

Elastomeric adhesives. Elastomeric adhesives are based on natural as well as a variety of synthetic rubber materials. These include polymers such as SBR nitriles (made from the monomers butadiene and acrylonitrile), butyl rubber, neoprene (a synthetic rubber polymer), EPDM (made from monomers ethylene, propylene, and a diene), and others.

Various polymeric organic silicon compounds form adhesives that are rubberlike and retain good flexibility at low temperatures, yet are capable of withstanding temperatures as high as 500° F (260° C) for extended periods of time. These silicone elastomers usually lack high strength and do not adhere to all substances, but they can be modified to increase adhesive characteristics.

Administrative Law

Administrative law derives from the need to create and develop a system of public administration under law, a concept that may be compared with the much older notion of justice under law. Since administration involves the exercise of power by the executive arm of government, administrative law is of constitutional and political importance as well as of juridical significance.

The law regulating public administration

There is no universally accepted definition of administrative law that fits precisely the diverse systems obtaining in the many countries in which it exists in one form or another. A rational method of legal classification, however, defines each branch of the law according to the subject matter that it regulates; and thus administrative law is the law regulating public administration. This includes the organization, powers, duties, and functions of public authorities of all kinds engaged in administration; their relations with each other and with citizens and nongovernmental bodies; legal methods of controlling public administration; and the rights and liabilities of officials. The line between constitutional and administrative law is hard to draw, and over much of the ground these two branches of public law are complementary. The organization of a national legislature, the structure of the courts, the characteristics of a cabinet, and the role of the head of state are generally regarded as matters of constitutional law, whereas the substantive and procedural provisions relating to central and local governments and judicial review of administration are clearly matters of

administrative law. But some matters, such as the responsibility of ministers, cannot be exclusively assigned to either administrative or constitutional law. Some French and American jurists regard administrative law as including parts of constitutional law. This is one way of avoiding the dilemma.

The huge mass of substantive law relating to public health, education, housing, and other public services could logically be regarded as part of the corpus of administrative law; but from a practical point of view its sheer bulk makes the subject too unwieldy to master in a systematic manner. It is better, therefore, to consider these specialized bodies of law as ancillary branches (such as the law of taxation, the law of public health) to be used freely when appropriate in illustrating particular powers, functions, practices, or procedures applicable to administrative law.

GROWTH AND CHARACTERISTICS OF ADMINISTRATIVE LAW

Modern expansion of functions of the state

The growth in the functions of the state has been a worldwide phenomenon during the 20th century. It is to be found in the more developed and in the less developed countries; in both old and new states; in democratic, authoritarian, and totalitarian regimes; in the Communist countries of eastern Europe and in the mixed economies of the West. The movement is far from having reached its zenith. With each addition to the functions of the state, additional powers have been acquired by the administrative organs concerned, which may be central ministries, local, provincial, or regional governments, or special agencies created for a particular purpose.

Distinctions between public administration and private action. Many functions of government have no counterpart in private activity. Traffic control, fire-protection services, the arrest of criminals, smoke abatement, the construction or repair of highways, the provision of currency, town and country planning, customs and excise—these and innumerable other services are peculiar to government. In carrying out such functions, the executive organs are assumed to represent the collective will of the community and to be acting for the common good. For this reason they are given powers not normally conferred on private persons. They are authorized to require citizens to surrender their property rights and to restrict their freedom of action in many different ways, ranging from the quarantining of sick or suspected persons to the payment of taxes. To take another example, the postal laws are much more favourable to the post office and more severe to the customer than the law applying to common carriers. Again, a public authority that is building houses or clearing a slum is in a different—and much stronger—legal position than is a speculative builder or a private developer who is engaged in similar operations.

The result of the distinction between public administration and private action is that administrative law is quite different from private law regulating the actions, interests, and obligations of private persons. Civil servants do not serve under a contract of employment but have a special status. Taxes are not debts, nor are they governed by the law relating to the recovery of debts by private persons. The interrelations between executive organs and their relations with private individuals are usually regulated by compulsory or permissive powers conferred upon the executive organs by the legislature.

Internal and external aspects of administrative law

Administrative law is not all of a kind. The law regulating the internal aspects of administration is different from that which relates to its external aspects. The former comprises such matters as the relations between the government and its officials, the relations between a local authority and its committees, or between a central department and a local authority. The external aspects of public administration, on the other hand, deal with the relations between the administration and private persons or interests. In practice the internal and external aspects are often closely interwoven, and legal provisions of both kinds exist side by side in the same statute. Thus, a law dealing with education may modify the administrative organization of the education service and also regulate the relations between parents and the school authorities.

Another distinction can be made between the type of administrative law that consists of a command addressed by legislation to the citizen, requiring him to act or to refrain from acting in a certain way, and the type that consists of a direction addressed to the administrative authorities telling them how they must or may act. When a rule of administrative law takes the form of an unconditional command addressed to the citizen, a criminal penalty is usually attached to its violation. The application of the penalty is entrusted to the criminal courts, which can review any administrative action of which complaint is made, in the course of the enforcement procedure.

The need for legal safeguards over public administration. Statutory directions addressed to the executive authorities may impose absolute duties, or they may confer discretionary powers that authorize the administrative organ to take action of a specified kind in certain circumstances if it thinks fit. There are many variations of these types. Such legislation may give general directions that the executive bodies are to follow in establishing or operating a system of factory inspection or a policy of slum clearance or making a town-planning scheme. The statute lays down the conditions in which it will be lawful for the administration to act and clothes the authorities with the necessary powers, many of which confer large discretions. In legislation of this type, the action of the executive is not confined merely to carrying out the directions of the legislature. The executive often shares in the law-making process by being empowered to issue regulations or ordinances dealing with specified matters not regulated by the statute. This may be regarded as part of the ordinary process by which legislative powers are delegated by the legislature or as an essential feature of modern government, in which many matters are too technical, or too detailed, or too subject to frequent change, or too dependent on unforeseen emergencies to be included in the main body of legislation, which is less easy to change than regulations.

Problems of executive power

Whatever the source of the rule-making power of the executive may be, safeguards are necessary to ensure that it is properly exercised. The regulation must not exceed the delegated powers; its provisions must conform with the aims of the parent statute; prior consultation with interests likely to be affected should take place whenever practicable; and the regulations must not contravene relevant constitutional rules and legal standards. In some states regulations are scrutinized by the council of state before they come into force; in others the parliamentary assembly acts as the watchdog; while yet another method is review by the ordinary courts.

In most countries the executive arm of government possesses certain powers that are not derived from legislation, customary law, or a written constitution. In England the prerogative powers of the crown are now exercised by ministers in regard to such matters as making treaties, declaring war and peace, pardoning criminals, issuing passports, and conferring honours. In Italy, France, Belgium, and other European countries, certain acts concerning the higher interests of the state are recognized as *actes de gouvernement* and are thereby immune from control by any court or administrative tribunal. In the German Empire (1871–1918) the principle that an administrative act carried its own legal validity was accepted at the end of the 19th century by leading jurists. This led to the notion that administration was only loosely bound to the law. This doctrine was rejected in the Federal Republic of Germany (1949), and efforts were made to reduce the area in which the executive was free to act outside the controlling influence of administrative law.

Public administration consists of the execution of public policy by public authorities. It represents, therefore, the means by which the purposes of the state are promoted and realized in action. Administrative law is the legal framework within which public administration is carried on. One of its principal objects is to ensure efficient, economical, and just administration. A system of administrative law that impedes or frustrates administration

would clearly be bad, and so, too, would be a system that results in injustice to the individual. But to judge whether administrative law helps or hinders effective administration or works in such a way as to deny justice to the individual involves an examination of the ends that public administration is supposed to serve, as well as the means that it employs.

In this connection only the broadest generalities can be attempted. It can be asserted that all states, irrespective of their economic and political system, or of their stage of development, are seeking to achieve a high rate of economic growth and a higher average income per person. They are all pursuing the goals of modernization, urbanization, and industrialization. They are all trying to provide the major social services, especially education and public health, at as high a standard as possible. The level of popular expectation is much higher than in former ages. The government is expected not only to maintain order but to achieve progress. There is a widespread belief that wise and well-directed government action can abolish poverty, prevent severe unemployment, raise the standard of living of the nation, and bring about rapid social development. People in all countries are far more aware than their forefathers were of the impact of government on their daily lives and of its potentialities for good and evil.

Problems of bureaucracy

Bureaucracy and the role of administrative law. An inevitable consequence of the expansion of governmental functions has been the rise of bureaucracy. The number of officials of all kinds has greatly increased, and so too have the material resources allocated to their activities, while their powers have been enlarged in scope and depth. The rise of bureaucracy has occurred in the Communist countries, in the dictatorships and Fascist regimes, and in the political democracies. It is as conspicuous in the new states of Africa and Asia as among the highly developed countries of western Europe or North America. A large, strong, and well-trained civil service is essential in a modern state, irrespective of the political character of its regime or the nature of its economy.

Fear of the maladies that tend to afflict bureaucracy has produced a considerable volume of protest in some countries; and, even in those where opposition to the government or the party in power is not permitted, criticism and exposure of bureaucratic maladministration are generally encouraged.

Bureaucratic maladies are of different kinds. They include the overdevotion of officials to precedent, remoteness from the rest of the community, inaccessibility, arrogance in dealing with the general public, ineffective organization, waste of manpower, procrastination, an excessive sense of self-importance, indifference to the feelings or convenience of citizens, an obsession with the binding authority of departmental decisions, inflexibility, abuse of power, and a reluctance to admit error. Many of these defects can be prevented or cured by good management and careful training. A whole range of techniques is now available for this purpose, including public relations, work–study programs, organization and management (or methods), operational research, and the social survey.

Administrative law has a valuable contribution to make as an instrument for controlling the bureaucracy. In social-democratic regimes, political and judicial control of administration are regarded as complementary, but distinct. The former is concerned with questions of policy and the responsibility of the executive for administration and expenditure. The latter is concerned with inquiring into particular cases of complaint. Administrative law does not include the control of policy by ministers or the head of state. In the people's democracies of eastern Europe, however, this distinction does not exist. The control exercised by an elected council or a presidium over a similar body at the next lower level of government is regarded as a form of legal control over administration. Internal methods of control are also regarded as falling within the ambit of administrative law. These include an appeal from the decision of an official within the same organization or an appeal to a higher administrative unit.

Socialist fusion of political and legal control

A distinctive feature of the Socialist countries of eastern Europe is that there is no definition of the powers of governmental organs at different levels. They are all assumed to be unlimited in scope but always subject to an equally unlimited right of intervention and restraint by the corresponding organ at the next higher level of government. This contrasts with the explicit definition of powers at each level of government that is found in the Western-type democracies. The admixture of political and legal control results in administrative law having a loose and imprecise meaning in the people's democracies of eastern Europe.

JUDICIAL REVIEW OF ADMINISTRATION

Judicial review of administration is, in a sense, the heart of administrative law. The aspects of an official decision or an administrative act that may be scrutinized by the judicial process are the competence of the public authority; the extent of its legal powers; the adequacy and fairness of the procedure; the evidence considered in arriving at the administrative decision and the motives underlying it; and the nature and scope of the discretionary power. An administrative act or decision can be invalidated on any of these grounds if the reviewing court or tribunal has a sufficiently wide jurisdiction. There is also the question of responsibility for damage caused by the public authority in the performance of its functions.

The nature and extent of judicial review of administration, as well as the institutions by which it is undertaken, vary greatly among the countries of the world. History, politics, and constitutional theory have all played a part in determining their position. There are, broadly, three major systems that can be identified (though it should be recognized that around the world there are countless variations on these prototypical systems). These three systems may be described as the common-law model; the French, or council of state, model; and the procurator model.

The common-law system. *Origins.* The common-law system originated in England, where the constitutional struggle in the 17th century played a decisive part in determining the relations between the courts and the executive. The Stuart kings came into open conflict with the judges over their right to decide questions affecting the royal power and even to pronounce an independent judgment in cases in which the king had an interest. Francis Bacon, in his essay *Of Judicature* (written in 1612), put the royalist point of view when he declared that the judges should be "lions, but yet lions under the throne." "It is a happy thing in a state," he wrote, "when kings and states do often consult with judges; and again, when judges do often consult with the king and state: the one, when there is matter of law intervenient in business of state; the other, when there is some consideration of state intervenient in matter of law." The subordination of the judicature to the royal will was strongly resisted by Chief Justice Sir Edward Coke, Bacon's great rival, who refused to comply with James I's wishes in a number of cases in which the royal prerogative was involved. The King harangued the judges more than once on their duty to respect the royal prerogative and power.

Independence of the judiciary

In the constitutional conflict that took place later in the 17th century, the judges and the lawyers made common cause with Parliament against Charles I. An essential feature of the settlement was to establish the independence of the judges. Henceforth there was to be one system of law to which all would owe obedience. Certain consequences resulted from this conflict. First, the executive possessed no inherent powers other than the carefully defined and limited prerogatives of the crown, recognized by the law. Second, the judges were expected to protect the subject against the executive. A more intangible consequence was the belief that "government" and "law" were often thought to be opposed to one another. The conflict between James and the judges survived in an antagonism between the legal profession and the executive, particularly the civil service.

These developments established the principle that the executive should never interfere with the judiciary in the

exercise of judicial functions. This was, indeed, almost the only strict application in England of the doctrine of the separation of powers. On the other hand, it was regarded as right and proper that the judiciary should interfere with the executive whenever a minister or a department was shown to have acted illegally. In this way the concept of the rule of law came gradually to be identified with the idea that the judges, in ordinary legal proceedings in the ordinary courts, could pronounce upon the lawfulness of the activities of the executive. Any attempt to divide the seamless web of the law, any suggestion of a distinction between public and private law, appeared to the generations brought up on this traditional view to destroy its universality and its power to keep the executive within bounds.

The principle that all public authorities are liable to have the lawfulness of their acts and decisions tested in the ordinary courts was applied in all the countries in which the common law was transplanted. In the United States the same conception prevailed, despite the much stricter interpretation given to the doctrine of the separation of powers by the Founding Fathers and the embodiment of the doctrine in the federal Constitution and the state constitutions. A complete separation of powers was not considered to be feasible by the framers of the Constitution, and they therefore modified the doctrine by adding to it the notion of checks and balances, whereby each of the three branches of government would be checked and balanced by the others. This actually strengthened the power of the courts to review the actions of the executive. Elsewhere in the common-law world, the role that the courts were expected to play in reviewing administration was applied without any public debate concerning the separation of powers or the need to protect liberty and prevent despotism by a system of checks and balances.

American checks and balances

Modification of the common-law system. The common-law system has been extensively modified in the course of the 20th century. It never corresponded with the realities of the situation in England because, prior to the Crown Proceedings Act, 1947, it was not possible to sue ministers and their departments in tort because of the legal doctrine that "the king can do no wrong." Moreover, the development of the social services has been accompanied by the creation of a large number of administrative tribunals to hear and determine disputes between a government department and a citizen. The jurisdiction of these tribunals is of a specialized and narrowly circumscribed character and relates to such functions as social insurance and social assistance, the National Health Service, rent control, assessment of property for local taxation, the compulsory acquisition of land by public authorities, and the registration of children's homes. There are about 2,000 of these tribunals, and, although since 1958 a permanent Council on Tribunals appointed by the lord chancellor exercises a general supervision over them, they remain an unsystematic and uncoordinated movement. The reasons for their existence are that they provide a method of administrative adjudication that is far cheaper, more informal, and more rapid than that offered by the courts; the members are persons possessing special knowledge and experience of the activity in which the disputes arise; they do not have to follow the strict and complex rules of evidence that prevail in the courts; and it is possible to introduce new social standards and moral concepts to guide their decisions. These tribunals have acquired general approval for the quality and impartiality of their work. An appeal on a question of law lies in most instances from the decision of an administrative tribunal to the High Court of Justice. There is still no comprehensive administrative jurisdiction in England to provide an opportunity for judicial review over the whole field of executive action and decision.

British development of administrative tribunals

In Australia a similar movement has taken place with the growth of a large number of administrative tribunals covering many different spheres of public administration, such as the regulation of industrial conditions; many branches of the public service; the award of pensions, allowances, and other state grants; the supervision of social conditions (in regard to town planning, the censorship of films, fair rents, and so on); the licensing of occupations calling for special skill or public responsibility; the supervision of trade, transport, and marketing; the assessment of taxes, rates, or duties; the protection of industrial design, patents, and copyrights; and compensation for interference with private-property rights in the public interest. As in England, the growth of these tribunals has been sporadic, and no attempt has been made to introduce a systematic or comprehensive administrative jurisdiction. A similar situation has occurred in some of the other Commonwealth countries.

In the United States the courts have been much more far-reaching and comprehensive in reviewing administration than in England. Nevertheless, much adjudication is now performed by public authorities other than the courts of law. The movement toward administrative tribunals began with the Interstate Commerce Act (1887), establishing the Interstate Commerce Commission to regulate and control railways and other carriers. The law introduced a new type of federal agency outside the framework of the executive departments, with a large measure of independence from the president. This was followed by a number of other regulatory commissions of a similar type, such as the Federal Trade Commission, the Federal Power Commission, the Federal Communications Commission, the Securities and Exchange Commission, the Civil Aeronautics Board, and the National Labor Relations Board. These bodies have had administrative, legislative, and judicial functions delegated to them by Congress, and the doctrine of the separation of powers can no longer be successfully invoked to challenge the constitutionality of such legislation. The regulatory commissions are often described by American jurists as administrative tribunals.

American development of regulatory commissions

Thus, in the United States, as in other parts of the Anglo-American common-law world, the concept of the exclusive exercise by the ordinary courts of all judicial powers and of the absence of special administrative tribunals has been substantially modified by these developments.

The council of state system. *The French system.* In France the separation of powers was given a place of honour in the Declaration of the Rights of Man and of the Citizen (1789), but a different interpretation was given to the doctrine. In the French view, if a court were permitted to review an administrative act or decision, it would contravene the separation of powers as much as if the executive could override the decision of a court. Just as an appeal from a court lies to a higher court, so an appeal from an administrative authority should lie to a higher administrative authority. Only thus would the true separation of powers be observed.

Herein lies the explanation of administrative law as a system of law separate from the body of law administered in the courts. A law of August 1790 declared that the judiciary was distinct from and would always remain separated from the executive. It forbade judges, on pain of dismissal, to interfere in any way with the work of administrative bodies. In October 1790 a second law stated that under no circumstances should claims to annul acts of administrative bodies fall within the jurisdiction of the courts. Such claims should be brought before the king as head of the general administration.

French conception of separation of powers

Napoleon laid down the basic organization of the modern Conseil d'État (Council of State). Among the functions accorded to it by the constitution of the year VIII (December 1799) was that of adjudicating in conflicts that might arise between the administration and the courts and on any matters previously left to the minister's discretion that ought to be the subject of judicial decision. In 1806 a decree created a Judicial Committee of the Council to examine applications and report thereon to the General Assembly. These were the forerunners of the administrative jurisdiction that was not clearly established until May 24, 1872, when a law delegated to the Conseil d'État the judicial power to make binding decisions and recognized the Conseil as the court in which claims against the administration should be brought.

The Conseil d'État is and always has been part of the administration. It has for long had the task of giving legal advice to the government on bills, regulations, decrees, and administrative questions. It is this that long led foreign jurists into believing that, when sitting as a court, its decisions would inevitably be biassed in favour of the executive. Nothing could be further from the truth, and today the Conseil is universally recognized as an independent court that provides French citizens with exceptionally good protection against maladministration. Suits that are directed against the French administration are heard in the Section du Contentieux, or Judicial Division.

French system of administrative courts

The Conseil d'État is the final authority in administrative disputes. Owing to the immense volume of work falling on it, the former prefectoral councils were transformed in 1953 into administrative tribunals of first instance, and the professional qualifications and career prospects of their members were improved. There are 22 of these tribunals in France, together with a special one for Paris. The great majority of cases go before them, and the Conseil d'État is the court of first and last instance only rarely when it is specially designated for that purpose.

If difficulty or doubt arises as to whether a case falls within the administrative jurisdiction or that of the ordinary courts, the question is resolved by the Tribunal des Conflits. This is a court specially established for the purpose, consisting of five judges from the Cour de Cassation (the highest civil court) and five from the Conseil d'État. The minister of justice, in his capacity as keeper of the seals (*garde des sceaux*), may preside and cast a tie-breaking vote.

Several other countries have established councils of state as a result of French influence. Among them are Italy, Greece, Belgium, Spain, Turkey, Portugal, Egypt, and Lebanon. It must be stated, however, that in no other country has a council of state acquired the high status, powers, authority, or prestige possessed by that of France.

The German system. Germany traditionally has had no council of state per se, but the Federal Republic of Germany today does have a fully articulated system of special administrative courts. In the states, or *Länder*, there are lower administrative courts and superior administrative courts, and for the federation there is the Federal Administrative Court, which acts mainly as a court of appeals from the superior administrative courts in the *Länder* and even from the lower administrative courts in certain circumstances. The Federal Administrative Court serves also as a court of first and last instance in public law disputes between the federation and the *Länder* or between two or more *Länder;* it hears petitions by the federal Cabinet on declarations that an association is prohibited under the Basic Law of the Federal Republic; petitions against the federation in matters concerning the diplomatic or consular service; and cases concerning the business of the Federal Intelligence Service.

German system of administrative and civil jurisdictions

A *Land* administrative court possesses jurisdiction concerning the acts of the *Länder* administrative authorities and also complaints against officers of the federal government located in the *Länder*. Some of the highest federal organs are exempt from the *Länder* courts. Few cases go beyond the *Länder* supreme administrative courts.

Recourse to an administrative court is available for public law disputes unless the matter has been assigned to another court by federal legislation. The Administrative Courts Code holds that property claims arising from services for the common good and restitution claims arising from violation of duties under public law shall be heard by the ordinary courts. In other words, the German system is complicated by the rule that only the ordinary civil courts can award damages against an official or the executive arm of government. Hence the distinction between the ordinary courts and the administrative courts depends on the remedy sought and not on the subject matter of the dispute or the nature of the parties. The jurisdiction of the administrative courts in West Germany is thus less comprehensive and clear-cut than in France.

The procurator system. The third system for ensuring administrative legality is the Procuracy, an institution founded in Russia by Peter the Great in 1722, who intended it to be the "eye of the tsar." Catherine II issued a directive in 1764 stating that the procurator general and his staff were to supervise the execution of the laws in the provinces, to ensure justice, and prevent abuses. This was designated general supervision. In 1864 the Procuracy was relieved of its responsibility for supervising administration, and its functions were confined to judicial matters, such as acting as public prosecutor in all criminal cases and conducting them on behalf of the government and the law.

The Procuracy was abolished in November 1917 but revived in 1922. The Soviet constitution charges the procurator general with the general duty of supervising the observance of the law by all ministries and institutions subordinate to them as well as by individual officials and citizens. The procurator general is appointed by the Supreme Soviet for seven years. He appoints subordinate procurators at all administrative levels from union republic to district and town.

Fluctuations in the functions of the Soviet procurator

The functions actually performed by the procurator have undergone many fluctuations and vicissitudes since 1922. His duty to act as a public prosecutor has remained stable but sometimes has been exercised mainly to enforce party policies or programs on recalcitrant citizens rather than to punish public officers or authorities for breaches of the law. Sometimes the task of general supervision has been emphasized; at other times it has been abandoned in favour of more urgent tasks connected with economic policy or the conduct of World War II. The present position of the Procuracy is laid down in a union law of May 24, 1955, and a decree of the Presidium of the Supreme Soviet made on April 7, 1956.

The procurator is not the president of a court or a tribunal but a watchdog of legality. His organization comprises a department for general supervision; a bureau of investigation for the supervision of preliminary inquiries in criminal matters; a department for the supervision of investigations carried out by the State Security Service (KGB); departments to supervise criminal and civil proceedings in the courts; a department to supervise prisons, compulsory-labour centres, and the like; and departments for statistics, administration, and research.

General supervision is defined by Soviet writers on administrative law as meaning supervision by the procurators over legality in administration. Procurators are expected to see that the laws are strictly observed, to oppose their violation by anyone whatsoever, to protect the citizens, and ensure that they fulfill their duties. The law of May 24, 1955, requires the Procuracy to ensure strict conformity of the regulations or decisions issued by ministries, departments, and their subordinate establishments and enterprises and cooperative and other public organizations with the constitution and laws of the U.S.S.R. and the union and autonomous republics and the decrees of the Council of Ministers of the U.S.S.R. and the republics. They are also to ensure strict execution of the laws by officials and citizens. The procurator is concerned solely with the legality, not with the efficiency or expediency, of administrative action.

Since the Procuracy is not a court, it cannot make a binding decision. The normal procedure (apart from cases of dereliction involving a criminal prosecution) is for the procurator to protest against any illegality that he may detect or that is brought to his notice or to initiate disciplinary action against an erring official. Every citizen has a right to lodge a complaint with the procurator, and denunciation and exposure of bureaucratic abuses are encouraged by the Communist Party. The fact that the Procuracy cannot make a binding decision does not necessarily prevent it from being an effective organ for securing administration according to law. Neither the French Council of State nor the courts in any country can enforce judgments against the central gov-

ernment, but this does not prevent the decisions of the council or declaratory judgments of the courts from being observed almost as a matter of course.

The other Communist regimes of eastern Europe have established procuracies based on the Soviet model. In Poland an additional institution to maintain administrative legality is the Supreme Chamber of Control, which is independent of the government and subordinate only to the legislature and the Council of State, a political body quite different from the French model. The functions of the Supreme Chamber of Control involve exercising general supervision over public administration, taking into account legality, economy, and opportuneness.

ADMINISTRATIVE PROCEDURE

Importance of administrative procedure

The administrative state is characterized not only by public administration but by the elaboration of what is termed the administrative process. The essence of the process is an orderly and ascertainable procedure that may be prescribed by legislation or regulations or laid down by the courts or specified by the administrative authority itself or by a higher level of government.

Administrative procedure is of great importance in any system of administration according to law. Well-considered procedure enables responsibility to be fixed on a responsible officer or body at each stage of the administrative process. It can safeguard the rights of citizens and protect the executive against the criticism of having acted in an arbitrary manner. It can ensure regularity and consistency in the handling of individual cases. Much depends, however, on the quality and purpose of the procedural requirements.

Codes of administrative procedure. Some states have general codes of administrative procedure embodied in legislation. Among them are Austria, Czechoslovakia, Poland, Yugoslavia, Spain, and the United States. The Yugoslav law regulating the general administrative procedure is a lengthy statute containing 393 sections. It enacts that the organs of the state administration and other state organs have to proceed according to this law whenever, applying rules directly, they decide in administrative affairs on the rights, obligations, or legal interests of individuals, corporate bodies, or other parties. The law deals in great detail with the right of appeal to a higher administrative body or, exceptionally, to another agency at the same level of government. Appeals from a people's committee go to the corresponding committee at the next higher level, while appeals from an assembly go before the next higher assembly. Each enactment is expressed in clear and precise language.

In addition to an appeal to the next higher level of authority in the administrative hierarchy, the Yugoslav code of procedure provides for an appeal on a question of law to the courts. Judicial control of the legality of administrative actions is vested in the supreme courts, which have separate divisions to hear administrative litigation. The intention is that decisions on the merits of administrative acts will normally be dealt with by the administrative hierarchy, since they are experts in public administration and familiar with its tasks and needs, while the legal aspects will normally be decided on appeal to the courts. Only in exceptional cases will the Supreme Court have power to consider the merit of the act.

Apart from the few states that have separate codes of this kind, there is in all other developed systems a mass of administrative law prescribing procedure. Much of it is to be found in the laws and regulations governing particular functions of government, such as, for example, taxation, public health, education, and town planning.

Scope of procedural rules

It is not possible to summarize the immense variety and scope of procedural requirements. Among the matters usually dealt with are the manner in which the administrative machinery is to be set in motion for a specified purpose, a reference to the relevant legal enactments, information about the rights of interested persons, a statement of how, when, and where an appeal may be lodged, any time limits that must be observed, the conditions to be satisfied by objectors, and the right of legal representation. The leading treatise on U.S. administrative law contains many chapters devoted entirely to such topics as rule making, requirement of opportunity to be heard, adjudication procedure, examiners, bias, evidence, official notice, findings, reasons, and opinions, all of which are wholly, or in part, procedural matters at some stage of the administrative process.

Natural justice and administrative procedure. In the common-law systems, the doctrine of natural justice has had a substantial influence on administrative procedure. The doctrine has evolved into two rules: one is that a man may not be judge of his own cause; the other (summed up in the maxim *audi alteram partem*, "hear the other side") is that a person shall not be dealt with to his material disadvantage, whether of person or property, or removed from or disqualified for office, without being given adequate notice of what is alleged against him and an opportunity to defend himself.

An indirect result of the second rule of natural justice is the widespread adoption of the public hearing by government departments (and in the U.S. by the regulatory commissions) in deciding matters involving individual or corporate rights. In Great Britain a public inquiry is now a recognized device for informing ministers and their departments on particular matters before a decision is reached or an appeal decided in a great variety of spheres, such as town planning, the creation of a new town, slum clearance, and compulsory acquisition of land.

In 1957 the Franks Committee was appointed in Great Britain by the Lord Chancellor to consider and make recommendations on the constitution and working of administrative tribunals and administrative procedures such as the holding of an inquiry or hearing by or on behalf of a minister. The committee declared that the work of administrative tribunals and of public inquiries should be characterized by openness, fairness, and impartiality, and their report applied these aims in great detail. Its recommendations were largely accepted and resulted in the Tribunals and Enquiries Act of 1958.

Although good administrative procedure is of great value, it is possible to exaggerate its importance. When that happens, the main test that an administrative decision subject to judicial review has to satisfy is whether the correct procedure was observed, with little or no attention being given to the substance of the decision.

Scope of judicial review. Judicial review, whether conducted by administrative tribunals or the ordinary courts, is the most appropriate method of inquiring into the legal competence of a public authority, the fairness and adequacy of the procedure it follows, the evidence on which it relied in a particular decision, the motives or considerations on which it was based, and the extent of the grant of any discretionary power it may possess. It is less effective as a method of inquiring into the wisdom, expediency, or reasonableness of administrative acts, and courts and tribunals are unwilling to substitute their own decisions for that of the responsible authority.

Appropriateness of judicial review

The extent to which discretionary powers are liable to be circumscribed by judicial review varies greatly. Sweden and France have gone furthest in subjecting the exercise of all discretionary powers, other than those relating to foreign affairs and defense, to judicial review and potential limitation. Moreover, in both these countries, the administrative tribunals will consider the merits of a decision.

It is of course impracticable to subject every administrative act or decision to investigation, for this would slow up the work of government to an unacceptable extent. The complainant must, therefore, always make out a prima facie case showing that some form of maladministration has occurred.

Administrative tribunals and courts can annul unlawful decisions, allow appeals, declare the law, and award damages. They cannot compel the state to act in a particular way because sanctions cannot be imposed on the government, which itself controls the use of force. Such remedies as an injunction, an order for specific performance, or an order for mandamus will not lie against

the central government. These inhibitions are of less practical importance than might be thought because nearly all governments (including those that have come to power by revolution) are eager to proclaim the lawfulness of the regime and seldom disregard the decisions of an authorized court or tribunal.

THE OMBUDSMAN

The type of official known in Scandinavia as an ombudsman must now be included within the scope of administrative law. The office originated in Sweden when the post of ombudsman for civil affairs was created by the constitution of 1809. The holder of the office is appointed by Parliament; he enjoys complete independence and is responsible only to the law.

Independence of the Swedish ombudsman

The Swedish ombudsman is entrusted with a general supervision of the entire sphere of civil affairs, including the judicature, the police, prisons, and the public administration, both central and local, but excluding ministers. He can act as a public prosecutor; as a receiver of complaints from aggrieved citizens; as an inspector undertaking careful investigations into such institutions as jails, mental hospitals, institutions for delinquent children, and retreats for alcoholics to discover if they are being administered in accordance with the law. In the past the ombudsman was mainly concerned with errors in the courts, including procrastination, improper conduct, and similar instances; currently the bulk of his work is directed to the civil administration. (A separate ombudsman supervises military affairs.)

Apart from occasional prosecutions, the ombudsman has little positive power other than the right to inspect and to demand the fullest information. But he is entitled to comment, to criticize, and to make recommendations as to the correct interpretation of the law. He can recommend that the government pay compensation to a complainant. He can propose changes in the law. He can expose maladministration.

Only ministers and the king are immune from the scrutiny of the ombudsman.

The idea of an official appointed for the express purpose of receiving and inquiring into complaints of citizens has taken root in several countries. The other Scandinavian countries have followed the Swedish example, and ombudsmen have also been appointed in, for example, New Zealand, the United Kingdom, West Germany, Israel, several U.S. states, and certain Canadian provinces and Australian states. A number of cities have appointed municipal ombudsmen, and in Great Britain a commission serves as a complaints mechanism for local governments.

Some specialized ombudsmen have been appointed in the U.S. to safeguard the rights of prisoners to medical treatment, and in Britain an ombudsman has been appointed to inquire into complaints concerning the National Health Service. In Israel the police have an office of public complaints and a military ombudsman. There are considerable differences in the powers and status of the ombudsman in these countries.

The ombudsman should be regarded as a part of the system of administrative law for scrutinizing the work of the executive. He is the appointee of the supreme legislative assembly and not of the executive. He enjoys a large measure of independence and personal responsibility and is primarily a guardian of the law. His function is to safeguard the interests of citizens by ensuring administration according to law, discovering instances of maladministration, and eliminating defects by various methods that include bringing pressure to bear on the responsible authority, publicizing a refusal to rectify injustice or a defective administrative practice, bringing the matter to the attention of the legislature, and instigating a criminal prosecution or disciplinary action.

Ombudsman as guardian of law

There is no doubt about the value of the institution in the states in which it has been established. Part of the ombudsman's usefulness lies in his ability to reassure citizens who believe they have been unjustly treated that careful inquiry into their complaints shows their suspicions to be groundless.

CONSEQUENCES OF LEGAL SCRUTINY OF ADMINISTRATION

Administrative law as a supplement to political controls

Most of this survey has been concerned with the control of public administration by methods other than those regarded as political, such as popular elections, legislative control of the executive, pressure groups, etc. The justification for this emphasis is that, as the powers of the administrative state increase, the need to safeguard the rights and interests of the citizens both individually and collectively becomes greater also. The safeguards concern both the rights of the individual in his dealings with the powerful machinery of the contemporary state and the interest of the community in ensuring that administration is carried on according to law. None of the methods of legal scrutiny, control, and prescription described above is intended to undermine the strength, effectiveness, and vigour of the administrative state. They are designed rather to reveal its shortcomings and to find remedies for its defects.

Administrative law can make the activities of the modern administrative state more acceptable to the citizens by preventing or correcting maladministration, by laying down standards of behaviour for ministers and officials, by insisting on just procedures, by refusing to permit discretionary power to be used for unauthorized purposes, by ensuring that equality of treatment is a condition of legality, and in various other ways. By becoming more acceptable to the citizens, public administration can also become more efficient.

BIBLIOGRAPHY. There are no works covering the whole subject of administrative law in its differing forms in many countries. The position in a number of European states is well described in B. CHAPMAN, *The Profession of Government: The Public Service in Europe* (1959). The general problem of controlling the bureaucracy is briefly considered in F. MORSTEIN MARX, *The Administrative State* (1957); and W.A. ROBSON, *The Governors and the Governed* (1964). SIR JOHN MARRIOTT, *The Crisis of English Liberty* (1930), describes the constitutional struggle in England between the king and the judiciary in the 17th century. For the present system in England, see H.W.R. WADE, *Administrative Law*, 3rd ed. (1971); J.A.G. GRIFFITH and H. STREET, *Principles of Administrative Law*, 4th ed. (1967); S.A. DE SMITH, *Judicial Review of Administrative Action*, 2nd ed. (1968); and J.F. GARNER, *Administrative Law*, 3rd ed. (1970). W.A. ROBSON, *Justice and Administrative Law*, 3rd ed. (1951), is a standard work on the rise and purpose of administrative tribunals. The leading work on American administrative law is K.C. DAVIS' monumental *Administrative Law Treatise*, 4 vol. (1958); the complex question of the control of administrative discretion in the United States is examined by K.C. DAVIS, *Discretionary Justice* (1969). A readable account of the American system may be found in B. SCHWARTZ, *An Introduction to American Administrative Law*, 2nd ed. (1962). See also W. GELLHORN and C. BYSE (eds.), *Administrative Law: Cases and Comments*, 4th ed. (1960). The French system is favourably appraised in C.J. HAMSON, *Executive Discretion and Judicial Control* (1954); a reliable description of its principles is contained in L. NEVILLE BROWN and J.F. GARNER, *French Administrative Law* (1967); a comparison between the Anglo-American system and the French is given by B. SCHWARTZ in *French Administrative Law and the Common-Law World* (1954). Leading treatises by eminent French jurists are G. VEDEL, *Droit administratif*, 2nd ed. (1961); M. WALINE, *Droit administratif*, 4th ed. (1968); and M. LONG, P. WEIL, and G. BRAIBANT, *Les Grands Arrêts de la jurisprudence administrative*, 5th ed. (1969). For Australia, see D.G. BENJAFIELD and H. WHITMORE, *Principles of Australian Administrative Law*, 3rd ed. (1966). On West Germany, E. FORSTHOFF, *Lehrbuch des Verwaltungsrechts*, 9th rev. ed. (1966); and H.J. WOLFF, *Verwaltungsrecht*, 4th rev. ed. (1961), are reliable works. The procuracy can be studied in G.G. MORGAN, *Soviet Administrative Legality* (1962); and more briefly in L.B. SCHAPIRO, *The Government and Politics of the Soviet Union*, 2nd rev. ed. (1967). Three wide-ranging books on the ombudsman are a symposium edited by DONALD C. ROWAT, *The Ombudsman: Citizen's Defender*, 2nd ed. (1968); and WALTER GELLHORN'S two volumes, *Ombudsmen and Others* (1966) and *When Americans Complain* (1966). An excellent work on Scandinavia is NILS HERLITZ, *Nordisk offentlig rätt*, 2 vol. (1958; Eng. trans., *Elements of Nordic Public Law*, 1969). The only accessible text in English of the Yugoslav procedural code is a translation of LEONIDAS PITAMIC, *Zakon o opštem upravnom postupku* (1957; Eng. trans., *The Yugoslav Law on General Administrative Procedure*, 1961).

(W.A.R.)

Adriatic Sea

Constituting an arm of the north central Mediterranean Sea, the Adriatic Sea thrusts northwestward between the eastern Italian coast and that portion of the western coast of the Balkan Peninsula occupied by Yugoslavia and Albania. It has been of great importance in the historical development of Mediterranean Europe and is of considerable scientific interest in itself.

There is a striking contrast between its two shores. The Italian coast is relatively straight and continuous, having no islands, whereas that of the Balkan Peninsula is full of both large and small islands, generally oblong in shape and running parallel to the continental coast. Many tortuous straits also form inlets between the islands similar to those of the Norwegian fjords and make the coastline very intricate. In overall dimensions, the Adriatic Sea can be viewed as a gigantic canal, about 500 miles long, penetrating far into the continental land mass from the Ionian Sea, which it leaves through the Strait of Otranto. Its average width is 100 miles, and its total area is 50,590 square miles (131,050 square kilometres).

Modern scientific study of the Adriatic has been carried out mainly under the auspices of a dozen or so Italian scientific institutes and their Yugoslavian equivalents. Each nation has a number of research vessels at its disposal.

The physical background. The depths of the Adriatic near to its shores bear a close relationship to the physiography of the adjacent coasts. Wherever such coasts are high and mountainous, the nearby sea depths are considerable, as in the case of the Istrian and Dalmatian areas of Yugoslavia. Where, on the contrary, low and sandy shores are found, the nearby sea is shallow, as in the case of the sea in the vicinity of Venice or, farther south, near the delta of the Italian Po River. Generally speaking, depths are small all along the Italian coast. The maximum depth of the Adriatic Sea is situated south of the central area, reaching 4,035 feet (1,324 metres). The average depth is 1,457 feet (444 metres).

Two sea bottom types

The Adriatic has two types of rather special sea bottoms, difficult to arrange in a rigorous classification but very common in the Mediterranean, namely, inlet-derived sediments and heat-altered sediments of the sea bottom proper. In general, the seabed consists of a yellowish mud and sand, containing fragments of shells, fossil mollusks, and corals. The main winds prevailing in the area are the bora, a strong northeast wind that blows from the nearby mountains into the sea, and a southeasterly wind named the sirocco that is less troublesome from a navigational point of view. During the six winter months, bora and sirocco alternate, with or without an interval of a few days calm. The tides of the Adriatic, which have been intensively studied, follow a complicated pattern, sweeping into the region from the south and being linked with those of the Ionian Sea.

The tidal range is about three feet, in contrast to the general Mediterranean tidal range of about 0.9 foot. The surface currents are chiefly influenced by the blowing winds, with currents spurred by north winds reaching a speed of four miles per hour.

Temperatures in the surface layers of the sea reach 75°–77° F (25° C) during the month of August, and the minimum readings, some 50° F (10° C), are usually reached during January and February. In the northern Adriatic, river mouth temperatures are even lower because the waters are cooled by melting ice and snow. At greater depths (820–980 feet) the maximum temperatures fluctuate around 57° F (14° C) while minimum temperatures are about 52° F (11° C).

Salinity in the south Adriatic is 38–39‰ (parts per thousand), decreasing further north to 36–37‰, and falling to 33‰, or even as low as 25‰, in the North Adriatic, as a result of the inflow of fresh waters.

Marine life. The Adriatic Sea, like the Mediterranean in general, is very deficient in life, and nutrient content, as indicated by the amount of phosphates and nitrates, is very low.

Three main areas of marine life may nevertheless be recognized. In the northern Adriatic area important winter cooling and a lowered salinity further impoverish the typical Mediterranean marine life. In the middle Adriatic area, life is much richer than further north, while the southern Adriatic area comprising the coastal regions on both sides of the central area has its own distinctive forms of life.

Adult Education

In the modern period education has come to be strongly identified with organized preparation of the young in schools and colleges for both their personal development and their subsequent social and economic roles in society. Throughout recorded history, however, it has been recognized that to deny oneself of later adult education is to deny oneself of a great part of education that is meaningful only to grown, experienced men and women. In brief, the term adult education can thus be defined as the organized provision of facilities to enable men and women to enlarge and interpret their experiences as adults. Such facilities may be provided—and, in different places and at different times, have been provided—by voluntary action and independent agencies, by state and municipal authorities, and by commercial enterprises.

A more explicit definition is contained in a 1970 report of the National Institute of Adult Education (England and Wales), which stated:

> In the widest sense adult education is any kind of education for people who are old enough to work, vote, fight and marry and who have completed the cycle of continuous education, [if any] commenced in childhood. They may want to make up for limited schooling [or for no schooling], to pass examinations, to learn the basic skills of trades or professions or to master new working processes. They may turn to it because they want to understand themselves and their world better and to act in the light of their understanding, or they may go to classes for the pleasure they can get from developing talents and skills—intellectual, aesthetic, physical or practical. They may not even "go to classes": they may find what they want from books or broadcasts or take guidance by post from a tutor they never meet. They may find education without a label by sharing in common pursuits with like-minded people. (National Institute of Adult Education, *Provision for Adult Education*, 1970.)

Varieties of adult education

Adult education thus comprehends such diverse modes as independent study consciously pursued with or without the aid of libraries; broadcast programs or correspondence courses; group discussion and other "mutual aid" learning in study circles, colloquia, seminars or workshops, and residential conferences or meetings; and full- or part-time study in classes or courses in which the lecturer, teacher, or tutor has a formal leading role. Types of adult education can also be classified as follows:

1. Education for vocational, technical, and professional competence. (Such education may aim at preparing an adult for a first job or for a new job, or it may aim at keeping him up to date on new developments in his occupation or profession.)
2. Education for health, welfare, and family living. (Such education includes all kinds of education in health, family relations, consumer buying, planned parenthood, hygiene, child care, and the like.)
3. Education for civic, political, and community competence. (Such education includes all kinds of education relating to government, community development, public and international affairs, voting and political participation, and so forth.)

4. Education for "self-fulfillment." (Such education embraces all kinds of liberal education programs: education in music, the arts, dance, theatre, literature, arts and crafts, whether brief or long term. These programs aim primarily at learning for the sake of learning rather than at achieving the aims included in the other categories.)
5. Remedial education: fundamental and literacy education. (Such education is obviously a prerequisite for all other kinds of adult education and thus, as a category, stands somewhat apart from the other types of adult education.)

In reference to the fifth category, adults frequently need to compensate for inadequacies of earlier education. If they are not remedied, they inhibit recourse to modes of education that are "adult"—adult, that is, in terms of sophistication in modern society and not in terms of age. Such education is required most extensively in societies changing rapidly from a subsistence to an industrial economy and concurrently changing politically and socially. Mass literacy acquires a new importance in these nations of Asia, Africa, and Latin America, and the establishment of universal primary education becomes a social imperative. To prevent a "generation gap" in reading skills and education while an effective school system is being created for the young, governments must attempt to provide parallel facilities for adults. Even in countries with mature systems of childhood education, however, opportunities for higher or even sometimes secondary education are unequal among various regional, occupational, and social groups. Hence there are adult programs for completing high school or preparing for examinations normally taken at the end of secondary school. Even in so highly developed a country as Sweden it has been considered necessary in recent years not only to try to extend secondary education to more children but also to offer equivalent second chances for adults. The implication is that "remedial" adult education is needed in societies in all stages of development and not merely in the so-called developing countries.

BACKGROUND OF MODERN ADULT EDUCATION

Education as a lifelong process

The idea of education as a lifelong process has been expressed by philosophers and educators throughout the centuries. It is explicit in the thought and writings of Confucius, Plato, Sir Thomas More, Comenius, and Benjamin Franklin, to cite only five examples widely separated in time and place. Attempts to give reality to such aspirations and to provide education for large numbers of adults, however, cannot be reasonably dated before the Industrial Revolution—and its accompanying social revolutions—of the late 18th and the 19th centuries. Changes in the ways of living—both occupationally and politically (as the franchise was extended)—produced a need for further education and re-education of adults. In the early and middle years of the 19th century these socioeconomic changes were strongest in Great Britain and the United States; and it is in these countries that adult education received greatest emphasis, although significant developments also occurred in Scandinavia. Even today, the provisions for adult education in such lands as France, Italy, and Latin America are relatively small compared to what they are in the countries that pioneered further education.

Early programs. The rise of organized adult education in Great Britain is generally dated from the late 1790s, when the first adult school and the foundations of the first mechanics' institute were established, in Nottingham and Glasgow, respectively. In the next 50 years adult schools created generally by religious people to reduce adult illiteracy and mechanics' institutes designed to spread among artisans knowledge of science and its applications in industry, all dependent on voluntary effort and voluntary finance, were founded in many parts of England. Both declined later in the 19th century, although the adult schools revived and were active in the 20th, and the institutes often became technical colleges or reading and lecture societies.

In the 1840s the early cooperative societies in Great Britain undertook adult education work that still continues, and the industrial and social conditions that inspired Christian socialism and other humanitarian movements also prompted the founding of people's and workingmen's colleges. The first of these was established in Sheffield in 1842, but the most influential was the London Working Men's College (1854). Others were short lived, and none was residential until Ruskin College was founded at Oxford in 1899 to equip workingmen for their responsibilities as citizens and trade unionists.

Meanwhile, in the United States, the first half of the 19th century was a period of national adjustment and the rich development of educational institutions, each one unique and often unrelated to the others but all providing new channels of learning. Most important were the lyceums, local associations of men and women who had had some formal education and were concerned both with their own further learning and with the creation of a public school system; their education came chiefly through hearing debates and lectures on timely topics. Paralleling the growth of the lyceums and to some extent developing out of them were libraries, museums, mechanics' institutes, lecture series, endowed institutions, publicly supported evening schools, and a host of other institutions, many of which became permanent.

The second half of the 19th century, particularly during and after the Civil War, was another period of America's readjustment and therefore another era of growth for organized adult education. Both the land-grant colleges and the U.S. Department of Agriculture were created, thus laying the groundwork for their later collaboration in the teaching of scientific agriculture and home economics to farmers and their wives. Institutions developed earlier gained strength; the most notable development of this sort perhaps was the growth of the public library, greatly stimulated by the benefactions of the steelman and philanthropist Andrew Carnegie. Sporadic university lecture series for the general public evolved into systematic programs of "university extension"—educational courses for adults who are not full-time students. (The idea that a university owed responsibility to a wider constituency than its enrolled students was first officially endorsed, however, in England at the University of Cambridge in 1873.) A new variation on the lyceums was the "chautauqua," a nationwide movement that was inspired by the example of the annual summer-camp meetings of teachers, social workers, and others at Chautauqua Lake in New York State, where lectures, study workshops, and popular entertainment were offered for moral and intellectual improvement. (The popularity of the chautauquas did not decline until the mid-1920s.)

National variations. Although the British and American programs in adult education were the ones to influence most strongly the development of adult education elsewhere in the world, the folk high schools in Scandinavia represent a noteworthy national development. These residential schools for young adults were first founded in Denmark in the middle of the 19th century to foster a sense of cultural unity, and they became a powerful instrument of national regeneration after the country's defeat by Germany in 1864. The man whose personality and writings stimulated their development in Denmark as well as the other Nordic nations was N.F.S. Grundtvig, who has been called the "father of the folk high school" and whose interests were unquestionably more political and nationalist than industrial or commercial. A theologian as well as an educationist, he stressed the need for a thorough knowledge of the mother tongue and of national and biblical history, and he put forward the idea that the years after 18 are those of real awakening to life. Such was the inspiration for the folk high schools in which young people of every class were to be encouraged to educate themselves and one another.

Past inadequacies of adult education

Even when such efforts in Scandinavia, Britain, the United States, and elsewhere were aimed at the educationally least privileged; however, several factors at first limited their success. The planners took insufficient account of the inadequacies of elementary education, and, in the absence of public subsidies or other aid, the programs were frequently priced beyond the capacity of

working men and women. They tended to appeal more effectively to those with already established educational appetites and to be eyed with suspicion by articulate workers attempting to institutionalize political and economic protest through trade unions, cooperative societies, and independent political parties.

Moreover, even though its importance has often been publicly affirmed, adult education has seldom in the past engaged the attention of legislatures. The most notable exceptions have been in the Scandinavian countries, in the eastern European countries under Communist regimes, and most recently in some of the newly emergent nations, such as Tanzania. In free enterprise economies and pluralistic societies, the interplay of philanthropy and social reformism and the promotion of particular religious, political, and social interests have all contributed to the creation of adult learning opportunities. But government action has largely resulted from the efforts of these independent pressure groups seeking official recognition and public financial support; thus specific legislative acts have usually not been concerned with a general theory or broad program of adult education so much as with the solution of particular problems brought forward by special interests. (Such a pragmatic or problem-oriented approach is illustrated by the setting up of agricultural experimental stations in the United States under the Hatch Act of 1887, which provided the basis for federal extension services in agriculture and home economics.)

The Scandinavian countries are unique in the numbers of legislators who claim personal experience of adult education, particularly in the folk high schools, and who are thus favourably disposed toward adult education. They are also the countries in which democratic practices are most deeply imbedded in a wealth of popular movements to which the state has come to entrust relatively large amounts of money for the development of adult education. One of the most recent examples is the Danish legislative act of June 1968 concerning "leisure time instruction." This act provides aid for youth schools, leisure-time activities for children and young people, leisure-time instruction for adults, supplementary cultural arrangements (that is, lectures, art exhibitions, concerts), university extension activities, correspondence schools, leisure-time instruction for seamen. Although the act specifies in detail the conditions that must be fulfilled by voluntary organizations and municipalities in order to qualify for state financial support, there is no attempt to define curricula or to restrict educational and ideological objectives. Similar "democratic" programs exist in all the Scandinavian countries.

In Great Britain, which continued in the early part of the 20th century to be a more distinctly hierarchic or class-structured society, adult education was frequently a case of the "privileged" accepting a responsibility for helping the "underprivileged." Some individuals with an elite education in independent schools and universities were willing to apply their education, example, and moral suasion to help the working classes to help themselves. Thus the Workers' Educational Association (WEA), founded in 1903 "to promote the higher education of working men and women," drew upon the services of tutors from the universities—in effect, broadening the activities of university extension. Emphasis on continuous academic study in small groups under the guidance of highly qualified tutors largely replaced the earlier tradition of lectures to large audiences. From almost the beginning the national board of education offered grants toward the teaching costs of such classes, and especially after World War II there was a rapid and substantial increase in the work of the WEA and of the university extension services based on increased grants from the new Ministry of Education (today entitled the Department of Education and Science). In addition there were established a number of new institutions concerned with adult education. Prominent among these were some 30 new residential colleges, some provided by universities, a small number by voluntary effort, but the majority by local education authorities. They all differed from Ruskin College and several others established earlier in that they provided only short courses, lasting from a weekend to a few weeks or occasionally two or three months. At the same time, local education authorities were increasingly fostering liberal studies in technical colleges and other institutions.

Traditions of voluntary participation and curricular freedom

Two traditions in adult education thus established themselves in the countries that pioneered adult education: the tradition of voluntary participation and the tradition of freedom from state control in matters of curricula and educational goals (even though the state might fund the programs). This contrasts with practices, for instance, in the U.S.S.R., which has put heavy emphasis on adult educational programs. According to an anonymous but typical text, *Education of Adults in the U.S.S.R.*, dated 1960, "The transformation of society into a Communist society now making headway in the U.S.S.R. involves the education of the wide masses of people, the development of their consciousness and the raising of their political and production activities." The provisions made to achieve these ends are impressive, but the key words here are *masses* and *society*—ignoring *individuals*. Adult education is promoted to enable people en masse to understand and adjust to change, not to enable them to exercise individual judgment about the character and direction of change.

Another kind of of contrast exists between the Scandinavian and Anglo-American countries on the one hand and France and other Latin nations on the other, where the Napoleonic aftermath of central direction of education is most marked. The public education authorities have taken little notice of adult education. As one English observer has noted:

> Those accustomed to the provision made for non-vocational adult education in the English-speaking countries have long found French practice in this sphere so foreign as to be incomprehensible. . . . In France, educational opportunities for adults are highly decentralised and informal, in the hands of a vast number of private societies, large and small, run by unpaid, part-time labour, whose records are often sketchily kept and whose finances are complicated. . . . The scene is further obscured because adult education is not considered as an independent branch of education as we tend to see it and the term itself is little used. For the French it forms only a part of a wider activity, called *éducation populaire* or *culture populaire*, which in its widest sense is defined as any communal non-vocational activity of a social, recreational, sporting or intellectual nature, carried on outside home, school, or work, which enriches and develops the personality. (From Colin J. Titmus, *Adult Education in France;* Pergamon Press Ltd., [1967].)

Irrespective of modes of provision and direction, however, adult education is also affected by the quantity and quality of education available in childhood and youth. Quite simply, the more education that people receive the more they are likely to want and the more likely they are to actively seek information about its provision. Raising the overall school-leaving age and increasing the proportions of young people proceeding directly to higher or continuative education are clearly associated with a rising demand for adult education for personal and social reasons. The same kind of increasing demand is associated with high economic productivity and the accelerated technological obsolescence that accompanies it. This sets in motion the need for vocational retraining in adult life that must be included in the modern concept of adult education.

AGENCIES AND INSTITUTIONS

Any classification of agencies and institutions involved in adult education must necessarily be arbitrary, given the great variety found not only among nations but within single nations. The following are the general types.

Varieties of schools and programs

The *folk high schools*, first established in Denmark and now found in all Scandinavian countries, are residential schools in which young adults who have completed formal schooling and usually have had some subsequent work experience pursue at least several months of study. The study aims at furthering both moral and intellectual development and instilling an understanding of local and

national traditions and conditions, thus still reflecting Grundtvig's original concept. Although at first they were independent or separate institutions, they are now frequently promoted or supported by communal boards of education. Although rarely exported with success in their pure form, the folk high schools have influenced the development of residential forms of adult education in countries as diverse as Canada, Kenya, India, and The Netherlands.

Nonresident adult education centres, the most widely distributed specialized institutes for adult education, are represented by "workers academies" in Finland, "palaces of culture" in the U.S.S.R. and some other Communist countries, "workers' universities" in Yugoslavia, "peoples' high schools" in West Germany and Austria, "adult education centres" in Great Britain, and "people's universities" in The Netherlands, Italy, and Switzerland. The distinguishing characteristics of these institutions are that they are independent of the general education authorities, at least in terms of programming; that student attendance is voluntary and part-time; and that teachers and administrators are either volunteers or professionals offering mainly part-time services. Traditionally these schools do not prepare students for examinations or offer training in advanced vocational skills. Typically the curriculum includes instruction in practical and domestic crafts, fine arts, music and drama, familial and social problem solving, and modern languages, as well as instruction designed to reinforce primary and secondary education. The workers' universities in Yugoslavia probably go furthest in trying to fuse these elements into an overall program to equip workers to play a role in the self-management of industrial and commercial enterprises.

Agricultural extension services, though almost wholly an American development, are conducted on a scale great enough to rate separate mention. The extension service of the U.S. Department of Agriculture conducts agricultural, home economics, and even public affairs programs in every county in the United States. It has had special significance in developing "demonstration" as a method of adult education, in emphasizing the adoption of new practices, and in providing a possibly appropriate model for newly developing countries.

The *open university*, a new British institution, is significant for its new dimension and sharp break with previous degree programs for adults. In some educationally advanced countries—such as Australia, New Zealand, Canada, and the United States—adults have long had opportunities to pursue part-time education leading to the award of university degrees, but these programs have usually been carbon copies of programs offered to regular undergraduates. The open university, in theory at least, aspires to a kind of universal higher education. It is intended to service only mature or older adults studying part-time; it has no standardized entry requirements; and it attempts to combine various educational technologies and techniques—correspondence instruction, mass-communication media, personal counselling, and short-term residential courses.

Commercial enterprises have provided correspondence courses or class instruction (part- or full-time) for adults who are usually seeking some form of vocational qualification (but who may, however, be simply seeking "self-improvement," as in speed-reading programs). Such schools may be licensed or supervised by state agencies (as in Sweden and The Netherlands), or they may be self-policing through associations offering accreditation. Some schools are nonprofit organizations. One interesting development has been Switzerland's *Klub-Schulen* ("club schools"), supported through the philanthropy of a commercial concern, the Migros trading organization, but operated on a nonprofit basis; the programs, furthermore, have no particular vocational emphasis.

Extension services include both public school programs for adults and the university extensions mentioned earlier. The school programs are administered by the public school systems, and they are popularly termed night schools because ordinarily they are housed in the same school buildings used in the daytime for school-age youth and also because some of the same teachers are often involved. (Much of the teaching, however, is also done by subject specialists not employed as schoolteachers.) Though often originating in efforts to remedy or supplement inadequate childhood education, many of these programs now cater to the same range of interests served by the "nonresident adult education centres" cited above. They often retain elements of vocational preparation at a less specialized level, generally for younger adults—for example, in commercial and trade skills.

The difficulties inherent in trying to provide adequate services to adults as a kind of marginal addition or afterthought to the education of children have led some local education authorities in Britain and the United States to design schools that can be used specifically for adults as well as children. The "village colleges" in Cambridgeshire and the Mott Foundation program in Flint, Michigan, involve a pattern of separate staffing for adult and child education and of comprehensive planning that enables a very large adult program to be provided within the school system. Such developments require the recruitment and training of larger cadres of full-time adult education teachers than have been customary in the past. The further growth and sophistication of public provision is likely to be a marked feature of adult education in the future.

The extension services offered by institutions of higher learning are of two broad types. The British tradition, influential in most Commonwealth countries and former colonial territories, has emphasized the provision of noncredit courses of "liberal" studies. The North American tradition, found in countries influenced by the United States and Canada, places a larger emphasis on credit programs duplicating courses offered to regular undergraduates; such programs are offered via television or correspondence or in separate "downtown" (urban) colleges. Both traditions seem in the process of modification—the British in the direction of offering more credit-earning and vocation-related refresher courses, the North American toward a wider acceptance of the provision of general liberal studies for the public at large and for specialized vocational groups. It is everywhere apparent that universities are assuming more responsibility for the continuance and renewal of education for the highly educated.

Organizations, libraries, and museums servicing adult activities

In addition to the various schools or services listed above, there are countless organizations whose main purposes may not be adult education but that offer some kind of instruction or leisure-time activities for adults. They include such bodies as the Young Men's Christian Association, the Young Women's Christian Association, political parties and labour unions (often operating through especially constituted "workers educational associations"), women's organizations like the Norwegian Housewives League, and temperance organizations like the International Order of Good Templars. Such a list could be almost endless. Other agencies for which adult education is a related rather than a primary function are libraries, museums, botanical gardens, and the like. Not only do these agencies provide the means of individual self-education but also they frequently promote group activities or put their accommodations and resources at the disposal of adult education agencies. Finally there should be mentioned the advisory and instructional services offered by various social and welfare agencies in the fields of health, safety, marital guidance, family planning, and so forth.

FUTURE PERSPECTIVES

Acceleration in the rate of change in human affairs is so much a cliché of contemporary discussion as not to require elaboration. It is summed up in the aphorism attributed to American anthropologist Margaret Mead that "no man today will die in the world in which he was born." The inescapable consequence is the need for continual renewal of learning in all forms of employment and in various phases of life. As one example of the problems involved, in those fields of advanced technology (such as aerospace and nuclear engineering) in which it

is impracticable to duplicate some operational plant in a separate educational milieu, education may have to be integrated with the productive process itself. Moreover, initial education in many fields is now so specialized and demanding on the time and energy of the young that a broad, general education may be impossible unless the whole of life, not merely the formative years, is accepted as time for learning.

Encouragement is given to these trends and to more widely ranging concepts of adult education by professional associations in adult education—associations whose objects are to promote cooperation between different schools and agencies, to foster enquiry and research, and to disseminate information. With differing structures and varying levels of development such organizations exist in Australia, Canada, Denmark, England and Wales, Finland, India, Ireland, The Netherlands, New Zealand, Norway, Scotland, Sweden, Switzerland, and the United States. Intercommunication beyond national boundaries has been encouraged by the United Nations Educational, Scientific and Cultural Organization (UNESCO) and by such regional bodies as the European Bureau of Adult Education, the African Adult Education Association, and the Asian-South Pacific Association for Adult Education. Still largely dependent on the personal efforts of a few individuals, these bodies are an index to the growing awareness of the importance of adult education throughout the world.

BIBLIOGRAPHY. Much of the literature of adult education is to be found in journal articles and in pamphlets, frequently issued in small editions and only accessible in specialized libraries, although sometimes now available on microfilm or microfiche. Some important general works, however, are: THOMAS KELLY (ed.), *A Select Bibliography of Adult Education in Great Britain*, 2nd ed. (1963), a bibliography of works published to the end of 1961; and *A History of Adult Education in Great Britain*, 2nd ed. (1970), on the development of both formal and informal means of adult education from the Middle Ages to the mid-20th century; J.F.C. HARRISON, *Learning and Living, 1790–1960: A Study in the History of the English Adult Education Movement* (1961), a text starting with the experience in England as the first industrial society and ending with the post-World War II search for social relevance; JOHN LOWE, *Adult Education in England and Wales: A Critical Survey* (1970), a recent general work on the English educational system; EDMUND DE SCHWEINITZ BRUNNER *et al.*, *An Overview of Adult Education Research* (1959), an inventory of research in nonvocational adult education made by the Bureau of Applied Social Research, Columbia University, that attempts to achieve valid generalizations applicable to the broad field of adult education; C. HARTLEY GRATTAN, *In Quest of Knowledge* (1955), a short sketch that concentrates on the western European background from primitive man to the Industrial Revolution and then focusses on the American experience, with a brief résumé of that in Britain; CYRIL O. HOULE, *The Inquiring Mind* (1961), a comprehensive study of the adult student; and J.R. KIDD, *How Adults Learn* (1959), a synthesis of theory and practice in the field of adult education; MALCOLM S. KNOWLES, *The Adult Education Movement in the United States* (1962), an informed, comprehensive study, containing a bibliography of general sources; COOLIE VERNER and A. BOOTH, *Adult Education* (1969), a well-documented basic text.

Adventists

Adventism is a term that has come to refer to a belief in the Second Coming of Christ, at which time he will separate the saints from the wicked and inaugurate his millennial (1,000-year) Kingdom. Though usually associated with the Seventh-day Adventists, the largest organized modern Adventist denomination, Adventism is deeply rooted in Hebrew and Christian prophetism, messianism (belief in a coming salvatory figure), and millennial expectations recorded in the Bible. A desire that God will overcome evil, vindicate his people, and manifest his power to make all things new has influenced the history of Jewish and Christian life in a variety of ways.

History. *Roots of modern Adventism.* Adventism, in its broader sense, has been an important aspect of Jewish expectations about the future. Jews have looked for the coming of a messiah, and one of the ways in which they have reminded themselves of this hope is by leaving an empty seat at the table during the celebration of Passover, which commemorates their Exodus from Egypt in the 13th century BC, in the hope of an awaited return of Elijah, a 9th-century BC prophet, who is believed to have been taken up into heaven. At various times, persons have appeared claiming to be the promised Messiah. Shabbetai Tzevi (1626–76), for example, made such a claim and announced to his followers that 1648 was the year of redemption. Jews in the Diaspora (those living beyond Palestine), harbouring messianic hopes, have longed for their return to Israel and the restoration of the Temple in Jerusalem. Christians maintain that Jesus is the Messiah, and in the early church they anticipated that he would return again soon after his death, interpreting these expectations in terms of prophecies in the Book of Daniel and in the book of Revelation. Because Jews do not accept Jesus as the Messiah, they may be said—in contrast to Christians—to be awaiting a first advent. In Asia Minor the prophet Montanus (mid-2nd century), assisted by Priscilla and Maximilla, two prophetesses given to ecstatic experiences, stimulated an interest in Adventism that lasted until the 9th century. This emphasis passed into two heretical sects: the Priscillianists, followers of Priscillian, a 4th-century Spanish mystic, and the medieval Cathari (Purifiers). During and after the Reformation, Adventism emerged among the radical reformers known as Anabaptists (*c.* 1534), the Fifth Monarchy Men in England (those who in about 1640 awaited the fifth kingdom; *i.e.*, of Christ), and the German Pietists (Lutheran) in the 17th and 18th centuries. There has always been a concern among Christians about the meaning of eschatology (the last times) and the Second Coming of Christ, and many have written about this subject: Augustine in *De civitate Dei* (*The City of God*); Isaac Newton in his *Observations upon the Prophecies of Daniel and the Apocalypse of St. John* (1733); and Jonathan Edwards in *A History of the Work of Redemption* (preached 1739, published 1774). Adventism in the 19th century drew upon the chronology of a book by Archbishop James Ussher (1581–1656) of Ireland, *Annales Veteris Testamenti* . . . (1650) . . . *Novi Testamenti* . . . (1654), which placed the creation of the world and of man in 4004 BC, the date by which millennialists calculated the Second Coming of Christ (see also MILLENNIALISM).

Expectations of the Messiah

Seventh-day Adventists. During the latter part of the 18th and the early part of the 19th centuries, great anticipation arose among Christians concerning the coming of Christ's millennial Kingdom. Millennialists searched the Bible, assured themselves about what prophecies had been fulfilled, and then figured out those yet to be realized. The Kingdom, they believed, was near at hand. Some theologians saw in the American and French revolutions the beginning of the downfall of papal power, which Protestants equated with the beast of Revelation, and the inauguration of a new age of justice, in which the whole world would be gradually converted to a belief in Christ.

Such Christians have been known as postmillennialists in that they expected Christ's return after 1,000 years. This expectancy was manifested in communitarian experiments of the Shakers and the Mormons, who believed that in Ann Lee (1736–84), the founder of the Shakers, and Joseph Smith (1805–44), the founder of the Mormons, God had manifested himself in special ways (see also MORMONISM).

It was in this atmosphere that William Miller (1782–1849), a founder of the Adventists, began to preach. Miller, while an officer in the U.S. Army in the War of 1812, had become a skeptic. After a conversion, he began to study the books of Daniel and Revelation and to preach as a Baptist, the faith of his father. He concluded that Christ would come on March 21, 1844, and was encouraged in his views by a number of clergymen (such as the reform-minded Joshua Himes of Boston) and numerous followers—about 100,000 according to some estimates. Miller was accused of fanaticism because of his millenarianism, and he stressed the coming of Christ in conjunction with a fiery conflagration, which distressed

The prophecies of William Miller

his hearers. Christ, however, did not return on the first appointed date, so Miller set a second date, October 22, 1844. The quiet passing of this day led to what is called the "Great Disappointment" among Adventists and the convening of a Mutual Conference of Adventists in 1845 to sort out problems. Those who met, however, found it difficult to shape a confession and form a permanent organization.

Among those who persisted after the failure of Miller's prophecy were Joseph Bates (1792–1872), James White (1821–81), and his wife, Ellen Harmon White (1827–1915). These Adventists, called Millerites in the press, continued to believe that Miller had set the right date, but they believed that they had interpreted what had happened in the wrong way. Reading Daniel, chapters 8 and 9, they concluded that God had begun the "cleansing of the heavenly sanctuary,"—*i.e.*, an investigative judgment that would be followed by the pronouncing and then the execution of the sentence of judgment. What actually began in 1844, then, in their view, was an examination of all of the names in the Book of Life. Only after this was completed would Christ appear and begin his millennial reign. Though they did not set a new date, they insisted that Christ's advent was "personal, visible, audible, bodily, glorious and premillennial" and imminent. They also believed that observance of the seventh day, rather than Sunday, would help to bring about the Second Coming. These Millerites founded a magazine in 1850—based on the earlier *Present Truth*—called the *Advent Review and Sabbath Herald* (now the *Review and Herald*), established a headquarters in Battle Creek, Michigan, in 1855, and became an official denomination (Seventh-day Adventists) in 1863. Adventists believe that Mrs. White, a former Methodist, had received the gift of prophecy. She had visions, travelled and lectured widely in America, Europe, and Australia, and wrote prolifically, including the "Conflict of the Ages" series (5 vol., 1888–1917) and *Testimonies for the Church* (9 vol., 1855–1909).

Other Adventist churches and movements. Other Adventist bodies emerged in the 19th century as a direct or indirect result of the prophecy of William Miller. These include the Evangelical Adventists (1845), Life and Advent Union (1862), Church of God (Seventh Day, 1866), Church of God General Conference (Abrahamic Faith, 1888), and the Advent Christian Church. The latter is the largest among these small bodies. It was organized in 1860 by Jonathan Cummings (fl. *c.* 1852), a follower of Miller. Cummings stressed the teaching of conditional immortality. Because of sin, man forfeited immortality. At death he remains in a state of unconsciousness until Christ's Second Coming, when the faithful will enter into life and the unrighteous will suffer extinction. The Advent Christians do not accept the teachings of Mrs. White as in any way prophetic. They also reject the teachings of the Seventh-day Adventists about sabbath observance and dietary laws. They are congregational in polity and coordinate work in the United States and throughout the world through the Advent Christian General Conference of America. In 1964 the Advent Christian Church united with the Life and Advent Union.

Adventist emphases in various religious groups

Adventist emphases may also be found among pentecostal and holiness groups that interpret the outpourings of the Holy Spirit, the manifestation of his gifts, and growth in sanctification as signs of the coming of Christ and his Kingdom. Charles Taze Russell (1852–1916), the founder of the Jehovah's Witnesses, came under the influence of Adventist ideas. His followers became known as Millennial Dawnists, who believed that this present world is under the reign of Satan and in conflict with Jehovah's (God's) rule. Millennial Dawnists considered it their responsibility to announce the Second Coming of Christ, which would be marked by the battle of Armageddon, in which Satan would be defeated, the faithful rewarded, and the wicked annihilated (see also JEHOVAH'S WITNESSES).

Beliefs, practices, and institutions. *Beliefs and practices.* Seventh-day Adventists share many basic beliefs held by most Christians. They accept the authority of the Old and New Testaments. They are Arminian (emphasizing man's choice and God's election) rather than Calvinist (emphasizing God's sovereignty) in their interpretation of Christ's atonement, and they argue that his death was "*provisionally* and *potentially* for all men," yet efficacious only for those who avail themselves of his benefits. In addition to the emphasis upon the Second Advent of Christ, two other matters set them apart from other Christians. (1) They observe the seventh day, rather than the first day of the week, as the sabbath. This day, according to the Bible, was instituted by God since the creation, and the commandment concerning sabbath rest is a part of God's eternal law. The keeping of this law by Adventists is both a testimony to God's sovereign freedom to set aside such a day and an eschatological testing for them. (2) They also avoid eating meat and taking all narcotics and stimulants, which they consider to be harmful. Though they appeal to the Bible for the justification of these dietary practices, they maintain that these are based upon the broad theological consideration that the body is the temple of the Holy Spirit and should be protected. To criticism that they have made Mrs. White's writings canonical, Adventists respond that all of their teachings are based upon the Bible; and to criticism that they have turned sabbath-keeping and dietary practices into a new works righteousness (*i.e.*, salvation through good works), they respond that these works are a result of salvation, not the means.

Adventists stress tithing and therefore have a high annual giving per capita that allows them to carry on worldwide welfare programs. Because of their educational program, Adventists have created an educational elite that—although there have been some tensions—has remained in the denomination. Adventists have never found it easy to keep Saturday as the sabbath in a society that, by law or by custom, has set aside Sunday for a day of rest. Because of their unwillingness to work on Saturday, they have suffered some job discrimination. This has made them deeply concerned about religious liberty. In recent years, despite some of the teaching against ecumenism in the writings of Mrs. White, consultations have been held between representatives of the Seventh-day Adventists and the World Council of Churches to discuss the relation of Adventists to the ecumenical movement.

Organization of the Seventh-day Adventists

Institutions. Sending out its first missionary, John Nevins Andrews (1829–83), in 1874, Seventh-day Adventism expanded into a worldwide movement. The General Conference, the main governing body, has its headquarters in Takoma Park, Washington, D.C., where it was moved in 1903 from Battle Creek. The meeting of the General Conference is held quadrennially and is made up of delegates from divisions, union and local, that are also called conferences. These local conferences provide pastoral oversight for the local congregations, which are governed by elected lay elders and deacons. The business of conferences between meetings is administered by a president and an executive committee. As of 1968 the General Conference governs some 76 union conferences, 374 local conferences, and 15,744 churches involving 1,845,183 persons all over the world. In the United States (1969), Adventists number 407,766 in 3,216 congregations. The conference also supervises the work of evangelism in over 1,000 languages, a large parochial school system, and numerous medical institutions called sanitariums, of which the first was established in Battle Creek in 1866. Publishing houses are operated in many countries, and literature is distributed door to door by volunteers.

Conclusion. The establishment of the State of Israel (1948) has stirred an interesting discussion among Adventists, including those who are members of Adventist denominations and those from other denominations who share with them Adventist beliefs about the Second Coming. Jews have interpreted the restoration of the State of Israel as an end to the Diaspora and as a fulfillment of the promises of God to give them a homeland. Some Fundamentalist Christians have tended to interpret this event as a fulfillment of the promises of God about the Jews and as a sign of the imminent coming of Christ. The Jerusalem Conference on Biblical Prophecy was held in

Jerusalem in 1971, under the leadership of Carl F.H. Henry (1913–), an American conservative religious leader, to study the implications of this event for Christians and Jews.

Though all of the longings and yearnings of Jews and Christians for the advent and the Second Advent of the Messiah, and for the establishment of his Kingdom, seem to remain unfulfilled, in Adventism there is always the element of hope.

(1950–54), a very rich description of adventist literature by an Adventist, helpful for research; JESSE O. GIBSON (ed.), *Seventh-Day Adventist Yearbook* (1970); DON F. NEUFELD *et al.* (eds.), *Seventh-Day Adventist Encyclopedia* (1966); FRANCIS D. NICHOL *et al.* (eds.), *Seventh-Day Adventist Bible Commentary*, 7 vol. (1953–57); ERNEST SANDEEN, *The Roots of Fundamentalism: British and American Millenarianism, 1800–1930* (1970); GERSHOM SCHOLEM, *The Messianic Idea in Judaism* (1971), excellent for advent ideas among Jews, especially for the treatment of Sabbatians, and for references; "The Seventh-Day Adventist Church," in *The Ecumenical Review*, 19:17–28 (1967), considered by Adventists as a very fair treatment of the subject; ELLEN HARMON WHITE, *The Great Controversy Between Christ and Satan* (1888 and 1911); ERNEST LEE TUVESON, *Redeemer Nation* (1968).

(J.H.Sm.)

Advertising

Advertising is a form of communication intended to promote the sale of a product or service, to influence public opinion, to gain political support, to advance a particular cause, or to elicit some other response desired by the advertiser. The advertising message, or advertisement, is delivered to its intended audience through the various media including newspapers, magazines, television, radio, billboards, and direct mail. Advertising is distinguished from other forms of communication in that the advertiser pays the medium to deliver the message. For this payment the advertiser receives the opportunity to control the message. Within legal constraints designed to prevent deception and assure fair competition, and within standards of practice enforced by the media, the advertiser is free to say what he wants to say the way he wants to say it. Within limits set by availability, he can select the particular issue of a newspaper or magazine in which the message will run; in the case of television and radio, he can select the hour and even the minute when the message will be broadcast. The style of presentation usually identifies the message as an advertisement. In some countries if the message is not readily distinguishable from a medium's editorial or program content, the notation "This is an advertisement" and the name of the advertiser or sponsoring organization are included.

Users of advertising

Different kinds of businesses use advertising to motivate different kinds of markets toward different kinds of responses. A retailer such as a department store advertises to build store traffic and patronage and to keep his regular customers informed about available merchandise. The manufacturer of a branded item such as a brand of soap advertises to build a brand preference—that is, to motivate a large number of consumers to buy his brand regularly at any of the many stores where it is carried. The manufacturer of industrial goods, such as steel, machinery, lubricants, and office equipment, advertises to other business firms to get them to use his product in their operations. The producer of ethical drugs, building materials, or textbooks advertises to doctors, architects, or educators to induce these professional people to prescribe, specify, or recommend his product to patients, clients, or students. An association of firms in a particular industry, such as sugar refiners, orange growers, or dairies advertise to stimulate consumption of a generic product such as sugar, orange juice, or milk. All business firms, whether they be retailers, manufacturers, or service institutions such as banks, insurance companies, and airlines, advertise to build a respected corporate identity, to make their corporate name well known and highly regarded.

Advertising is also used to awaken, enlighten, and activate the public at large concerning matters that affect society generally. Private, nonprofit organizations in some countries create and distribute various public service advertisements including those for forest fire prevention, rehabilitation of the handicapped, traffic safety, drug abuse information, crime prevention, and continuing education.

Volume of advertising

Of the 64 non-Communist countries surveyed by the International Advertising Association, the United States led in advertising expenditures with more than $18,000,000,000 in 1968, which was 61 percent of the world's total expenditure. West Germany was second with expenditures close to $4,000,000,000 (16 billion deutsche marks); Japan was third with $1,500,000,000 (540 billion yen); Great Britain was fourth with $1,200,000,000 (451 million pounds). In France and Canada expenditures were approaching the level of $1,000,000,000. As a percentage of gross national product, on the other hand, advertising expenditures in 1968 were highest in West Germany at 2.87%. Next was Switzerland at 2.42%, then Jamaica at 2.11%, and the United States at 2.06%.

Per capita advertising expenditures in the United States in 1968 were placed at $89.20. In three other countries, Switzerland, West Germany, and Sweden, expenditures were over $50 per inhabitant. In several countries advertising expenditures were less than 20 cents per capita (Nepal 5 cents, Pakistan 14 cents, Ceylon [now Sri Lanka] 16 cents, India 16 cents). This wide range of per capita expenditures demonstrates that advertising is more prevalent in highly industrialized countries where consumer purchasing power is broadly distributed, where the economic system is competitive, and where mass communications media are more generally available. (Although consumer advertising exists in some Communist countries, its volume is relatively insignificant.)

ESTABLISHMENT OF MODERN ADVERTISING

The first advertising was by public criers in ancient times who circulated through the streets calling attention to the sale of such items as slaves, cattle, and imports. An ancient written advertisement, perhaps 3,000 years old, was discovered by an archaeologist delving in the ruins of Thebes. It offered a "whole gold coin" as reward for the return of a runaway slave named Shem. During the Middle Ages the spoken word in Europe was the principal means of communication, and there was little of the activity that is now called advertising. The invention of movable type about 1450 by Johannes Gutenberg made it possible to produce many copies of books and periodicals cheaply and quickly and ushered in the modern era of advertising.

Printing made possible the transition from simple announcement to the system of argument and suggestion that constitutes modern advertising, and the medium of this development was the newspaper. The weekly papers sometimes carried a few advertisements, including the first offerings of coffee (1652), chocolate (1657), and tea (1658) in England. In June 1666 the *London Gazette*, No. 62, announced the first advertisement supplement as follows: An Advertisement—Being daily prest to the publication of Books, Medicines, and other things not properly the business of a Paper of Intelligence. This is to notifie once for all, that we will not charge the *Gazette* with Advertisements, unless they be matter of state; but that a Paper of Advertisements will be forthwith printed apart, and recommended to the Publick by another hand.

Advertising was prospering by the following century, and in 1758 Samuel Johnson could write in "The Idler": "Advertisements are now so numerous that they are very negligently perused, and it is therefore become necessary to gain attention by magnificence of promise and by eloquence sometimes sublime and sometimes pathetick."

The 19th century was a period of expansion in advertising as well as in business generally. The Industrial Revolution expanded the output of factories, and advertising helped market this output. The growth of the penny press and of magazines, combined with an increase in the educational level in the Western nations, brought forth an in-

crease in audiences. Improvements in transportation made it possible to distribute magazines geographically on a wide scale, thus permitting vast increases in circulation and reductions in price. Slogans and jingles became favourite advertising techniques. Some of the trademarks famous today were popularized during this period.

During the first two decades of the 20th century, advertising was re-examined. Certain excesses in its claims had developed and caused widespread resentment. Regulation came both from within industries and from governments.

After World War I came the era of salesmanship; advertising became "salesmanship in print." Advertising was accepted as an essential tool in selling the booming output of all the nations' factories. "It pays to advertise" became a standard slogan. Soap companies and automobile companies were among the most important advertisers. It was discovered that testimonials by movie stars were effective in selling such items as perfumes and cigarettes.

A major new advertising medium, radio, was added during the 1920s. At first, most radio commercials were indirect and there was doubt as to whether advertising would be allowed on the air. In such countries as Great Britain and France, it was banned from public-owned radio; in the United States, however, commercial radio thrived, and by 1928 it accounted for $10,500,000 in advertising.

Another new medium, television, was added to the advertising scene immediately after World War II. It had a spectacular growth in the U.S.; it became the second largest advertising medium (after newspapers) in terms of total dollars spent and the largest in the top national advertisers' budgets. In the postwar era, too, American advertising agencies began popularizing the concept of the "brand image." According to one agency president, "Every advertisement should be thought of as a contribution to the complex symbol which is the brand image. . . . Every advertisement is not a one-time shot, but a long-term investment in the total personality of the brand." The concept of a brand image was extended to building favourable images for corporations, retail stores, service institutions, and political candidates.

ADVERTISING MEDIA

Advertising media can be classified as follows: newspapers, magazines (consumer magazines, business publications, farm publications, professional journals), television, radio, direct mail, outdoor media (signs, posters, painted bulletins, electric displays), transit media (car cards, outside displays, station posters), and miscellaneous (dealer displays, theatre-screen advertising, specialties, directories).

There is no single best medium for all advertising situations. Each has its own character, and each advertising situation presents a unique set of circumstances. A medium that is best for one advertiser may not be best for another, and each medium must therefore be considered in terms of how well it meets the individual advertiser's requirements.

Newspapers

Newspapers because of their big circulations are the most widely used advertising medium. They offer something for everybody: news of what is going on in the world as well as in the local community, editorial comment on current issues, sports coverage, financial pages, homemaker sections, and entertainment features. With often 60 to 70 percent of their space devoted to advertising newspapers keep their readers informed of the myriad of goods and services available in the marketplace, including the apartment for rent, the house for sale, and the employment opportunity appearing in the classified section.

The newspaper is an ideal medium for most retailers. Its circulation area generally conforms to the retail trading area. Retailers located in suburban shopping centres of major cities usually have access to a local community newspaper, and many major metropolitan papers offer zoned editions, whereby the circulation is split into geographic areas or zones, making it possible for a retailer to buy only that part of the circulation going into his trading area. A newspaper's daily publication readily fits the day-to-day selling and quick action promotions that characterize most retailing. Consumers regularly turn to their newspapers for shopping information including pictures of the merchandise, product specifications, and prices. The wide range of space sizes and publication dates gives small as well as large advertisers an opportunity to advertise profitably.

Big advertisers can achieve wide coverage by using many newspapers, and they use newspapers for a special purpose: to supplement other media such as television and magazines that provide inadequate coverage in particular cities, to concentrate effort where there are exceptionally promising sales opportunities, to gain the support of local dealers, to counter strong local competition, or to test the introduction of a new product.

Magazines

Magazines offer a wide range of advertising opportunities. General magazines such as *Reader's Digest* (U.S.), *Paris-Match* (France), *Der Spiegel* (West Germany), and *Asahi* (Japan) are edited to serve the interests of many different population segments, thereby offering advertisers the opportunity to reach a broad cross section of people in all parts of a nation. Women's magazines such as *Elle* (France), *Good Housekeeping* (U.S.), and *Vogue* (both U.S. and France) appeal to the various special interests of women, thereby offering advertisers the opportunity to reach these important consumers in a variety of editorial environments. For men there are magazines concentrating on sports, or on business or science. There is a magazine for just about every interest group imaginable. Each type of magazine offers the advertiser an opportunity to reach his best prospects when they are reading subject matter relevant to the advertiser's product. A manufacturer of milking machines, for example, can reach dairymen in a receptive frame of mind when he advertises in a dairyman's journal. The greatest number of magazines exist in the fields of business, in which there are one or more publications for every industry and occupational grouping. Advertising in business magazines paves the way for a company's salesmen and at various levels reaches management people who might influence a buying decision. Finally, there are the many professional journals that are read by doctors, dentists, engineers, architects, and educators who are in a position to prescribe, recommend, or specify what others will buy.

The geographic selectivity of consumer magazines has been increased through regional editions that enable advertisers to place an advertisement in a part of the circulation that goes into a particular market area. The advertiser must buy a certain minimum circulation, but this is likely to be sufficiently low to permit him to advertise in only one of the major cities. Regional editions let local and regional advertisers benefit from the prestige of a national publication.

The ideal measure of a newspaper's or magazine's value to a given advertiser would be the number of his prospective customers who read it. It would be extremely difficult, however, to isolate and count prospects for each and every advertiser. Therefore, research organizations that measure advertising for advertisers report the composition of magazine audiences in rather standard demographic terms such as age, sex, occupation, income, and family size. Using these breakdowns the advertiser selects newspapers and magazines whose audiences best match the demographic characteristics of his market.

Television

In the affluent nations today, more people spend more time with television than any other medium. In the United States, for example, during the peak viewing hours of an average winter evening over 50 percent of the households are tuned in. Viewing per household averages six hours daily. Viewing declines about 20 percent during the summer months. Changes in the hour-by-hour activities of various members of the family influence the composition and size of the television audience. Men do most of their viewing at night and on weekends. Preschool age children watch more daytime television than

school-age children. Women usually do more viewing than men in all time categories. The older age groups, 50 and over, do more viewing than younger groups. The audience composition varies by program types. Adults over 50 prefer western, drama, and variety shows. Adults under 50 prefer feature films, whereas nonadults watch more situation comedies.

Television advertisers buy units of time: a minute, thirty seconds, twenty seconds, ten seconds, a quarter hour, a half hour, an hour or longer. In such countries as West Germany all commercials are placed between programs; there are no program interruptions. In the United States they are placed both between programs and within programs. The advertiser may specify the time his commercial is to be broadcast or for a lower rate he may leave its placement to the station's discretion. Program time units may be bought for exclusive sponsorship or multiple sponsorship. Through exclusive sponsorship a single advertiser gains the full benefit of being identified as the program's sponsor, but he also must bear the full cost. Multiple sponsorship gives two or more advertisers the opportunity to be identified with a particular program while sharing the cost.

Rating systems for television

The United States employs by far the greatest variety of methods for measuring television audiences. The "Audimeter," for instance, developed by the A.C. Nielsen Company, is an electronic device that is connected to all television receiving sets in a representative sample of households. The Audimeter makes a minute-by-minute record on photographic film of the time periods when each set is turned on, the specific stations to which the set is tuned, the dialing from one station to another, and the length of time spent with each station. The film cartridges are sent in every two weeks to the Nielsen organization where the data are tabulated and matched against the program schedules of the television stations involved. Although the Audimeter provides a precise record of set tuning, it does not show how many people were viewing nor which members of the family were doing so. The "coincidental telephone" method consists of telephoning a sample of households and asking if a television set is turned on and if so, to what station or program. This method is relatively inexpensive and therefore is used extensively in local market areas. The "roster-recall" method involves personal interviews in which a roster of all stations and programs readily available in the area are presented to a sample of people. The respondents are asked to check those programs or stations they recall having watched. This method is useful for surveying homes without telephones and various ethnic groups. The "diary" method requires that individual members of the family use a prepared diary form and keep a record of their viewing as it occurs. This method makes it possible to estimate the composition as well as the size of the audience.

Commonly used measurements of television audiences are: "program rating," which reveals the percentage of all households in the sample turned to the particular program; "share-of-audience," which gives the percentage of households using television tuned to each program; "projected-audience," which gives the estimated number of households reached by a program (a projection of the program rating to total population); and "audience-composition," which offers a breakdown by sex, age, family size, income, and so forth.

Radio is the most ubiquitous medium; but in most countries the stations are government owned, and advertising is absent. In the United States radio-advertising time is sold much the same as television time. Also, the same methods of audience measurement are used. Radio audiences, however, are not measured as frequently or as extensively with regular surveys. American radio is also primarily a local medium; retailers account for about two-thirds of all radio advertising expenditures.

Direct mail

By mail the advertiser can send his message directly to individual prospects. The message can take one of many forms: letter, folder, booklet, brochure, post card, catalog, or coupons. In letter form the message can be personalized by addressing the recipient by name, by appealing to his personal concerns, and by using the language and style of a personal letter. The advertiser also can single out special groups for special appeals. He can be fairly certain that the message will be at least partly read by most recipients and that it will be read on the date it is received.

The mailing list is a critical factor in direct-mail advertising. Frequently used sources of names and addresses are telephone and city directories, trade directories, professional directories, commercial rating books, tax lists, club membership lists and the records of local governmental bodies. Some firms make a business of compiling lists and selling them to advertisers.

Organized outdoor media include painted signs, electric displays, and printed posters, the latter being the most important. The standard poster or billboard is located mainly on heavily travelled routes in and around urban markets. The fleeting exposure to motorists and passers-by demands a brief message, one that can be seen or read in a glance. A single, simple, visual idea with a caption usually is most appropriate. This brevity of message, however, limits the use of posters to reminder advertising.

Other media

Transit advertising including car cards, outside displays, and station posters reaches the millions of riders of public transportation in urban areas. Like outdoor advertising, transit advertising offers frequent exposure to large numbers of people at low cost. Its limitations are brevity of message and an environment low in prestige.

Dealer displays reach consumers at the point of purchase and therefore serve as a reminder or as an invitation to immediate buying action. Display space, however, in crowded, self-service supermarkets is at a minimum.

Theatre-screen advertising offers the opportunity to reach a captive audience with the impact of sound and motion pictures on a big screen.

Advertising "specialties" include calendars and other useful items that are imprinted with the advertiser's name. They include ash trays, lighters, thermometers, key chains, ballpoint pens, memo pads, paperweights, and rulers. Being items that are used frequently, they serve as frequent reminders and engender some goodwill.

ADVERTISING STRATEGY

Advertising strategy is based on a series of answers to these key questions: (1) To whom should the advertising be addressed? (2) What communication objectives should be sought? (3) What should the message contain? (4) What media should be employed? (5) How should expenditures be budgeted? Advertising often is characterized as a means of selling to the masses. This leads to the misconception that advertising should be addressed to everyone. Any population, however, is composed of different individuals with different needs and wants, different lifestyles, and different tastes. The most efficient strategy is thus to single out those segments of the population who are the best prospects and address the advertising to them. Communication objectives include the central idea to be learned, the image to be perceived, and the action to be taken by the target audience. Strategic decisions on message content concern the visual, verbal, and aural devices, the tone or style, and the technique of presentation to be used. Media selection includes the classes of media to be used—for example, daytime television, billboards, or women's magazines. Budgeting involves deciding how much to spend and how expenditures are to be allocated to markets, to media, and to dates. Thus, advertising is essentially a decision-making process. To aid the decision maker, research is used in a variety of ways.

Research

Researching the consumer gives the advertiser a better understanding of the people whom he wants to influence. Motivations that underlie their buying behaviour, their attitudes toward particular product categories and brands, their perceptions of competitive brands, their satisfactions and dissatisfactions with the products they use, their reactions to new product concepts: these are

some of the kinds of information that help the advertiser to identify his best prospects and to select the strongest appeal, thereby increasing the effectiveness of his advertising. Complicating the process is the fact that motivation is multiple. There is seldom one reason for any response. Also, there is no universally strongest motive. The strength of a particular motive depends on the value systems of the particular persons and particular cultures. An effective strategy is therefore to use a different appeal for different market segments.

Motivation research utilizes depth interviewing and projective techniques such as word associations, sentence completions, and various other tests drawn from clinical psychiatry. Use of these techniques to educe subconscious motives led to the fear in the 1950s that advertisers were gaining the power to manipulate consumer behaviour. The fear was not well founded, for it overlooked the power of the individual to resist persuasion against his own perceived interest. To the degree that techniques of persuasion have become more sophisticated and effective, people have developed resistance to manipulation.

Market research seeks to determine the sales potential of various segments and areas. For many product categories a small proportion of the population consumes a large proportion of the product. Twenty percent of total households in the U.S., for example, buy 99 percent of the prepared dog food. Once the heavy user group is isolated it can be further described. Traditionally, market segments have been described in demographic terms such as sex, age, income, and occupation. Recently there have been more attempts to use psychological measurements such as personality traits and motivational variables. Geographically, the market for most products is concentrated in urban areas, where most of industrial populations now live. Regional differences in climate, ethnic groups, and life-style produce different sales potentials for different products. Because markets are dynamic, however, continuing research is necessary to keep up with the changes.

A company's advertisement is best viewed as one of a series building a consistent identity for the product or the company. Creative strategy, therefore, should produce a central idea or unifying theme for a continuing campaign. The theme may be expressed verbally in the form of a brief proposition, a headline, or slogan. It may also be expressed visually in pictorial content, layout style, and graphic treatment. A copywriter for a television commercial, for instance, develops the message idea and draws on the myriad of elements of photocinematography—the visual, aural, and optical elements. He functions much as a motion-picture scriptwriter does. He develops the plot; visualizes the scenes; plans the action; writes instructions to the producers, performers, and technicians. Often a writer and an artist work together in the creative stages. A story board—an illustrated script or diagram of the commercial—is used to present ideas, to gain approval prior to incurring heavy costs, and to facilitate production. Every advertisement thus exploits the unique communication opportunities offered by the medium.

Media strategy

Creative requirements have important implications in media selection. If superior full-colour reproduction in print is required, magazines have an advantage over newspapers. New product introductions benefit from the "news" format of newspapers, radio, and television. If the copy approach seeks to inspire confidence or dispel doubt, an authoritative medium such as a professional journal is appropriate. The environment in which the message appears has an appreciable influence on the effectiveness of the message itself.

The basic variables of media strategy are "reach" and "frequency." Reach refers to the number of households or individuals exposed to the advertising message in a given period of time. Frequency is the average number of times that they are exposed. These variables are interdependent. With a given budget it is possible to reach more people less often or fewer people more often. The optimum combination depends on the requirements of the particular advertising situation. When introducing a new product whose market is unknown, for example, one may try to reach as many people as the budget permits. When the market is well defined, however, one may try to "expose" the message as frequently as possible. If the marketing strategy requires getting new users, reach is more important. If marketing strategy requires concentrating on particular persons and sustaining brand loyalty, frequency is more important.

The scheduling of advertising, the seasons, months, days, and hours when the ads will run, is another strategic decision. Advertising often should run immediately prior to, or in the early part of, seasonal buying or gift-buying periods. The day of the week and the hour of the day can be selected to reach certain groups when they are available and most receptive.

The contribution of advertising to sales and profits cannot be readily isolated from all the other variables in the marketing mix. Determining the size of the advertising budget is, therefore, a rather arbitrary procedure. Assuming that a relation exists between advertising and sales (even though it cannot be precisely measured), a common practice is to express the advertising budget as a percentage of sales. The percent is high for some products—about 20 percent for cosmetics—and low for others—about one percent for insurance. The procedure involves forecasting sales and establishing a percent of sales for advertising. The size of the advertising budget tends to be greater when most of the selling burden is placed on advertising instead of personal selling, when a new product is introduced, when there is little or no discernible difference among competing brands, or when competitive practice requires heavy advertising.

Testing effectiveness

Various techniques have been developed to test advertising ideas prior to publication or broadcast. Opinion and attitude tests involve showing alternative advertisements to a sample of persons, or "prospects," and measuring their expressed preferences and scaled attitudes (degree of liking or disliking). Recall tests use memory as a criterion of effectiveness: prospects are exposed to the advertisements in a folder or in a simulated publication or in a laboratory setting where the length of exposure can be controlled; then they are asked to recall whatever they remember—the best remembered being presumably the most effective. All these tests involve some degree of artificiality. Whenever people are forced to examine advertisements in an interview situation or in a laboratory setting and whenever they are forced to respond to questions bearing on some aspect of communication, the conditions are different from those under which advertising works in real life. Results, therefore, should be treated as tentative findings rather than precise measurements.

To approximate reality, controlled experiments are conducted in the field. The advertising actually is placed in the media so that it reaches people during their normal reading, viewing, or listening. Exposure is voluntary. Responses are voluntary and objectively observed. One form of experiment is the inquiry test. Using a split run, two or more advertisements are placed in the same position in the same issue of the same publication so that matched samples of readers will be exposed to each advertisement. Their responses in the form of an inquiry or a mailed coupon to a coded address indicate which of the advertisements is most effective. For mail-order selling this is an ideal test. For other kinds of selling, the inquiry merely indicates that the advertisement was seen and succeeded in motivating a certain response. The most sophisticated experimental design is one that runs the advertising in selected local test markets and observes ensuing fluctuations in sales. For control purposes similar markets are selected in which no advertising is run in order to take account of sales fluctuations due to all other causes. The difference between test and control markets should indicate the contribution of advertising. Various multivariable experimental designs test several variables simultaneously—for example, various combinations of media.

An advertising agency, Reynell and Son, was founded in London as early as 1812, but advertising agencies have

Advertising agencies

achieved their greatest development in the United States. In 1841 Volney Palmer, who had been an editorial writer and later a member of the advertising staff of the *Pottsville* (Pa.) *Miner's Journal*, opened in Philadelphia what is generally considered to have been the first advertising agency in the U.S. Unlike modern agents, he was primarily an agent for the publishers, who paid him a commission of 25 percent for selling space, although he did not assume liability for the credit extended to advertisers. Shortly after he began operations he had several competitors.

George P. Rowell, who opened an agency in 1865, added two features—wholesaling and the "list system." He contracted with a large number of weekly newspapers to sell him a column of space for a certain period of time; he then offered this space to advertisers in smaller units at retail rates that were below rates charged by competitors. He was, like Palmer, primarily a seller of space, but he offered exclusive lists of newspapers and magazines, and any advertiser who bought space in these had to buy through the exclusive agent.

In 1875 N.W. Ayer & Son of Philadelphia developed marketing policies that gave advertisers access to the true rates charged by the publishers. Ayer thus put the emphasis on the agency's service to the advertiser rather than on selling space for the media.

The next major step was the development of a full line of services for the advertiser. In the late 19th and early 20th century the emphasis was on the creation of advertising copy. After copy came art services, advertising production, and the selection of media. By 1920 most agencies could plan complete campaigns for their clients, including research and budgeting, and could also execute these campaigns by preparing the advertisements and arranging for their insertion in the various media, which now included outdoor advertising and direct-mail. By 1970 there were more than 4,000 bona fide advertising agencies in the United States—as contrasted, for instance, to 500 in Great Britain. Thirty-three U.S. agencies handled over $100,000,000 worth of advertising in 1970; the only agency outside the United States to have billings of over $100,000,000 was in Japan.

The typical advertising agency today is staffed to perform the following services for its clients: (1) planning marketing and advertising strategies; (2) writing copy; (3) preparing artwork, layouts, and television story boards; (4) buying artwork; (5) arranging for mechanical reproduction of printed advertisements; (6) producing television commercials; (7) budgeting expenditures; (8) selecting media; (9) contracting for space and time; (10) checking, billing, and paying media; (11) researching markets, media, copy, and results; (12) merchandising promotional programs to the trade; (13) counselling and engaging in public relations activities. Agencies performing all these functions are referred to as full-service agencies and are likely to be the larger firms. Many smaller agencies concentrate on planning, preparing, and placing advertising.

ECONOMIC AND SOCIAL ASPECTS

Advertising has been most highly developed in countries having an economic system that is basically a free market system, in which consumer choices largely determine what goods and services will be produced. The many suppliers competing for consumer favour use advertising to influence these choices by informing consumers that a given product exists, that it offers certain want-satisfying qualities, that it is priced at a certain amount, and is available at certain retail outlets. Advertising performs these communication functions quickly and efficiently. Although personal selling can be appropriate for reaching relatively small, well-defined, highly concentrated markets such as industrial buyers, advertising is the only feasible means for communicating with millions of ultimate consumers.

Manufacturers are willing to invest in research and development of new products because they know they have the means to introduce a new or improved product quickly to a large market, thereby increasing their chances of building a profitable volume of sales and recovering their initial investment in a reasonably short period of time. Having the means to tell the consuming public about a new product is, in itself, an incentive to invention and innovation.

The fact that large sums of money are spent on advertising and the knowledge that consumers ultimately pay this cost in the prices they pay has led some people to believe prices would be lower without advertising. Defenders of advertising argue that this overlooks the fact that advertising facilitates mass production with its concomitant lower unit costs and that a free market system counts on competition to pass along the benefit of such cost reductions in the form of lower prices.

The prices consumers pay are an indicator of the value they place on the product, and value is something more than the sum total of all the production and marketing costs. Value to the consumer is the sum total of his perceptions of the product and the gratifications he attaches to it. Anything that enhances his perceptions adds value. Advertising adds value by endowing a product with subjective qualities. Consumers who pay a 20 percent higher price for a well-known advertised brand over an unadvertised brand are indicating the greater confidence, and therefore higher value that they place on the advertised brand.

The use of advertising to build a brand preference among consumers and the fact that few firms can afford costly national advertising programs giving them the power to dominate particular product categories leads to the assumption that advertising tends to build monopolies. When a manufacturer registers a trademark or brand name, he is granted an exclusive right to use that mark or name. In effect he is granted a monopoly to sell the product bearing that brand name. Whatever reputation he is able to build for the brand accrues solely to that brand. Through advertising he seeks to differentiate his brand from competing brands, to embellish it with attractions so that a large number of consumers will prefer it over all others. He thus gains a degree of monopoly power. He can charge a premium price. He can count on some stability in sales. Whatever control he gains, however, is based on the loyalty of his customers to the brand. If the price differential becomes too great, he risks losing customers to competing brands. Brand monopolies, therefore, are subject to the whims of consumers and the machinations of competitors.

The high cost of using national media such as television on a large scale restricts the use of such media to the few advertisers who can afford them. Their ability to bear the high cost of introducing new products nationally and to outspend small competitors is thus assumed to discourage would-be entrants and to make it difficult for others to survive. It is further assumed that large firms gain a larger share of market because they can afford to gain a larger share of the public mind and that they can afford to hire the most sophisticated marketing managers thereby widening their competitive advantage. Undoubtedly, large firms with great financial resources can do many things—including large-scale advertising—that small firms cannot do. The opportunity to advertise, however, gives the small businessman a chance to get started. If he has a good product or service fairly priced he can advertise and build a market. He obviously cannot match the giant firms on a national scale, but he might be able to outspend them in his local market area. As his business grows he can use advertising to enter new markets and expand his own competitive capabilities.

The fact that the press in most of the non-Communist world is usually supported financially by advertising raises some questions about the freedom of the press from advertiser control. Many newspapers and magazines get 60 to 70 percent of their revenue from advertising. Commercial television and radio are financed by advertising. The notion that "he who pays the fiddler calls the tunes" underlies the suspicion that advertisers influence news coverage by suppressing and distorting the

news to their own advantage. There are some studies, however, that suggest if advertisers do dictate policy it seems to occur among the weaker or smaller newspapers or radio stations. A financially stable newspaper is generally able to resist pressure from advertisers. Moreover the advertiser's dependence on the press may be a deterrent to his intrusion on press freedom. He needs their circulation and audiences to advertise effectively. It is at least arguable that if he influenced news coverage, the press would risk losing public confidence, which in turn would reduce circulation and jeopardize the effectiveness of the press as an advertising medium.

(V.R.F.)

Advertising Design

The purpose of advertising is to influence the minds of the people to whom it is addressed in a way conducive to the success of a campaign or promotional scheme. Among the means used to achieve this end is advertising design, which represents the aspect of "visual communication" in advertising media and advertising aids. Advertising media consist of sales letters, insertions in newspapers and magazines, enclosures, prospectuses, brochures, catalogs, leaflets, books, posters, films and slides, television tapes, aerial advertising, billboards, shop window displays, exhibits, and so on. Advertising aids may be of a direct or indirect kind. The direct aids include packaging, wrapping paper, book jackets, phonograph record sleeves, and the like, which serve not only to protect and identify the contents but also to advertise. Indirect aids include any number of items that tend to inspire confidence in a firm and help to shape its image favourably, such as calendars, greeting cards, and various gifts.

Varieties of advertising media and aids

Advertising requires that its ideas be given a visual form by artistic and graphic design. The means used to this end are typography, drawing, photography, and colour. The secret of good and effective design is to conceive the composition as a whole in which form and content, and representation and expression, are interdependent and matched to each other.

GENERAL CONSIDERATIONS

The relation of advertising design to other arts. The function of advertising design is primarily a practical one directed toward a particular end. It must communicate quickly and clearly and, in so doing, (1) attract attention; (2) lodge the advertising message in the conscious or unconscious mind; (3) induce an active, positive attitude to the message instead of a passive one; and (4) impress a favourable memory of the message on the mind. Because advertising design is aimed at producing an effect desired by an advertiser, it is obviously not free to choose its theme as the fine arts are. The function of the fine arts is primarily aesthetic. Even so, both advertising design and art use the same resources for the realization of their ideas: form, colour, and composition. Advertising design may use these effects successfully without necessarily producing art; it has served its purpose if image and text create the desired effect. A free work of art, on the other hand, becomes true art only when all the components of the design have genuine qualities of form and colour and together make up a vital composition which is complete in itself. Advertising design, however, can also rise to art if the designer has a strong artistic personality and an original imagination and if the commission allows the artist a certain freedom in the way he presents his theme and selects his artistic means—for example, the famous posters of Toulouse-Lautrec.

The relation of advertising design to technology. Both the nature of advertising design and the tasks that it has to perform have been profoundly influenced by advancing technology. New sophisticated techniques of reproducing and representing acoustic and visual material have given advertising new scope. To relief, intaglio, and lithography has now been added silk-screen printing. Hand composition, monotype, and linotype have been supplemented by phototypesetting techniques. Cinema slides and advertising films have been joined by television commercials. Stationary, two- or three-dimensional signs have been supplemented by moving displays that enable objects to be seen in all their perspectives. Many such displays are programmed by computers.

Techniques used in design

The technical and artistic demands on the advertising designer have become more exacting. The variety of tasks that he has to accomplish calls for detailed knowledge of printing techniques and composition, of cinema and television techniques, of the properties and working qualities of a great diversity of materials used in exhibition design, of the technique of audiovisual presentation and multiprojection, of the potentialities of electronic sign advertising, and of the aids that can be obtained from computers. The advertising designer must familiarize himself with these new techniques and their effects, thereby acquiring more scope for his artistic imagination, a greater field of application for his ideas, and a more comprehensive impact for his advertisements.

The role of psychology in advertising design. The success of advertising design depends on the topicality of what is depicted, on the quality of the design, and, to no less extent, on psychological factors. These largely determine the reactions of the person to whom the advertisement is addressed. Consciously perceived information is capable of inducing moods and feelings that are in harmony with the intention of the advertisement or at variance with it. The static use of the designer's resources in a composition, for instance, may express rest, solidity, conservatism, security, and trust, whereas a dynamic use may evoke love of experiment, flexibility, a forward-looking attitude, aggressiveness, and youthfulness. The correct choice of colours is especially important. Colours with a symbolic significance in politics or religion are taboo and must be used with caution, depending on the country and religion involved.

The role of the advertising designer or commercial artist. With the increasing sophistication of advertising after World War II, the importance of the free-lance advertising designer naturally diminished. Advertising campaigns, some of which have become very extensive and complex, can be planned and carried out only by specialists working as a team. A full service advertising agency will handle all the problems arising in connection with an advertising assignment, including budgeting, and thus has a far greater capacity than the designer working on his own. The free-lance advertising designer, generally speaking, can only execute commissions for smaller firms or take on jobs assigned to him by the agencies in connection with advertising campaigns.

students equally in both fields; in effect it aimed at preparing the artist-designer for the industrial problems of mass production.

The Bauhaus revolutionized graphic design as well as other areas of art and architecture. The aims of the Bauhaus school of artists were pursued by many other more independent artists. Jan Tschichold, for instance, laid down the principles of "basic typography," which were to be functional, utilitarian, and designed to convey a message that was short, simple, forceful, and free from ornamentation.

When the Nazis closed the Bauhaus in 1933, some of the professors emigrated to the United States and Switzerland. In 1937 László Moholy-Nagy opened the Institute of Design (known as the New Bauhaus) in Chicago, where he continued as director and teacher to propagate the Bauhaus ideas. Using a variety of fonts, the American advertising designer gained acceptance for functional typography, and eventually the characteristic American typography developed out of it. Photomontage, the technique of combining photographs that Moholy-Nagy, Herbert Bayer, and Herbert Matter had experimented with in Europe, was taken up and widely used for commercial purposes. In the 1960s Art Nouveau, a romantic use of asymmetrical, undulating lines, and Pop art, a direct depiction of comic and commonplace things, found their way into graphic design. After World War II Switzerland became a refuge for Bauhaus ideas; Johannes Itten went to Zürich and became director of the Kunstgewerbeschule (School of Arts and Crafts) there. The so-called Swiss school (including Richard P. Lohse, Josef Müller-Brockmann, Hans Neuberg, and Karl Gerstner) acquired an international reputation through its systematic and functional advertising.

Prospects for use of information theory

A newer development that is still in the experimental stages is the adoption of information theory to assist advertising design. Information theory is concerned primarily with the discovery of mathematical principles governing systems designed to communicate and manipulate information. It attempts to measure the capacity of various systems, including the human brain, to transmit, store, and process various pieces of information. Measurements of the effects of colours, lights, sound levels and pitches, frequency of signals, and so on have obvious usefulness for the designer.

Other notable developments since World War II include the formation of national and international bodies representing the interests of the profession, the appearance of professional journals and annuals, and also books on design problems, and finally the organization of international design conferences and international poster and graphic design biennials.

Aegean Civilizations

The adjective that is traditionally used to name those Bronze Age civilizations that arose and flourished in the area of the Aegean Sea between *c.* 3000 and 1000 BC is Aegean.

The area consists of Crete, the Cyclades and some other islands, and the Greek mainland, including the Peloponnese, central Greece, and Thessaly. The first high civilization on European soil, with stately palaces, fine craftsmanship, and writing, developed in the island of Crete. Later, the peoples of the mainland adapted the Cretan civilization to form their own, much as the Romans adapted the civilization of later Greece. The Bronze Age civilization of Crete has been called Minoan, after the legendary King Minos of Knossos, the chief city of the island throughout early times. The Bronze Age of the Cyclades is known as Cycladic, that of the mainland as Helladic, from Hellas, the Greek name for Greece. Early, middle, and late stages have been defined in each of these, with further subdivisions according to recognizable changes in the style of pottery and other products associated with each. The civilization that arose on the mainland under Cretan influence in the 16th century BC is called Mycenaean after Mycenae, which appears to have been its most important centre. The term Mycenaean is also sometimes used for the civilizations of the Aegean area as a whole from *c.* 1400 BC onward.

Dating of the Aegean Bronze Age. The dates suggested here are approximate and conventional. In a general way, they are based on correlations with Egypt, where, from the beginning of the Dynastic Period (*c.* 3100 BC onward), a historical chronology can be established with a leeway of a few centuries and is fixed within reasonably narrow limits after *c.* 2000 BC. Bronze Age pottery from the Aegean has been found in datable contexts in Egypt, and many Egyptian objects have been recovered in the island of Crete.

Two important landmarks are fragments of Cretan pottery from the town at Kahun in the Fayyūm, built for

Principal sites associated with Aegean civilizations.

workers who were engaged in the construction of a pyramid for the pharaoh Sesostris II (1897–78), and a large quantity of Mycenaean pottery from the mainland found at Tell el-Amarna, site of Akhenaton's capital, and imported during his reign (1379–62). Radiocarbon dates appear consistent with those based on correlations with Egypt.

History of exploration. The poems of Homer, although they reflect Greek society in the 8th century BC, describe warriors using obsolete bronze weapons and objects such as helmets plated with tusks of wild boar that went out of use before the end of the Aegean Bronze Age. Massive Bronze Age defense walls survived at Mycenae and elsewhere on the mainland and were called Cyclopean because, according to Greek tradition, the Cyclopes had built them. Apart from these Cyclopean walls, virtually nothing was known about the Aegean Bronze Age before the middle of the 19th century, when, in 1876, a German businessman, Heinrich Schliemann, discovered unplundered royal shaft graves at Mycenae and thought that the men buried in them were the Greek heroes of Homer's siege of Troy. Actually, the graves spanned the 16th century BC and proved to be older than any likely date for a Trojan war. Schliemann's discoveries, however, led to intensive exploration of Bronze Age and earlier sites on the Greek mainland. Meanwhile, in the 1860s, Bronze Age settlements of the period of the Mycenae shaft graves had come to light under the debris of an immense eruption on the volcanic island of Thera (Thíra). Later in the 19th century, Christos Tsountas, a Greek archaeologist, dug cemeteries of earlier phases of the Bronze Age on other Cycladic islands and continued the work begun by Schliemann at Mycenae. At the end of the century, a British expedition excavated an important Bronze Age town at Phylakopi on Melos (Mílos). When Crete eventually became independent of Turkish rule in 1898, attention was turned to Bronze Age sites there. In 1900 Sir Arthur Evans, an English archaeologist, began to uncover the palace at Knossos, the largest Bronze Age centre of the island, discovering clay tablets with the first positive evidence for Bronze Age writing in the Aegean. Greek, U.S., French, and Italian excavators added further knowledge of the Cretan Bronze Age during the years that followed, and U.S. and German expeditions opened new sites on the mainland. Inscribed clay tablets such as those found at Knossos in Crete at the turn of the century were recovered beginning in 1939 at Pylos in Messenia by the American archaeologist Carl Blegen; others have come to light at Mycenae and elsewhere on the mainland. The belief that the language of these tablets might be Greek was established by an English archaeologist, Michael Ventris, in 1952, though acceptance of this is not yet universal. In 1962 a large palace, destroyed by fire *c.* 1450 at Zákros (Zakro) in eastern Crete, was found. In 1967 the clearing of a major settlement that was buried by the eruption of Akrotíri, on Thera, began.

I. Early Aegean civilizations

EARLY CULTURES

Paleolithic (Old Stone Age). Chipped stone tools made by Paleolithic hunters have been found in many parts of mainland Greece, but none are yet recorded from Crete or the other islands. As elsewhere in Europe, the latest Paleolithic industries evolved into Mesolithic (Middle Stone Age) ones with diminutive stonework. During this Mesolithic stage, obsidian, a volcanic glass, was brought from the island of Melos for making implements, indicating that boats capable of sea voyages were already in use in the Aegean area by then.

Neolithic (New Stone Age). If radiocarbon dates are to be trusted, agriculture was being practiced in some parts of the Aegean area as early as the 7th millennium. The first agriculturalists in the Aegean, like those of Anatolia and Palestine, may have been ignorant of the art of making fired clay vases—traces of agricultural settlements without pottery have been identified at several places in Thessaly and at Knossos in Crete. The island of Crete appears to have been uninhabited before this time, and the first agriculturalists must have reached it by sea from western Anatolia or from somewhere more distant, such as Cilicia. Other immigrants from the east may have brought agricultural techniques and ways of life to the mainland, where they mingled with the Mesolithic hunting peoples whom they found there. The Aegean is one of the most favoured regions of the Mediterranean basin. Immigrants from the coastal areas of Anatolia, Syria, or Palestine would have found the climate and ecology similar to what they had known in their homelands. The olive and vine, sources of oil and wine, the staples of Mediterranean diet, grow in most parts of the Aegean area and may have been native there. Water, which is a problem in the present century, was probably more abundant in early times when forests were more extensive than they are now.

Ecology of the Aegean

Agricultural communities were eventually established in every part of Greece, making pottery by hand and grinding stones to shape edged tools, axes, adzes, and chisels. Wheat and barley were among crops grown. Hunting and fishing still played their part in obtaining food alongside raising of cattle, sheep, goats, and pigs. Arrowheads of chipped stone were used on the mainland and in the Cyclades, but none is recorded from Crete, where bone points may have served to tip arrows. Another long-range weapon was the sling, and clay sling pellets were made in Thessaly where suitable beach pebbles were not to hand. In Crete, clubs were armed with stone heads as in Egypt and elsewhere in the Near East in early times. Houses with rectangular rooms are attested at Knossos in Crete, at Saliagos in the Cyclades, and in Thessaly. But some Aegean communities may have lived in circular huts of the kind found in Predynastic Egypt and in early Syria and Cyprus. Caves appear to have been used as cemeteries in Crete. Some cremations are assigned to the end of the Neolithic on the mainland. By that time, to judge from a house, larger than the rest, occupying a central position at Dhimíni (Dhimínion) in Thessaly, some communities may have been organized under chiefs. Several Thessalian settlements were surrounded by defense walls or ditches. Copper tools—simple, flat axes and knives—were in use before the end of the Neolithic both in Crete and on the mainland. Indeed, some of the pottery shapes characteristic of later phases of the Neolithic in Thessaly appear to be copied from those of metal vases. But this Thessalian late Neolithic may actually overlap in time with the beginning of the Bronze Age farther south.

THE BRONZE AGE

The Early Bronze Age (c. 3000–2200). The transition from Neolithic to Bronze Age in the Aegean was marked by changes in pottery and other aspects of material culture. These may reflect the arrival in Crete and the Cyclades of new people from more civilized lands farther east bringing knowledge of metalworking with them. In Crete and the islands the changes that inaugurated the Bronze Age were more or less contemporary with the beginning of Dynastic times in Egypt. What is defined as the Bronze Age in the Peloponnese appears to have begun later under the influence of settlers from the islands. The Bronze Age in central Greece and Thessaly may have begun later still. Evolved types of metal tools appear to have been current considerably before the end of the Neolithic there.

Flourishing metal-using cultures were established by the middle of the 3rd millennium in Crete, the Cycladic islands, and the southern part of the mainland. Each of these three cultures had its own distinctive characteristics; but they shared much in common, and their peoples may have spoken the same or similar non-Greek languages. Many place-names throughout the Aegean, notably ones ending in *-nt-* and *-ss-*, such as Corinth and Knossos, seem to reflect a time when the same language (or a group of related languages) with Anatolian affinities was spoken there before the introduction of Greek. A large number of words came to be adopted into Greek from this earlier language group.

Early metal tools

These Early Bronze Age peoples of the Aegean seem to have employed similar types of metal tools, including axes, adzes, and short daggers, but double axes may have been special to Crete. Tweezers were used for plucking facial hairs and rectangular stone palettes for grinding face paints with small pestles made of attractive veined stones or Spondylus shell.

Architecture. Lerna and other settlements on the mainland were eventually surrounded by massive walls with projecting towers, but whether similar defenses existed in the Cyclades and in Crete is uncertain. Houses with several rooms were being constructed in most parts of the Aegean by this time, and buildings at Knossos and at Vasilikí in Crete have been identified as the residences of local rulers. The so-called House of Tiles at Lerna, destroyed by fire toward the end of the period, appears to have been another of these "palaces." It was a large rectangular building with two stories taking its name from the baked clay tiles found in its ruins. These small, flat tiles are thought to have come from a sloping roof and may be the earliest roof tiles known. Similar tiles were recovered from a huge circular structure of the same period at neighbouring Tiryns, of which only a section has been excavated, as it lies deep below the level of the later Mycenaean palace there. It was evidently a public building of some kind, a meeting place, perhaps, or possibly even a temple. Some shrines of this period in Crete may have been circular, as were many of the early Cretan tombs.

But circular buildings at Orchomenus in central Greece are interpreted as granaries or huts. A remarkable stone

vase of this period, from Melos, is in the shape of a granary complex with round silos, such as the granary of the later palace at Mallia (Mália) in Crete. The vase shows an entrance porch with a gabled roof, but it would appear that the roofs of houses in the Cyclades and in Crete were mostly flat at this time and later.

Minoan burials. Cretans in the Early Bronze Age buried their dead in communal tombs. These belonged to clans or extended families and might remain in use for many generations. Traces of hundreds of burials have been noted in some of them. Caves and rock-shelters, as well as buildings of various kinds, were used as tombs. Circular tombs were characteristic of the Mesara (Mesarás) region of southern Crete. They were built above ground, and none has survived complete; but the massive walls that are left seem designed to support the weight of vaults, which may have been constructed of rough fieldstones held together with mud, as were the walls. Some of the largest tombs, however, with a diameter of 40 feet (12 metres) or more inside, may have been vaulted in mud brick. Annexes with cult rooms were built in front of the entrances of some tombs, and others had chambers for offerings around the sides. When a tomb became full, a new floor was laid above the earlier burials, or parts of the tomb's annex were brought into use as burial chambers. Sometimes the remains of earlier burials were removed to separate buildings or enclosures nearby. These circular tombs may have been introduced to Crete by people whose ancestors had lived in round huts. The inhabitants of the Neolithic settlement at Khirokitia in Cyprus, for instance, buried their dead under the floors of the round huts in which they lived. Communal tombs in some parts of Crete had rectangular compartments or rooms and flat roofs, such as those in contemporary houses. At Knossos, where the local rock was soft, artificial caves were dug as tombs. Everywhere in Crete the dead were normally trussed into a tight contracted position, knees to chin. Sometimes the bodies were then squeezed into large storage jars or small clay chests or coffins. There was evidently much ceremonial in connection with burial, and, apart from objects of personal use, such as seals, jewelry, and weapons, left with the dead, vases with offerings were regularly placed inside or outside the tombs.

Cycladic burials. In contrast to the Cretans, the people of the Cyclades during the earlier part of the Bronze Age buried their dead in small graves that held a single body, sometimes a pair, and never more than six or seven. The graves were often grouped in family cemeteries, which might be surrounded by a wall. The bodies were placed in them lying on one side in a loosely flexed position. Some Cycladic graves were little, stone-built chambers with an entrance, although the standard type consisted of a box (cist) made with large slabs set on edge and roofed with slabs.

Helladic burials. Less is known about contemporary burials on the mainland, but the graves there normally contained several bodies, which suggests that they belonged to families but not to large units, such as the clans that existed in Crete. Various types of mainland graves of this period are known, including chambers cut in the rock and stone-built tombs, such as those in the Cyclades. Circular cairns, each covering several burials, on the island of Levcas in western Greece appear to go back to this time.

Early pottery

Aegean arts. Pottery was still made by hand throughout the Aegean area. A useful type of vase first attested there at the beginning of the Early Bronze Age was a handled jug with a spout for pouring. Some of the earliest jugs from Crete have round bottoms and yellowish surfaces, as if they were copies of vessels made from gourds. Distinctive spouted bowls of oval shape that may have been drinking cups but are nicknamed sauce boats were quite typical of the Early Bronze Age on the mainland and usually have a fine reddish or dark overall wash. Pottery with a similar wash and with the surface often deliberately mottled is found in Crete and is known as Vasilikí ware, after a site with a little "palace" where large amounts of it were recovered. The pottery of the Cyclades during this period shares features in common with that of Crete and the mainland. The art of making stone vases flourished in the Cyclades from the beginning of the Bronze Age and may have spread from there to Crete, but it was hardly practiced on the mainland after the end of the Neolithic. The techniques used were simple and included boring with a hollow reed, which twirled an abrasive, either emery from Naxos or sand. The people of the Cyclades used their fine white marble not only for vases but for remarkable figurines, mostly female but including men, some playing double pipes or seated on chairs with harps. While the majority of these figures are only a few inches high, some females are larger and a few are nearly life-size. Some have traces of painted decoration. These marble figures were often placed in graves, and groups of them have been found in sanctuaries, though whether they represented gods and goddesses is uncertain. They were exported to the mainland and Crete and may have been imitated there. Vessels of gold and silver were current in the Aegean by now, and a few have survived, including two gold sauce boats of mainland type and gold and silver bowls from the islands. Gold and silver jewelry of this period, mostly from Crete, includes bracelets, necklaces, earrings, headbands, and hair ornaments of various kinds. Some of the finest of this early jewelry was found in communal tombs at Mochlos (Konídha) on the northern coast of Crete. The inspiration for it no doubt came from the east, and much of that from Mochlos, notably hairpins with flower heads, is reminiscent of jewelry from the royal tombs at Ur in Mesopotamia.

Seals began to come into use in the Aegean about the middle of the 3rd millennium. In an age before the invention of locks and keys, seals were employed to stamp wet clay, which was used to secure doors or affix lids to storage jars or other containers. The design impressed by the seal might add the threat of magic to that of detection if the sealing was broken. Many seals resembling those current in Egypt and Syria have been recovered from early tombs in Crete. Some of these early Cretan seals were made of ivory, possibly obtained from Syria, where elephants still abounded. Others were made of bone or soft, easily cut stones, such as serpentine and steatite. They were of various shapes, some of animals or birds or their heads, others cylindrical, adapted from Syrian versions of early Mesopotamian cylinder seals. They were engraved with a variety of designs, including abstract patterns and pictures of animals, notably dangerous lions and scorpions or poisonous spiders (rogalidhas) of a species native to Crete. Seals appear to have been in use in the Cyclades and on the mainland during this period, but very few have been recovered there. A stone cylinder seal from Amorgos resembles early Syrian ones. Most Aegean seals of this period, however, even in Crete, may have been made of perishable wood. Clay-seal impressions, preserved by fires that destroyed buildings at Lerna, including the palatial House of Tiles, look as if they had been stamped by wooden seals. The designs on these Lerna impressions resemble those found on seals in Crete.

Protective seals

Pictures of boats with many oars or paddles were scratched on clay vases of this period in the Cyclades and on the mainland. The boats have a high prow often surmounted by a fish ensign, the stern being low with the keel apparently projecting beyond it. Similar vessels, though with a single mast for a square sail in addition to oars, are represented on early Cretan seals. Ships of this kind would have been capable of voyages to Syria and Egypt, whence skills and fashions were reaching Crete along with imports such as Egyptian stone vases and Syrian daggers.

End of the Early Bronze Age on the mainland (c. 2200–2000). The comparative unity of incipient civilization in the Aegean area was eventually shattered by new movements of people into the Cyclades and the southern part of the mainland. Toward the end of the 3rd millennium, many of the settlements on the mainland, such as that at Lerna, were destroyed by fire, and the houses built afterward were of a different type and more primitive. These

new houses were long and narrow, only one story high, and apparently gable roofed. The entrance was at one end, and there was often a small compartment, which might be semicircular (apsidal), at the other. The new houses were evidently built by foreign invaders settling in the places they had destroyed. But some of the previous inhabitants may have survived as hewers of wood and drawers of water. There was continuity in the pottery, although new shapes and fabrics appeared alongside the old and sauce boats were no longer made. The site of the House of Tiles appears to have been reserved as sacred or unlucky ground, with a ring of large stones above its burnt ruins.

Either now or, possibly, somewhat later, there is evidence of a complete revolution in burial customs on the mainland. Family tombs were replaced by individual graves, usually lined and covered with slabs, such as the cist graves of the Early Bronze Age in the Cyclades. But these later graves on the mainland are often found inside the settlements, whereas before this burial outside the settlement area appears to have been the rule everywhere in the Aegean. The custom of "intramural" burial had lingered, however, in the hinterland of Anatolia, where houses were built in the style of those introduced to the mainland by the invaders who destroyed the mainland settlements *c.* 2200. Perhaps they came from there, but this remains uncertain.

About the same time as this invasion of the mainland, other people from Anatolia settled in some of the Cycladic islands, such as Syrus (Síros) and Ceos (Kéa) and in Euboea. On a rocky hilltop at Khalandrianí in Syrus, they built an impressive fortified settlement that may have replaced an earlier native one that lay across a gorge to the south and had extensive cemeteries around it. It is clear from their pottery that these people who settled in the islands came from the coastal regions of western Anatolia, which had been comparatively civilized by then by sea contacts with Cilicia and Syria. Some of their pottery was made on a fast wheel, a useful invention that had originated many centuries earlier in Mesopotamia and began to be adopted on the mainland and in Crete at about this time.

The Middle Bronze Age on the mainland (c. 2000–1550). The mainland seems to have undergone further disturbances at the beginning of the 2nd millennium. Settlements such as those at Lerna and Eutresis were destroyed again at this time. There is some slight evidence to suggest that the destroyers on this occasion came from the north. Small handmade pots of primitive appearance with possible relatives in the Balkans were found at Lerna in houses built immediately after this second destruction. Scraps of pottery of a different kind, with string-impressed decoration, at Eutresis may come from vases brought by the people who destroyed the settlement there.

The Kurgans

Corded ware such as this was made by the Kurgan people, who had spread from their original homeland in south Russia into the Balkans. Kurgan is the Russian word for a mound and refers to their custom of burying their dead in artificial mounds or barrows. Burial mounds similar to theirs are found in many parts of the mainland, notably in the western Peloponnese but also in Attica from this time onward. The Kurgan people were pastoralists and breeders of horses, and horse bones are first attested in mainland settlements at this time. Since the Kurgan people have a good claim to be regarded as Indo-Europeans, the first people of Indo-European speech, if not, as is widely believed, the first Greeks, may have begun to settle in southern Greece at this time. As often happened in ancient times, when pastoralists overran settled agricultural communities, these invaders appear to have adopted the material culture of those they had conquered. Longhouses of the kind introduced by the invaders a couple of centuries earlier remained in use, and the custom of burial inside the settlement, which is first attested for certain now, although it may have been practiced by the earlier invaders, continued alongside burial in mounds. There is some evidence for the existence of a new class of rulers who may have been the ancestors of the princes buried in the later shaft graves and tholos tombs of the mainland. An isolated mound at Elátia (Dhrakhmáni) in central Greece, covering the richly furnished grave of a princess, appears to be an early forerunner of these. A complex of buildings around a spacious yard dominated by a longhouse in the level immediately after the destruction at Lerna may have been the "palace" of the new ruler there.

Middle Helladic culture

The development of civilization on the mainland continued to lag behind the Cyclades and Crete, and many centuries were to elapse before the art of writing spread from Crete to the mainland. But gold jewelry is found with some burials, and, by the time of the Mycenae shaft graves in the 16th century, a luxuriant style of native goldwork had been created. The people of the mainland remained in touch with the more civilized world of the Cyclades and Crete. Cretan pottery found its way to Lerna, and a fashion for decorating vases with designs in dark lustreless (mat) paint, which began on the mainland soon after the invasion, appears to have been adopted from the Cyclades. Much of the pottery on the mainland continued to be made on the fast wheel, and a class of gray burnished ware, already fashionable before the invasion, was now usually wheel made, with sharp angular shapes copied from those of metal vases. The polished gray surfaces of this "Minyan" ware (as it was named by Schliemann after the legendary inhabitants of Orchomenus in central Greece, where he first came upon it) look as if meant to imitate silver.

The Shaft Grave period on the mainland (c. 1600–1450). *The spread of Cretan influence.* On the island of Cythera (Kíthira) between western Crete and the southern tip of the Peloponnese, a colony of Cretans appears to have replaced a settlement of people from the mainland toward the end of the 3rd millennium. In the 17th or 16th century, Cretan colonies were established at Triánda in Rhodes and at Miletus on the western coast of Anatolia. Later Greek legends seem to refer to colonies from Crete, if not from Knossos, in some of the Aegean islands. Much Cretan pottery found its way to the Cyclades and was imitated there; but, although the Cycladic people adopted fashions and ideas from Crete, they retained their own distinctive traditions. Cycladic imitations of the designs on pottery from Crete tend to be less refined but more lively than their Cretan models. Wall paintings found at Phylakopi in Melos may be the work of Cretan artists, but others of about the same date from the Akrotíri settlement on Thera, in spite of conventions and techniques learned from Crete, are very different in style and spirit from Cretan ones. Settlers from Crete, however, may have made their homes in Cycladic towns such as Phylakopi, and many of the islands might have been tributary to Knossos for a time.

The mainland, like the islands of the Aegean, came increasingly under the influence of Cretan civilization, which seems to have extended to every aspect of life, including religion and dress. Its spread is vividly illustrated by the contents of the unplundered royal shaft graves at Mycenae.

The Mycenaean shaft graves. These royal shaft graves belonged to leading, if not royal, families of the place that would eventually supplant Knossos as the chief centre of the Aegean. The burials in them seem to range over a period of 100 years or more, from shortly before *c.* 1600 to the beginning of the 15th century. The princes buried here were not Cretans, although it is possible that they paid tribute to Crete. The story of Theseus suggests that Athens was tributary to Knossos at one time, but there is no hint in legend of any such payment of tribute by the rulers of Mycenae. Two groups of shaft graves have been discovered at Mycenae in different parts of a large cemetery area. Each group was eventually surrounded by a circular enclosure wall. The circle designated B with the earliest burials lay outside the limits of the later Bronze Age defenses, but the other circle A, enclosing the richest burials in six large graves, was deliberately incorporated within them. Schliemann excavated the graves of circle A in 1876, but it was not until 1951 that circle B was noted. The graves consisted of deep, rectangular shafts with stone-walled burial chambers at the

bottom. After the bodies were placed in them, the chambers were roofed with timbers, and the shafts above filled again. Both men and women were buried in the graves, many of which contained several bodies. Sometimes the remains of earlier burials seem to have been pushed aside to make room for later ones; but, if so, the shafts must have been laboriously reopened to admit new burials. Large stone slabs with carvings in flat relief had been set above some of the graves. The carvings included spiral designs and pictures of the dead riding in their chariots to war or to the hunt. According to another interpretation, they are taking part in their own funeral games with chariot races as described in Homer. These tombstones provide the earliest evidence for chariots on the mainland. With the dead and, more especially, with those in the graves of circle A had been placed a fantastic array of gold and silver cups, jewelry, and dress ornaments. Golden diadems and elaborate hairpins decked the heads of women. Beads in necklaces were of amethyst, probably from Egypt, and amber from the Baltic. The men were buried with supplies of bronze weapons, including great slashing knives and spearheads and rapier-like swords of types in use in Crete at the time. Several of the swords had blades ornamented with reliefs; others had gold-plated hilts and pommels of polished stone or ivory. Over the faces of some of the men were gold portrait masks, which show them with beards and moustaches, unlike Bronze Age Cretans but curiously like Celts and Germans of Classical times.

Earliest evidence of chariots on mainland

Some bronze dagger blades were inlaid with remarkable pictures or designs in other metals, chiefly gold and silver and electrum (a mixture of gold and silver) in various shades. Black niello was used as a background for these pictures or to heighten the incised detail. The most famous of the shaft-grave daggers shows men armed with bows, spears, and great body shields, hunting a pride of lions; another has catlike animals chasing wild fowl among papyrus flowers beside a silver stream. This technique of "painting in metals" appears to have originated in Syria, although the workmanship and style of the pictures on the Mycenae daggers look Cretan. Whereas other daggers, however, and some metal cups with inlaid designs of this kind have been found on the mainland, none has yet been recovered in Crete. But many of the treasures from the shaft graves are imports from Crete, among them a faience ritual cup such as some from the palace at Knossos; others may have been made by Cretan craftsmen working at Mycenae or by native craftsmen trained by Cretan masters. There were comparatively few clay vases in the rich graves of circle A but large numbers in those of the earlier circle B. While some of these clay vases were Cretan imports, most of them were locally made in traditional mat-painted or Minyan ware. A few, however, with designs in dark shiny paint on a light burnished surface, represent a new style that had developed on the mainland under Cretan influence. This Mycenaean pottery, very different from the mat-painted and Minyan wares it came to replace, seems to have originated in Messenia in the southwestern tip of the Peloponnese, whence it spread to other parts of the mainland and eventually as far north as Thessaly.

Mycenaean pottery

The use of Mycenaean pottery is the hallmark of the Mycenaean civilization of the Late Bronze Age. Other distinctive features of Mycenaean civilization that may have developed in Messenia under Cretan influence during the 16th century are the stone-built tholos tomb and the rock-cut chamber tomb. Cretan influence was so strong in Messenia at that time as to suggest the presence of communities of Cretan settlers there. But no positive evidence for the existence of Cretan settlements has been discovered. The tholos tomb (*tholos* is the Greek word for a round building), with high corbelled vault the shape of an old-fashioned beehive, is found in every part of the mainland to which Mycenaean civilization spread. But tholos tombs are most thickly concentrated in Messenia, and the oldest of them have been identified there. Some of the oldest of the Messenian tholos tombs resembled the early circular tombs of Crete in that they were built above ground and were used by families or clans for successive burials. But, in one important respect, they differed from the Cretan tombs. For, like all later tholos tombs, they were invariably covered with a mound. Burial mounds with many graves in them were common in Messenia throughout the Middle Bronze Age, continuing in use alongside tholos tombs in backward areas. The tholos tomb, which is in effect a circular tomb of the earlier Cretan type covered by a mound, appears to have been created therefore in Messenia either by settlers from Crete or more probably by natives of the region who had learned how to build round vaulted tombs in the Cretan manner.

Most tholos tombs on the mainland were built in a deep pit that was usually cut into the slope of a hillside. The top of the corbelled vault projected above the surface and was covered with a mound. The entrance to the circular chamber was roofed with huge slabs, and it was approached down a long passage (dromos) that was left open to the air. The most splendid of these tombs evidently belonged to kings or princes and may have been intended for only one occasion of burial. The few unplundered princely tholos tombs that have been excavated, notably one at Dhéndra (Dendra) near Mycenae, held several burials. Unless the tombs were reopened for successive burials, this would imply that wives and retainers were killed to accompany their lords and masters in death. The earliest of a group of three princely tholos tombs at Peristéria in Messenia was in use during the time of the Mycenae shaft graves. But the fashion for majestic stone-built tombs of this kind rapidly spread from Messenia to other parts of the Peloponnese, and at Mycenae they appear to have replaced shaft graves as the resting places of the local rulers about the middle of the 15th century. Nine tholos tombs have been discovered at Mycenae, and the largest and most splendid, the so-called Treasury of Atreus and Tomb of Clytemnestra, appear to be among the latest. These great tombs, built of squared masonry and richly decorated, may have been constructed early in the 14th century, although arguments for a date as late as the 13th can be advanced. The mound that covered the Tomb of Clytemnestra overlay part of the earlier shaft grave circle B, and this might seem to imply a change of dynasty at Mycenae from rulers who buried in shaft graves to ones who used tholos tombs. But the later circle of graves A was respected and eventually incorporated within the defense walls when they were built in the 13th century.

The great tombs of Mycenae

While stone-built tholos tombs became the standard resting places for kings and princes in all parts of the mainland to which the Mycenaean civilization penetrated, the mass of the population changed from a custom of burial in single graves, whether in mounds or cemeteries or inside settlements, to the use of family vaults. In some regions, such as Messenia and the frontier area of Thessaly, families built small tholos tombs for themselves. But the most common type of Mycenaean family tomb was a rock-cut chamber with a dromos leading down to the entrance. The entrance was blocked with stones and the passage filled with earth after each burial. The rock-cut tomb may have been developed in Messenia during the 16th century under Cretan influence, like the tholos tomb. In the Knossos region of Crete, rock-cut tombs had been in use for communal burials for many centuries before this. Whatever its origin, the idea of family burial in rock-cut tombs soon spread to Mycenae and other parts of the mainland. Some rock-cut tombs in Messenia and elsewhere were carved in the shape of the beehive vaults of tholos tombs. A few large rock-cut tombs, including some of this shape, were used for royal or princely burials.

Period of the Early Palaces in Crete (c. 2200–1700). Crete does not seem to have been affected by the movements of people into the Cyclades and the mainland at the end of the 3rd millennium. But important changes were taking place there. Great palaces of a distinctive type built around large rectangular open courts seem to have been constructed within a comparatively short time at the leading centres of Knossos, Phaestus, and Mallia. The art of writing is first attested for certain in Crete at

Earliest writing in Crete

the beginning of this Palatial period. These developments in Crete appear to be the result of local evolution. It has been suggested that the models for the great palaces were Anatolian, but the Anatolian palaces, like that at Beycesultan, which have been compared with them, are different in plan and may be later in date. It is always possible, however, that immigrants from some other part of the civilized world of the Near East gave an impetus to these developments, if they did not impose their rule on Crete. Another suggestion is that refugees might have reached Crete from the mainland when it was invaded *c.* 2200. Seal impressions from the House of Tiles at Lerna, which was destroyed at that time, show designs reminiscent of those on Cretan seals of the period immediately before the rise of the great palaces. If the fashion for seals with designs of this kind became established in Crete only after the destruction of Lerna, mainland refugees might have been responsible for their adoption. But the dating of events on the mainland in relation to what was happening in Crete is not yet established with certainty, and the seals that made the impressions found at Lerna may have been Cretan ones or local imitations of them.

Middle Minoan culture. At all events, Crete advanced rapidly along the path of civilization during the period of the Early Palaces, while the mainland relapsed into comparative barbarism. The art of the seal engraver made great strides in Crete at this time. Hard stones, such as jasper and rock crystal, began to be employed for some of the finer seals. A new and much favoured shape, which may have been adopted from Anatolia, was the signet with a stalk. Anatolian seals found their way to Crete and impressions of them have been identified in a great deposit of clay sealings from the early palace at Phaestus. Cretan seal designs now included elegant abstract patterns incorporating spirals and concentric circles neatly made with the drill, as well as lifelike pictures of animals, birds, and insects, together with mythical beasts, such as sphinxes and griffins adapted from Egyptian or Oriental models. Attractive hard stones, such as gabbro, were attacked by the Cretan vase makers, although they still made use of the softer chlorites and serpentines. Some of the fine stone vases from communal tombs in the Mesara region and at Mochlos may date from this period, rather than earlier, in the light of discoveries since 1950 in the early palace at Phaestus.

The fast potter's wheel began to come into use in Crete about the same time as in the Cyclades and on the mainland. Meanwhile, a revolution in the style of Cretan pottery was taking place. During the Early Bronze Age most of the finer vases everywhere in the Aegean area had been decorated with designs in dark rather shiny paint—shades of red, brown, and black—on a light surface. But, toward the end of that period in Crete, there was a change to a "light-on-dark" style of decoration in which the vases were given an overall wash of the shiny paint previously used for decoration and designs were applied to this dark surface in white. This new "light-on-dark" fashion was also adopted, to some extent, in the Cyclades and on the mainland; but in Crete it was developed much further, and, from the beginning of the Palatial period, decoration in white was regularly supplemented with red to create a striking polychrome effect. This kind of pottery, which flourished in Crete throughout the time of the first palaces and later (*c.* 2200 to 1600), is known as Kamáres ware from a sacred cave of that name on Mt. Ida, where vases with fine polychrome decoration were recovered at the end of the 19th century. Most of the smaller vases in Crete, notably the drinking cups, now copy metal ones in their shapes and often in their molded or impressed decoration, and the exquisite "eggshell" ware, made in the workshops of the great palaces, with walls as thin as those of metal vases and shiny black surfaces adorned with abstract flowerlike designs in a combination of white, red, and orange, is among the finest pottery ever produced in Greek lands. The imitations in clay suggest that vessels of precious metal—gold and silver—were in general use in the palaces of Crete by this time. A silver, two-handled goblet of this period was recovered from a tomb at Gourniá in eastern Crete, and the treasure of silver cups, more than 150 in all, buried along with foreign lapis lazuli in temple foundations at Tod in Egypt in the time of Amenemhet II (1929–1895), may well be Cretan. Silver was more valuable than gold in Egypt at this time. It occurs in the Cyclades, and it was being mined before the end of the Bronze Age near Laurium in Attica on the mainland.

"Eggshell" ware

Commerce. There were many contacts between Crete and the rest of the Levant during this period. Scarabs and stone vessels from Egypt reached Crete and were imitated there. Cretan Kamáres ware was exported to Cyprus, Syria, and Egypt, where it has been found in tombs and on town sites. Letters recovered from the ruins of the city of Mari on the Euphrates, destroyed by Hammurabi *c.* 1760, refer to objects of Cretan workmanship. It seems that Cretan metalworkers were already pre-eminent in the civilized world of the time. The daggers they made were of types ultimately derived from Syria, but they were exported to Cyprus in exchange, perhaps, for copper, although supplies existed in Crete. Westward, they may have reached Italy, where native copper daggers are of Cretan shapes and flint imitations of them seem to have been made. It was during this period that tin-bronze began to come into more general use in the Aegean, replacing copper or bronze made by adding arsenic, an effective process but dangerous for the craftsman who undertook it. Tin may have reached the Aegean first from Iran through Syria, although Etruria on the western coast of Italy was another possible source.

Burial in Crete was still normally in communal tombs, and many of the Early Bronze Age ones continued in use; but cemeteries of burials in storage jars are also attested at this time. No royal tombs of this period have been identified, however, and kings and queens may have been laid to rest, like their subjects, in the tombs of their clans. A large rectangular building with many rooms or compartments in the cemetery area just outside the city at Mallia might have been the tomb of the royal clan there. The local inhabitants plundered it during the 19th century, and its modern name—Chrysolakkos ("Gold Hole")—suggests what they found. A gold cup and jewelry, including elaborate earrings and pendants, acquired by the British Museum in 1892 and allegedly from a Mycenaean tomb on the island of Aegina near Athens, appears to be plunder from Chrysolakkos. French excavations there in the 1920s led to the recovery of similar jewelry, notably a gold dress-pin with flower head and a pendant in the form of a pair of bees (or wasps) facing each other over a disc, which may be meant for a honey cake. This pendant shows that the Cretan jewellers were masters of the art of hard soldering and could use it to fix wire (filigree) or minute globules of gold (granulation) to a background. But the jewelry from Chrysolakkos is difficult to date, and it may belong to a slightly later period, after the destruction of the early palaces at Knossos and Phaestus.

The Chrysolakkos treasure

Middle Cycladic culture. Life in the Cyclades seems to have continued much as it had in the Early Bronze Age. But, apart from signs scratched or painted on pottery from Phylakopi in Melos, there is little evidence of acquaintance with writing or the use of seals. Some time after the beginning of the period of the Early Palaces in Crete, Phylakopi was defended by a massive wall. Cretan Kamáres ware and Minyan ware from the mainland were imported to Phylakopi and doubtless reflect the trade in Melian obsidian, which may have been still in demand for cheap knives and razors, although metal ones were already in use in the Aegean area from the Early Bronze Age onward. Chamber tombs cut in the rock at Phylakopi appear to go back to this period, but burial in slab-lined cists continued elsewhere in the islands. At some point the fortified settlement at Khalandriani on Syrus was destroyed by fire and abandoned.

Period of the Later Palaces in Crete (c. 1700–1450). Various disasters occurred in Crete about the turn of the 18th and 17th centuries BC. The palaces at Knossos and Mallia were damaged, while that at Phaestus and a building that may have been the residence of a local ruler in a large settlement at Monastiráki west of Mt. Ida were de-

Destruction of the palaces

stroyed by fire. What caused these destructions is uncertain. Accident, internal warfare, or foreign invasion are among possible agents. The damage at Knossos might have been caused by one of the earthquakes that afflict that area. It has been suggested that Crete was first conquered by Greeks at this period or by people from Anatolia speaking another Indo-European language called Luwian and related to Hittite. But there is no strong evidence for an invasion of Crete at this time.

The flowering of Minoan culture. The two or three centuries following these disasters were indeed the most flourishing of the Aegean Bronze Age, during which Cretan civilization reached its zenith. The palaces at Knossos, Phaestus, and Mallia were restored with greater splendour than before. From the dimensions of the new and entirely rebuilt palace at Phaestus, it has been possible to calculate the unit of length used by the Cretan architects: a foot only a fraction shorter than the standard English foot. In plan, the later palaces were basically the same as the earlier ones, with agglomerations of rooms clustering around long, rectangular central courts oriented roughly from north to south either for ritual or for catching the best of the winter sun. Many parts of these palaces were two or three stories high. A section on the eastern side of that at Knossos, built into a cutting in a steep slope below the level of the central court and housing the royal living quarters, may have had five stories. Large areas of the palaces, especially at Knossos, were reserved for cult, while other parts were occupied by storerooms for the produce brought as taxes in an age before the existence of money. Wide, paved squares flanked the palaces, and around them spread extensive towns, which, by this time, if not earlier, seem to have been unwalled. Cobbled streets with raised central paths of smooth squared blocks for the convenience of pedestrians ran through the towns. Surface water was carried away by covered drains, and skillfully jointed clay waterpipes were found in the palace at Knossos. The only settlement of this period that has been entirely excavated is a small town at Gourniá in eastern Crete. This was built on the slopes of a ridge overlooking the sea on top of which stood a little palace with a small open court in the centre and a public square beside it on the sheltered landward side. Down the ridge from the palace toward the sea was a small shrine facing the end of a path that led to it from the main street. Even in a small town such as that at Gourniá, many of the houses were evidently two stories high, and houses with three stories are depicted on faience inlays from the palace at Knossos assignable to the 17th century BC.

In palaces as well as houses, the lower parts of walls were still normally built of rough fieldstones held together with mud, the upper stories being continued in mud brick. But carefully squared and fitted blocks of limestone were employed for some important facades. Now, as earlier, walls were often laced together with a framework of timbers set vertically and horizontally in their faces and joined by crossbeams running through them. There was also an extensive use of timber for columns and pillars and for the rafters supporting upper floors and roofs, which, it seems, were usually flat. Pictures of wooden columns show them with a characteristic downward taper, which may reflect an original custom of placing tree trunks upside down. The lower parts of the walls inside the palaces and great houses were often clothed with large slabs of attractively veined gypsum, a soft crystalline stone that outcrops in the region of Knossos and Phaestus. Gypsum was also much employed for pavements, but a hard lime plaster was more commonly used for coating walls and floors. Plastered walls were decorated with brightly coloured pictures, which may be an innovation of this period, since they are not yet attested for certain earlier in Crete. These pictures are described as frescoes because they were normally painted while the plaster was still damp. Lines impressed with string in the wet plaster helped to guide the artists. White, red brown, or blue were usually chosen as a background, while yellow and black were among other basic colours used. Many of these pictures, especially those from the palace at Knossos, were concerned with religion and show elaborately dressed goddesses, together with sacred dances and ceremonies, such as bull leaping, which may have had a religious or magical basis. But scenes such as a frieze of partridges and hoopoes adorning a room in what appears to have been an inn for strangers opposite the palace at Knossos look entirely secular. Monkeys, imported from Egypt, are depicted more than once, along with native wild goats and extraordinarily lifelike flowers, sometimes of identifiable species but often imaginary. The pictures ranged in scale from those with life-size figures, which might occupy most of the wall surface, to panels and friezes, including a class of miniatures with little figures of men and women two or three inches high. Parts of some wall pictures at Knossos were in relief, and plaster reliefs of this kind are occasionally found elsewhere in Crete. Floors and ceilings might also carry painted decoration.

Minoan frescoes

Their wall paintings were probably the finest achievements of the Cretan artists, but only battered or fire-discoloured fragments of these have survived. The minor arts are better represented in the archaeological record. Now, if not earlier, hard rock crystal began to be used for making vases and seals, together with the volcanic glass, obsidian. A variety of this, flecked with spots of white pumice from Yialí (Glass Island), near Cos (Kos), was favoured for vases. Other fine stones imported for vase manufacture were Egyptian alabaster (calcite) and green and red marbles (antico rosso and lapis lacedaemonius) from the southern Peloponnese. Antique stone vases from Egypt might be adapted to local tastes by the addition of spouts and handles. Vessels with narrow necks were carved in two pieces that were afterward joined together, an example being a crystal libation vase from Zákros (Zakro) with the handle formed of crystal beads threaded on copper wire. A number of cult vases are carved with pictures in relief, including an octopus, a mountain shrine, a ritual dance of some kind, and games, such as bull leaping, wrestling, and boxing, which appear to have had magical or religious connotations. Soft stones, such as chlorite or serpentine, were used for making these vases, the surfaces of which were often coated with gold leaf to judge from scraps of it that have survived. This economical system of gilding was sometimes applied to seal stones, although solid gold and silver seals also occur. A class of gold signet rings has oval bezels engraved with ritual scenes that may include episodes from the story of a goddess and her consort, with his death and resurrection. Seals of other shapes, in a wide range of attractive stones, display a variety of designs, including pictures of animals, such as lions, bulls, and wild boars. Sometimes a bull is being attacked by a lion, or a wild goat is escaping or standing at bay before a hound. Birds, fish, and butterflies also figure on these seals, and most of the designs on them appear to be entirely secular in character. But a class of gems crudely engraved with pictures of jars and leafy branches may have been rain-charms. Their skill in carving hard stones for seals and vases and their ability to model large plaster reliefs suggest that the Cretans might have sculptured stone reliefs and statues had they wished. But there is little evidence for Bronze Age sculpture in Crete, apart from a few small stone heads that may have come from statues with wooden bodies. Some bronze curls from the palace at Knossos appear to have adorned the head of a more than life-size wooden statue of a goddess. Figurines cast in solid bronze and mostly representing worshippers, both men and women, placed as votives in sanctuaries are often of great beauty. Statuettes of bull leapers and perhaps of gods and goddesses were made of imported ivory in several pieces cunningly joined together by means of pins and dowels. The technique of faience manufacture was presumably learned from Egypt. Exquisite faience plaques of animals, along with statuettes of goddesses or priestesses and small vases of the same material, appear to be products of the palace workshops at Knossos.

Rings and seals

The art of the potter, however, was in eclipse in Crete for a time, which may reflect the widespread use of gold and silver plate for tableware. Even cooking vessels were

now being made of copper or bronze, including huge cauldrons in which a sheep or goat could be boiled whole. Among a variety of serviceable bronze tools were axes, adzes, and double-bladed axes such as those of earlier times. The sockets of these were improved toward the end of the period from a circular to an oval shape, which prevented twisting of the haft. New tools current by then included long bronze chisels and immense saws capable of slicing the gypsum required for paving and wall veneer, as well as for cutting timber. During this period, if not earlier, little trowel-like blades were replaced by leaf-shaped ones as razors. Helmets of copper or bronze are depicted on faience inlays from Knossos and stone relief vases, but plate armour is attested only from the end of the 15th century onward. For defense the Cretans of this time appear to have relied on huge rectangular or eight-shaped shields of bull's hide. (Homer's reference to the shield of Ajax "like a tower" preserves a memory of body shields of this kind.) Weapons included spears and daggers, as well as rapiers with long slender blades and short tangs for affixing wooden hilts. Massive pommels of attractive stones, such as rock crystal, or of gold-plated wood or ivory helped to balance the blades. Toward the end of the period, swords are found with strong, flanged hilts and short blades adapted for cutting as well as thrusting strokes.

Evidence of writing. Signs scratched or painted on clay vases, not only in Crete but on the mainland and in the islands, from about the middle of the 3rd millennium onward may reflect some acquaintance with writing among the peoples of the Aegean area then. But the first positive evidence for the use of writing in the Aegean is found in Crete at the beginning of the Palatial period—*c.* 2200 or somewhat later. This earliest Cretan writing is known as pictographic or hieroglyphic because its signs are pictures of animals or things in the manner of Egyptian hieroglyphs. But only a few of the signs resemble Egyptian ones, and the system appears to be of Cretan origin, even if the idea of writing was inspired by Egypt or Syria. During the period of the Early Palaces and while the Cretan hieroglyphic script was still in use, a simplified linear script was being scratched on clay tablets at Phaestus. A more evolved script with linear signs of this kind is attested in various parts of Crete during the period of the Later Palaces and is known as Linear A, to distinguish it from the variety of script (Linear B) current both in Crete and on the mainland from the end of the 15th century onward (see below). Most of what has survived of Aegean Bronze Age writing is on clay tablets of the kind used in Syria and Mesopotamia in early times. But ink was used to write Linear A inscriptions around the insides of two clay cups from Knossos, and the bulk of what was written in the Aegean during the Bronze Age may have been in ink on some kind of paper, made from papyrus as in Egypt or from palm leaves, as later Greek tradition hints. Palm trees grew in Crete during the Bronze Age and some of the later (Linear B) clay tablets there and on the mainland seem to have been made in the shape of palm leaves.

Linear A and Linear B

II. The decline of the early Aegean civilizations

THE ERUPTION OF THERA (C. 1500) AND THE CONQUEST OF CRETE (C. 1450)

Cretan civilization reached its highest peak in the 16th century. An important change of fashion that began in Crete then was the abandonment of the "light-on-dark" style of vase decoration of Kamáres tradition in favour of a return to "dark on light." The new-style Cretan pottery, with attractive designs of plants and flowers in shiny black or brown paint, was soon to inspire the development of Mycenaean pottery on the mainland. But this flourishing period in Crete ended in a series of disasters. About 1500 the volcano on the island of Thera, long, it seems, quiescent, erupted to bury the settlements there under many feet of pumice ash. The story of Atlantis, if Plato did not invent it, may reflect some Egyptian record of this eruption, one of the most stupendous of historical times. Knossos was shattered by a succession of earthquakes that preceded or accompanied the eruption, while great waves resulting from it appear to have damaged settlements along the northern coast of Crete. Later Greek traditions, such as the story of Deucalion's flood, may enshrine a memory of similar waves that swept the coasts of the mainland at this time. Some Cretan settlements might have been wrecked by blast from the eruption, although Thera lies about 70 miles (110 kilometres) away from Crete. But, whatever the damage caused, it appears to have been soon repaired. Similarly, in the Cyclades there are few signs of any gap in occupation as a result of the eruption. The so-called Second City at Phylakopi in Melos was totally destroyed, but the surviving inhabitants appear to have set to work at once to build the Third City on its ruins. The settlements on Thera, however, lay buried deep in pumice, and the largest of these, at Akrotíri, opened by excavations since 1967, offers a unique picture of a Bronze Age town, the walls of the houses standing in places two stories high, with paintings miraculously preserved on them, and the floors with storage jars and other objects resting on them as they were left when the inhabitants escaped from the eruption or from the earthquake that is thought to have preceded it.

After the eruption, Crete appears to have enjoyed comparative prosperity for a time, while the influence of Cretan civilization continued to spread on the mainland. Alongside vases with plant and flower designs, the Cretan potters began to make ones decorated in an attractive Marine Style, with octopuses and other sea creatures. The Marine Style may have originated at Knossos, but vases with this type of decoration, many of them of a ritual character, were exported all over Crete, as well as to the Cyclades and the mainland. About the middle of the 15th century, however, a generation or so after the eruption of Thera, most of the important sites in central and southern Crete were destroyed by fire. Whether this horizon of fire destruction can be traced in western Crete is uncertain because of the lack of excavation there. Destruction was not confined to palaces and towns but extended to country houses, farms, and rural shrines. Many settlements were never inhabited again, such as that at Mochlos, where the excavators found the remains of numbers of people who had perished in the destruction. The site of the destroyed town at Gourniá was eventually occupied by a scatter of houses, but the palace there was not rebuilt. The large palaces at Mallia and Zákros were also destroyed by fire and afterward abandoned.

The Marine Style

A new social order. The fact that palaces and country houses, centres of landed estates, were not rebuilt suggests a total overthrow of the existing social order. A number of magnificent stone ritual vases and bronze tools have been recovered from the ruins of the palace at Zákros in excavations since 1962, but virtually no gold or silver objects were found. Indeed, it looks as if the palaces and houses everywhere in Crete had been ransacked before they were destroyed. Alone of the four great palaces, that at Knossos may have escaped serious damage at this time, but parts of the city there were wasted by fire. In the early days of Cretan exploration, it was taken for granted that these destructions were the result of war. Since the 1930s, however, it has been suggested that they were, in some way, caused by the eruption of Thera. But the eruption began and ended a generation or more before this horizon of destruction, while conquerors are found in Crete immediately after it. The destruction appears to have been their work.

They evidently came from the mainland and made their capital at Knossos, but they seem to have established another centre of power at Phaestus; and legend hints at a third based on Kydonia (modern Khaniá) in western Crete. Vases of shapes already popular on the mainland, such as drinking cups with high feet, became fashionable at Knossos after the conquest and eventually spread to other parts of the island. A rather stiff, formal "Palace Style" of vase decoration, using motifs derived from the earlier Plant and Marine styles, may reflect an adaptation of Cretan fashions to cruder mainland tastes. The old clan tombs went out of use in the Knossos region and were replaced by rock-cut tombs of the type evolved un-

der Cretan influence on the mainland. Some of these contain the burials of warriors and their families, accompanied by rich assortments of weapons and jewelry, resembling the Mycenae shaft graves and the mainland tholos tombs. There was a cemetery of similar rock-cut tombs, with richly furnished burials (the Tombe dei Nobili), at Phaestus. Tholos tombs sunk in the ground and covered by mounds appear to have been introduced to Crete from the mainland now. One, on the Kefála ridge north of the palace at Knossos, may have been built soon after the conquest.

A decline in taste and artistic imagination becomes marked during the period after it throughout the Aegean area. But skills and techniques remain at a high level, and the fabric and firing of pottery improve both in Crete and on the mainland. Great advances were made in military equipment, to judge from the formidable and often elegant and richly ornamented bronze weapons from the warrior graves of the time. Short, strong swords had blades adapted for cutting as well as thrusting. Their hilts were sometimes sheathed in gold, and pommels were made of fine stones or ivory, as in the past. Warriors were armed with large thrusting spears as well as throwing spears or javelins. Bronze arrowheads, virtually unknown in Crete before the conquest, are of types introduced from the east or copied from the flint and obsidian arrowheads long current on the mainland. Conical helmets of felt or leather might be cased in bronze, such as one from a warrior grave of *c.* 1400 at Knossos, which was surmounted by a knob for holding a plume and had separate cheekpieces. An old mainland custom of plating helmets with the tusks of wild boar is first attested in Crete during this period. Ivory plaques from the mainland show men wearing such helmets, and Homer describes one in detail. One placed in a tomb at Dhéndra, near Mycenae, *c.* 1400 had separate bronze cheekpieces, and the warrior to whom it belonged also had a pair of bronze greaves (leg guards) and a corslet of bronze plates cunningly fitted together. Similar corslets are depicted on Linear B clay tablets from Knossos as part of the issue to chariot warriors. Plate armour of this kind may have been developed in connection with chariot warfare for which the old body shield was impractical. Small, round shields also began to come into use in the Aegean area at about this time. Some Aegean ships by now had railed platforms at prow and stern joined by a gangway down the length above the heads of the rowers. Before the end of the Bronze Age, ships of this type had been developed as warships with rams.

Advances in weaponry

Events on the mainland. While there are many signs of mainland influence in Crete in the period after it, the conquest may have helped to spread Cretan fashions and techniques on the mainland through the medium of captive artisans sold as slaves. The earliest wall paintings on the mainland appear to date from this time and are thoroughly Cretan in style. But the Mycenaean civilization of the mainland remained very different from that of Crete. Mycenaean pottery is distinguishable from Cretan, and religious customs, such as worship in caves or hilltop sanctuaries, which continued in Crete, do not appear to have taken root on the mainland. The standard mainland palace of this period, although built with Cretan techniques and adorned with wall paintings by Cretan artists or in the Cretan manner, differed from the traditional Cretan palace centred around a large, rectangular court. The focal point of a mainland palace, such as that at Pylos (Pílos) in Messenia, was a great hall with the roof supported on four pillars and a vast circular central hearth. The hall was entered through an anteroom with a columned porch beyond it. This complex appears to be an adaptation of the type of longhouse found on the mainland since the end of the 3rd millennium. The descriptions of palaces in Homer are evidently based on memories of palaces such as these, and what Homer calls the megaron corresponds to the great hall.

Mainland palaces

Conquest of the Cyclades. People from the mainland overran the Cyclades when Crete was conquered or a few years later. Settlements such as that at Ayía Iríni on Ceos (Kéa) were destroyed by fire, and the old Cretan colony on Cythera was abandoned. The so-called Third City of Phylakopi on Melos suffered damage, and, immediately afterward, a small palace of mainland type was built there. Similar palaces may have been built in Crete after the conquest. The largest house of this period at Gourniá is very similar in plan to the palace at Phylakopi. Massive foundations at Ayía Triádha near Phaestus may have belonged to the hall of a palace of orthodox mainland type. But the great palace at Knossos retained its traditional Cretan form, in spite of many alterations that were made to it. The paintings on its walls in the period after the conquest were still largely of a religious nature and included scenes of bull leaping and friezes of people taking part in processions or ritual. These friezes were inspired by Egyptian models, although their monumental character may have appealed to mainland tastes. The rulers of the mainland also adorned their palaces with religious pictures of this kind, but they appear to have indulged a passion for scenes of warfare and hunting to a degree that is not attested at Knossos.

Linear A was the script in use in Crete at the time of the conquest. But this had been replaced by Linear B by the end of the 14th century. Linear B clay tablets have been recovered from Knossos and from several of the palaces on the mainland. The people of the Cyclades may have been acquainted with the Cretan Linear A script, to judge from signs of it on local vases from settlements on Thera buried by the eruption of *c.* 1500, but it is doubtful if a version of this script was used on the mainland. If it was, the people of the mainland might have adapted it to form the Linear B script for writing their own language before they conquered Crete. Alternatively, Linear B may have been evolved afterward at Knossos. The Linear B tablets consist mostly of short lists or inventories, and picture signs (ideograms) often give an indication of what is listed on them. Thus, some tablets from Knossos, with a chariot, horse's head, and corslet, evidently record equipment issued to warriors. Ever since the first Linear B tablets were discovered at Knossos in 1900, many people have thought that their language might be Greek, and it was deciphered as Greek by Michael Ventris in 1952. His decipherment has been widely accepted, but, with short inscriptions of the kind available, it is difficult to verify. Those who doubt his decipherment include some who agree that the language of the Linear B tablets is Greek, whereas others think it is a non-Greek language spoken by the conquerors of Crete or a form of the old Cretan language that they adopted for official purposes at Knossos and on the mainland.

The fall of Knossos and the Mycenaean empire. The new rulers of Crete evidently thrived for several generations after the conquest. Great tombs were built and richly furnished. The unplundered burial of a princess of this period has been found at Arkhanes near Knossos. Then, suddenly, this comparative prosperity was brought to an end. The palace at Knossos was destroyed by fire and never rebuilt. Since 1960 the date of this final destruction of the Knossian palace has been disputed with a range of opinion from *c.* 1400 to 1150, but it probably took place in the 14th century, when there is evidence for destruction at other Cretan sites, such as Mallia, and when burial in the warrior graves of the Knossos region and at Phaestus ceases. The elimination of the warrior aristocracy that had flourished in Crete since *c.* 1450 was surely the work of enemies, possibly from the mainland. But the mainland also appears to have undergone changes for the worse about this time. The era of great princely tholos tombs on the mainland seems to come to an end now or not much later. From the beginning of the 14th century, the arts of wall painting, seal engraving, and vase decoration everywhere show symptoms of stagnation and decline. The pottery of the 13th century is remarkably standardized and homogeneous throughout the Aegean area. After the fall of Knossos, the chief centre of power in the Aegean appears to be Mycenae, which may have exercised control over an empire including Crete and the islands. From *c.* 1400 or earlier, the records of the Hittite Empire in Anatolia mention a state called Ahhiyawa, which may be some Mycenaean dependency,

Final destruction of the palace at Knossos

if not an empire ruled by Mycenae. Ahhiyawa could be the same word as Achaioi (Achaeans), the name given to the Greeks in Homer.

THE END OF THE BRONZE AGE IN THE AEGEAN (C. 1200–1000)

There is no evidence that any palaces existed in Crete after the final destruction of that at Knossos; but, on the mainland, palaces continued to flourish at centres such as Mycenae, Tiryns, and Pylos. In the 13th century massive defense walls were built at many of these mainland centres, including Mycenae and Tiryns and Athens, where the acropolis was fortified. At Athens and Mycenae underground passages led to springs concealed beyond the walls. The Lion Gate at Mycenae dates from this time, although the limestone relief of confronting lions above it may have been carved earlier. A wall appears to have been constructed during this period across the Isthmus of Corinth against enemies from the north.

Toward the end of the 13th century, the chief centres of the Peloponnese were destroyed by fire, and their palaces were never rebuilt. Centres farther north, such as Thebes and Gla, may have been destroyed some time before this. The site of Pylos was afterward deserted, but occupation of a kind continued at Mycenae. This destruction of Mycenaean centres on the mainland seems to herald a collapse of civilized life throughout the Aegean area. Wall painting, gem engraving, and writing vanish from the scene; but a more efficient type of slashing sword appears in the Aegean about this time, and the skill to make complicated military equipment, such as chariots and warships with rams, was not lost, while eventually iron replaced bronze for weapons and tools, as elsewhere in the Near East. After the destruction of the Mycenaean centres in the Peloponnese, there is evidence for depopulation there and for a great exodus of the former inhabitants, some westward and southward to Cephallenia and Crete, others eastward to the Cyclades and as far as Cyprus and Cilicia, where their settlements have been noted. An important cemetery of this period has been excavated at Peráti on the eastern coast of Attica.

Introduction of iron

There has been much speculation as to the causes of these disasters and upheavals. Revolutions or civil wars and vast piratical raids by land or sea have been blamed for the destruction of the Mycenaean centres. The dispersal of refugees from the Peloponnese has been explained in terms of climatic changes leading to drought and famine there. But the evidence for such changes is doubtful, and the refugee movements look very much like flight before the onslaught of invaders.

Invasion from the north. There are indeed signs that barbarous peoples from the north had begun to enter the Peloponnese by the 12th century. Traces of them are slight and controversial, because they adopted elements of the Mycenaean civilization, and most of their pottery was made on the fast wheel in a version of Mycenaean style and, at first, presumably by Mycenaean craftsmen whom they had enslaved. Burial in single graves, current on the mainland before the rise of the Mycenaean civilization, had lingered in regions beyond its frontiers, such as Epirus and northern Thessaly. Now, single graves, which may be those of invaders, are found in the Peloponnese and elsewhere on the mainland alongside family tombs of Mycenaean tradition. Pairs of long dress pins, with burials of women, are among northern features that appear in the Mycenaean area at this time. These pins, worn one on each shoulder, suggest the introduction of a new type of garment, different from anything Mycenaean and akin to the simple blanket-like peplos still retained by the womenfolk of conservative Dorian Greeks in Classical times.

The coming of the Greeks. The Classical Greek dialects fall into an eastern and a western group, which might reflect two successive movements of people of Greek speech into Greece. According to tradition, the Dorians, or West Greeks, only entered the Peloponnese in the 11th century. It is therefore difficult, although not impossible, to regard them as the destroyers of the Mycenaean centres there *c.* 1200. As to when the bearers of the East Greek dialects first appeared in Greece, there is a wide range of opinion. At one extreme is the idea that the Neolithic inhabitants of the Aegean already spoke a form of Greek. According to another view, both groups of Greek dialects were actually formed on Greek soil early in the Bronze Age, the East Greeks being the creators of the Mycenaean civilization, while the West Greeks remained in primitive conditions beyond its frontiers until the 12th century or later. One widely held view brings the ancestors of those who spoke the East Greek dialects from Anatolia or the north in the centuries around 2000, when there is evidence of successive invasions on the mainland. At the other extreme is the belief that Greek was not spoken in the Mycenaean area until *c.* 1200, when the bearers of the East Greek dialects came as the destroyers of the Mycenaean centres in the Peloponnese and adopted a barbarized version of the Mycenaean civilization as their own. This view, however, is naturally difficult to reconcile with a belief that the language of the Linear B tablets is Greek.

Theories of the origin of Greek dialects

THE PEOPLE OF THE BRONZE AGE AEGEAN

Physical appearance. The inhabitants of the Aegean area in the Bronze Age may have been much like many people in the Mediterranean basin today, short and slight of build with dark hair and eyes and sallow complexions. Skeletons show that the population of the Aegean was already mixed by Neolithic times, and various facial types, some with delicate features and pointed noses, others pug-nosed, almost negroid, are depicted in wall paintings from the 16th century. But men and women are always represented with black hair, and the presence of fair-haired people is not attested in the Aegean until later Greek times. Some very tall men buried in the Mycenae shaft graves may be descendants of invaders who entered the mainland at the end of the 3rd millennium. A few skeletons from the single graves that appear on the mainland at the very end of the Bronze Age suggest the presence of new people from the north.

Dress. Clay figurines of *c.* 2000 from Crete show men wearing a narrow codpiece with a belt or loincloth and bare above the waist. This was to remain the basic fashion for Cretan men throughout the Bronze Age. Cretan women wore short-sleeved jackets, which left the breasts bare, and ankle-length flounced skirts, although shorter skirts to just below the knees are also attested. Marble figurines of men from the Cyclades assigned to the Early Bronze Age have belts and narrow codpieces such as the Cretans. There is little evidence for dress on the mainland until the time of the Mycenae shaft graves in the 16th century. A considerable variety of dress is represented from that time onward throughout the Aegean area, but it is difficult to recognize fashions peculiar to the mainland. Tasselled shorts worn by men on the Mycenae lion-hunt dagger are also attested in Crete at the time. Aegean envoys painted on the walls of the tomb of Rekhmire, vizier of the Egyptian pharaoh Thutmose III (ruled 1504–1450), at first wore large codpieces of a type fashionable in Crete in the Shaft Grave period, but these were later changed into kilts without codpieces as worn by men in paintings at Knossos after the mainland conquest of Crete, *c.* 1450. This might reflect mainland envoys coming to Egypt after the conquest and wearing a different type of dress from the Cretan. But kilts of this kind appear to be represented in Crete both before and after the conquest. Curious scaly cloaks and long single-piece robes are among a variety of ritual garments in Crete. Linen was known in Crete by the beginning of the Bronze Age and fragments of it were recovered from the Mycenae shaft graves. But in Crete, at any rate, clothes were mostly, it seems, made of wool, and wall paintings show them woven with colourful and intricate designs, including pictures of animals and birds and even musical instruments. One of the dyes used was purple crushed from murex shells. Cretan men wore knee boots and sandals with upturned toes. Men with leggings or greaves are represented in wall paintings on the mainland. Caps of various kinds appear on the heads of men and high, pointed hats and tiaras on those of women and of gods and god-

desses or their priests. Clay figurines of the Early Palace period show Cretan women with elaborate hair arrangements. Women put jewelry in their hair, including strings of beads. Necklaces, earrings, bracelets, and armlets were displayed by men as well as women. Seal stones were carried on strings around the neck or on the wrist. Cretan men normally left their hair long but were clean shaven. Beards and moustaches are attested on the mainland in the Shaft Grave period and later.

Society. In the 3rd millennium the whole Aegean area appears to have been divided into small units ruled by chiefs with "palaces" not much larger than houses. But the Early Palaces in Crete suggest larger kingdoms there by *c.* 2000, with a stratified society including nobles and probably classes of scribes and free artisans, as well as slaves. In the period of the Later Palaces, if not earlier, every sizable settlement in Crete was dominated by a large house, or palace, evidently belonging to the chief family of the place. These families may have formed a nobility owing allegiance to the kings of the great palaces at Knossos, Phaestus, Mallia, and Zákros. The kings may have shared power with councils of nobles, if not with popular assemblies, but this is speculative and based on doubtful analogies with early Sumeria. Primitive customs of the kind loosely called matriarchal, such as inheritance through the female line, may have survived in Crete, and women evidently played an important part in religious cult there. The Mycenaean society of the mainland appears to have had an aristocracy of conquest. Toward the end of the Bronze Age, the evidence suggests the formation of larger states extracting tribute from local rulers and eventually perhaps suppressing them to exercise direct control.

Social organization

Trade. Foreign manufactures reaching the Aegean and especially Crete during the Bronze Age included Cypriot pottery, Mesopotamian and other Oriental cylinder seals, and Egyptian stone vases, ivories, and scarabs, while Cretan and eventually Mycenaean pottery is found in Egypt and elsewhere in the Levant. But the bulk of what was traded evidently consisted of perishable fabrics and foodstuffs and, above all, raw materials. Obsidian from Melos reached other parts of the Aegean from Mesolithic times onward. Imported tin became a necessity during the Bronze Age, and copper was brought from Cyprus to supplement native sources. Massive copper or bronze ingots of an international type are found in Crete and elsewhere in the Aegean from the 15th century onward. Ostrich eggs and stone for making vases were among imports to Crete from Egypt, and ivory came from there or from Syria. Amber from the Baltic reached the mainland in some quantity during the Shaft Grave period and later but is rarely found in Crete. Exports from the Aegean may have included woollen goods, olive oil, and timber, as well as silver. In Crete, at any rate, foreign trade may have been largely under palace control, but a class of private merchants engaged in overseas commerce no doubt existed in the Aegean.

Transport. Ships with a mast and square sail in addition to oars or paddles are attested in the Aegean from the Early Bronze Age. On land, goods were no doubt transported by pack animals or on poles slung between bearers, a principle also adopted for passenger chairs, of which there are clay models. A model of a four-wheeled cart from Crete is datable to *c.* 2000 or earlier. The wheels of such carts were evidently solid, and they were no doubt drawn by oxen, although horses may have been ridden in Crete by then, as they seem to be depicted on early Cretan seals. These horses could have come from the east, a different breed being introduced into the mainland from the north at the beginning of the Middle Bronze Age *c.* 2000. The light spoke-wheeled chariot drawn by horses appears to have developed in Syria or northern Mesopotamia early in the 2nd millennium but spread rapidly throughout the Near East, owing to its usefulness in war. Chariots are depicted on tombstones of the Mycenae shaft graves and on Cretan seals before the time of the mainland conquest *c.* 1450. Apart from warfare, they were used in the Aegean for hunting and probably for travel. During the later part of the Bronze Age, terraces were built to support roads wide enough for wheeled vehicles both in Crete and on the mainland. Such roads were carried across streams on bridges, examples of which have survived in the region of Mycenae.

Warfare. Short daggers of types derived from Syria were in use in the Aegean during the Bronze Age. Long rapiers, evolved from those in Crete, are found on the mainland by the time of the Mycenae shaft graves in the 16th century BC. Short swords adapted for cutting as well as thrusting begin to appear in the following century and may have been developed in connection with chariot warfare. Bronze armour and small, round shields more serviceable in chariots replace the old Cretan body shields at approximately the same time. Bows and slings were probably used everywhere in the Aegean area, but, whereas arrowheads of flint and obsidian are found on the mainland, they are virtually unknown in Crete, where arrows may have been tipped with bone or wood until the appearance of bronze arrowheads in the 15th century. Settlements on the mainland and in the Cyclades were defended by walls from the Early Bronze Age onward, and the town at Mallia in Crete appears to have been protected by a wall during the period of the Early Palaces; but, by the time of the Later Palaces, Cretan towns may have been unwalled. Faience inlays of the 17th century from Knossos, however, seem to show an attack on a walled town such as that depicted on a silver-relief vase from the Mycenae shaft graves. The town, in each case, appears to be in the Aegean but not necessarily in Crete. Methods of warfare had become highly developed by the end of the Bronze Age, with improved weapons, complex and well-designed fortifications, extensive use of chariots, and warships with rams.

Development of fortified towns

Religion. Little is known about religion in the Cyclades and on the mainland before the period when they came under strong Cretan influence. An open-air sanctuary filled with marble figurines on the island of Kéros (Káros) is assignable to the Early Bronze Age. In Crete during the Early Palace period, there were many open-air sanctuaries on the tops of hills and mountains. Some of these had small shrines in them, and shrines with one or more rooms and benches for offerings and cult statues are found in the countryside and in the towns in Crete. Parts of the palaces and of large houses there were also set apart for cult. Shrines not unlike Cretan ones existed in settlements in the Cyclades and on the mainland in the Late Bronze Age; but hilltop sanctuaries are not well attested there, and most of those in Crete appear to go out of use after the mainland conquest, *c.* 1450. Caves were also used as sanctuaries in Crete, and cults in some of these continued until the end of the Bronze Age and later.

The chief deity everywhere in the Aegean in the Bronze Age was evidently a goddess. Perhaps there were several goddesses with different names and attributes. Clay statues of goddesses have been found in shrines in Crete dating from the 15th century. Shrines with clay goddess figures have also come to light at Ayía Iríni in Ceos and at Mycenae. But most cult statues were probably made of wood everywhere in the Aegean throughout the Bronze Age. There is evidence for the worship of a male god, who may have been a counterpart of gods such as the resurrected Osiris in Egypt. Much of Aegean Bronze Age religion survived into later Greek times, and the idea of an Elysion, or Isles of the Blessed, very different from the gloomy Hades of Homer, appears to be a legacy from Bronze Age Crete.

(M.S.F.H.)

Aegean Sea

The Aegean Sea was the cradle of two of the great early civilizations, those of Crete (Kríti) and Greece, from which much of modern Western culture is derived. During the classical period it also served as a naval school, providing knowledge to all the people of the known world. In addition, it is an important natural feature of the Mediterranean region, possessing several unique characteristics that make it of considerable scientific interest. (For additional information see AEGEAN CIVILIZATIONS.)

It constitutes an arm of the Mediterranean Sea, located between the Greek peninsula on the west and Asia Minor on the east. About 380 miles long and 186 miles wide, it has a total area of some 82,625 square miles (214,000 square kilometres). The Aegean is connected through the straits of the Dardanelles, the Sea of Marmara, and the Bosporus with the Black Sea, while the island of Crete can be taken as marking its boundary on the south. The sea has an intricate configuration and could well be considered as a bay within the eastern Mediterranean Basin, to which it is connected by the straits to the west and east of Crete. It also has a good connection with the Ionian Sea to the west, through the strait lying between the Peloponnese peninsula of Greece and Crete. Virtually throughout the Aegean area, numerous islands large and small emerge from the clear blue waters. These are the mountain peaks of Aegeis, the name given to a now-submerged land mass. At the dawn of European history, these islands facilitated contacts between the people in this area and of three continents. Throughout the entire Aegean shoreline—that is, both the continental shores surrounding the Aegean Sea and those of the islands—bays, ports, shelter creeks, and so on are also abundant. These also facilitated the task of seamen travelling in the Aegean Sea, making longer and longer voyages possible at a time when shipbuilding was in its infancy. No other maritime area of the Mediterranean has such a great shoreline development as compared with its size.

Recent scientific investigation of the Aegean area has been carried out by various research vessels belonging both to Greek and foreign institutes. The latter include modern, well-equipped vessels from the United States, the U.S.S.R., France, and Sweden. Greek scientific bodies, however, continue to play a leading role in research.

Physical characteristics. The maximum depth of the Aegean is to be found in the east of Crete, where it reaches 11,627 feet (3,543 metres), although the average depth is 1,188 feet. The rocks making up the floor of the Aegean are mainly limestone, though often greatly altered by volcanic activity that has convulsed the region in relatively recent geological times. The richly coloured sediments in the region of the islands of Santoríni (Thíra) and Mílos, in the south Aegean, are particularly interesting. By the 1970s, Santoríni, in particular, had become a topic of major international scientific importance, analysis of its surrounding sediments having been linked with a possible explanation of the ancient legend of the "lost" island of Atlantis.

Winds and tides

North winds prevail in the Aegean Sea, although from the end of September to the end of May, during the mild winter season, these winds alternate with milder southwesterlies. The tides of the Aegean Basin seem to follow the movements of those in the eastern Mediterranean generally and have a limited tidal range of about 12–16 inches (30–40 centimetres). The tide of Euripus (Porthmós Evrípou)—a strait lying between continental Greece and the island of Euboea (Évvoia), in the heart of the Aegean—is, however, extremely important, as it displays a tidal phenomenon of international significance, to which it has, in fact, lent its name. The euripus phenomenon—characterized by violent and uncertain currents—has been studied since the time of Aristotle, who first provided an interpretation of the term. Aegean currents generally are not smooth, whether considered from the viewpoint of either speed or direction. They are chiefly influenced by blowing winds.

Maximum temperature values on the surface levels of the sea amount to 75°–77° F (24°–25° C) during the month of August but generally only reach 50°–52° F (10°–11° C) in February. In depths of up to about 1,600 feet, temperature fluctuates around 57°–64° F (14°–18° C), while it is practically steady around 57° F at sea level. Aegean Sea temperatures are influenced by the cold water masses of low temperature that flow in from the Black Sea to the northeast.

Salinity fluctuates around 36–39 parts per thousand, according to the season of the year, with the low level of Black Sea salinity (15 parts per thousand) influencing the salinity rate of the northern Aegean.

Marine life. The Aegean Sea, like the Mediterranean in general, is the most impoverished large body of water known to science. The nutrient content, as indicated by the amount of phosphates and nitrates in the water, is on the whole poor: the less saline waters coming from the Black Sea have a distinct ameliorative influence, but the role of their fertility in the Mediterranean in general has been little studied. Generally, marine life in the Aegean Sea is very similar to that of the northern area of the western basin of the Mediterranean. In view of its limpidity and as a result of its hot waters, it is not surprising that the Aegean Sea accommodates large quantities of fish at the time of their procreating maturity. Such fish enter the Aegean from other areas, notably from the Black Sea.

The resources of the Aegean other than its fish have been little utilized, although recent research has revealed the possibility of the existence of oil deposits beneath the seabed, to say nothing of mineral and chemical materials on the sea floor.

Aerial Sports

Aerial sports have a fundamental position in aviation and encompass the true origins of aviation. Individuals in

the 1800s and early 1900s imagined, contrived, and developed contraptions that would enable them to experience the unique sensation of being airborne. The development of aircraft for commercial and military purposes came much later. Flight was founded in sport, and sport flying still thrives.

The Fédération Aéronautique Internationale was founded in Paris in 1905 to encourage the progress of world aeronautics. It has long exercised general supervision over most phases of aerial sport, certifying world records and sanctioning international competition. It includes national federations from more than 50 countries in its membership.

This article is intended for the general reader who may have no knowledge of the activities described. It deals chiefly with the four most popular varieties of aerial sport—power-plane sports, soaring (or gliding), sport parachuting (skydiving), and sport ballooning—sketching the history and present status of each. For more detailed information on specific activities, the reader should consult the works listed in the bibliography.

POWER-PLANE SPORTS

Power-plane activities involve flight with an airplane that is self-propelled. They began with the Wright brothers' first successful powered, sustained, and controlled airplane flights in 1903 and have expanded and diversified greatly ever since. Aside from simple recreational flying of stock aircraft, most current activity falls into one of five categories: air racing, aerobatics, and flying of homebuilt craft, antiques, and rotorcraft.

Air racing. *History.* Men began competing with each other in airplanes even before they knew how to fly them well. The first international races were held at Reims, France, in 1909, and three-fourths of the 38 entries crashed at least once during the week-long contest.

Between 1909 and World War II, air racing captivated the enthusiasm and attention of designers, manufacturers, governments, and the public. The major national and international events such as the Bennett Cup, Schneider, Thompson, Bendix, and Pulitzer races drew huge crowds: up to 500,000 persons for annual races and an estimated 1,000,000 for one Schneider race at London. Many of these were closed-circuit races: the Pulitzer was run over a three-cornered, 29-mile (47-kilometre) course.

Technological improvements to planes came very fast and several countries held leading positions at some point during this period. An American, Glen Curtiss, won the 1909 Bennett Cup contest at Reims. The French took over leadership for the next few years with their Nieuport and Deperdussin racers. From 1921 to 1926 the American Curtiss biplanes set records and won the major international contests. From 1927 to 1930 Great Britain excelled with its Supermarine racers, predecessors of the Spitfire, a celebrated World War II fighter. In the early 1930s Italy's design achievements were outstanding, and in 1933 an Italian aircraft set a 440-mile-per-hour (708-kilometre-per-hour) seaplane speed record that still stands. Landplane speed records were dominated in the 1930s by a succession of privately designed U.S. race planes. So rapid was the design progress during this period that one year's Pulitzer or Thompson winner was inevitably outclassed a year later. In 1939 a German Messerschmitt 209V1 flew an official 469.22 miles per hour (about 755 kilometres per hour), setting a speed record that remained until 1969, when American pilot Darryl Greenamyer established a new standard of 483.041 miles per hour (about 777 kilometres per hour) in a modified Grumman Bearcat.

Speed races

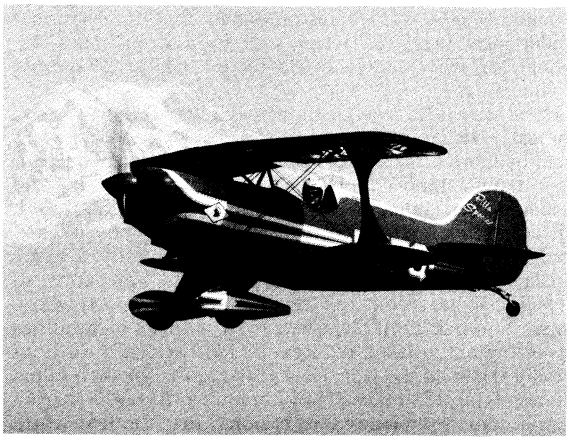
The early races were more than simply sporting events. They were a professional challenge for designers, mechanics, and pilots to develop new ways to increase aircraft speed, range, and dependability. Many of the ideas and methods spawned in racing were utilized by military and commercial aviation. Racing pilots were either military pilots or professionals subsidized by related industries such as oil companies. Racing planes were expensive and required the economic support of government or industry.

Sport racing. Not until after World War II did the fever for design improvement give way to interest in pure sporting competition. The withdrawal of most commercial support and increasing costs brought a decline in racing. Another factor was the rising number of fatal accidents that plagued closed-circuit racing as speeds increased. In 1947, however, a new racing class was established for midget monoplanes with limited power engines and other design restrictions. This was a class that the sport racing pilot could afford. Midget races on closed courses soon became popular with both pilots and spectators, who could now see the entire race course instead of only the finish line.

In 1964 the first U.S. National Air Races since 1949 were held at Reno, Nevada. Competition classes included midgets (later called Formula One), sport biplanes, and unlimiteds (modified World War II fighters). After 1964 air racing improved, as many more cities hosted races, and classes expanded to include stock planes, military trainers, and a promising new category of Volkswagen-engined planes. Many women are active in air racing. An association of woman pilots called the Ninety-Nines hosts the Powder Puff Derby, an annual U.S. transcontinental stock plane race. (For world air speed records see RELATED ENTRIES under SPORTING RECORD in the *Ready Reference and Index.*)

Aerobatics. An increasing number of pilots are learning to enjoy aerobatics—the art of guiding a plane through unusual attitudes of flight. Aerobatics are strenuous exercise for both plane and pilot. The plane must be strong, for it is subjected to great stresses. The pilot is challenged physically and mentally because the precise control of the craft during manoeuvres requires concentration, coordination, timing, and judgment.

History. Until 1964 aerobatics were mostly performed by professional stunt pilots as an airshow attraction and by military student pilots as part of their proficiency training. In the United States, a new enthusiasm for sport and competition aerobatics began in 1964, when the first sanctioned national aerobatic contest was held at Reno, Nevada. At about the same time the Champion Aircraft Corporation introduced the Citabria, the first aerobatic production plane since before World War II. Many amateur-built aerobatic planes began to appear, and numerous flight schools introduced aerobatic courses.

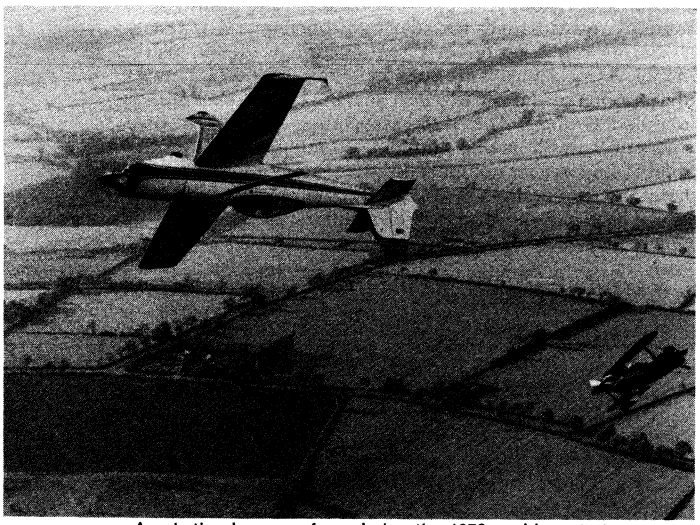


Aerobatic airplanes. Several U.S. aircraft companies manufacture planes stressed for primary aerobatics. Advanced aerobatics require aircraft with special features in addition to extra strength—they need high power and low weight; a wing that will develop lift in either upright or inverted flight; large control surfaces and fuel and oil systems that will allow the engine to operate during inverted flight.

The Yak (U.S.S.R.) and Zlín (Czechoslovakia) are the top European aerobatic aircraft. Both are manufactured as pilot trainers but have proven to be excellent aerobatic craft when equipped for inverted flight. In 1970 Germany introduced a new aerobatic ship called the Akro Star.

U.S. competition aerobatic planes are mostly antiques and trainers that have been rebuilt and modified by their owners. An exception is the Pitts Special, a tiny biplane with a 17-foot (five-metre) wingspan that was conceived as a sport and aerobatic homebuilt plane in 1948 and has been duplicated in dozens of home workshops. Later Pitts Specials with more powerful engines won several aerobatic championships and performed well in international competition.

Competition. Competition is at three levels: primary, advanced, and unlimited. Primary is the most popular category. In it, the competitor flies at between 1,500 and 3,000 feet (460 and 900 metres) and must complete ten predefined manoeuvres within eight minutes. Competitors in the advanced and unlimited categories fly a greater number of more difficult manoeuvres and are allowed a much lower altitude limit. Besides the predetermined group of manoeuvres, these competitors must devise and fly a free group sequence according to certain rules. Aerobatics judging is based on methods introduced by José L.



Bases for judging

Pitts Special aerobatic biplane.
Jim Larsen

Aresti, Spanish master of aerobatics, who devised a shorthand method of diagramming and scoring manoeuvres. Each manoeuvre has a "difficulty coefficient," or K factor. In competition judges observe each manoeuvre and score it from one to ten according to how well they think it was performed. This figure is multiplied by the manoeuvre's K factor. Local, national, and international aerobatic meets are held. The Experimental Aircraft Association (U.S.) hosts one of the largest contests with 80 or more participants. A world meet is held every

Flight International

Aerobatic planes perform during the 1970 world meet at Hullavington, Wiltshire.

two years under the auspices of the Fédération Aéronautique Internationale. Competition has been dominated by the U.S.S.R. and Czechoslovakia. With 11 countries competing, the U.S. team won for the first time in 1970.

Homebuilts. A strong motivation to fly in a machine of his own creation has kept many pilot-craftsmen busy gluing, rivetting, welding, bolting, and painting in home workshops throughout the world. The greatest amateur activity is in the United States, where there were about 3,000 "homebuilt" craft registered in 1970.

History. As early as 1912 plans were available to the home craftsman for simple gliders and primitive power planes. Some of these early products were so crudely designed and built, however, that flight in them was akin to suicide. Starting about 1927 government regulations imposed new high standards on all aircraft construction. These new rules provided no category for recreational flight in homebuilt planes except for racers able to meet new quality, testing, and licensing requirements. "Homebuilders" were discouraged, and there was little activity in home shops until 1947, when homebuilt racing was revived. In 1947 amateur pilot George Beaugardas flew a small, homebuilt plane from Portland, Oregon, to Washington, D.C., to demonstrate the dependability of amateur-built aircraft and to petition the government for more liberal regulations. Officials were impressed and a new amateur-built aircraft category was established.

Kinds of planes. Most homebuilts are one- or two-place designs intended strictly for recreational use in good weather. They are usually built on a small budget and four passenger or larger sizes are uncommon. Most of the planes are made from published plans of a proven design. They are easily constructed and may have folding wings for easy storage and transport. Some homebuilders are inspired by notable planes of antiquity, such as the SPAD, S.E.5, Fokker Triplane, and Sopwith (all World War I fighters), and many full-scale replicas have been made from original plans. Even more common are three-quarter scale replicas, which are more practical to build and operate yet still offer great nostalgic rewards.

Antiques. Aircraft technology has progressed so rapidly that a 30-year-old plane is regarded as an antique. Many aviation enthusiasts are fascinated by the planes of yesteryear, and a surprising number of relics have been restored and maintained in flying condition.

Kinds of planes. Antiques are classified into three principle categories. The first covers planes of World War I and older vintage. They have special mechanical and operational problems and are flown mainly for exhibition purposes.

The most popular class covers planes of the 1928 to 1941 era. Most of these are small biplanes, two-seat Aeroncas, Cubs, and a few four-place Stinsons. These planes have an operating cost within reach of the recreational pilot.

The third class of antique is composed of the larger biplanes and cabin monoplanes, which were the commercial airliners and mailplanes of the 1930s. They are not practical for sport flying, but many still function as workhorses. Many Travel Airs, Steermans, Howards, and even a few Ford Trimotors still earn their keep as crop dusters, cargo planes, and jump planes for sport parachutists.

Modified antiques

Many antiques are not pure but have been modified to make them more practical to fly. A more modern and dependable engine is one common modification. Tail skids were the rule on early sod flying fields, but hydraulic brakes and a steerable tailwheel increase the safety of ground operations on modern hard-surfaced airports. These changes do not disqualify the plane as an antique. If the plane is of totally new construction, however, either full-sized or in scaled-down proportions, it becomes a homebuilt replica and not an antique.

Organization. Antique aircraft organizations include informal clubs made up of owners of a particular kind of airplane as well as national groups.

Rotorcraft. By virtue of their slow-speed manoeuvrability the rotary winged aircraft hold great fascination for many sport flying enthusiasts. Helicopters are beyond the economic reach of most recreational pilots, but the autogyro provides almost as much manoeuvrability with only a small fraction of the expense and complexity of the helicopter. Autogyros were developed and used commercially in the 1920s and 1930s, but then were abandoned in favour of the more versatile helicopter. In about 1956 Igor Bensen introduced one-man rotorcraft and his company has marketed plans and kits under the trade name Bensen Gyrocopter. Autogyros licensed in the amateur-built category acquired a large following in the 1960s.

Design. Instead of wings to provide lift the gyrocraft uses a pair of rotor blades about ten feet (three metres) long that rotate about a centre pivot. Suspended from the pivot bolt is a simple tubular framework with three wheels and a seat for the pilot. The rotor gets its rotational power from airflow and not from engine drive. This eliminates the need for a complicated transmission, blade controls, and a tail rotor, which are required on a helicopter. The craft cannot take off vertically or hover as a helicopter does, but it is extremely manoeuvrable

and can fly as slow as 15 miles per hour (24 kilometres per hour). It can be flown without an engine like a kite in the wind or by towing behind a car. In this configuration it is called a gyroglider. The same framework can be used for a self-powered gyrocopter by installing an engine to drive a pusher propeller. The versatile gyrocraft framework can also be attached to plywood floats for operations on the water. The unpowered version is called a hydroglider and must be towed by a power boat. A more powerful engine and longer rotor blades are recommended for the hydrocopter to offset the added weight of the floats. By following the steps shown in available training manuals a pilot can teach himself to fly and obtain a private pilot license.

Organization. Canada, the United States, Great Britain, France, Germany, Czechoslovakia, New Zealand, and Australia all have gyrocraft activity. The Popular Rotorcraft Association was founded in 1962 to help unify the efforts of rotorcraft enthusiasts. Its membership had topped 12,000 by the 1970s with about 40 U.S. and four foreign chapters.

SOARING

Soaring, or flying, in a motorless sailplane, or glider, is a favourite sporting pastime for many who desire the feeling of being airborne without the distractions of engine noise and vibration.

A sailplane, or glider, pilot usually begins his flight with a tow to 2,000 feet (600 metres) from a small power plane. After releasing from the towline the pilot seeks to fly within areas of "lift" or upcurrents of air to gain altitude. If his judgment is good and the proper weather prevails, he may be lofted to 10,000 feet (3,000 metres) or above.

Altitude is wealth to a sailplane pilot, for each foot of height will yield 30 or 40 feet of horizontal travel. Altitude can be spent exploring through miles of sky searching for more updrafts, or it can be spent performing aerobatic stunts, such as loops, rolls, and wingovers.

Sailplanes, or gliders, are popular in almost all countries of the world with most activity occuring in North America, Great Britain, Germany, Poland, France, Australia, New Zealand, and the Soviet Union.

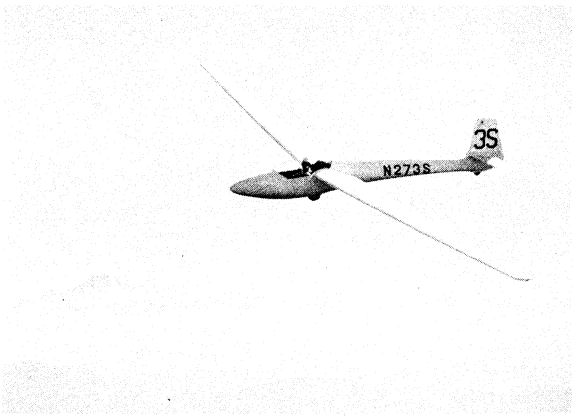
History. Gliding is really the most basic mode of flight and predates power-plane flight by almost half a century. In 1855 a Frenchman, Capt. Jean-Marie Le Bris, actually got off the ground in a glider towed by a horse. Between 1891 and 1896 German aeronautical pioneer Otto Lilienthal made thousands of flights in a primitive glider—running downhill until airborne, with handholds for support, he could maintain the craft in balance by shifting his weight.

Weight shifting was not satisfactory for American inventors Orville and Wilbur Wright, who worked intently around 1900 to develop a more sophisticated method of achieving control and stability. They achieved a 9 minute 45 second glider flight at Kitty Hawk, North Carolina, in 1911, a world record that stood for ten years.

Following World War I the Germans were denied the use of power planes by the terms of the Treaty of Versailles. Their enthusiasm for flight was directed toward gliders, and in 1920 the first of a series of yearly glider meets was held at the Wasserkuppe, a hill in the Rhön Mountains. Wolfgang Klemperer dominated the 1920 and 1921 events. In 1921 Klemperer flew his "Blaue Maus" for 13 minutes utilizing thermal upcurrents and achieved an altitude of 400 feet (120 metres) above his launch point.

Slope soaring in Germany

At the 1922 Wasserkuppe meet a glider called the "Vampyr" was flown with many of the design features of modern sailplanes. It was a high-wing monoplane with unusually long and slender wings and an almost fully enclosed cockpit. It had a sinking speed of only 2.6 feet (0.8 metres) per second. The plane was designed and built by the Technical University at Hannover, Germany. Using techniques of slope soaring (soaring from hills) developed by A.H.G. Fokker, the "Vampyr" was kept aloft for two hours.



On a wave of enthusiasm generated by this flight the London *Daily Mail* sponsored the first international glider meet in 1922. It was won by a Frenchman, M. Maneyrol, who made a world record 3 hour 21 minute flight.

There was little organization to gliding activity before the early 1930s, and a majority of soaring records were held by Germany and Austria with only limited competition from other countries. Next, Great Britain, the U.S.S.R., the United States, France, and Poland all took an active interest in soaring, and records moved back and forth between countries with great rapidity. During this period national soaring federations were formed, bringing supervision and regulation to a sport whose reputation had been tarnished by a number of fatalities involving enthusiastic novices. In 1934 Richard du Pont briefly regained the world distance record for the United States, flying 158 miles (254 kilometres). By 1937 soaring had become sufficiently international that the first world championship contest was held in Germany on the Wasserkuppe.

Following World War II the Germans were again restricted for a time from operating power planes and again turned to the betterment of sailplane design. Richard Eppler and F.X. Wortmann both achieved recognition for their success in aerodynamic design improvements. Most of the principle glider factories use wing designs originated by either Eppler or Wortmann.

Organization. Current organizations include national groups such as the Soaring Society of America (SSA), formed in 1932, which with 10,500 members is the principle U.S. soaring pilots' organization and is designated by the Fédération Aéronautique Internationale (FAI), the world governing body, to conduct contests, maintain records, and award badges for soaring proficiency. The major soaring organization in Great Britain is the British Gliding Association. The club originated in 1930 and publishes one of the world's best soaring magazines, *Sailplane and Gliding*. The 1-26 Association is a group of owners of Schweizer 1-26 sailplanes, a popular make and model. 1-26 contests compare to class racing in sailboats, where the competitors are equally matched in equipment. There are more than 500 sailplane clubs in Germany alone.

High-performance glass fibre sailplane over Mt. Ralnier in Washington.

Glide ratio

Performance. A sailplane's performance or efficiency is measured by its maximum glide ratio (the ratio of distance travelled horizontally to distance dropped vertically) and minimum sink speed (rate at which a glider loses altitude). A medium performance sailplane has a glide ratio of 25:1 and minimum sink of 2.5 feet (0.8 metres) per second. High performance designs will glide at 40:1 or above and sink at about 1.8 feet (0.5 metres) per second. One of the most sophisticated modern designs, made in Germany especially for competition, boasts a specially built wing with a 72-foot (22-metre) span and a glide ratio of 5:1 at a gliding speed of 56 miles per hour (90 kilometres per hour).

Probably the most important single factor in determin-

ing sailplane efficiency is the aspect ratio of the wing, expressed as a number which is the wingspan divided by the average wing width. In the 1920s, it was realized that a long, narrow wing offers less resistance to the air than a short, wide wing of the same area. Early gliders had an aspect ratio of eight or ten. As construction problems were solved and stronger materials utilized, such as aluminum and fibre glass, designers were able to increase aspect ratio to 30 and above. A recent construction development utilizes hard and stiff carbon filaments laminated into fibre-glass wing spars.

Competition. Soaring is a competitive sport. Through application to his national organization, a pilot may be awarded silver, gold, or diamond achievement badges which are issued by the Fédération Aéronautique Internationale and recognized the world over. To qualify for the badges a pilot must make soaring flights that meet certain minimum standards of endurance, distance, and altitude gained. For a silver badge he must remain aloft for five hours, fly a distance of 31.1 miles (50 kilometres), and gain 3,281 feet (1,000 metres) above the release altitude. These "tasks" or "legs" are usually accomplished on separate flights. A gold badge requires a 186.4-mile (300-kilometre) cross-country leg and a 9,842-foot (3,000-metre) altitude gain. A diamond badge requires a 310.7-mile (500-kilometre) cross-country flight and a 16,404-foot (5,000-metre) gain of altitude, plus a flight of 186.4 miles (300 kilometres) to a predeclared goal.

In addition to this personal level of competition, pilots match skills at national and international contests sponsored in nearly every country that has soaring activity. There are two categories of competition: open class, in which planes have no wingspan restrictions, are allowed water ballast, variable geometry wings, and drag chutes; and standard class, in which planes must have a wingspan of 15 metres (49 feet) or less, speed-limiting dive brakes, and a fixed-geometry airfoil. Both classes allow retractable landing gear. Winners in national events are participants in a world meet, held every two years.

Flying the sailplane. *Controls.* The primary controls on a sailplane are the same as those on a power plane. A control stick between the pilot's legs operates the ailerons and elevators (the movable horizontal control surfaces at the trailing edge of the wing and tail). Two pedals on the floor control the rudder, and a spoiler handle actuates movable panels in the wings that are useful during landing approach to increase the glider's descent rate. Instrumentation is simple—normally an altimeter, an airspeed indicator, a compass, and a variometer (an instrument sensitive to air pressure, which tells the pilot of slight altitude changes). A two-way radio and an oxygen system are often carried on cross-country or high-altitude flights.

Although sailplanes are incomparably graceful when airborne, they are cumbersome to handle on the ground. Two or more people are needed for ground manoeuvring. The long wings make them difficult to hangar, so most sailplanes are kept on a trailer with wings removed. The trailer is an important accessory, as it is also used for retrieving the plane from its landing point.

Launching. Sailplanes most commonly begin their flights by being towed to an altitude of 2,000 to 3,000 feet (600 to 900 metres) by a small power plane. A 200-foot (60-metre) length of line is attached to a towhook at the tail of the power plane and to another towhook on the nose of the sailplane. The power plane takes off and climbs with the sailplane pilot working constantly to maintain a precise position behind the towplane. The towhook can be released by either pilot if trouble develops. The aerotow has proven to be the safest method of launching.

The ground-launch method of towing a sailplane aloft with an auto or winch is still used at some glider fields where a long runway is available.

Sustaining flight. After releasing from the towline the pilot of a sailplane is able to bank and turn, exploring the air for favourable air currents. By reference to the variometer the pilot can tell if "lift" is encountered. More experienced pilots learn to judge where upcurrents are most likely to occur, as over the upwind side of a hill, some distance downwind from a hill or ridge, over sun-warmed buildings or fields, along a cold front, or beneath or within cumulus clouds. A sailplane can gain altitude by flying a pattern within these rising currents of air. By the 1970s, world soaring records were over 46,000 feet (14,000 metres) in altitude, 700 miles (1,100 kilometres) in distance, and 95 miles per hour (150 kilometres per hour) in speed over a 100-kilometre (60-mile) course. Sailplanes can make only one landing approach after each flight so they are equipped with efficient air brakes, called spoilers, a wheel brake, and sometimes a drag chute.

Motor gliders. In an effort to gain independence for the soaring pilot, experiments have been made with small auxiliary engines mounted in the sailplane. Without aid of support crew these planes can taxi about on the ground, take off, and climb to altitude. The motor may then be shut down and the pilot can proceed with the pleasures of soaring. By restarting the engine in flight the pilot can regain altitude or fly across country when necessary.

Powered sailplanes are commonly called motor gliders, and factories in Germany, Great Britain, and France have produced several models. Interest in motor gliding is expanding rapidly. The Powered Sailplane Association was founded in the United States in 1970 and publishes the magazine *Motorgliding*. The first German national motor glider contest was held in 1970.

SPORT PARACHUTING

Sport parachuting, or skydiving, is the fastest growing aerial sport. In the 1960s parachuting expanded from an infant group of less than 1,000 participants to an organized body of over 250,000 men and women in 28 countries, including the United States, Canada, Great Britain, France, East and West Germany, Poland, Yugoslavia, Czechoslovakia, the U.S.S.R., Australia, and New Zealand.

History. The parachute was developed before 1900, but for the first 50 years it was used mainly by military and civilian pilots as an emergency method of escape if their aircraft became disabled in flight. It was also used by a few individuals who made a profession of jumping at air shows.

In France in the early 1950s a small group of hardy individuals were making jumps for the fun of it. They discovered that by packing the parachute into a cloth sleeve, the opening shock at high speed was reduced from an abrupt snap to a more comfortable tug. They were also responsible for developing the fundamentals of a stable body position for free fall (before the parachute opens) and the steerable parachute. The French techniques and enthusiasm for sport parachuting spread during the 1950s, and by 1960 there were parachute clubs at small airports in many areas of the world.

The sport. The basic techniques of the sport are virtually the same everywhere. Equipped with two chutes each, main and reserve, a group of three or more jumpers rides aloft over a target area called a drop zone. As the plane climbs, the jumpers note the landing point of a bright yellow sheet of weighted crepe paper, which they dropped over the drop zone. This tells them the average wind speed and direction. At a chosen altitude from 2,000 to 12,000 feet (600 to 3,600 metres) above the ground the pilot makes an upwind pass across the drop zone. One of the jumpers scrutinizes the ground below from the doorway of the plane and signals heading corrections to the pilot. At the chosen exit point, either singly or as a group, the jumpers launch themselves from the plane into the air.

During free fall the jumper savours the unique sensation of falling at a constant speed of 120 miles per hour (190 kilometres per hour), supported by resistance of the air. Free fall may last from a few seconds to a full minute or more, depending upon the exit altitude. Chutes are always opened at 2,000 feet (600 metres) to allow ample time for opening the reserve chute, if necessary.

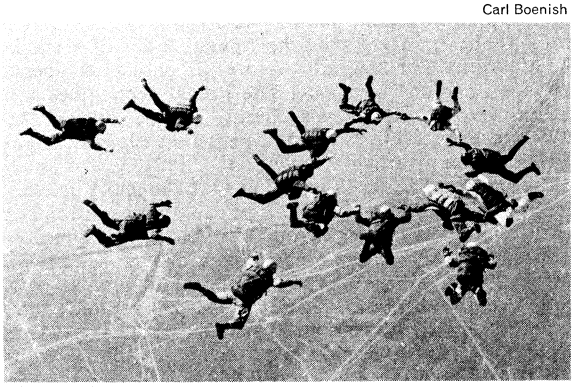
The opening is an abrupt, but not uncomfortable, cli-

max to the free fall. The next two minutes are spent gliding and guiding the canopy with steering toggles toward the chosen landing point. The landing may be a gentle standing touchdown under ideal wind conditions, or the brisk, tumbling roll common on target accuracy jumps.

There are three principal reasons for the rapid growth of parachuting as a sport. The intense thrill of the jump may be one; another relates to the social enjoyments of close companionship during training, packing, riding in the plane, and returning from the drop zone. Mass hookups can make a social experience out of the free fall itself. The third reason is that parachuting is relatively inexpensive. Older model aircraft and reworked surplus chutes may be used, and costs shared among members of the participating group or club. Initial expenses for training vary with location.

Training. Length of training varies from a commercial four-hour jump course to the full day of preparation before a beginner's first jump allowed by most clubs.

During the training period a student jumper learns how to leave the airplane in a poised and stable position, how to use a reserve chute, how to steer the parachute, and how to fall and roll when landing. At least five jumps are usually required before a student is allowed to pull his own rip cord.



Static line jumping

The static line is a length of webbing used in lieu of a rip cord. One end of this is fastened inside the airplane to a special hook. The jump instructor also grips the static line in his hand. At the other end it is attached to the student's main parachute in such a way as to cause the container of the main parachute to open immediately when the static line is pulled taut and allow the canopy to begin deployment.

Curiously, it appears to take more courage to make the next few subsequent jumps than it does the first. Only about one-third of the first jump students return for further training jumps, and most of these succumb to anxieties and quit somewhere between the third and tenth jumps. If a student can persevere through ten jumps, prejump anxiety begins to subside and enjoyment increases. A jumper needs to experience about 100 jumps before he is proficient.

Advanced jumpers who have mastered the exacting art of free-fall manoeuvring can perform relative work, establishing contact with others. "Stars" or "snowflakes" are formed when eight or more jumpers link together in free fall to form a circle. Hookups of as many as 20 jumpers have been formed.

Carl Boenish

Nine-man free-fall hookup at approximately 4,500 feet above Elsinore, California.

Equipment. There are three principle types of main parachutes in use. The most economical chute is the military surplus chute that has been modified for sport use and is often used for student training jumps. The larger sizes are used for women, men over 35 years of age, or anyone over 180 pounds (80 kilograms). Surplus chutes are reliable and are sufficiently manoeuvrable to learn the fundamentals of descent and steerage. A second type is the commercial parachute, designed especially for sport use and used by both competition and recreational jumpers because of its good forward glide speed (about 12 miles per hour) and quick turning response (360° in about four seconds). A third type originated in 1970, when a way was discovered to inflate a fabric airfoil section with air ramming into openings in the leading edge, producing a parachute with a 3 to 1 glide ratio and a forward speed approaching 30 miles per hour (48 kilometres per hour).

Besides a main parachute the sport chutist wears a reserve chute, to be used in the extremely rare instance that the main chute might malfunction. Special high-topped boots with air cushion soles, goggles, helmet, and coveralls complete the parachutist's equipment. Some jumpers may also wear an altimeter and a stopwatch.

Competition. Parachuting competitions are usually of two kinds: accuracy and style. Accuracy contests usually allow three to six jumps per contestant and require the jumper to guide his canopy so that he can touch his foot upon a six-inch (15-centimetre) target disk. Judging is by measurement of distance from disk centre to the nearest landing point. The final score is simply the accumulated distance in centimetres for all of the contestant's jumps in the meet, and the winner is the one with the lowest score. Good competitors often make several consecutive landings directly upon the target disk.

Judging jumpers for style and speed

In style contests jumpers are judged by the speed with which they can complete a series of free-fall manoeuvres. Commonly two loops in the vertical plane and four 360° turns in the horizontal plane constitute a series, and ten seconds or less to complete this series is considered a competitive score.

Other events, such as team free-fall hookup events, may be arranged at the discretion of the contest directors.

Local clubs usually host meets. In the United States regional meets are sanctioned by the United States Parachute Association to choose the 120 best jumpers to compete nationally. The top ten men and top five women at the national meet make up a national team that participates in international contests.

Sport parachuting came into its own at the first world championship meet, held in Yugoslavia in 1951 under the sponsorship of the Fédération Aéronautique Internationale with five nations participating. World championship meets have been held every two years since 1954, with Czechoslovakia and the U.S.S.R. usually producing the strongest teams, although the United States and France have also performed well. (For lists of world champions and records see RELATED ENTRIES under SPORTING RECORD in the *Ready Reference and Index*.)

SPORT BALLOONING

History. Balloons were the first aerial conveyance by which man succeeded in sustaining himself aloft. Two brothers, Étienne and Joseph Montgolfier, made the initial successful balloon experiments at their paper factory at Annonay, France, about 1782. They proved that a balloon 40 feet (12 metres) in diameter could lift a man if the air inside it was warmed.

Hydrogen soon was discovered to be a good lifting gas if contained by a rubberized cloth balloon. Flights of many hours' duration were possible in gas balloons, but many accidents occurred due to the highly flammable properties of hydrogen. Helium is a safer gas now used for this type of balloon.

Gas ballooning for sport never really became popular because of the high cost of the gas and because of the tremendous output of labour necessary to make an inflation. A crew of perhaps 12 persons would be occupied for several hours tending the envelope and adjusting sandbags for a single inflation. Although there are still a few annual events for gas balloons each year in Europe and the United States, hot-air ballooning has become more popular for sporting purposes.

Hot-air ballooning. In the late 1950s a new type of sport hot-air balloon was marketed in which heat was provided by a propane burner. It proved to be efficient and economical and finally gave the sport balloonist an answer to his need for an economical lifting force, as the amount of propane needed to make a flight is quite inexpensive. In this type, fuel tanks are attached to the

gondola and a burner is mounted above the pilot on a platform. Vertical control of the balloon's flight path is achieved by valves that regulate the amount of propane flowing to the burner. Inflation can be accomplished by a crew of four in just a few minutes.

There are two basic designs. The ripping balloon has an opening at the top that can be pulled open to accomplish deflation. The dumping balloon has no opening at the top and is deflated by inverting the balloon with a line attached to the top after releasing it from the gondola attachment.

Balloons are classified by the Fédération Aéronautique Internationale according to volume with an AX number from 1 to 10. The popular single-place 30,000-cubic-foot (850-cubic-metre) model is an AX-4. The next most popular size of 56,000 cubic feet (1,600 cubic metres) will carry three people and is designated AX-6.

Competition. Most competition is on the local level, and there are many ways for pilot skills to be matched. In a hare-and-hounds race a single balloon, the hare, takes off and flies for a certain period of time. After a short delay the competitors take off, and the winner is the balloonist who navigates skillfully and lands his craft closest to the hare. A similar contest is the spot landing event, in which a predetermined target is chosen downwind, and the competitors attempt to land as close to it as possible. The cross-country distance event is won by the balloonist who travels the farthest in a certain period of time. In this event the balloonist attempts to choose a flight level with the strongest wind flow. The Fédération Aéronautique Internationale maintains world duration, distance, and altitude records in each balloon class for races held under sanctioned conditions. (For world ballooning records see RELATED ENTRIES under SPORTING RECORD in the *Ready Reference and Index*.)

Aeronautical Engineering

Aeronautical engineering traditionally applies the principles of the physical and mathematical sciences to the development, design, construction, testing, and operation of flight vehicles that operate in the Earth's atmosphere. During the decade of the 1960s aeronautical engineering was broadened to include all vehicles that operate above the surface of the Earth, in space as well as in the atmosphere. The terms aerospace engineering or aeronautical and astronautical engineering are sometimes employed in place of aeronautical engineering to describe the broadened engineering process.

The principal technologies encompassed by aeronautical engineering are those of aerodynamics, propulsion, structures and stability, and control. The aeronautical engineering process begins in academic, industrial, and government laboratories with the evolution of new concepts and devices. Industrial designers, using the latest technological developments, continue the process by laying down an initial vehicle design that is calculated to satisfy the project's requirements. The definition of an initial design is followed by a long process, lasting months and sometimes years, in which the detail design and development of the many vehicle components are carried out by aeronautical engineers. The design process precedes a period of construction and testing of one or more prototype vehicles. Satisfactory completion of flight testing of prototypes is followed by quantity production and operation. Aeronautical engineers participate in all steps of the total process.

Initial vehicle design

Historical survey. Following the first heavier-than-air flight by the Americans Orville and Wilbur Wright on December 17, 1903, the design of aircraft was based on empirical knowledge and crude construction techniques. The resources of science were not brought to bear on aircraft design and development for another decade, when it became apparent that the airplane was a potentially useful military weapon. It was recognized by engineers before World War I that the effective development of the airplane as a military weapon depended upon application of the physical and mathematical sciences to the numerous technical problems involved in such research. Perhaps the first organized attempt to apply science was the establishment in 1909 of an Advisory Committee for Aeronautics at the National Physical Laboratory in Great Britain. In 1915 the United States government followed with the establishment of a similar laboratory organization under the direction of the National Advisory Committee for Aeronautics. During this period, under the stimulus of World War I and with the rapid application of scientific principles, the airplane progressed in a few years from a relatively unimportant machine shown at aerial exhibitions to an effective military vehicle.

Development during the World Wars. World War I brought demands for increased payloads, greater speeds, and higher altitudes. It was recognized that increased engine power was needed to satisfy these demands. One of the most significant power-plant developments during this period was that of the American Liberty, a 400-horsepower engine with a V-12 arrangement. After the United States automobile industry was enlisted to produce Liberty engines, they were turned out in greater quantity than the aircraft designed to use them. As a result, surplus Liberty engines were used well into the 1930s in a variety of civilian and military aircraft.

As early as 1915, the basic elements of modern aircraft construction, the full cantilevered wing with metal monocoque (in which the metal skin carries the stresses of the fuselage), had been incorporated in the German Junkers J.1 monoplane and tested in flight. Another 20 years passed, however, before these elements were universally employed. The welded steel fuselage and wood spar wing, both fabric-covered, with biplane or externally braced monoplane configurations, dominated the 1920s and 1930s. By the late 1930s, hastened by preparation for World War II, the all-metal, stressed-skin monoplane construction was universally adopted.

The development of aeronautical engineering was again accelerated by World War II. The internal combustion engine, although used predominantly during World War II, began to give way to the turbojet before the war ended. The first flight with a turbojet engine took place when a German Heinkel He 178 fighter flew on August 27, 1939. Wartime research and development on jet propulsion in Britain and Germany progressed vigorously. By the summer of 1944 the Royal Air Force had the jet-powered Gloster Meteor in service, and shortly thereafter the German Luftwaffe introduced the Me 262 jet fighter into wartime combat. Although the turbojet engine was quickly adopted by aeronautical engineers for military aircraft, commercial applications developed slowly because of its high fuel consumption. The turboprop engine, in which a propeller is driven by a gas turbine, was used on commercial aircraft for about a decade until the specific fuel consumption of the turbojet engine was reduced to economical levels by research and development.

Turbojet engine introduced

Postwar advances. The availability of rocket and turbojet engines in the post-World War II period permitted new aircraft to be driven at ever increasing speeds. The first supersonic flight in manned aircraft in level or

climbing flight was made by Capt. Charles E. Yeager of the U.S. Air Force at Muroc, California, in a rocket-powered research airplane, the Bell X-1. As aircraft speeds approached and exceeded the speed of sound in air, pronounced changes in external air-flow patterns resulted. Much of the work of aeronautical engineers in the post-World War II period has been directed toward mastery of the aerodynamic, stability, and control problems that result from flight near and above the speed of sound.

The post-World War II period was one of rapid change in aeronautical engineering, as new knowledge in the fields of aerodynamics, structures, propulsion, stability, and control developed at increasing rates. Its application improved the performance of aircraft still further and raised new problems: low-speed aerodynamics gave way to transonic, supersonic, and hypersonic aerodynamics; frame structures were replaced by thin metallic shells that required the development of new aluminum, magnesium, titanium, and steel alloys; internal combustion engines were replaced by rocket and turbojet engines; and manual control developed into automatic control. The result was a new era of aeronautical engineering in which scientific methods were logically applied by teams of engineers in order to develop new high-performance airplanes with a high level of predictability of the final result.

Development of aeronautical engineering as a profession. Aeronautical engineering as a profession evolved along with infusion of the physical and mathematical sciences into the design and construction of aircraft. Aeronautical-engineering professional societies emerged in most advanced industrial countries of the world as the airplane achieved greater importance. The Royal Aeronautical Society in England, founded in 1866, became the principal society for aeronautical engineers in that country. The Institute of Aeronautical Sciences was formed in the United States in 1933. As interest in space exploration grew in the early 1960s, the American Institute of Aeronautics and Astronautics was formed, absorbing the Institute of Aeronautical Sciences. This organization grew to more than 36,000 members during the decade of the 1960s.

Fundamental principles. The practice of aeronautical engineering rests upon principles that are fundamental to all flight vehicles: a propulsion system with high thermodynamic and propulsive efficiencies; a structure of minimum weight and maximum strength; an external shape that is stable in flight with maximum aerodynamic efficiency; a precision control and guidance system; and a suitable design compromise among all these elements that allows the vehicle to achieve the required performance. An understanding of these principles depends upon knowledge of the engineering sciences: material science, solid and structural mechanics, thermodynamics, fluid mechanics, and electrical science. In turn, the engineering sciences rest upon the basic sciences: physics, chemistry, and mathematics.

Sciences required in aeronautical engineering

Bréguet's equation, defining the range of flight, may be used as an illustration of how the performance of an airplane depends on the fundamental principles discussed above. Louis Bréguet, a French aviation pioneer, showed that the range of an airplane, or the maximum distance it can travel, depends on two main factors—flight efficiency and the ratio of fuel weight to the gross airplane weight at the end of cruising flight. Range is equal to the flight efficiency multiplied by the logarithm of 1 plus the ratio of the weight of fuel at the beginning of the flight to gross airplane weight at the end of the flight: $R = (\text{flight efficiency}) \times \log (1 + W_F/W_L)$. Bréguet conceived the flight efficiency as a composite measure of the aerodynamic and propulsive efficiencies of the plane, obtained by dividing the product of the speed (Mach number) and lift-to-drag ratio by the engine's specific fuel consumption:

$$\text{flight efficiency} = \frac{\text{ML/D}}{\text{SFC}},$$

in which

$M = V/c$ = Mach number of cruising flight;
L/D = lift-to-drag ratio of the airplane in cruising flight;
SFC = specific fuel consumption of engines in cruising flight;
W_F = weight of fuel on board at start of cruising flight;
W_L = weight of airplane at end of cruising flight;
V = speed of cruising flight;
c = speed of sound at altitude of cruising flight.

It is apparent from Bréguet's equation that, if everything else remains the same, flight efficiency increases with increasing Mach number, M. This is one of the reasons why very high-speed flight is attractive to engineers. The second component of flight efficiency is the lift-to-drag ratio, L/D, of the airplane. The lift-to-drag ratio is a measure of the airplane's aerodynamic efficiency. The lift is an upward aerodynamic force on the airplane that is perpendicular to the path of flight. The drag is the total resistance the airplane encounters in driving through the air. It is a rearward acting force parallel to the flight path. When the airplane is in steady level flight, the lift force is equal and opposite in direction to the downward-acting airplane weight, while the drag force is balanced by the forward-acting engine thrust. Much of the work of aeronautical engineers applies the principles of aerodynamics to the calculation of lift and drag. The wind tunnel, one of the principal experimental tools used by aeronautical engineers, is used to measure airplane lift and drag by placing models in a moving airstream. Well-established similarity rules are used to scale up the measurements made on models to those of full-scale aircraft.

Lift and drag

The third factor in Bréguet's definition of flight efficiency is that of engine specific fuel consumption, SFC. The engineer attempts to reduce the specific fuel consumption to its lowest possible level by improving the overall thermodynamic efficiency of the engine and by improving the propulsive efficiency of the driving or thrusting system.

As the Bréguet equation suggests, flight efficiency is not the whole story in the achievement of range. In order to extend range, a designer must also strive for a high ratio of fuel load at the beginning of the flight to gross weight of airplane at the end, W_F/W_L. This is tantamount to saying that for a given fuel load and payload, he must reduce the empty weight of the airplane as much as possible. This has been the perennial problem of aeronautical engineering from the earliest days of aviation.

Educational programs. A beginning in aeronautical engineering education was made by the College of Engineering of the University of Michigan, where regular courses were introduced in February 1915. Courses in aeronautical engineering were introduced shortly thereafter at the Massachusetts Institute of Technology. In the late 1920s, especially after the stimulus of Charles Lindbergh's solo flight from New York to Paris in 1927, aeronautical engineering curricula were developed in scores of universities throughout the world.

Instruction in aeronautical engineering in the 1920s and 1930s was often based on a curriculum in mechanical engineering with elective courses in applied aerodynamics and airplane design. These courses usually included wing theory, wind-tunnel testing, static stability and control, dynamic stability, performance calculations, and general airplane design considerations. Applied aerodynamics and airplane design characterized aeronautical-engineering education in the 1920s. Airplane structures of this period were similar to bridge and building structures, and airplane structural analysis and design were largely in the hands of engineers educated in university departments of civil engineering. The emergence of stressed-skin monocoque shells in the 1930s, however, caused a departure from traditional civil-engineering practice, and courses in airplane structures were added to aeronautical-engineering curricula.

As aeronautical engineering courses continued to develop through the 1930s and 1940s, separate departments

Development in the 1930s and 1940s

of aeronautical engineering were formed in most schools of engineering. A modern curriculum in aeronautical engineering begins with a firm grounding in the basic sciences, with an emphasis on mathematics, physics, and chemistry. The engineering sciences build on the basic sciences in the areas of material science, rigid-body and solid mechanics, thermodynamics, fluid mechanics, and electrical science. The aeronautical engineering student then studies theoretical and applied aerodynamics, structures, propulsion, stability and control, including automatic control, and design.

In the United States the standards for university engineering education are set by the Accreditation Board for Engineering and Technology (ABET; until 1980 known as the Engineers Council for Professional Development), which accredits engineering colleges to grant degrees in aeronautical engineering. By the early 1980s about 50 institutions in the United States were accredited to offer degrees in aeronautical or aerospace engineering. These did not include those institutions offering aeronautical-engineering options in their mechanical-engineering departments.

Although university graduates occupy the key technical positions in aeronautical engineering, there is a large demand for technicians. The aviation industry requires a wide range of scientific and technical education that ranges from that of the Ph.D. who is engaged in research to that of the technician, who supplies the industry with mechanical and electronic skills. Technician training is provided by technical institutes, junior and community colleges, and mechanics and flight schools. These institutions, which require relatively short periods of study—a year or two—do not provide the more intensive education in mathematics and the basic sciences that is ordinarily found at the university level. The object of such training is usually to prepare the graduate for immediately useful occupations.

Responsibilities of the aeronautical engineer. The largest employers of aeronautical engineers are the large private-aircraft, missile, and spacecraft industries and the supporting subcontractors associated with these industries. Aeronautical engineers employed in this complex of activities are engaged in a wide variety of duties ranging from research for new fundamental knowledge to hardware design and production. Most engineers engaged in industrial work hold B.S. degrees from four-year university programs in aeronautical engineering, although an increasing number of M.S. and Ph.D. holders are entering these activities.

In most countries throughout the world the national government is the second largest employer of aeronautical engineers, who work in most countries principally in research and development and in procurement. Aeronautical engineers are also employed by commercial airlines and universities. The airlines need engineering expertise in order to operate and maintain existing aircraft and to procure new equipment. University needs for aeronautical engineers are primarily for the faculty and research laboratory staffs.

Role of research and development

Research and development is a major part of the aeronautical engineering process. Because of the complex nature of modern high-performance aircraft, the production of new aircraft models is usually preceded by a lengthy research and development process that culminates in flight tests on one or more prototype vehicles. Research and development work is performed in industrial, government, and university laboratories. In general, university laboratories engage in research leading to further understanding of fundamental aeronautical phenomena. Examples of such research include studies of shock wave boundary layer interaction, studies of the behaviour of materials, development of improved methods of computing flutter speeds in supersonic flight, studies of the complex three-dimensional flow in compressors and turbines used to power aircraft, and studies of stability and control in transonic flight. Research of this type is, for the most part, conducted by faculty members and graduate students, although a few universities employ full-time research staff members.

New aircraft are developed by industry with large design teams, which are usually divided into specialized groups. One of these groups devises a preliminary design, or initial conceptual design, of the new airplane. The other groups divide the remainder of the detail design effort among them. The aerodynamics group is responsible for conducting wind-tunnel tests, designing the overall aerodynamic shape, computing the performance, and taking part in any design activities that involve an understanding of the internal and external flows of air. The structures group designs a structure that conforms to the desired external shape, which must also be sufficiently strong and light to allow the airplane to achieve its desired performance. The power-plant group is responsible for selecting an engine that will give the airplane its desired performance and for designing the power-plant installation. Most aircraft design teams have a group that is responsible for ensuring that the airplane is stable and fully controllable over the speed range at which it is intended to operate. Modern high-performance aircraft usually require stability-augmentation systems in order to achieve stability about all three of the airplane axes throughout the full speed range. Stability-augmentation systems employ electromechanical devices that move the control surfaces automatically in response to motion sensors in such a way as to augment the stability of the basic airplane. Aeronautical engineers who design stability and control systems combine a knowledge of aerodynamics, airplane dynamics, electronics, and control theory. The flight testing of the prototype of a new airplane is conducted by a group consisting of aeronautical engineers and engineering test pilots. The flight testing is carried out carefully and scientifically, using a variety of sensors to measure the behaviour of the airplane and its systems under a wide range of operating conditions.

Future developments. The role of aeronautical engineers in meeting transportation needs is increasing. An example of new flight vehicles is the advanced short-haul transport, which incorporates advanced technology to achieve all-weather operations from landing strips that may sometimes be no longer than 1,500 feet (450 metres), while at the same time retaining high-cruise efficiencies. These aircraft may be used to provide service from large airports serving domestic and transoceanic jets to smaller, close-in airports in cities that are located from 100 to 1,000 miles (about 160 to 1,600 kilometres) apart. They could also be used for trips from outlying suburban areas to major centres. A second advance in air transportation is the supersonic transport, which began operation in the mid-1970s. A third major advance has come through increases in total performance of aircraft derived from existing long-range subsonic jets. Another advance in aviation that has emerged from new technology is the private, or personal, aircraft. Although the personal aircraft has not yet found widespread use, new developments in aeronautical engineering, and particularly in the field of stability and control, have led to their increased use, especially by corporations.

New flight vehicles

Hypersonic aircraft, powered by air-breathing hydrogen-fuelled engines, are another example of potentials and challenges for aeronautical engineering. Three may be mentioned: (1) Earth-to-Earth transport offering higher efficiencies and speeds than existing aircraft; (2) first-stage boosters offering flexibility in spacecraft launches; and (3) Earth-to-orbit space shuttles offering the final closure between atmospheric and orbital flight. Of these three, the space shuttle is the only vehicle to have been developed. The U.S. space shuttle made its first flight in April 1981.

Aerospace Industry

A combining and contraction of "aeronautics" and "space flight," "aerospace" covers all vehicular flight both inside and outside of the Earth's atmosphere. The aerospace industry is the complex of manufacturing concerns that are engaged in the production of flight vehicles, including unpowered gliders and sailplanes, lighter-than-air craft, ground-effect machines, heavier-than-air craft of both fixed-wing and rotary-wing varieties, military missiles, space-launch vehicles, and manned or unmanned spacecraft; propulsion systems and other thrusting devices; onboard equipment that is essential to the design purpose of the flight vehicle; and ground-based support equipment that is needed for the operation and maintenance of the flight vehicle. An additional area of the industry's effort, one that is expanding rapidly, is fabrication of nonaerospace products and systems that have been derived from aerospace technology.

The aerospace industry, which must devote a considerable portion of its effort to research and development in the broadening realm of flight, is a leader of world technological advance. Despite the lack of statistical detail from the Communist nations, it is clear that the aerospace industry is among the world's largest manufacturing industries in terms of employment and the monetary value of its product output.

Nations with extensive industrial development

The two largest aerospace industrial complexes are those of the United States and the Soviet Union, which, with France and the United Kingdom, have achieved a high degree of aerospace sophistication and have the ability to manufacture home-designed systems embracing the entire range of aerospace vehicles. Japan, whose aircraft industry was destroyed during World War II, did not resume production activity until 1952; it expanded rapidly thereafter, producing some home-designed products, but relying for the most part on U.S. licenses. Canada has a relatively small but advanced industry. West Germany has little aerospace production capacity but has developed a strong research and development base. China had been building aircraft of Soviet design since the early 1950s, and began producing home-designed aircraft in the 1970s; its demonstrated ability to launch space satellites was an indication of an advancing technology in other aerospace areas. Sweden's aerospace industry has been small, but the national policy of selective specialization has brought about a high degree of competence in a narrow focus of effort. There are about 40 nations that are engaged in some form of aerospace production activity, primarily the manufacture of light and medium aircraft of home design or production of heavier aircraft and high-thrust propulsion systems under license from major-nation companies.

For the major aerospace nations of the world, their own governments and, increasingly, other governments are the largest customers. Next in importance as buyers are the world's commercial airlines, a market dominated by the United States since World War II, although the French and British have a large share. In terms of units, the production of general-aviation aircraft, private, business, and nonairline commercial planes is high, but the average unit cost of these aircraft is very low by comparison with jetliners; as a result, the sale of general-aviation equipment represents a relatively small part of the overall volume. In the United States nonaerospace systems, primarily for state and municipal governments, utilities, surface-transportation companies, hospitals, and other segments of the medical community, represent a significant portion of total sales. Although the ratios vary among the major nations, the distribution of shares of the market for 1970 sales volume of the United States aerospace industry could serve as a general indicator of customer breakdown: government (defense), 59 percent; government (space), 11.7 percent; commercial (airlines), 17.1 percent; commercial (general aviation), 1.4 percent; nonaerospace, 10.8 percent.

This article is divided into the following sections:

I. Development of the aerospace industry
II. Aerospace product line
  Major product: flight vehicles
    Aircraft
    Guided missiles
    Spacecraft
    Propulsion systems
  Other products
    Secondary aerospace products
    Tertiary aerospace products
    Nonaerospace products
III. Research and development
  New commercial aircraft
    Computer design
    Wind-tunnel testing
    The prototype
    Flight testing
  Missiles and spacecraft
    General considerations
    Testing
  Other areas of research
  Cooperative programs
IV. Manufacturing facilities and techniques
  Basic fabrication techniques
    Metal processing
    Joining methods
    Use of electronic computers
  Product assurance
  Assembly methods and facilities
  Maintenance facilities
    Airframe and engine overhaul
    Remanufacture process

I. Development of the aerospace industry

The aerospace industry can trace its origin to December 17, 1903, the date on which Orville and Wilbur Wright made the first powered flights of a heavier-than-air machine. An industry, however, is by definition a business activity, and for several years after 1903 the Wrights were engaged in a purely experimental effort. A more accurate date for the industry's origin is therefore about 1908, when the Wright Company sold its patent rights for France to a syndicate called the Astra Company, the first recorded commercial transaction of the aerospace industry. In the same year, the Wrights contracted with the U.S. Army for the first military airplane, which was successfully concluded the following year after army acceptance tests.

The first aerospace transaction

In 1909 the list of the world's airplane producers was increased by Glenn Curtiss in the United States and by Henri Farman, Louis Blériot, Gabriel and Charles Voisin, and Léon Levavasseur in France. The Wrights licensed production of their airplane in England, and experimental groups that began regular production a year or two later were active in both Germany and Russia. The planes being built differed in design but were similar in construction: wing and fuselage frames were constructed of wood, usually spruce or fir, and covered by a coated fabric. This kind of airplane construction predominated until after World War I.

Over the next five years, France and Germany, both aware of the war potential of the flying machine, began aircraft construction on what was then a large scale. By the outbreak of war in August of 1914, France had built about 2,000 airplanes of all types, 1,500 of them military machines. Germany started the war with about 1,000 military machines. Great Britain was third in production, and the United States had completely abdicated its former role as the world's aeronautical leader; in the years prior to 1914 the United States built fewer than 100 airplanes, less than half of them military. The French industry, assisted by rapidly expanding facilities in Britain, carried the Allied aircraft-production load through most

of the war. When the United States joined the Allies, two types of British-designed bombers were assigned it for production, along with one American-designed plane (the Curtiss Jenny trainer). The U.S. did not develop enough production by the war's end to have much effect militarily, but the 400-horsepower Liberty engine, a very advanced power plant for its day, provided the foundation of an aero-engine industry.

Worldwide aircraft production went into a sharp decline after the war, until commercial air transportation, started in 1919, gained public acceptance. The airplane itself was considerably refined in terms of design and performance during the '20s, the most notable change being the gradual ascendancy of the monoplane over the biplane. From the standpoint of manufacturing, the largest change was a swing to metal construction, a wartime innovation introduced in Germany by Hugo Junkers, who also introduced the cantilever wing, which required no external struts or braces. The combination of cantilever wing and metal construction met with rapidly widening acceptance. Metal (steel and aluminum alloys) initially was used only in the airframe structure, but, in the latter years of the decade, it was extended to the wing and fuselage skins, and by 1930 the all-metal airplane was appearing with increasing frequency.

In the 1930s a tremendous acceleration of aeronautical research brought the airplane to design maturity. There were hundreds of innovations, among the more important being large increases in aircraft-engine power, new propeller efficiency, cabin pressurization, retractable landing gear, landing flaps, the autopilot, better instruments and controls, and new aids to navigation for all-weather flying. Performance increased; a major reason was the trend toward "cleaning up," or streamlining the airplane for reduced air resistance. Except for light private planes, all-metal construction became standard (see AIRCRAFT; AIRCRAFT, MILITARY).

Coming of the large transports

The most notable impact on manufacturing processes in the 1930s was aircraft size. The growing need for greater capacity in commercial transports, coupled with military requirements for longer range and heavier bomb loads, brought a generation of large-size aircraft. Britain and Germany led the way in the early 1930s with transports capable of carrying as many as 40 passengers; the U.S. took over in the latter half of the decade and introduced the first really modern, highly productive airliners, which were later to see almost universal service. The British, French, Germans, and Russians all produced four-engine bombers of varying efficiency, but again it remained for the U.S., in the latter '30s, to develop and begin production of the airplane that was to become the standard daylight strategic bomber of World War II.

In World War II the production situation of the earlier war was reversed; this time it was the United States that predominated among the Allies. From a 1939 base of fewer than 6,000 planes a year, the U.S. industry, once again bolstered by nonaviation firms, doubled production in 1940 and redoubled it in 1941 and 1942. In the six-year period 1940 through 1945, the U.S. turned out an incredible 300,718 military aircraft.

The transition to jets

The postwar years were marked by a rapid shift to jet propulsion as the power source for military aircraft. The first successful turbojet engine had been tested in Britain in 1937 and a rival engine first flown in Germany in 1939. Both nations introduced the jet in war service, though not in significant numbers, and wartime development paved the way for the great transition of the 1940s and 1950s. Jet power was applied first to military fighters, then to bombers, finally to commercial airliners. Military aircraft progressed from the subsonic (below the speed of sound), 600-mile-per-hour level of the late '40s to supersonic flight in the early '50s, to double sonic (twice the speed of sound; Mach 2) capability in the late '50s, then to Mach 3, which represented the upper speed limit of the fastest operational aircraft in the early 1970s. Each increment of performance gain brought an attendant increase in aircraft complexity, producing an across-the-board impact on the manufacturing process, from tools, materials, and facilities to composition of the labour force. At the same time, it started a trend in which research and development became a much more significant part of the total industry effort. The most notable effect, because greater performance permitted fewer airplanes for the assigned mission, was the transition from mass production of many types to short-run production of fewer but much more complex types. Never since the introduction of jets has aircraft production approached World War II levels. The best post-World War II year, in terms of combined military- and civil-aircraft production, was 1966; total output in that year came to barely 20 percent of the record wartime year.

While the jet transition was moving into high gear, the industry fell heir to a new responsibility, the development and production of guided missiles. It was a logical inheritance, because some of the missiles were aerodynamic, lift-supported like an airplane, and the others shared with the airplane at least a similar set of major components—an airframe, a propulsion system, a method of guidance and control, and a payload.

Wartime Germany had pioneered long-range missiles, introducing as operational weapons two types of surface-to-surface missiles and developing a wide range of other types. German experience provided a departure point from which the victorious nations advanced their own experimental programs in the latter 1940s. Initial missile production got under way in the early 1950s; first-generation missiles included artillery-like battlefield weapons, anti-aircraft weapons, pilotless tactical bombers, and air-launched weapons. In the United States and the Soviet Union the 1950s witnessed the state of production of long-range strategic missiles. Missile sophistication increased through successive generations of automated weapons in the 1960s, and production capability spread to other nations; by 1971 there were 14 missile-building nations, most of them confining their efforts to short-range battlefield- and air-defense systems (see also ROCKETS AND MISSILE SYSTEMS).

The impact of missilery on manufacturing processes was felt in two primary areas: completely new facilities were required, and the labour-force composition, already changing markedly as the result of the jet transition, was further altered as production of automated weaponry dictated greater emphasis on highly skilled workers—scientists, engineers, and technicians—and less on low-skill personnel.

Impact of Sputnik

Before missilery had reached full maturity, a third manufacturing responsibility was thrust upon the aircraft industry, when the Soviet Union sent the first man-made object into orbit, on October 4, 1957. Their success accelerated the American space effort. In 1959 the U.S. Aircraft Industries Association, Inc. changed its name to Aerospace Industries Association of America, Inc., which, the organization stated, "more properly reflected the changing nature of the effort." Initially confined to the United States and the Soviet Union, manufacture of space systems quickly became a significant portion of the total work load, particularly in the rapid evolution of ever more advanced manned spacecraft.

Space-equipment fabrication compounded all the previously established industrial change trends, particularly the trend toward heightened emphasis on research and development. Once simply a prelude to production of a flight vehicle, research and development soon became an integral part of the manufacturing process, extending to all of the major systems that comprise the flight vehicle, to the tools and methods of fabrication and assembly, and to the multitude of testing devices designed to insure an unprecedented level of equipment reliability (see also SPACE EXPLORATION).

II. Aerospace product line

MAJOR PRODUCT: FLIGHT VEHICLES

The product line of the aerospace industry is necessarily a broad one, because each of the primary products—that is, the flight vehicles—requires hundreds, thousands, or in a few cases millions of systems, subsystems, components, and individual parts.

Aircraft. Among the primary products, manufacture of aircraft has continued throughout the years as the major work load of the world's aerospace industry. A majority of those nations with such industries build only aircraft and aircraft engines. In the United Kingdom and France, missile–space efforts are relatively small in comparison to aircraft output. Even in the United States and the Soviet Union, both heavily engaged in missile and space work, aircraft manufacture holds first position by any measure of productivity.

Airplane builders fall into two categories: producers of general-aviation planes and producers of heavy aircraft. General aviation embraces planes and light helicopters used for private pleasure flying, personal transportation, business travel, and short-haul commercial operations, such as air taxis and commuter airliners with low takeoff weights (specifications vary internationally). Included in the general-aviation bracket are specialized aircraft such as agricultural sprayers, acrobatic craft, sailplanes and gliders, air ambulances, pipeline-patrol craft, geophysical-survey platforms, and a broad variety of other civil applications. Also included are certain light military aircraft used for observation, liaison, and utility duty and incorporating only minor military modifications to their basic civilian-type design. Although many modern general-aviation planes are jet- and turboprop-powered, all are subsonic. General-aviation aircraft constitute the bulk of airplane manufacture in terms of units but little in terms of sales volume.

Types of heavy aircraft

The heavy-aircraft category includes nearly all military planes, commercial airliners, and large corporate aircraft adapted from airline designs. Among the more technologically demanding craft in this category are the supersonic military planes, huge military and commercial transports weighing up to 800,000 pounds (360,000 kilograms), and supersonic jetliners (production of the latter was confined in the early 1970s to the Soviet Union and the United Kingdom–France in combine). Also belonging to this group are specialized craft such as the vertical takeoff and landing (VTOL) vehicle, initially a military type but one with broad potential in commercial operations; large helicopters, employed as combat weapon systems, as intratheatre military transports, and as passenger-carrying commercial carriers; unmanned reconnaissance drones and target aircraft used for training of gun and missile crews; and ground-effect machines, or air-cushion vehicles, which operate close to the surface, supported by a column of high-velocity air generated by the machine's engines. The term heavy, as applied to this category, is not entirely a matter of weight but refers as well to the heavier demands of work load per unit to produce the stronger structures, more powerful engines, and more complex ancillary equipment required for the vehicles' design missions.

Guided missiles. Second to aircraft in worldwide industry productivity is manufacture of guided missiles and related products. From the standpoint of manufacturing work load, missiles can be grouped in two basic categories. The first group embraces battlefield, tactical, and air-defense weapons and short- to medium-range systems that carry either conventional high-explosive or low-yield nuclear warheads and that have speed capabilities ranging from subsonic to about Mach 3. Production of such weapons is relatively straightforward, within the capabilities of some of the less sophisticated aerospace industries of the world; in the early 1970s, companies in 14 nations were producing such missiles.

Far more technologically demanding are the strategic missiles that carry multimegaton-yield nuclear or thermonuclear warheads at hypersonic speeds (far beyond the speed of sound; above Mach 3) over distances ranging from more than 1,000 miles to intercontinental. Although it is a defensive rather than an offensive system, the antiballistic missile must be included in this category because of its complexity. By the start of the 1970s, only the United States and the Soviet Union had demonstrated capability for producing the antiballistic missile; in addition to these two, France and the People's Republic of China produced strategic missiles.

Strategic missiles and space-launch vehicles

A close relative of the strategic missile is the space-launch vehicle. (In space terminology, the launch vehicle is the rocket system that lifts a payload into orbit; the payload itself, whether manned or unmanned, is called a spacecraft, and the combined launch vehicle–spacecraft is known as a space vehicle.) Only in the United States and the Soviet Union have launch vehicles been produced on a quantity basis. The Soviet Union has followed the practice of modifying long-range missiles for space-launch work; the U.S. used converted missiles for the majority of its space launches but additionally developed families of launch vehicles designed from the beginning for space-launch duty. France, Britain, China, Japan, and the European Launcher Development Organization, a consortium of several European nations plus Australia, have all built launch vehicles on a limited basis.

Another missile-related product is the sounding rocket, known in Europe as the probe rocket. Used for upper-atmosphere and near-space research, the sounding rocket is a small launch vehicle that does not orbit a research payload but sends it instead on a brief, parabolic flight above the atmosphere and back to Earth. Sounding rockets generally have one to four rocket stages that fire in sequence to achieve the altitude desired for the experiment; payloads usually run from 50 to about 500 pounds (23 to 230 kilograms), and altitude capability ranges upward to about 1,000 miles (1,600 kilometres). Many countries are engaged in sounding-rocket programs, but the vehicles are primarily of American origin.

Spacecraft. The third major area of aerospace-industry effort is fabrication of spacecraft. Spacecraft are individually tailored to specific research programs and, therefore, do not fall into logical groupings of systems with similar construction characteristics. Unmanned spacecraft, called satellites when they operate in Earth orbit and probes when launched on a deep-space trajectory, have weighed from three pounds (1.4 kilograms) to almost 19 tons (17,000 kilograms) and have been configured in so many different forms that no basic description is possible. Manned spacecraft, naturally, impose far greater fabrication problems than unmanned systems, because of the equipment necessary to sustain human crews in space and bring them back to Earth. Modern manned spacecraft, weighing up to 100 tons (91,000 kilograms), are the most complex of all aerospace vehicles, and their production has been confined to the United States and the Soviet Union. In addition to these two nations, unmanned spacecraft have been built and orbited (in most cases by means of U.S.-provided launch services) by France, the United Kingdom, Canada, Italy, Australia, Germany, Japan, China, and the European Space Research Organization, a ten-member combine. A number of other countries have built individual systems and experiments for cooperative space programs sponsored by the United States and the Soviet Union.

Propulsion systems. Rounding out the primary-product line are the propulsion systems for all of the flight vehicles described. There are three basic types of power plants: piston, or reciprocating, engines; turbine engines; and rocket engines. No longer used in current-model heavy aircraft, the piston engine still has wide utility as a power plant for light single- and twin-engine general-aviation planes (see also GASOLINE ENGINE). The turboprop (turbine spinning a propeller) finds its primary applications in light–medium commercial and business transports and in military planes when greater range is more desirable than speed. The turboshaft (turbine driving a rotor system) engine is becoming the standard propulsion system for the larger helicopters, particularly those of the twin-engine variety. The pure jets, turbojet and turbofan engines, power all supersonic aircraft except research vehicles and a wide range of subsonic types from light single-engine trainers to the mammoth jumbo jetliners (see also JET ENGINE).

Types of propulsion systems

The primary employment of the rocket power plant is in propulsion for guided missiles and space-launch vehicles. There are two basic types of rocket engines: solid-fuelled and liquid-fuelled. Because of the requirement for long storage, the great majority of missiles are now pow-

ered by solid-fuel systems, as most liquid fuels have to be stored at cryogenic (very low) temperatures. Conversely, most space-launch vehicles employ liquid-propellant rocket systems, although large solid rockets are frequently used as boost-stage auxiliaries for greater thrust in the initial phase of a launch. An additional usage of the rocket engine is for spacecraft on-board propulsion, permitting changes of orbital path. These engines, relatively low-thrust systems, are used only on manned spacecraft and some of the most complex unmanned craft and consequently do not figure prominently in the production work load. Engine manufacturers also produce, in limited quantities, a variety of specialized rockets, including small monopropellant or bipropellant thrusters for adjusting the attitude of an orbiting spacecraft; solid rockets for explosive separation of launch-vehicle states; rockets for high-speed track-borne research sleds; stabilizing thrusters to control roll in missiles and launch vehicles; and aircraft auxiliary rockets.

Nations with substantial aerospace-engine industries, including those that build other nation's designs under license, include the U.S., the Soviet Union, France, Britain, Australia, Canada, China, Czechoslovakia, Germany, Israel, Italy, Japan, Poland, and Sweden.

OTHER PRODUCTS

Secondary aerospace products. The secondary-product line of the aerospace industry is composed of the great many items of on-board equipment required by the various design missions of the flight vehicles. An airframe and a propulsion system sufficed for the initial flights of the Wright brothers, but the modern aerospace vehicle admits of no such simplicity; depending on design purpose, a flight vehicle may have thousands of separate functional equipment units. The list of individual items is too lengthy for even a catalog listing, but a sampling of the more important systems and subsystems illustrates the breadth of the secondary-product line.

Aircraft equipment. This includes aerodynamic controls and actuating devices; engine controls; cockpit instruments and displays, including instrument-landing systems and other aids to bad-weather approaches; communications systems; radar for weather avoidance, target acquisition, search missions, and identification signals to ground stations; navigation equipment other than basic instruments, including radio, optical, and electronic systems and, in the most advanced aircraft, computer-directed inertial navigators; air-conditioning and pressurization equipment; landing-gear brakes and steering controls; data recorders; trouble-warning systems; radar, photographic, infrared-imaging, and other sensory devices for intelligence gathering, together with on-board intelligence-processing equipment; armament for military planes, including armour systems, launchers for airborne missiles, high-speed cannons and gun turrets, bomb and rocket fuses, and arming devices; electronic countermeasure equipment for confusing enemy defenses; engine starters and auxiliary power units for on-board electricity; seats, galleys, and passenger-service equipment for commercial airlines; and escape devices such as parachutes, surface-survival aids, and, for higher speed aircraft, ejection seats and separable cabins.

Missile and launch-vehicle equipment. This includes automatic guidance systems, ranging from heat-seeking homing devices to computerized navigation systems; on-board power systems; controls, including actuating devices for course-changing fins, thrusters, or gimballing engines; communications systems, including receivers for reception of command signals from Earth and transmitters for relaying vehicle-condition data to Earth, sensors to assay vehicle conditions, and trouble-warning devices; abort–destruct systems; engine-ignition and cut-off systems; automatic fuel-flow systems for liquid-fuelled vehicles; tank-pressurization systems; warhead systems; and, for strategic missiles, re-entry vehicles protecting the destructive payload from the friction heat of re-entry into the atmosphere.

Spacecraft equipment. This category includes an extremely broad variety of experiment packages, including instruments ranging from simple micrometeoroid counters to complex automatic telescopes; communications systems, including antenna arrays, telemetry transmitters for reporting data to Earth, recorders to store data for later transmission, encoders to translate data into coded signals, receivers for acceptance of Earth commands, decoders to interpret command signals, and command-distribution devices for translating commands into compliance; power sources, including solar-cell arrays, batteries, fuel-cell power plants, and nuclear generators; stabilization systems and station-keeping devices to maintain a desired spacecraft position or attitude; spacecraft-condition sensors; radio and optical beacons to facilitate Earth tracking; ejection and descent systems for payloads recoverable from orbit; photographic, radar, infrared, and other types of sensory devices for military intelligence gathering and for civil use in meteorological and Earth-resources-survey spacecraft. Additionally, for manned spacecraft there are environmental-control systems; guidance and navigation systems, including sophisticated computers for acceptance and processing of Earth-acquired data; cabin instrumentation and displays, including trouble-warning systems; special-purpose radars, such as those used for in-space rendezvous or lunar landing; pressure suits for extravehicular activity; and galleys, water dispensers, and waste-management systems designed for operation under zero-gravity conditions (see also LIFE-SUPPORT SYSTEMS).

Experimental equipment

Tertiary aerospace products. The industry's tertiary-product line includes those ground-based items necessary for support of flight vehicles, either directly, such as engine starters, or indirectly, such as training devices. A major area of effort is the production of ground radars and antennas with associated data-processing systems (see also RADAR). This equipment is employed for air-traffic control and airport control-tower operations; for detection and tracking of potentially hostile flight vehicles; for the Earth-command type of missile guidance and for interception guidance of air-defense aircraft; and for tracking spacecraft. Another major area is production of automatic checkout equipment for complex aircraft, missiles, and space vehicles; such equipment electronically "interrogates" each of the vehicle's systems and verifies that the system is in proper working condition or pinpoints faults for quick correction. A third area involving considerable work load is fabrication of simulation systems, used for training aircraft, missile and spacecraft crews, and research and development processes. Among other examples of ground-based aerospace equipment are radio transmitters for aircraft navigation; airport lighting and landing aids; ground-based air-conditioners, power units, and airplane-servicing equipment; transporters, erectors, launchers, and fire-control systems for mobile battlefield missiles; and the systems that make up a space mission-control centre, such as communications circuitry, computers, and display consoles.

Ground-based equipment

Nonaerospace products. Nonaerospace products and systems, general-usage offshoots of aerospace technology, constitute a fourth area of industry work load, not significant as a proportion of total work load except in the United States and presumably in the Soviet Union. The United States industry has for several years been engaged in a strong effort to transfer its wealth of technology to general use, in an attempt to further diversify its product line and minimize dependence upon government business. By the early 1970s this program had met with considerable success; the list of nonaerospace items ran into the thousands, and annual sales volume approached the level of $3,000,000,000. Examples of new applications of aerospace-developed technology include many medical aids, ranging from a thimble-sized cardiac-pacemaker power source to a computerized hospital-management system; in transportation, hydrofoil ships and boats, vastly improved railroad cars, truck and bus transmissions, motor-vehicle traffic-monitoring systems, inflatable crash-bag systems for autos, and turbine propulsion systems for both land and water vehicles; in con-

struction, prefabricated low-cost housing and lightweight, superstrong structural materials; in electric power, a number of types of nuclear and nonnuclear power-generating systems; and, in environmental control, a broad range of antipollution systems.

III. Research and development

The ultimate aim of aerospace research and development is the creation of flight vehicles more advanced than their predecessors, but so succinct a statement of goal oversimplifies the enormous scope of research and development activity. It is a fact of aerospace life that expansion of the operating capacity—the "envelope" of a flight vehicle—almost invariably entails corollary advances in on-board systems, ground-support equipment, and even the methods of construction. Frequently, desired performance gains dictate not merely improvement of existing ancillary equipment but entirely new inventions. Aerospace research and development is a continual process of across-the-board thrusting into the unknown and frequently moves beyond the traditional areas of investigation into new byways embracing practically all of the technological disciplines.

Types of research and development

Aerospace research and development is of four types. Basic research involves investigations that have no immediate practical objective; it is the advancement of knowledge for potential rather than direct interest. Applied research is investigative effort aimed at the practical application of knowledge. Development, by definition, is "the use of scientific knowledge directed toward the production of useful materials, devices, systems or methods, including design and development of prototypes and processes"; it is the translation into hardware of the results of applied-research studies. Operational research is concerned with the solution of problems encountered by flight vehicles already in regular service. The aerospace industry engages in a certain amount of basic research, but it is negligible as a percentage of total research and development work load. Operational research is conducted to a greater degree, but the primary focus in the industry is on applied research and development related to the betterment of existing products and the emergence of completely new products.

The level of research and development activity naturally varies a great deal among companies and countries, the determining factor being the types of flight vehicle to be built. Light, general-aviation aircraft, for instance, are not overly demanding of research and development. Like automobile manufacturers, light-plane builders offer their products in a number of price categories and cost is a restricting influence on size, weight, and performance. General-aviation manufacturers, whether airframe, engine, or equipment builders, do conduct considerable research, but it is aimed at small increments of improvement that can be obtained without cost increases that would take the plane out of its competitive category.

NEW COMMERCIAL AIRCRAFT

Development of a new commercial airliner demands extensive research and development, but the requirement is substantially reduced by the fact that the jetliner operates in an already-explored flight regime. Traditionally, military aircraft reach a given plateau of performance a decade or more before the airliner achieves the same capability. Thus, designers of commercial aircraft have available at the outset a vast storehouse of aerodynamic, propulsive, and other knowledge relative to the flight regime in which they propose to operate. This is not to suggest that they can bypass those areas in which prior research has been accomplished; rather, they can use the knowledge available as a departure point for a research and development program in which the emphasis is on utmost efficiency within a known flight bracket rather than initial penetration of an unknown regime.

Jetliner developmental teams focus on two primary areas of research and development: safety and economic viability. Safety involves such major considerations as stronger structures, ultrareliability of engines and onboard equipment, and provision of the most advanced navigation and all-weather landing systems. Economy of operation embraces capacity; maximum flight efficiency, which is translatable into greater range and payload; maximum propulsive efficiency, for reduced fuel costs; lowest possible turnaround time for best utilization of the airplane; longer equipment life for extended periods between overhaul; and ease of maintenance.

Expanding the aircraft envelope

The industry's major research and development effort is expended on those programs that seek major expansion of one or more facets of a flight vehicle's envelope, the bounds of its performance capabilities. More often than not, a speed greater than its predecessor's is the primary performance gain sought for a new vehicle, but the research effort may also be directed toward other elements of improvement. The goal, for instance, might be an increase in range or payload, as is the case in global-ranging military bombers and transports; it might be manoeuvrability, a vital consideration in fighter-aircraft design; it might be greater destructive capability, as in multiple-warhead strategic missiles; it might be duration, as in an extended-stay orbiting vehicle; it might be extremely high altitude, for a reconnaissance airplane; or it might be a combination, as in the case of a new bomber under development, of supersonic speed for long periods at minimal altitudes, a particularly demanding area of research because of different shock-wave characteristics at sea level as opposed to those of high altitude. There are other factors involved, and rarely are the sponsors of a new project willing to settle for improvement in only one area.

High-technology programs of this nature are almost always government sponsored. Because they probe unknown areas of flight, they require exceptionally high funding outlays, millions of research and development man-hours, and an elaborate complex of research and development facilities, some of which may have to be created especially for the particular project. A brief outline of the step-by-step process in the development of a new high-technology vehicle—a high-performance military aircraft, for instance—serves to illustrate the extraordinary human skills required and the complex array of tools and facilities needed to bring such a program to fruition.

Computer design. The design phase is largely theoretical. Drawing upon the general fund of aeronautical knowledge and their own preliminary research, scientific and engineering specialists produce a mathematical model of an airplane that they think will meet all of the project sponsor's specifications. The team's primary tool is the electronic computer, used in a variety of ways. It provides rapid and accurate answers to the millions of mathematical calculations required. It stores in its memory banks the design input fed into it and creates an electronic image of the airplane. Coupled with an automatic plotter, it displays on a TV-like screen pictures of the complete airplane or any section of it, such as the wing, flaps, tail section, or nacelles, affording the team a visual presentation of current analysis. Programmed with atmospheric data, it can "fly" the hypothetical airplane and report to the team the aerodynamic response of the design to any condition of flight, from takeoff to landing, from straight-and-level cruise to combat manoeuvres. Through a lengthy series of such simulated flights, the team refines its design, until the electronic airplane meets or exceeds all specifications.

Wind-tunnel testing. The next step is wind-tunnel testing of a physical model, a carefully constructed scale replica of the computer-aided design, for verification of the performance predictions. The wind tunnel, which actually predates powered flight by more than 30 years, is an apparatus in which air is blown over a model mounted in a test section, creating an effect comparable to airplane flight. There is wide variance in the size of wind-tunnel test sections, depending upon airflow-velocity requirements. Some low-speed tunnels have test sections large enough to accommodate a complete small airplane or a wing–nacelle section of a larger plane; in a higher speed system the test model may be only the size of a desk model, and in the very high velocity tunnels used

for missile and space testing the model may be as small as a match. Tunnels are classified according to airflow-velocity range in five categories: subsonic, up to Mach 0.8, or 80 percent of the speed of sound; transonic, Mach 0.8 to Mach 1.2; supersonic, Mach 1.2 to Mach 6; hypersonic, Mach 6 to Mach 12; and hypervelocity, above Mach 12.

Methods of operation of wind tunnels

There are two basic methods of feeding air to the test section. In the continuous-flow tunnel, airflow is generated by a battery of fans or compressors, forced through the tunnel to the test section, then directed through a curving tunnel section back to the starting point for reuse. The alternate method involves storing high-pressure air in a tank, releasing it by valve controls to pass through the tunnel and test section into a capture tank. This type of system, the intermittent-flow tunnel, is generally used for very brief bursts of high-velocity airflow.

Some wind tunnels are almost as complex as the flight vehicle under development. They have variable throats to permit changing airflow velocity, conditioning systems to change air characteristics for simulation of different altitudes, and heating devices to simulate the friction heating encountered by high-speed flight vehicles. Mounted within the model are tiny transducers that acquire a variety of data and transmit it to recording systems outside the tunnel. Specially designed colour cameras photograph shock waves and other airflow phenomena. The computer digests the data from the test run, analyzes it, and presents a report on the flight vehicle's performance.

Most major manufacturers have some type of wind tunnel, usually of the intermittent-flow type, and for more demanding programs they have access to the complex government-operated supertunnels that no single company could afford. After a series of wind-tunnel "flights," the design may be further refined to incorporate the findings of tunnel research; then the airplane is ready for prototype construction.

The prototype. In the prototype-construction phase, emphasis shifts from research to testing. A customary procedure is to build one or more static test airplanes, designed not to fly but to verify the structural integrity of the design. This requires another array of facilities, including ovens for applying high temperatures to materials; acoustic chambers, in which engineers can study the effect of high-frequency engine noise on structures; rigs for measuring landing impacts; and rapid-cycle vibrators for investigations of wing-panel flutter. A major facility is the load-test rack. A flight load is the force experienced by the airplane in its various manoeuvres; designers provide for an ultimate load factor, which represents the greatest load the airplane may encounter in the most violent manoeuvre plus a comfortable safety margin. The load-test rack consists of a series of instrumented hydraulic jacks that push, bend, and twist the airplane to the point of failure, verifying that the ultimate load factor called for in the design has been met in construction.

While the prototype airframes are being built, the manufacturers of on-board equipment are going through a parallel process to devise and test the airplane's many systems and subsystems. The broad variety of ancillary equipment precludes description of the testing process, since it differs with each system. Generally, equipment is checked out, repetitively and exhaustively, by a battery of electronic test equipment tailored to the system being tested. In the laboratory, the test set electronically monitors the system as it is run through its performance cycle and signifies okay or detects and isolates faults for correction. In many cases, complete systems are further checked in altitude chambers that simulate the environment in which they will later be operating. Engines are tested in the propulsion research equivalent of the wind tunnel, the test cell capable of simulating the conditions of flight; test engines are heavily instrumented, and the data findings are transmitted to a computer for processing. To qualify for installation in a prototype airplane, a new engine is normally put through several hundred hours of cell testing, embracing the entire range of speed and altitude capacity of the airplane for which it is intended.

Flight testing. As a general rule, prototype flight testing is conducted at government-operated installations in lightly populated areas, due to the possibility of accident to an experimental airplane. Flight testing is necessary to validate what has been to this stage really only theory, but so thorough and extensive are modern procedures of computerized design and tunnel testing that the flight-test phase rarely dictates a major design change. Rather, it serves to debug the airplane, to correct the many minor faults that somehow find their way into a new airplane despite the most painstaking efforts to avoid them.

The modern test pilot

Modern flight testing bears little resemblance to the once-familiar motion-picture portrayal of the daredevil pilot trying to fly the wings off the airplane. The modern test pilot is a thoroughly experienced flyer who is also an engineer; he is selected for his flying ability and for his ability to observe and report in technical detail on the handling qualities and peculiarities of his airplane. He is backed by a forest of sensitive test instruments, gathering volumes of data, which are relayed by radio telemetry to computers on the ground. The flight program is carefully planned, again with the help of a computer. It begins with ground-taxi tests and progresses to brief flights at the lower end of the performance spectrum, then to longer flights of gradually increased performance until the limits of the design envelope have been reached or surpassed. The test program for an advanced airplane may take several months and complete evaluation of the data additional weeks or months.

MISSILES AND SPACECRAFT

General considerations. The research and development effort that goes into development of missiles, launch vehicles, and spacecraft parallels that of the airplane in the design and ground-test stages but differs when the flight-test stage is reached. The shorter range battlefield and tactical weapons pose no major testing problems; they are fired more or less like artillery systems at large-area land ranges. Major launch vehicles and strategic missiles are more demanding as regards test techniques. The absence of man on board, the great expense of a single launch, and the inability to recover and re-use the test vehicle all combine to exert two major influences: more elaborate instrumentation, both in the vehicle and on Earth, and extraordinarily intensive preflight checkout to prevent a costly abort.

Additionally, the distance covered in a major unmanned flight-vehicle test, which is several thousand miles in the case of an intercontinental ballistic missile, requires the use of spread-out test ranges with downrange tracking and data acquisition stations. These ranges are necessarily government operated, but generally contractors have their own facilities at the launch centre for prelaunch testing. In the United States the U.S. Air Force Eastern Test Range includes both the John F. Kennedy Space Center and the Cape Kennedy Air Force Station, launch bases for civil space flights and military missile testing; surface stations extend 10,000 miles down the South Atlantic. A second major United States facility, the Western Test Range, centred at Vandenberg Air Force Base, California, extends into the Pacific. The Soviet counterpart of Cape Kennedy is the missile-space-launch centre at Tyuratam, on the Aral Sea, with impact areas for long-range flights in the Pacific Ocean. The Soviet Union operates two other major facilities, one at Plesetsk, near the White Sea port of Arkhangelsk, the other at Kapustin Yar, north of the Caspian Sea. France operates a range that extends into the Atantic from a base at Kourou, French Guiana. Other major ranges are operated by Australia and Japan, with launch centres at Woomera and Kagoshima, respectively. There is no information available on the Chinese range facilities.

Major world testing ranges

Unmanned spacecraft are unique in that they undergo no prototype test flights; if their launch vehicles perform successfully, they go into orbit, so they carry their full complement of operational instrumentation. In a sense, then, all unmanned spacecraft are test vehicles. since

they report details of their own operation as well as scientific-data findings, providing the basis for design refinement in later models of the same family. The substitute for prototype testing is Earth-based simulation, usually in two types of simulators: the space simulator, which duplicates all the environmental conditions in which the spacecraft will operate, and the mission simulator, which permits conduct of the entire range of manoeuvres and systems operations that would be performed on an actual flight.

Manned spacecraft are not only prototype tested but are subjected to the most rigorous ground-test program experienced by any flight vehicle. The program defies detailed description, since it involves literally millions of separate tests. Some idea of the intensity of the test effort and the broad variety of research and development facilities needed may be obtained by a recounting of the major ground-test operations of a manned spacecraft, such as the United States' Apollo mooncraft.

Testing. *Aerodynamic testing.* Although most of its lunar mission takes place outside the atmosphere, Apollo does fly within the atmosphere briefly en route to orbit and during re-entry and parachute descent to the ocean. To verify design predictions as to aerodynamic loads, acoustic effects, friction heating, and lift-to-drag ratios at the hypersonic speed of re-entry, Apollo was put through more than 7,500 hours of wind-tunnel testing.

Vacuum chamber tests. In these the environmental-control system was tested at conditions ranging from sea-level pressure to hard vacuum.

Impact tests. In these a full-scale command module was slammed into a water tank by a huge pendulum arm, simulating various angles of splashdown and impacts much greater than would be encountered on a normal descent.

Space-simulation tests. In these the complete spacecraft was placed in a large facility capable of simulating the total space environment, including hard vacuum, solar radiation, and temperature extremes, to determine effects on systems and materials.

Oven–freezer tests. In space, Apollo is at times positioned so that one side is in the undiluted sunlight while the other is in cold shadow. For simulation of these simultaneous extremes of temperature and observation of structural effects, the spacecraft was electrically roasted on one side at 600° F (320° C), while the other side was sprayed with liquid nitrogen at −320° F (−200° C).

Load tests. In a facility that is the spacecraft equivalent of the hydraulically operated airplane load test rack, Apollo was subjected to immense loads far greater than any normally anticipated.

Dynamic tests. These include acoustic, vibration, shock, and acceleration investigations. A huge "cocktail shaker" rapidly shook the complete spacecraft to simulate the vibration and buffeting of the launch phase.

The above are a few samples of a broad range of ground tests conducted repetitively over a period of several years. Running concurrently was a series of unmanned suborbital and orbital flights. For the initial series the contractor built a number of test vehicles known as boilerplates, replicas of the actual spacecraft in size, shape, structure, mass, and centre of gravity but not equipped with the myriad functional systems. The boilerplates were used on ten flights to test the spacecraft's compatibility with its launch vehicle, the launch escape system, and the general stability and structural integrity of the spacecraft in orbital flight. The boilerplate tests were followed by six additional flights in which completely equipped spacecraft were flown in orbit on an unmanned basis to check out all systems under actual space conditions and to verify the performance of the all-important re-entry heat shield. For these flights, the stand-in for the human crew was a robot controller capable of directing systems operation either automatically, by preprogrammed instructions, or by command from Earth monitors. The meticulous preparation for each flight, coupled with the evaluation time for the vast amount of data acquired, stretched the 16 unmanned flights over a period of four and a half years.

The boilerplate test series

OTHER AREAS OF RESEARCH

In addition to project-oriented research and development, the effort involved in a specific flight-vehicle program, the aerospace industry conducts a tremendous amount of research and development of a general nature designed for competitive readiness for the next generation of aerospace products. Among the more active areas of general research are:

Propulsion. Anticipating continuing demand for greater thrust, particularly in the airplane field, engine manufacturers are designing and developing new families of superpowered propulsion systems. In addition to thrust ratings, research is aimed at lower engine weight in relation to power output, better combustion efficiency, and further extension of the time between overhauls. A special line of research in recent years has been concerned with reduction of engine noise and emissions.

Electrical power. Continually increasing flight-vehicle performance means more on-board systems and greater capability of the individual system, hence a requirement for more electrical power to operate the systems. Manufacturers are paying particular research attention to fuel-cell power plants and thermoelectric converters, along with a variety of conventional generators of more advanced design.

Materials. Probably the greatest single influence on aerospace design is weight, and researchers are constantly looking for new materials that offer weight reductions without sacrifice of strength. The quest extends to materials for all parts of all types of flight vehicles, but the greatest emphasis is on temperature-resistant materials for high-performance vehicles. Conventional materials weaken under extended exposure to combustion-induced heat, solar-induced heat, friction-induced heat, and hot–cold extremes. Seeking simultaneous improvement in temperature resistance and strength-to-weight ratio, researchers are exploring in particular such exotic metals as columbium, molybdenum, and tantalum; ceramics; composites, combinations of two or more materials in which the resultant has better properties than the individual constituents; and vehicle-skin coatings for prevention of oxidation.

Significance of weight in aerospace design

New systems. "New," in this sense, means not developmental improvements of existing equipments but completely new systems that do not exist in operational status and for which a need is clearly indicated. An example is an automatic collision-avoidance system for aircraft.

Miniaturization. A traditional method for reducing weight and at the same time cutting down on systems volume requirements is making things smaller. The missile–space era brought such great strides in this area that manufacturers call it microminiaturization. This type of research is continual, first because the trend in high-performance flight vehicles is generally toward more equipment and second because the initial version of a system, designed primarily for performance, usually leaves considerable room for later miniaturization.

New manufacturing processes. A large portion of general research and development work is devoted to research in new manufacturing processes, in order to combat ever-mounting costs, reduce fabrication time, and assure greater product reliability. Additional effort goes into development of machines and techniques for shaping and forming the new materials being introduced to production status, which almost invariably are more difficult to handle than their predecessors.

COOPERATIVE PROGRAMS

As aerospace flight vehicles and systems grow in performance capability and consequently in complexity, research and development costs mount steadily. Even the United States and the Soviet Union, with their vast resources, are finding it difficult to finance essential research and development, and among the smaller nations financial limitations would make it necessary to bypass promising areas of research and development were it not for the cooperative-program approach.

In western Europe the cooperative approach has been growing for two decades and has reached significant pro-

portions. In these programs, two, three, or more nations pool their financial resources and their facilities on projects that would be beyond the means of any one of them. In some cases, developmental responsibility and financing are divided equally among the participants; in others, one nation assumes the major burden but is backed by associate participants. Project management may be assigned to a single major company, or the project may be directed on a consortium basis, with alternating national leadership.

In this fashion, European countries are accomplishing considerable research that would otherwise not have been undertaken. Several have banded together as the European Space Research Organization; a parallel group is the European Launcher Development Organization, which seeks to develop and produce space-launch vehicles. Other projects are more directly oriented toward commercial markets; the British–French Concorde supersonic plane is the prime example, but there are many others, involving jetliners, military aircraft, helicopters, missiles, turbine engines, and a communications satellite for a contemplated European network. Participants in cooperative programs include France, the United Kingdom, the Federal Republic of Germany, Italy, Sweden, Belgium, Switzerland, The Netherlands, Spain, and Denmark; Australia, which supplies a launch range, is also a participant in the European Launcher Development Organization.

The Concorde project

IV. Manufacturing facilities and techniques

No one company builds an entire flight vehicle, not even the simplest light plane, because of the exceptional range of skills and facilities required. Aerospace manufacturers are specialists, operating as either independent companies, divisions of very large corporations, or bureaus of a nationalized industry (among the major producers the Soviet Union is completely nationalized, France almost exactly half and half as regards the personnel division between the *secteur nationalisé* and the *secteur privé*, and the United States and United Kingdom entirely private industry). The primary areas of specialization are airframes, propulsion systems, airborne electric and electronic systems, other airborne systems, and ground-based equipment. Within these broad areas there is sharper focus of specialization; for instance, one electric–electronic company has separate divisions manufacturing guidance and navigation systems, control systems, electric-power systems, instruments and life-support equipment, and scientific-data-acquisition systems.

A major aerospace production program may involve literally thousands of individual suppliers operating as subcontractors to a team leader, usually the airframe builder, known variously as the prime contractor, principal constructor, "mother" manufacturer, systems integrator, or design bureau, the last a Soviet term that embraces not only design but also supervision of the complete manufacturing process. Subcontracting covers not only the on-board equipment but, in most major programs, the airframe itself. Production of the British–French Concorde serves as an example: the airframe is broken down into 21 separate components built by 11 different companies and divisions, then delivered to the team leader's plant for mating. Work-load sharing of this nature takes advantage of additional pools of skill and facilities and helps compress production time. On commercial projects it is also employed as a method of spreading the requisite financing for materials, tooling, and other production preliminaries.

BASIC FABRICATION TECHNIQUES

The variety of the product line, from individual parts to major systems to the complete flight vehicle, precludes description of a typical manufacturing plant, since each factory is tailored to the items produced. In general, the primary work areas of any plant are the fabrication facilities, in which the individual parts and components are made, and the assembly facilities, ranging from moderate-size rooms to huge, high-bay buildings covering several acres.

Metal processing. In the fabrication stage, each of the thousands of parts must be precisely shaped, and there are a number of ways of doing this. Fabrication tools and techniques fall into two major categories: chipless operations, performed without cutting tools, and material-removal operations. Chipless operations include die-casting, or pouring molten metal into a mold; molding, which is casting under pressure; and a number of methods of pressure forming. Aircraft skins, for instance, are made by rolling machines that squeeze and flatten hot sheet metal to the desired thinness; other parts are made from metal sheet, plate, foil, ingot, and bars by stamping; by forging, or pressing the metal over dies; by extruding, or forcing heated metal through a die, like squeezing toothpaste; by stretch forming, giving the metal a permanent bend by stretching it over a curved die; or by braking, pressure bending a clamped metal workpiece. A relatively new method is explosive forming, in which an explosive charge is detonated against a water-submerged workpiece and the resulting blast slams the metal against a shaped mold (see also MATERIALS PROCESSING).

Metal-removal operations are primarily those in which metal is trimmed away from a workpiece by tools such as milling machines, lathes, shearing machines, borers, punch presses, knives and saws, sanders, grinders, and polishers. In addition to these cutting and friction tools, metal removals are accomplished by electrical devices, such as an electrical-discharge borer, and by chemical means; in the latter method, an acid bath eats away the excess metal while a coating protects the desired shape. In either chipless or metal-removal operations, the particular technique selected for a given part is dependent upon a number of factors; for example, the type of basic material, the intricacy of the shape, requisite strength, and, when it becomes a part of the flight vehicle, the degree of exposure to load forces and temperatures.

Metal-removal operations

Joining methods. Individual parts, once fabricated, must be mated, or joined, with other parts. The most familiar method is mechanical joining by means of rivets, bolts, screws, pins, and other special-purpose fasteners. In cases in which a tighter seal is necessary or where the assembly will be subjected to great loads, manufacturers employ welding, which in most cases is accomplished by melting the metal at the joint, applying molten metallic filler, and allowing the joint to cool. Electric-arc welding, in which heat is supplied by an electrical circuit created between the workpiece and the welding tool, is in wide aerospace usage. Other methods include cold welding, or joining by pressure without high temperature, and forge hammering with heat application. A more advanced technique, diffusion bonding, involves the application of both heat and pressure in a nitrogen atmosphere, creating an exceptionally strong, lightweight joint. Another joining method in wide use is adhesion bonding, or simply gluing the parts together by means of supercapable adhesive coatings, such as plastic resins.

In the production of components that must bear high loads yet be as light as possible, aerospace fabricators have evolved a technique for changing the properties of a material by engineering. The most notable example is the so-called honeycomb sandwich. The core of the sandwich is the honeycomb, a structure composed of row upon row of framed cells, or holes, resembling the honeystorage facility of a beehive. To each side of the core are bonded extremely thin sheets of metal, creating the sandwich, which is far lighter yet has greater resistance to bending than a comparable thickness of metal plate. Aluminum is the most used metal, in both the core and the facing sheets, but the technique is applicable to a great many metallic and nonmetallic materials. Sandwich construction is a major part of aerospace manufacturing, one used to some degree in almost every type of flight vehicle.

The honeycomb sandwich

Most of the basic fabrication techniques have been employed for years in aerospace manufacture, and the difference today is in the degree of sophistication of the tools and techniques; like the product line itself, tools and techniques have progressed through several plateaus of technological advance. For example, simple hand-

torch welding would not suffice for the stringent joining requirements of a current spacecraft; it is necessary to enclose the weld station in a pressurized, temperature-controlled, contamination-free portable room. Similarly, while forming machines perform the same functions as their forebears, they differ considerably because of new and more difficult to handle materials, such as titanium, magnesium, and beryllium in airframe construction and the superalloys of iron, nickel, and cobalt in engine production. Additionally, the modern machine must work to incredible tolerances to produce parts of greater precision than the finest watch movement. Not long ago, machining to a thousandth of an inch was considered a tremendous accomplishment; some modern systems demand tolerances measured in millionths of an inch.

Use of electronic computers. The primary difference between today's manufacturing facility and its World War II or immediate postwar counterpart is the machining precision and efficiency made possible by the electronic computer. In a process broadly known as computer-aided manufacturing (CAM), computers are employed to direct the operations of machine tools. CAM embraces a number of types of computing equipment and various methods of controlling the machine. In general, the computer serves as a translator between the human programmer and the machine tool. The design of the part to be manufactured is reduced to symbolic computer language, and the programmer feeds the computer instructions as to the necessary machining operations. The computer in turn relays the instructions, in the form of command signals punched on tape, to an automatic controller, which directs the machining with extreme precision. Advanced CAM systems include multiple-operation machines, equipped with a battery of different tools; by computer-direction, the machine can perform any combination of operations in a prescribed sequence and even change the tools as required. Some huge tools can turn out large single-piece components and structures of intricate shape, eliminating the need for joining several individual parts. Computer-aided manufacturing shortens production time, thereby reducing cost, and in addition makes possible greater accuracy in parts fabrication.

The CAM system

PRODUCT ASSURANCE

Reliability is an important factor in the manufacture of any type of vehicle, but it assumes obvious urgency when the vehicle is one that flies. In aerospace production, exhaustive measures are taken to ensure utmost reliability and to guarantee that the completed vehicle or system or subsystem meets all the specifications prescribed by the end user of the product. The terms vary by company and by nation, but generally the collective precautionary measures are known as product assurance, which includes two subdivisions of effort: reliability engineering and quality assurance.

Reliability engineering, which begins in the design phase, essentially is a process of intensive study of alternative methods of performing a particular function and selection of the approach with the best predictable reliability. Reliability-engineering teams are frequently at odds with other designers, because the most reliable system is often one that demands compromise in such matters as cost and weight. An example is the practice of assuring reliability by means of redundant systems; a particular unit or system is provided an identical backup, together with a monitoring package that automatically activates the backup when it detects a malfunction of the primary. In some flight vehicles triple redundancy (two backups and a primary) is employed.

Reliability through redundancy

Quality assurance encompasses the entire manufacturing effort. It begins, as a management function of the project-team leader, with selection of the multitude of suppliers. The team leader studies the suppliers' own capability estimates, inspects their facilities, and investigates their history of performance before assigning a production task.

Quality-assurance groups focus a good deal of their attention on people. Despite the high degree of automation and the sophistication of fabrication tools, human effort still plays the dominant role in aerospace production. Quality assurance reaches into the processes of selecting skilled personnel and training employees. By lectures, bulletins, and posters on the potential consequences of carelessness, the quality-assurance group seeks to reduce human error. Some plants adopt extraordinary error-reduction measures; for example, some producers, to guard against the possibility of a potentially damaging tool being left behind in an engine assembly, provide workers with fitted toolboxes that are inspected after each shift.

The major aspect of quality assurance is quality control, the process of monitoring every step of the manufacturing cycle, from reception of raw material through delivery of the finished product. Quality-control technicians inspect new material coming into the plant to make sure that it is the specified type and has adequate properties. As the material is formed into parts and then subassemblies and assemblies, items that are considered critical are inspected after each work step, sometimes visually, sometimes by X-ray, microscopic, chemical, and ultrasonic devices that uncover invisible or subsurface cracks, voids, and other defects. Noncritical items, those whose failure could not influence the safety of the flight vehicle, are inspected on a spot-check basis.

Functional systems are subjected to repetitive tests after each workstep to insure that they operate exactly as they are supposed to when incorporated into the flight vehicle. There are hundreds of different types of testing equipments, each specially designed for a particular product, the bulk of them electronic testers that check out the operation of the product and report any deviation from specified performance. There are tests of individual parts, of assemblies formed by a number of parts, then of complete systems. Systems are checked out separately in their assembly facilities, later in their actual position in the flight vehicle.

ASSEMBLY METHODS AND FACILITIES

Assembly of an aerospace vehicle and the systems that go into it is a pyramidal process. The base of the pyramid corresponds to the mating of two or more individual parts designed to work together. Moving up the levels of the pyramid, these parts assemblies are joined with other assemblies to form subsystems, then systems. The terms system and subsystem are not sharply defined, other than that either is an assemblage of parts or equipment that *in toto* perform a particular function in the operation of the flight vehicle. Thus, in military terminology, a strategic missile is a system, and its inertial navigator is a subsystem; in the plant of the guidance-equipment manufacturer, however, the inertial navigator is considered a system, composed of such subsystems as the computer, the gyroscopic sensing platform, and the electrical-power source and circuitry. Few on-board systems are manufactured in a single plant; in most cases, parts and subsystems are produced elsewhere and delivered to the prime-system contractor for assembly.

At the top of the pyramid is assembly of the complete flight vehicle in the plant of the team leader, to which flow from a great many plants the airframe components or subassemblies, on-board systems and subsystems, and a variety of individual items that do not merit classification as systems.

The types of facilities employed in the assembly of on-board equipment differ considerably, as do assembly-line methods. Generally speaking, this type of aerospace product, small by comparison with airframe components, is assembled in low-bay buildings containing a number of separate work stations at which specific steps in the assembly process are accomplished. The growing assemblage is moved from station to station by conveyor or by wheeled cradling fixtures, frequently inspected or tested along the way. Some relatively simple equipment needs no assembly line; it is put together, inspected, and tested all at one work station.

In extensive use among aerospace manufacturers is the "clean room" type of facility, where assembly is conducted in a contamination-free atmosphere that rivals the surgical theatre. Clean-room assembly is imperative

"Clean room" assembly

for a great many systems that go into missiles, launch vehicles, and spacecraft (and, to a lesser extent, aircraft), complex equipments that are especially sensitive to environmental contamination; a particle of dust or a temperature outside certain rigid limits could cause a malfunction.

A typical clean room has an atmospheric-control system that rigidly controls temperature and humidity and bars entrance, by means of filters, of all but the tiniest mote of dust. Walls and ceilings are of one-piece plastic with no cracks where dust might collect and are washed and vacuumed daily. Maintenance cannot be done within the room: plumbing, wiring, and lighting are so arranged that maintenance can be handled in crawl spaces above the ceiling. The room has no sharp corners; they are rounded off to forestall dust collection.

Before entering, workers don special clean suits, including head covering and boots, and pass under an "air shower" that removes all loose particles of matter. The parts that make up the assembly are thoroughly cleaned and polished before delivery to the clean room, which they enter through an air lock.

Clean-room assembly is expensive and is used only when necessary, in most cases for the late stages or the final phase of the assembly procedure. The size of the room varies with the product; it may be from living-room size to a huge area considerably larger than a football field. Introduced in the latter 1950s with the development of sophisticated strategic missiles, clean-room assembly expanded over the years as systems became more complex.

Final assembly

The final assembly of the complete aerospace vehicle usually takes place in a large structure with a very lofty ceiling and no interior partitions or columns. Major aircraft require the tallest bays; some have tail sections reaching more than 65 feet (20 metres) above the floor. Additionally, the facility must accommodate a network of overhead rails over which ride heavy-lift cranes capable of moving large segments of the airplane.

Although flight-vehicle assembly bears little resemblance to systems assembly, the technique is the same in terms of movement through progressive work stations. At each work station, equipped with its own tools and workstands that provide access to all parts of the segment being worked upon, a certain number of assembly operations are performed according to a carefully considered manufacturing plan.

Assembly of an airplane begins with subassemblies. A typical subassembly for an airline-type plane is the rear fuselage section, itself composed of several segments. The segments are dollied or craned to the subassembly area, fitted together, and joined into a unit, and certain of the interior equipment is installed. In similar manner, plant teams put together other subassemblies; that is, other fuselage sections, wing sections, the tail section, and engine nacelle. The various subassemblies then join the main assembly line.

Mainline operations normally start with the joining, or mating, of two fuselage sections craned onto a supporting jig, or fixture. When all of the attendant joining and interior operations are completed, the embryo airplane moves to the next work station for mating with another subassembly. Light- and medium-weight aircraft may be moved on wheeled fixtures; heavier aircraft may be craned; and movement of modern supersize planes is accomplished by an adaptation of the air-cushion technique. The supporting fixture is a massive steel structure with a great many holes in its underside. Compressed air is pumped into the structure to escape downward through the holes. The thrusting force of the escaping high-pressure air lifts the entire structure and assembly off the floor a fraction of an inch, enough to permit movement of the assembly by an ordinary tractor. In this fashion, the budding airplane moves through a series of work stations, acquiring additional subassemblies one at a time and gradually accumulating its on-board systems and the maze of wiring, ducting, control cables, and other interior plumbing. Major steps include the matings of nose and tail sections, the wing, the engines, and the landing gear. Upon completion of work at the last station, the airplane is rolled out of the assembly plant to the flight line for production flight test, a process that by no means compares with the exhaustive research and development testing but that nonetheless involves a thorough check-out of specified performance.

There are many types of small missiles that require no such elaborate techniques or facilities. Composed basically of a cylindrical shell, a warhead, a guidance system, and a rocket motor, they are readily assembled in a simple low-bay plant. The larger missiles of the ballistic type and space-launch vehicles are assembled aircraft fashion in a high-bay facility, although most of them, horizontally mounted on the line, do not require the extreme bay heights of modern jumbo jet planes.

Spacecraft are unique among the flight vehicles because final assembly takes place under clean-room conditions. Preliminary assembly covering the mating of the structural elements is carried out in a conventional work area, after which the spacecraft goes through an air lock into an atmosphere-controlled chamber, where it is vacuumed and, in some cases, machine tumbled to shake loose dust particles. It then moves on to the final assembly clean room. Some spacecraft are assembled at progressive work stations; others remain in a fixed position while teams of specialists successively install the myriad on-board systems. Since the spacecraft gets no flight test, the equivalent, an intensely detailed acceptance checkout, is handled in the clean room by automatic test equipment. Then the spacecraft is encased in a steel container for shipment.

MAINTENANCE FACILITIES

The maintenance support provided by aerospace-industry firms revolves mostly around aircraft of the corporate, airline, or military types. Light-plane maintenance is generally handled by local fixed-base operators, not considered a part of the aerospace industrial complex. Launch vehicles and spacecraft, although they are maintained throughout their prelaunch life by constant checking and correction, are single-use systems. The smaller military missiles are maintained in the field by specialists in the operating unit. Major missiles similarly undergo routine maintenance at their field installation or silo base, but certain types of work are beyond the capabilities of field units. Overhaul of an inertial guidance system, for instance, requires special equipment and clean-room assembly, so it is usually returned to the plant of the original builder for re-manufacture.

Routine maintenance, normally accomplished by the civil or military operator, includes frequent inspections, sometimes after every flight, sometimes after a series of flights or a stated interval of time, and minor maintenance, such as replacement of a part or repair of a faulty item of equipment. This type of maintenance can be handled at most airline terminals and military bases.

Major maintenance of aircraft

Major maintenance involves complete rework of an airplane or engine that has had considerable service time. Some of the larger airlines have their own extensive facilities for major overhaul, and major military air forces have similar facilities. Even in these cases, however, some major maintenance work is contracted, as is the work of all other operators who do not have adequate facilities, to maintenance-specialist firms operating either independently or as a division of a major aerospace company.

These firms require facilities almost as elaborate as those of the original airplane or engine manufacturer: high-bay plants or hangars, machine tools, many types of inspection and test systems, engine-test cells, disassembly and assembly tools, parts- and components-cleaning equipment, equipment for overhaul of many of the on-board systems, and a complete inventory of spare parts. Maintenance companies are closely monitored as to capability and safety standards by appropriate government agencies. A maintenance firm must be certified by the agency for each type of product it overhauls, and a repair operation must be supervised by an agency-certified mechanic. Maintenance companies operate under

two additional guidelines: the original manufacturer of the equipment provides a manual outlining maintenance requirements and detailing specifications that must be met, down to the tolerance of an individual part, and the operator provides a similar manual, which lays down his own demands as to maintenance procedures and standards.

Airframe and engine overhaul. In a major airframe overhaul, the entire structure is disassembled, and each component is visually inspected for wear or damage. Additionally, structures are examined by X-ray, fluorescent, ultrasonic, and dye-penetrant methods to detect defects not visible to the eye. Corrosion is removed by sandblasting or vacuum blasting. Defective components are repaired or replaced, sometimes requiring machining operations to make a part. The airplane is reassembled, in much the same manner as it was originally assembled, repainted, then rolled out to the flight line for post-maintenance ground and air test, which is as thorough as the original production test.

Engine overhaul procedure

The procedure is similar in engine overhaul: complete disassembly, down to individual parts; removal of grease or carbon from each part; inspection of individual parts and measurement by precision equipment to insure conformance with the tolerance limits tabled in the manufacturer's manual; repair or replacement of any part that is even marginal; then reassembly via the progressive-workstation technique. After assembly the engine is mounted in a test cell and run through a lengthy series of tests as directed by the manuals. In all maintenance and overhaul operations, whether on airframe, engine, or accessories, technicians follow the same quality-control procedures that were in effect during original manufacture.

Remanufacture process. The most elaborate type of program under the general heading of maintenance is the remanufacture process, a military measure that combines a general overhaul with an updating of the airplane's performance capability. It is customary practice in aircraft manufacture to progress through several models of a basic airplane type, the later models incorporating design changes and better on-board systems dictated by service experience with the original model. Thus, older aircraft differ considerably from advanced models of the same type. If it is decided that a particular model, in service for several years, still has years of useful life, it is cheaper to upgrade its performance by remanufacture than to build additional aircraft of the advanced model.

Remanufacture is usually handled by a division of a major airframe company—perhaps, though not necessarily, the one that built the plane originally. The remanufacture facility needs additional capabilities; it must, for example, have design and engineering groups for the extensive modifications needed, and it must have the ability to manufacture large structural segments of the airplane if design changes so dictate. In this type of work the airplane is disassembled and stripped of its interior equipment and its engines, which almost always are replaced by improved models. After inspection and repair, the airframe segments that can be retained move through progressive work stations for step-by-step mating with new components. Similarly, the on-board equipment that is still usable is overhauled and delivered to the work stations for reincorporation, along with the new systems that design progression has specified. Reassembled, painted, and production-tested, the airplane begins life anew, a machine in most respects superior to the original.

(J.J.Ha.)

Aerospace Medicine

Beginning with determinations of oxygen requirements for pioneer balloonists by Paul Bert, a late 19th century French physician-physiologist, aerospace medicine has evolved as a highly specialized branch of medicine with innumerable responsibilities in support of flight in the atmosphere—aviation medicine—as well as beyond the atmosphere—space medicine. The ultimate aim of this specialty is to promote the safety and effectiveness of humans while they are exposed to the stresses encountered in aerospace flight.

In the role of clinician, specialists in civil and military aerospace medicine establish and apply appropriate medical standards for the certification and selection of pilots and other flight personnel to assure that they have no physical limitations or medical conditions that could impair their performance under usual or emergency flight conditions.

The work of aerospace medicine specialists

Aerospace medical specialists plan and help to carry out flight crew training in first aid and in the prevention of illness and injuries among passengers; they also assist in training paramedical personnel in the aerial transportation of patients. Such specialists also apply the principles of preventive medicine against the spread of disease by air travel and for the protection of aircraft crews and passengers from serious illnesses during trips to developing areas. They also conduct preflight and postflight medical evaluations of astronauts to assure fitness for space flight and to identify any adverse effects of space flight on the body. During space flight, they monitor physiologic responses of astronauts and advise them on the management of in-flight medical problems with the aid of the limited medical provisions on board the spacecraft. When any hazardous research or equipment testing causes exposure of human beings to simulated or actual aerospace environments, physicians establish safety standards and provide monitoring and therapeutic medical support as needed.

Beyond the scope of clinical medicine, aerospace medical specialists work with the multidisciplinary teams that develop the vehicles, emergency systems, and protective equipment for manned aerospace flight. With physiologists and psychologists, the medical specialists determine safe tolerance limits and performance capabilities. With the aid of other specialists—including those in biology, nutrition, and radiation—they provide aerospace engineers with data required for designing systems compatible with effective pilot functioning, comfort, and health. In the investigation of aircraft accidents, their role is to cooperate in the identification of causes of accidents, injuries, and death.

STRESSES OF AEROSPACE FLIGHT

Aerospace medicine is based on an understanding of the physiological, pathological, and psychological effects on humans of the various stresses encountered during flight.

Gaseous stresses. Although the percentage of oxygen in the Earth's atmosphere remains fairly constant, its partial pressure decreases along with the decrease in atmospheric pressure during ascent and thus produces oxygen deficiency, called hypoxia, in the exposed individual. At 10,000 feet (about 3,000 metres) hypoxia can significantly impair pilot performance. Above 10,000 feet, hypoxic symptoms, such as impairment of judgment, deterioration of fine muscular coordination, drowsiness, light-headedness, and unwarranted self-confidence, appear earlier and with greater frequency and severity after exposure to relatively small changes in altitude.

Problems from decrease of oxygen tension

Hypoxia can be aggravated by such factors as physical activity, fever, ingestion of alcohol, illness, and the taking of any of a number of drugs. Hypoxia can limit useful function within 10 to 15 minutes of exposure to the atmosphere at an elevation of 12,000–15,000 feet. At 20,000–

23,000 feet, unconsciousness can occur within several minutes; at 35,000 feet, within one-half to one minute; and at 43,000 feet and above, within 13–15 seconds. The time until death also diminishes rapidly with altitude, ranging from several hours at 22,000 feet to a few minutes at the highest altitudes, where breathing ceases and irreversible brain damage begins within four minutes of exposure. Ebullism, or boiling of body fluids, occurs immediately after exposure to altitudes above 63,000 feet and may significantly increase hypoxic effects.

Hypoxia can be prevented by maintaining an adequate atmospheric pressure in aircraft and spacecraft cabins, by supplying oxygen by mask, and by inducing acclimatization to altitude. For the safety of flight crews and passengers, the air pressure in cabins on airliners and military transport aircraft must be kept greater than the atmospheric pressure at 8,000 feet. Oxygen must be provided by mask if significant failure in cabin pressurization occurs. Spacecraft cabin atmospheres have varied considerably, from use of 100 percent oxygen at five pounds per square inch absolute (atmospheric pressure at sea level is 14.7 pounds per square inch absolute), in Mercury, Gemini, and Apollo spacecraft of the United States, to use of a mixture of 20 percent oxygen and 80 percent nitrogen at near sea level pressure in the Vostok and Voshkod spacecraft of the Soviet Union.

In small unpressurized and partly pressurized civilian and military aircraft, oxygen is provided by mask, either by continuous flow or on demand from an oxygen regulator. To conserve oxygen, most demand regulators gradually increase the concentration of oxygen in the inspired air, providing 100 percent oxygen at 34,000 feet altitude, at which the pressure of pure oxygen is equivalent to that of oxygen in air at sea level. For prolonged exposures from 34,000 to 43,000 feet and brief exposures up to 50,000 feet, oxygen must be supplied under pressure. At even higher altitudes man must be enclosed in a pressure suit to enable him to breathe oxygen at a life-sustaining pressure. Space suits used in some space missions have been pressurized with 100 percent oxygen at about 3.7 pounds per square inch absolute. Finally, even though improvement in altitude tolerance occurs after several days of exposure in a low-pressure chamber, such altitude acclimatization has not been practical in light of the protection offered by pressurized cabins, oxygen systems, and pressure suits.

Symptoms of hyperventilation

Hyperventilation—excessive rate and depth of breathing—with associated symptoms of dizziness, numbness and tingling, muscle tremors and spasm, and, finally, unconsciousness caused by the removal of abnormally large amounts of carbon dioxide from the blood, is much more likely to occur during exposure to high altitude than at usual elevations. Predisposing factors are anxiety, decreased air density, unfamiliarity with oxygen-breathing equipment, and hypoxia. To avoid serious impairment of performance, all aviators must learn to recognize hyperventilation at its onset and so take corrective action by consciously controlling rate and depth of breathing.

Re-entry problems during descent

During ascent, expanding gas in the middle ear always leaves it by way of the eustachian tube without difficulty, so that the middle ear and surrounding atmospheric pressures remain the same. During descent, however, gas re-entry can be impaired by inadequate opening of the eustachian tube; this often occurs in conjunction with the common cold. Aerotitis media—inflammation of the middle ear—with severe pain and hearing loss, can then occur from the effects of negative pressure on tissues surrounding the middle ear cavity. Another condition known as aerosinusitis, with associated excruciating pain, can be produced by inadequate pressure equalization of the nasal sinuses during descent, and occasionally ascent, in persons with severe inflammation of nasal tissues. Gas trapped in the stomach or large bowel can cause agonizing pain and fainting, and expanding gas trapped under dental fillings can produce excruciating pain. Rapid expansion of internal gas, as in sudden loss of aircraft, spacecraft, and space suit atmospheric pressure ("explosive" decompression), can damage lung tissues, even with respiratory passages open during decompression.

A potentially dangerous effect of exposure to high altitude is the formation of bubbles of nitrogen and other gases that had been dissolved in body fluids. This can lead to one or more manifestations of decompression sickness, including joint pains and, with much less frequency, chest pains and cough, skin symptoms, bizarre nervous system problems, and often fatal circulatory failure, or shock. Although 30,000 feet is generally considered the critical altitude for decompression sickness, strenuous physical activity, obesity, rapid ascent, and prolonged exposure to altitude have contributed to the occurrence of symptoms at as low as 18,000 feet. Decompression sickness is prevented by the maintenance of an adequate atmospheric pressure during flight or by "prebreathing" 100 percent oxygen for a period to reduce nitrogen in body tissues to a safe level before exposure to altitude (see COMPRESSION AND DECOMPRESSION INJURIES).

Toxic gas accumulation in the atmosphere is of particular concern in space flight. Carbon dioxide, a waste product of body metabolism, can reach toxic levels and severely limit mental and physical functions within minutes in space suits, or within hours in spacecraft cabins, if systems that remove carbon dioxide from their atmospheres fail or are temporarily overloaded. Highly toxic gases can also be introduced in aerospace atmospheres by accident and as by-products of combustion and thermal breakdown of materials. Possible toxic effects of trace contaminants that are produced in sealed environments by man, materials, and machinery assume increasing importance as space missions become longer in duration.

Kinetic stresses. The unique kinetic, or motion, environment of aerospace flight can be misinterpreted by the organs of equilibrium, leading to spatial disorientation. Failure to monitor or believe aircraft instruments that provide orienting information when flight situations produce sensory illusions is a common cause of fatal aircraft accidents.

Excessive stimulation of the organs of equilibrium, particularly by complex angular, or turning, head motions during aerospace flight, can produce motion (air) sickness, characterized in progressive order by stomach awareness, drowsiness, dizziness, cold perspiration, nausea, vomiting, and prostration. Apprehension, overheating, disagreeable odours, and high noise levels may be contributory factors. Motion sickness may be prevented by adapting to flight motions through training, by restricting head movement in flight, and by taking a motion sickness drug, such as scopolamine, meclizine, or cyclizine, well before flight (see MOTION SICKNESS). Motion sickness drugs frequently produce blurred vision and drowsiness, however, and thus they cannot be taken by pilots.

The forces of acceleration and deceleration, as encountered in aircraft banking turns, nosing over and pulling out of a dive, and in catapult takeoff, spacecraft engine firing, ejection escape, arrested landings, and parachute openings, can impair pilot performance and produce injuries. Accelerative forces of flight are stated in terms of multiples of the force imposed by the Earth's gravity, or *G*. Application of accelerative forces in the head-to-foot direction, or positive *G*, at levels of 4.5 to 6.0 *G* for longer than six seconds not only restricts muscular actions markedly because of the greatly increased body weight but also produces loss in peripheral vision (gray-out), then loss of central vision (blackout), then unconsciousness, because of the pulling of blood away from the head to pool in lower parts of the body. Tolerance to the high positive *G*-levels encountered in flying high-performance combat aircraft is considerably increased by applying pressure to lower parts of the body with a constricting garment, or *G*-suit. Human tolerance to headward, or negative, acceleration is only 2.5 to 3.0 *G* for a few seconds.

Effects of acceleration

Transverse *G*, or accelerative forces applied at right angles to the body's long axis, is tolerated well at levels up to 20 *G* for several seconds; this is particularly relevant to determining safe body positions for the sustained high *G*-loads imposed during launch and re-entry phases of

space flight, and for high impact forces, as occur in crashes. Tumbling and spinning from loss of control of aircraft and spacecraft, as well as from inadequate ejection system stabilization after escape from high-speed aircraft, can prevent physical attempts to regain control and produce marked spatial disorientation, motion sickness, and injuries. Severe vibration throughout the body is encountered, in particular, in high-speed, low-altitude flight, helicopter operations, and the boost and re-entry phases of space flight. Although this stress can seriously impair pilot performance, it rarely inflicts injury.

Aerospace systems, including propulsion units of aircraft and spacecraft and auxiliary maintenance apparatus, produce the most severe noise environments in existence. Excessive noise not only annoys, fatigues, diminishes performance, and interferes with speech communication but also produces temporary and permanent hearing loss and ear pain. Control of noise at its source is not practical in many aerospace situations, so hearing conservation programs must be instituted to monitor and control duration of noise exposure, provide personal sound protectors (such as earplugs, earmuffs, and helmets), and periodically evaluate hearing.

Exposure to weightlessness during space flight has resulted in a temporary intolerance of standing upright on return to Earth because of an excessive pooling of blood in the lower extremities. If this problem is indeed significant and is not counteracted by donning a constrictive lower body garment on return to Earth, simulation of *G* effects on blood vessels of the lower extremities by such measures as periodically applying negative pressure or accelerative forces to the lower part of the body may be necessary during long space missions. Significant, but by no means dangerous, loss of minerals from the bones and reduced work capacity observed after space flights may also require preventive measures during flights of long duration. Nausea and disorientation reported in Soviet space flights and stomach awareness and nausea experienced during early phases of American space flights have been attributed to excessive complex angular (turning) head movements while moving about freely in the weightless space environment. This problem has been prevented by intensive preflight training in high-performance aircraft and simulators and by controlling head movements for a period of hours to a few days into space flights.

Radiation stresses. The risk of exposure to microwaves with frequencies and intensities sufficient to damage the lens of the eye must be considered whenever radar and microwave ovens are used in aerospace systems. Thermal stresses of aerospace flight range from the high heat exposures that can result from inadequacies or breakdown of temperature control systems in high-speed aircraft, in spacecraft, and in space suits to the exposures to extreme cold that can occur during inadequately protected ejections from aircraft and during extra-vehicular operations in shaded space environments. Man's range of thermal comfort is rather narrow, and insufficient thermal protection in aerospace flight can lead to discomfort, heat disorders, burns, lowering of body temperature, and cold injuries.

Risks of eye injury

In high-altitude and space flight, the glare can be dazzling, with associated eye discomfort and reduced visual efficiency. The greater irradiance from the Sun in near Earth space than at sea level and absence of atmospheric scattering of light to give a warning glow as the line of sight approaches the Sun impose significant risks of transient and permanent visual impairment during space flight unless adequate light shielding is provided. Absorbed high in the atmosphere, ultraviolet radiation is of little concern in atmospheric flight, but in space it can produce so-called arc-welder's eye injury, or snow blindness, in relatively short unprotected exposure.

Harmful effects from exposure to the particulate radiations (*i.e.*, radiations of subatomic particles) in space are of concern in space mission planning and in spacecraft and space suit design. Avoidance of prolonged flights within the Van Allen radiation belts (zones of geomagnetically trapped protons and electrons surrounding the Earth) minimizes the risk of skin injury that could result from prolonged exposure. Essentially unpredictable in frequency, time of occurrence, and intensity, solar flares are the most uncertain and probably by far the greatest radiation hazard in space. Radiation measurements in near Earth aerospace environments indicate that even with the shielding provided by present-day manned spacecraft hulls, high-energy protons and possibly alpha particles emitted by several large solar flares in a few days, with astronauts beyond the protective umbrella of the Van Allen belts, might produce sufficient skin injury and possibly influenza-like symptoms to impair performance. It is not known whether galactic cosmic radiation, consisting of extremely high-energy atomic nuclei, is a hazard in space and whether virtual absence of magnetic fields in space will impose a significant stress on man, who has been exposed for aeons to the Earth's strong magnetic field.

Temporal stress. Man's circadian, or 24-hour, rhythm of wakefulness and sleep, with associated changes of practically all physiologic functions, is synchronized with the local geographic, light–darkness, day–night cycle. Although apparently not injurious, desynchronization of these cycles by flights across several time zones and into space can produce discomfort for many days from hunger, sleepiness, and wakefulness at the wrong times of day. Therefore, whenever flight personnel must perform at peak proficiency, their rest–activity cycles must either continue to synchronize with their originating time zone or be allowed time to resynchronize with a new time zone before flight. Various drugs for hastening resynchronization are being evaluated.

System stresses. Overestimation of man's mental and physical capabilities and inadequate provision for his comfort and basic needs in the design of aerospace systems can compromise his performance and health. Prolonged monitoring of flight panel instruments that are difficult to read, too numerous, provide too many data for continued comprehension, or are poorly arranged in terms of importance and range of effective visual scan can lead to serious piloting errors from visual and mental fatigue. Flight controls that are difficult to reach and manipulate or that coordinate poorly with aircraft and spacecraft response can also be mentally and physically fatiguing. Such psychologically and physically stressful factors as confinement, isolation, lack of privacy, uncomfortable seating, poor eating and sleeping arrangements, poor illumination, uncomfortable surrounding colours, extremes of humidity, noxious odours, hazardous equipment and protrusions, and insufficient accommodations for leisure and recreational activities are to be avoided if at all possible in both aircraft and spacecraft design. Particularly in spacecraft, and to a degree on military aircraft that fly missions of long duration, adequate supplies of food and water, provisions for elimination of bodily and other wastes from the environment, facilities for personal hygiene, and medical provisions all are necessary for optimum efficiency and health.

Psychological and physical stresses

AVIATION MEDICINE

History. As early as 1910, the German military was selecting pilots only with superior physical and mental qualifications and then making every effort to keep them at peak fitness and morale. This program placed both the American and the British air forces, which had not fully recognized the need for a special medical service for aviation, at a distinct disadvantage during the early years of World War I. Faced with an unbelievably high accident rate of one crash per 241 flying hours in 1917, the following year the United States Army established the Air Service Central Medical Research Laboratory, at Hazelhurst Field, Long Island, New York, "to investigate all conditions which affect the efficiency of military pilots and to consider all matters pertaining to their selection and their physical and mental fitness." This organization immediately began to improve medical standards for pilot selection, examine pilot candidates, identify and study stresses of flight, and train medical officers in the specialized duties of flight surgeon.

Having essentially the same responsibilities as flight surgeons of the 1970s, the first flight surgeons were to make medical support directly and personally available to all flight crew members, living and flying with them and understanding all stresses of flight in order to make medical care directly applicable to flying situations. In 1922 all instruction and research in aviation medicine in the American military services were conducted in the new School of Aviation Medicine at Mitchell Field, Long Island, with Louis H. Bauer, author of the first text on aviation medicine, as its first commander. This facility was the predecessor of the great existing military aerospace medical institutions in America, including the United States Air Force (USAF) School of Aerospace Medicine at Brooks Air Force Base, Texas; the United States Naval Aerospace Medical Center at Pensacola, Florida; and the USAF Aerospace Medical Research Laboratory at Wright Patterson Air Force Base, Ohio.

Early work at School of Aviation Medicine

As medical director of the new Aeronautics Branch of the Bureau of Air Commerce, Bauer developed the first medical standards for the certification of civil airmen and designated and trained the physicians to whom all civil airmen were to report for periodic medical certification.

Another milestone in the history of aviation medicine was the founding of the Aero Medical Association by Bauer in 1929. Now called the Aerospace Medical Association, this organization has grown from a group of 35 physicians to an international, interdisciplinary, active membership of more than 5,000 medical specialists, life scientists, and engineers in the field of aerospace medicine and bio-astronautics. Its constituent associations, which also participate in its annual scientific meetings, include the Airline Medical Directors Association, the Civil Aviation Medical Assocation, the Aerospace Industrial Life Sciences Association, the Society of U.S. Air Force Flight Surgeons, and the Space Medicine Branch. The Aerospace Medical Association publishes a monthly journal, *Aerospace Medicine*, formerly the *Journal of Aviation Medicine*.

The growth of aviation medicine has followed parallel routes in most countries. War efforts gave rise to intensive aeromedical research and flight surgeon training in such facilities as the Royal Air Force Institute of Aviation Medicine, Farnborough, England; the Royal Canadian Institute of Aviation Medicine, Toronto, Canada; the Kaiser Wilhelm Institute, Heidelberg, Germany; and the Army Aero Medical Laboratory, Tachikawa, Japan. Many other governments have established similar standards for medical certification of airmen, with the International Civil Aviation Organization, a specialized agency of the United Nations, serving as international coordinator, especially with respect to certification of airline pilots. The large European airlines have been active in all phases of aviation medicine. Chapters of the Aerospace Medical Association throughout the world and numerous other aeromedical organizations, including the International Academy of Aviation and Space Medicine, the International Astronautical Federation, and the European Congress of Aviation Medicine, sponsor international meetings for the exchange of knowledge in aerospace medicine. Other aerospace medical journals are *Aeromedica Acta*, *Space Life Sciences*, *Japanese Journal of Aerospace Medicine and Psychology*, and *Voyenno-Meditsinsky Zhurnal*.

International Civil Aviation Organization

Medical standards. In America, Part 67 of the Federal Aviation Regulations applies to the medical certification of civil airmen—including crews of fixed-wing powered aircraft, helicopters, powered gyrocopters, airships, and free balloons—by more than 7,000 designated aviation medical examiners across the country. Their primary concern is with any physical impairment or medical condition that could compromise safe pilot performance. The type of airman activity determines which minimum class of medical certificate must be held. A first-class certificate is required only for airline transport pilots, is valid for six months, and must be obtained from a specially designated senior aviation medical examiner. A second-class certificate is required for other commercial pilots, for flight engineers, and for flight navigators and is valid for 12 months. The third-class certificate is required for private, student, and free balloon pilots and is valid for two years. For medical certification, there is no age restriction, which is already determined by the various airman certificates required for specific flight activities. Citizenship is not a requirement for medical certification. Notably, all airmen must obey the regulation that states that

> no person may act as a pilot in command, or in any other capacity, as a required pilot flight crew member while he has a known physical deficiency that would make him unable to meet the physical requirements for his current medical certificate.

The airlines currently do not conduct certifying medical examinations on their pilots for the Federal Aviation Administration (FAA). Airlines having medical departments or contract arrangements for medical services conduct more comprehensive medical examinations, often including psychological testing, and apply more stringent standards in pilot selection than in FAA certification. In other countries many airlines conduct certifying examinations for their governments.

The military services conduct comprehensive physical and psychological examinations and apply stringent medical standards in pilot selection. Periodic medical examinations are given to all aircrew members by flight surgeons. When a flight surgeon must deny recertification for flight duties, further medical evaluation is usually conducted at a major military aerospace medical institution and final decision rendered by a panel of senior flight surgeons, all aerospace medical specialists.

Medical criteria for passenger flying. The ever-increasing number of passengers travelling by air includes a certain proportion who have various types and degrees of clinical disorders. In 1961 the Committee on Medical Criteria for Passenger Flying of the Aerospace Medical Association established guidelines for the airline industry and all physicians to improve the proper selection of patients for transportation by air. The guidelines were expected to minimize the risk of adverse effects of flight stresses on patients, disturbance of fellow passengers, requirements for special attention during flight, and the interruption of schedules and great expenses imposed by unscheduled landings to disembark ill passengers.

The committee advised physicians of the need to focus attention in particular on effects of atmospheric pressure changes on pre-existing clinical problems. It emphasized the risks of air travel for persons with serious heart or lung conditions or severe anemia; for infants under seven days of age; and for some women in the ninth month of pregnancy. The committee suggested that a person subject to epilepsy or unable to take care of his own physical needs be accompanied and that the safety of other passengers be considered before acceptance as a passenger of any person in a psychiatric state. It was advised that persons with contagious disease or whose behaviour might be hazardous be denied passage.

Medical training of flight crews. Instruction provided to airline cabin attendants, such as stewards and stewardesses, in the recognition and first-aid treatment of the more common medical problems that can occur during flight varies considerably. In general, airlines flying long, overwater routes have provided comprehensive aeromedically oriented first-aid courses, whereas short-route airlines have usually given minimum instruction in the basics of first aid. Flight deck crews—pilots, flight engineers, and navigators—of many airlines also receive aeromedical indoctrination, with particular emphasis on consequences of loss of cabin atmospheric pressure and instruction in the recognition of medical problems. Notably, no airline currently specifies that a nurse be a member of any cabin crew.

In the military services, all flight personnel initially receive thorough instruction in the stresses imposed by atmospheric flight and are thoroughly familiarized with the personal protective equipment available to them. Periodic refresher training may be required, depending on the type of aircraft flown. Instruction is conducted in an aviation physiology training unit by a team usually con-

Indoctrination of military flight personnel

sisting of a flight surgeon, aviation physiologist, aviation physiology technicians, parachute riggers, and other protective equipment technicians. A typical program includes discussion of flight stresses, their effects and protection from these effects, familiarization with various types of oxygen-breathing and other protective equipment, including *G*-suits, full-pressure suits, emergency escape systems, and parachutes. In high-altitude indoctrination, aviation personnel briefly experience hypoxia and, if required, training concerning the ejection seat, night vision, parachute and water survival, and flash blindness.

Aerial transportation of patients. Large-scale transportation of the ill and injured by specially equipped aircraft with in-flight medical attendants has mainly occurred in military services. For example, the Military Airlift Command of the United States Air Force operates a global network of aeromedical evacuation flights returning patients from overseas theatres to the United States and transferring patients within the United States to appropriate treatment centres. The air evacuation of battle casualties may be carried out in one or more highly coordinated steps, depending on severity of injuries. The injured soldier may be taken quickly by air ambulance from the battlefield to a forward hospital, where his condition is stabilized and treatment of his wounds is initiated. When he is ready to be moved, a cargo aircraft adapted for the purpose may transfer him to the nearest major or general hospital serving the theatre. If he is not likely to return to duty within a specified period, the soldier may be transported to the special military treatment centre nearest his home. All of these steps require the support of trained aeromedical crews. Medical technicians on air ambulances have sufficient training to permit them to continue first-aid treatment in flight and to recognize and cope with emergencies that may arise before the patient reaches the first medical treatment centre. In aircraft used in subsequent steps of the evacuation process, in-flight care is provided by specially trained flight nurses and aeromedical technicians. At each stop along any aeromedical evacuation route, physicians and nurses are informed on problems that may be encountered in flight. Also, the physicians who release patients for flight must know what medical complications can occur from flight stresses.

The civil aerial transportation of patients has not reached the magnitude of the corresponding military operation, since most illness or injury occurs when persons are reasonably near their homes and patients seldom have to travel far for special care. Nevertheless, there has been a marked increase in the use of air taxis to transport patients from one city to another and in the use of helicopter ambulance services to move patients quickly over short distances from accident sites to emergency hospitals. Helicopter ambulance services generally carry trained paramedical personnel and necessary medical equipment and supplies on board. Few air taxis, however, provide comparable aeromedical support. Consideration is being given to establishing standards for operation of any air ambulance service.

SPACE MEDICINE

History. In 1948 the United States Air Force School of Aviation Medicine, then at Randolph Air Force Base, Texas, sponsored the first symposium on space medicine; among the participants were several leading German scientists in the field of aviation medicine and space science. The following year, the school established the first department of space medicine in the world, with the former director of aeromedical research in the German Air Force, Hubertus Strughold, as its first professor of space medicine. Now acknowledged as the father of space medicine, Strughold had theorized for many years on the medical implications of space flight. Aware of the space flight ambitions of Gen. Walter Dornberger and rocket specialist Wernher von Braun of the V-2 rocket program at Peenemünde, on the Baltic, he estimated that intensive space medical research, paralleled by great technological advances, would make manned space flight feasible within 15 to 20 years. At that time, it appeared that with the exception of solar radiation and weightlessness, the stresses of space flight would be logical extensions of the not insurmountable stresses of atmospheric flight. This was borne out by data from ground-based research on the effects of acceleration, deceleration, and vibration noise, and atmospheric control, and from observation of pilot performances in the rocket-powered aircraft, as well as from knowledge gained from high-altitude balloon flights. Also in the pre-Sputnik era, American Aerobee rockets and captured V-2 rockets were used for the first time to expose living creatures to space flight conditions and to study effects of radiation and weightlessness in space on seeds, fruit flies, mice, and monkeys. Prior to his launch into space, man could be exposed to weightlessness only for periods of less than a minute in high-speed aircraft flown in parabolic trajectories.

First symposium on space medicine

Medical selection of astronauts. Early astronauts were a highly select group, in a medical sense, in that they were all military test pilots who had volunteered their services and were homogeneous in terms of flight experience and keen interest in the space program. After a medical records review and initial psychiatric and psychological screening, medical examination included conventional medical, family, and sociological histories; investigation into the attitudes of the immediate family toward hazardous flying; a physical examination conducted by flight surgeons, internists, and many other medical specialists; many laboratory tests; X-rays of the teeth, sinuses, chest, gastrointestinal system, heart, and lower backbone; and tests of lung function and exercise capacity. Many psychological tests were administered to determine personality and motivation, intelligence and special aptitudes. The astronaut candidates were subjected to a large number of stress tests of both a physiological and psychological nature.

Biomedical monitoring during space flight. Early in the American space program, aerospace medical specialists realized the need for continuously monitoring physiologic responses of astronauts during flight in order to make decisions about the medical feasibility of additional flight objectives, to assure the health and safety of astronauts, and to obtain biomedical information for predicting the effect of space flights of extended duration on man. The monitoring instrumentation had to provide reliable physiologic data, could not interfere with crew comfort or function, and had to be compatible with other spacecraft systems and be under virtually automatic control. Great advances subsequently made in developing new biosensors (devices for monitoring physiologic processes), in miniaturizing instrumentation, in transmitting physiologic data great distances, and in immediate analysis of these data by computer not only made possible the monitoring of man's physiologic state during aerospace flight but also provided the field of general medicine with tools for continuously monitoring patients undergoing diagnostic studies while they are confined to bed and during day-to-day activities.

Reasons for monitoring of astronauts

In later flights, body temperature, blood pressure, heart rate (determined by means of electrocardiograms), respiration, and voice transmissions of the astronauts were monitored by aerospace medical specialists while spacecraft were over tracking stations. Brain wave patterns and heart sound patterns were also recorded in Gemini flights on an on-board recorder. Electrocardiograms and respiration were recorded for one astronaut at a time during the first two Apollo flights and in later flights for all three astronauts at a time; their temperatures could be ascertained at any time. While spacecraft were behind the Moon, data were stored on a tape recorder and were transmitted to Earth as soon as the spacecraft came back into radio contact. When an astronaut was outside the spacecraft, his electrocardiogram and respiration were determined either through the space suit "umbilical" or by means of telemetry from equipment carried by the astronauts.

Medical experience in manned space flight. Over the years, many harmful consequences of space flight have been predicted on the basis of experiences in atmospheric

flight and on conjecture about effects of known and unknown stresses of the space environment on man. Man has tolerated all stresses thus far encountered in space flights without impairment of his performance or deterioration of his health. Medical experience in Mercury, Gemini, and Apollo missions is briefly summarized below.

Spacecraft cabin and space suit pressures were maintained without difficulty, and the astronauts lived in a comfortable, "shirt-sleeves" environment on later flights.

Effects of prolonged exposure to pure oxygen

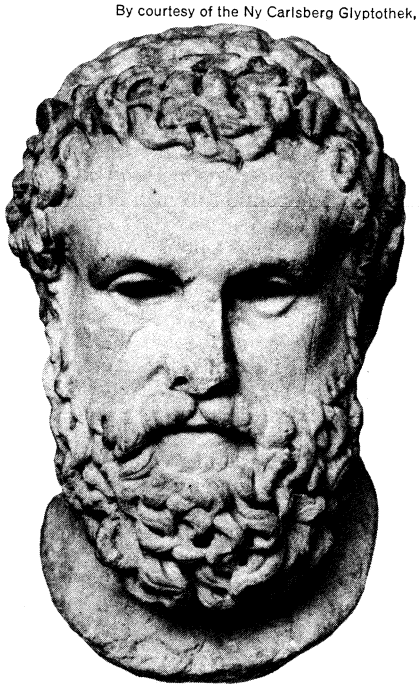
The only identified effect of prolonged exposure to the atmosphere of 100 percent oxygen at five pounds per square inch absolute of the pressure used in the spacecraft cabins has been a slight decrease in blood cell mass; this rapidly returned to normal in the postflight period. Removal of nitrogen from the blood by breathing 100 percent oxygen for three hours before flight has prevented decompression sickness.

Accelerative forces imposed during the launch and reentry have been well within man's limits of tolerance. Effects of weightlessness have been touched upon in the section above on *Stresses of aerospace flight*. Otherwise, adaptation to unusual sensations and effortless movement in the weightless environment has occurred rapidly, without any effect on proficiency. All extra-vehicular tasks in the lunar environment were also accomplished without significant difficulty. Predicted problems in eating and drinking were avoided by proper packaging of food and water. There was no difficulty in swallowing, digestion, or urination in space. Although greatly improved waste-management systems are required, collection and disposition of urine and feces under weightless conditions was accomplished without environmental contamination.

Even with penetration of the Van Allen belts, all radiation doses received during space missions were exceedingly small. No solar flares occurred while man was in space. Harmful effects of light and ultraviolet radiation were prevented by visual shielding and avoidance of gazing directly at the sun.

Passing through a day and night every 90 minutes in orbiting missions did not disrupt circadian rhythm. As more was learned about sleep in the space environment and more confidence gained in systems reliability, work–rest cycles of all astronauts were synchronized whenever possible with prelaunch schedules, and spacecraft were artificially darkened by covering windows. Sleep in the weightless environment was normal, except for being somewhat hampered early in missions as the crews adjusted to the desire for contact with some object during sleep.

Modified isolation of astronauts for 21 days before flight was employed in Apollo lunar missions in an attempt to reduce the risk of communicable illness during flight to a minimum. Colds, gastrointestinal upset with vomiting, eye irritation, minor skin problems, and urinary infection occurred in space; most symptoms were controlled effectively with medications from on-board medical kits. To preclude the possibility of contaminating the Earth's biosphere with lunar organisms, Apollo astronauts were subjected to strict decontamination and isolation procedures and were quarantined under close medical observation for 21 days after returning from lunar explorations. There was no evidence of infectious diseases that resulted from lunar material. This material contained no identifiable organisms and had no adverse effects on animal and plant life. The isolation procedure was abandoned in later missions.



BIBLIOGRAPHY. HUGH W. RANDEL (ed.), *Aerospace Medicine*, 2nd ed. (1971), is recognized as the principal reference textbook for specialists in aerospace medicine and aeromedical scientists throughout the world. JOHN A. GILLIES (ed.), *A Textbook of Aviation Physiology* (1965), provides detailed information on human responses to the aerospace environment and on aircrew protective equipment. ROBERT J. BENFORD, *Doctors in the Sky* (1955), traces the growth of organized aviation medicine in America as a narrative history of the Aero Medical Association. The USAF SCHOOL OF AVIATION MEDICINE, *German Aviation Medicine, World War II*, 2 vol. (1950, reprinted 1971), a historic classic, continues to serve as a basic reference for researchers in aerospace medicine, biomechanics, and human tolerance. DOUGLAS E. BUSBY (ed.), *Recent Advances in Aerospace Medicine* (1970), well demonstrates the scope of aerospace medicine in presenting key papers from the *Proceedings* of the 18th International Congress of Aviation and Space Medicine.

(D.E.Bu.)

Aeschylus

The first of classical Athens' three great writers of tragedy, Aeschylus lifted the art from its dim origins as choral and largely static recitative to fully developed drama, the presentation of action. At centre stage of most of Aeschylus' dramas stands man as a political being, reflecting the playwright's concern and the time in which he lived. Aeschylus was born under tyranny (in Greece, a government—not necessarily abusive—in which absolute power is vested in a single ruler), grew up in the turbulent period when the Athenian democracy had to prove itself against self-seeking politicians at home and invaders from abroad, and himself took part in his city's first struggles against the Persians. He later watched the political battle between liberals and conservatives, each fighting to turn Athens into their idea of what it should be. It is the tension between the often conflicting concerns of a leader for his people and for himself that provides the focus of tragic action in Aeschylus' plays.

By courtesy of the Ny Carlsberg Glyptothek, Copenhagen

Aeschylus, Roman copy of a Greek original, second half of the 4th century BC. In the Ny Carlsberg Glyptotek, Copenhagen.

Birth and background. According to the generally reliable Parian Chronicle (an inscription containing important dates in Greek history set up in the 3rd century BC), Aeschylus was 35 years old in 490 BC, the year of Marathon (the battle in which the Athenians routed Persian invaders), which puts his birth in 525 BC. His youth was spent in a time of ostensible if repressive political peace, when the sons of Peisistratus, a tryant who had held sway earlier in the century, held supreme power. A tradition that Aeschylus' family resided at Eleusis (northwest of Athens) may be true though it may rest only on a misunderstanding of a line in *The Frogs*, by the comic playwright Aristophanes. The historian Herodotus described a person whom other sources call the brother of Aeschylus as a resident of Pallene, which may indicate that the family really lived there. Of their father nothing is known beyond his name, Euphorion.

Dramatic career. In about 501 or 500 BC, Athens' major dramatic competition, the urban Dionysia, seems to have been reorganized; and, in one of the immediately

succeeding years, Aeschylus is recorded as having competed—probably for the first time. He won his first victory in the theatre in the spring of 484 BC (the title of the winning play is unknown).

In the meantime, he had helped to fight his country's battles. At Marathon, in 490, the poet, according to one tradition, was carried wounded off the field, his participation in this battle being singled out years later for mention on his epitaph. In 480 the Persians again invaded Greece, and once again Aeschylus saw service, fighting at Artemisium (on northernmost Euboea, off Greece's east coast) and at Salamis (near Athens), his role in the latter battle being attested by the poet Ion.

Aeschylus thus saw at firsthand how close Greece had come to annihilation, how truly miraculous had been its deliverance, above all, how much it owed to the foresight and planning of Themistocles (a statesman and general). These impressions took root in his imagination and blossomed in his play *Persians*, the earliest of his works to survive. Produced in the competition of the spring of 472 BC, it won first prize. The whole panorama of the enemy's onslaught and the Greeks' repulse is here: the colossal ambition of Persia's king thwarted by a force of democratically governed Athenians responding with vigour and precision to the commands of their inspired leader.

Earliest surviving work

Aeschylus acceded to the request of the Sicilian tyrant Hieron I to present *Persians* again at Syracuse (in Sicily), where, either on this same occasion or, as seems more likely, some years before, he had also staged a pageant, *The Women of Etna*. Ancient biographical traditions contain a number of elaborate but self-contradictory stories about the poet's visits to Sicily. According to one tale, he went there out of pique at losing to Simonides, a well-known writer of victory songs and commemorative dedications, in a competition to memorialize the heroes of the Marathon; or again he was said to have been escaping his countrymen's superstitious wrath when the theatre's seats collapsed during one of his performances. Neither account rings true: the first is likely to be nothing more than an embellishment on the known fact that Aeschylus wrote an elegiac poem about the Marathon campaign; the second was also told of the contemporary dramatist Pratinas. The presence of Aeschylus at the court of Hieron I does, however, raise large questions, about how a poet whose loathing of tyranny resounds through every line of *Prometheus Bound* could have written *The Women of Etna*, a piece honouring the foundation of the tyrant Hieron's new city of Etna. An answer may be found in the tone the poet took: if a papyrus fragment published in 1952 contains, as is now widely believed, a passage from Aeschylus' lost pageant, the prominence of the figure of Justice in it may be significant; Justice, in Aeschylus' words, "sits by the throne of Zeus . . . honouring the just life of those who are just." This is more admonition than praise, an ideal to which the dramatist is urging Hieron to aspire. A production of *Persians* at Syracuse may also be interpreted in this light. The tyrant's brother and predecessor, Gelon, had refused to answer a Greek summons for help before Salamis but had successfully routed an invading force from the North African city of Carthage that coincided with the Persian invasion, and Hieron himself had repulsed the Etruscans at Cyme, Italy, in 474 BC. Rivalry and animosity must now be laid to rest, Aeschylus may be saying, and, with the eastern and western barbarian invaders driven off, Greece must now unite under the standard of freedom and justice.

The sources attest Aeschylus' acquaintance with a number of other writers, some of whom he must have met, though probably not for the first time, at Hieron's court. The Byzantine scholar Eustathius records Aeschylus' association with the lyric poet Pindar, who was seven years his junior and who, as a young man, had studied at Athens, where he won a dithyrambic (dithyrambs were types of choral ode) contest in 497/496 BC. The two poets show certain similarities of theme and treatment (a taste for unusual metaphors and graphic personifications of Mt. Etna's eruption, for example), and Pindar was later said to have acquired his "grandiloquence" from Aeschylus. Aeschylus' city-centred and essentially democratic view of man, however, is a world away from Pindar's praise of manliness as manifested in the athletic contests, a virtue that is supranational and, so ultimately, rootless. Apart from a probably spurious story of Aeschylus' defeat by the prolific and versatile lyric poet Simonides, no direct evidence links the two men. It is likely, however, that they had met in the circle about Themistocles, for both manifested in their own ways the extent to which each had fallen under the general's spell; and, since Simonides is mentioned as an habitué of Hieron's court, the two may have renewed their acquaintance there. Just as Aeschylus had taken over (particularly in *Persians*) some techniques from the older tragic dramatist Phrynichus, Sophocles, another of the great Athenian tragedians, fell under Aeschylus' influence, as he himself was later to admit when he described his early style as one of Aeschylean "weightiness." (There are signs that, during the decade or so when the two were competing at Athens, some reverse influences may also have been at work; for *Prometheus Bound*, considered by many critics to be Aeschylus' last play, shows a surprisingly large number of Sophocles' tricks of style.) It was probably in the 460s that Aeschylus first met Ion, a young poet from the Greek island of Chios, who had recently arrived in Athens.

Association with Pindar and Sophocles

Aeschylus' later career is a record of his dramatic success—and one stunning defeat, at the hands of the neophyte Sophocles, whose maiden performance at the Dionysiac festival of 468 BC was victorious over the older poet's entry. But suspicious circumstances surrounded the victory. The Greek biographer and historian Plutarch (*c.* AD 46–*c.* 119) records that the usual judging procedures were suspended, and the board of generals, headed by the conservative politician Cimon, received the honour of deciding the winner in the drama competition. It is hard to avoid the conclusion that politics clouded the general's critical faculties and that Cimon may have been reacting to Aeschylus' support—four years earlier, in *Persians*—of Themistocles, his bitter rival. A palpably erroneous tradition has the dramatist resentfully going off once more to Sicily; in fact, Aeschylus recouped the loss with a victory in the year 467, with his Oedipus trilogy, of which only the finale, *Seven Against Thebes*, survives. "A drama full of Ares [the Greek God of War]," the professor of rhetoric Gorgias called it, and the vivid picture it presents of Thebes (about 45 miles northwest of Athens) under attack by an invading force from Argos (Sparta's rival in southern Greece) was probably coloured by memories of the Persian threat to Athens in 480 BC. Eteocles, the play's hero, acts according to his lights to defend his city but goes off to slay his brother Polyneices and in turn be slain by him under the curse of blood from which the ill-starred family of Oedipus suffers. Also dating from the 460s is the Danaid (named after Danaus, a major figure in the legend dramatized by Aeschylus) trilogy, of which only the opening play, *Suppliants*, survives. The drama presents the agonizing dilemma of a leader who is approached by refugees demanding protection and asylum; if the King grants their request, he is likely to embroil his own people in bloody war. The anguish felt by the mythical Pelasgus is similar to that which Athens must have experienced when it was approached by the Ionian revolutionaries in 499 BC and also, more recently, by the Argives, who had given shelter to the outcast Themistocles; neither parallel can have been far from Aeschylus' mind when he wrote his emotion-filled piece. In 462 the Athenian constitution was reformed along radical lines and the conservative Cimon exiled, not without the infliction of deep political wounds by the opposing factions and the actual shedding of blood. Aeschylus' Orestes trilogy of 458 reflects this atmosphere of citizen armed against citizen, "tribal war" in the poet's own phrase; but, in the Aeschylean resolution, strife gives way to harmony, bloodshed to peace, revolution to the rule of law. Old divinities such as the Furies are transformed and given a constructive function in Athena's city, and they thus become its Eumenides, or "Well-Wishers."

The Oedipus and Danaid trilogies

After the *Oresteia*, Aeschylus went to Sicily for the last time; Aristophanes has his comic Aeschylus say in *The*

Frogs that he "did not get on with the Athenians," which need not be taken entirely seriously. A later, sensationalizing tradition invented a full-scale trial before the Areopagus (the Athenian council of justice)—much like the trial conceived by Aeschylus himself for Orestes in *Eumenides*—for revealing the content of the secret rites held at Eleusis. All of this seems to be sheer fiction. The chronographers recorded his death at Gela (on Sicily's south coast) in 456/455, aged 69. A ludicrous story that he was killed when an eagle dropped a tortoise on his bald pate was probably fabricated by a later comic writer. At Gela he was accorded "heroic" honours, a public funeral with sacrifices and dramatic performances held at his grave, which subsequently became a place of pilgrimage for writers. A later tyrant of Syracuse, Dionysius I, was said to have taken pains to acquire the poet's writing desk, which he revered as a sacred relic.

Reputation and influence. Aeschylus' career had been outstandingly successful. One account, perhaps based on the official lists, assigns him 13 first-place victories; in short, out of over 80 known titles, 52 won first prize. The Athenians took the unprecedented step of decreeing that anyone who wished should be allowed to reproduce his works in the festival competitions; and it may have been on this occasion that he was awarded the title "Father of Tragedy," which is mentioned by the Sophist philosopher Flavius Philostratus (*c.* AD 170–*c.* 245). No specific dates of repeat productions are known, but the sources speak of victories won by posthumous performances of his plays, and comic reminiscences in Aristophanes (especially in *The Birds* and *The Frogs*) suggest that there may have been revivals during the Peloponnesian War (431–404 BC). On the motion of the Athenian politician Lycurgus, bronze statues of the three great classical tragedians were set up in the Theatre of Dionysus (below the Acropolis in Athens) in the 330s. Several Roman copies are thought to derive from this "official" statue, which in any case could have been nothing more than an idealized impression. A bust in Rome's Capitoline Museum, which portrays a bald-headed pensive man well beyond middle age, may derive from a true likeness, the original perhaps having been commissioned by the citizens of Gela.

Aeschylus' two sons also achieved prominence as tragedians. Although one of them, Euphorion, is said to have won four victories with posthumous new productions of his father's plays, he also won first prize in his own right in 431 BC over Sophocles and Euripides' *Medea*.

Aeschylus' artistic innovations

Aeschylus' influence on the development of tradedy was considerable. He is said to have introduced into Greek drama the second actor who had an individual character and dialogue, thereby supplanting the theatrical convention of having only a single performer and a chorus. This innovation allowed much more variety and dynamic tension in plot construction and dialogue. Although a stage designer, Agatharchus, is mentioned as an associate of his, it is doubtful whether full-scale painted scenery (*e.g.*, a realistic Causasus mountain backdrop for *Prometheus Bound*) could have been in use so early. His works were in any case known for their spectacular scenic effects (*e.g.*, the bizarre modes of conveyance for characters in *Prometheus*; the sleeping, snorting Furies tableau in *Eumenides*) and exotic, often terrifying masks and costumes; the first appearance of his chorus of *Eumenides* was said to have struck terror in the spectators. It appears that he reduced the size of the chorus and standardized their number at 12, as well as altering the chorus' function. Although the dominance of the chorus in early tragedy is a mere hypothesis, it is probably true that, in the words of the Greek philosopher Aristotle, Aeschylus "reduced the chorus' role and made the plot the leading actor." At the same time, he dispensed with the services of a choreographer, training his choruses himself and even devising new dance steps for them to perform. He probably acted in most of his own plays, following the practice usual among dramatists at the time.

Although the Roman statesman and orator Cicero cites and even translates numerous passages from Aeschylus' works, by the 1st century AD the Romans' grasp of his difficult language began to slip; the rhetorician Quintilian, for example, found him "rough and disjointed." By the 2nd century AD, Aeschylus had slipped to a position of secondary popularity. In 1475 the papal library of Sixtus IV contained but three manuscripts of Aeschylus. In the late 18th century, however, Aeschylus was "rediscovered"; the *Agamemnon* was a favourite of Napoleon's, and the distinguished French writer Victor Hugo fully appreciated the poet's genius. With Percy Bysshe Shelley's *Prometheus Unbound* (1820), Aeschylean inspiration entered the mainstream of English poetry. In the 20th century the writers who have fallen most deeply under his influence are the French poet and dramatist Paul Claudel and the U.S. playwright Eugene O'Neill, whose *Mourning Becomes Electra* (1931) captures better than perhaps any other modern work the brooding grandeur of Aeschylus.

MAJOR WORKS

TRAGEDIES: *Persai* (472 BC; Latin, *Persae;* Eng. trans., *Persians*); *Hepta epi Thebas* (467 BC; Latin, *Septem contra Thebas;* Eng. trans., *Seven Against Thebes*); *Hiketides* (463 BC; Latin, *Supplices;* Eng. trans., *Suppliants*); the trilogy known as the *Oresteia* (458 BC), comprising *Agamemnon, Choephoroi* (Eng. trans., *The Libation Bearers*), and the *Eumenides* (Eng. trans., *The Furies*); *Prometheus desmotes* (date uncertain, probably late; Latin, *Prometheus vinctus;* Eng. trans., *Prometheus Bound*).

BIBLIOGRAPHY. The Greek text of the complete plays is available in editions by ULRICH VON WILAMOWITZ-MOELLENDORF (1914, reprinted 1958); and GILBERT MURRAY, 2nd ed. (1955); a new edition by D.L. PAGE appeared in 1972. H.J. METTE has edited the fragments (1959), in German. H. WEIR SMYTH provides a literal prose translation in his "Loeb Classical Library" edition, 2 vol. (1922–26; reprinted 1956 and 1963), of which the second volume also contains a translation of the major fragments, and HUGH LLOYD-JONES contributes an appendix of recent discoveries. The "University of Chicago Greek Tragedies Series" provides verse translations by RICHMOND LATTIMORE *et al.* (1953; also available in paperback) and the "Prentice-Hall Greek Drama Series" is issuing up-to-date translations with literary commentary (1970–). Studies of special topics relating to Aeschylus' plays are: A.J. PODLECKI, *The Political Background of Aeschylean Tragedy* (1966); and A.F. GARVIE, *Aeschylus' "Supplices": Play and Trilogy* (1969). Articles on specific subjects include: E.R. DODDS, "Morals and Politics in the *Oresteia*," *Proceedings of the Cambridge Philological Society*, 186:19–31 (1960); HUGH LLOYD-JONES, "Zeus in Aeschylus," *Journal of Hellenic Studies*, 76:55–67 (1956); and C.J. HERINGTON, "Aeschylus in Sicily," *ibid.*, 87:74–85 (1967). The various candidates for Aeschylus' portrait are illustrated by G.M.A. RICHTER in *The Portraits of the Greeks*, vol. 1, figures 577–610 (1965). For a useful collection of modern criticism, see MARSH H. MCCALL (ed.), *Aeschylus* (1972).

Aesthetics

Nature and scope of aesthetics as a discipline

The discipline called aesthetics may be described broadly as the study of beauty and, to a lesser extent, its opposite, the ugly. It may include general or theoretical studies of the arts and of related types of experiences, such as those of the philosophy of art, art criticism, and the psychology and sociology of the arts. The word general is emphasized because a narrowly specialized study of a particular work of art or artist would not ordinarily be regarded as an example of aesthetics, although it might provide data for aesthetics. Aesthetics has often been defined more specifically as the science of the beautiful, a definition implying an organized body of knowledge covering a special field of subject matter. Although this raises the question of what properly is a science and what is its subject matter, it at least has the advantage of bringing aesthetics into some relation with the familiar special sciences of today and suggesting that it may be a recent development—which in fact it is.

The arts may include the visual and theatre arts, music, dance, and literature. In the ancient world, there was no clear distinction between aesthetic and useful art.

Aesthetics as a philosophic or scientific discipline is not to be confused with art, though it may undertake to study the arts in a more or less intellectual, logical way. To develop an empirical science of aesthetics or a philosophi-

cal approach to one, it is not enough to create or enjoy works of art. It is necessary also to try to understand, explain, and perhaps evaluate them. Aesthetic evaluation, however, has been slow to develop toward science.

For related articles dealing with the broadest aesthetic principles in all of the arts, see ART, PHILOSOPHY OF, which stresses the experience of artistic creativity (while the present article stresses that of the viewer and appreciator); ARTS, CLASSIFICATION OF THE; ARTS, CRITICISM OF THE; ARTS, SOCIAL AND ECONOMIC ASPECTS OF THE; ARTS, PRACTICE AND PROFESSION OF THE; ARTS, STYLE IN THE; PRIMITIVE, FOLK, AND POPULAR ARTS. For discussions of aesthetic principles operative in the major mediums of the arts, see LITERATURE, ART OF; DANCE, ART OF; MUSIC, ART OF; THEATRE, ART OF; ARCHITECTURE, ART OF; SCULPTURE, ART OF; PAINTING, ART OF; PHOTOGRAPHY, ART OF; MOTION PICTURES, ART OF. (Th.M./S.C.P.)

NATURE AND ORIGIN OF MODERN AESTHETICS

For the Greeks there were no special sciences; yet they had a voracious appetite for knowledge. There were special skills and techniques such as shoemaking, carpentry, shipbuilding, sailing, fishing, farming, and animal breeding. But among the men who were pursuing knowledge for its own sake, the so-called philosophers, though there were vigorously opposed schools of thought on numerous issues, there were no divisions of subject matter. The special sciences did not break away from philosophy till many years later, largely in the 17th century and thereafter. The breaks came when there was so much to be known in a special field that it was all that one man could do to master it.

Philosophy as the mother discipline

Philosophy, however, continued as a centre for nonspecialized knowledge and general comprehension and as the seat for potential specialties yet to come. The last of the special sciences to break away from philosophy was psychology, a break that occurred in the mid-1920s, previous to which time psychology had been a special subject within the field of philosophy. This position, however, is held today by aesthetics: it remains a part of philosophy, rather highly specialized but not so specialized as to break away completely.

Baumgarten's naming of the field. Aesthetics was even late in recognizing itself as a special field within philosophy and in acquiring its name. The name aesthetics first appeared in *Reflections on Poetry* (1735), by Alexander Baumgarten, a follower of the Rationalistic school of philosophy under the influence of René Descartes, the father of modern philosophy, and Gottfried Wilhelm Leibniz, a polymath German philosopher. These men had not given attention to aesthetic matters; their concern had focussed upon what Descartes had distinguished as "clear and distinct" ideas, by which was meant systematic thought as developed in logic and mathematics. This distinction restricted cognition to conceptual knowledge. Baumgarten noticed, however, that sensory and perceptual cognition was thereby excluded. It appeared to him that here was to be found just the sort of cognition developed in poetry and the other arts and that the Cartesian restriction resulted in a serious omission; thus he set to work to correct this oversight.

In Descartes's terms, "clear" meant what was unquestionably apparent to an attentive mind and "distinct" what was precisely differentiated from other things or internally articulated. In a geometrical system all of the terms and propositions are presumably clear and distinct. Ordinary discourse is usually just the opposite: obscure and confused. Sensations and perceptions were regarded as intrinsically confused. They could be clear, however; and when they were so, men had a definite kind of cognition (though of a lower order than clear and distinct logical cognition). This perceptual cognition is what Baumgarten found in poetry (and by extension in the other arts). Drawing upon the Greek word for perception (*aisthēsis*), Baumgarten coined the word aesthetics for the science of perceptual cognition—*i.e.*, of perception as clear but confused knowledge. His book is a systematic exposition of this subject matter, with many examples from Latin and Greek poetry indicating that the greater the perceptual clarity achieved in a poem the greater its poetic perfection. Thus Baumgarten's term aesthetics has become a permanent part of the vocabulary of philosophy.

Proportions of clear and confused ideas

The basic conclusion of his analysis can be stated in these terms: the aesthetic value, the beauty, of a poem is proportional to the extent of clear, as compared with confused, ideas that it contains; or—paraphrased in the terms of contemporary theory—the aesthetic value of a work of art is proportional to the intuited vividness of the fused quality of the experience that it evokes.

Baumgarten's work is important in the history of aesthetics. In spite of its strange terms and its forbidding mode of exposition (presented like a Euclidean geometry with axiomatic definitions and deduced propositions) and in spite of its poetic illustrations in languages that almost no one can understand today, it is well worth reading, for it marks the beginning of aesthetics as a special field of investigation.

Toward a well-rounded conception of aesthetics. To get a well-rounded conception of how aesthetics has developed since Baumgarten started it out on its own, it is necessary to review some of the principal aesthetic theories that have come to prominence and maintained themselves. The crucial question is what constitutes the subject matter for this sort of special study. In a general way Baumgarten has already demarcated it: its subject matter is the sort of responses and experience that works of art were created to produce, to which may be added natural objects and any other things that can evoke the same sort of experience. The central material here is the aesthetic experience.

But works of art themselves cannot be neglected either. Actually, for any extended investigation of the field, there is a reciprocity between the works of art and the aesthetic experience. No aesthetic theory will stand up if it cannot explain why certain works of art are outstanding exemplifications, embodiments, or stimuli for the aesthetic experience. The works need not be limited to the so-called classics (though these manifest a high degree of persistence in demanding recognition). They may be artifacts of primitive people; they may be fairly enduring rituals or traditions or customs of certain sorts or routines as for a dance or techniques. The justification for an aesthetic theory, the evidences for it, will almost inevitably in the end be sought in the aesthetic arts.

Baumgarten constantly appealed to passages of poetry to support his theory. It is as if the instigating problem for aesthetics were to account for the values attributed to these arts—to poetry, drama, dance, music, painting, sculpture, architecture. Having explained the values of the arts, a theory may then expand these values as widely as they may go to natural objects, to acts of living, eating and drinking, playing and loving, and even to dreaming. But it is the explanation that can be given for deeply prized works of art that stabilizes an aesthetic theory.

Philosophical theories reflected in aesthetics

The various conceptions of aesthetic value (or aesthetic experience) may be summarized as they have developed under the guidance of four or five philosophical theories that have been widely influential in modern times. Their development as aesthetic theories has been relatively recent, though traces of them—or even partial systematizations of some of them—can be found as far back as the ancient Greeks. There is now no single dominant theory of aesthetic value. Nor can these four or five views be consistently amalgamated into one; for each holds to be dominant a certain feature that the others would accept only as subordinate. But a sympathetic understanding of each will illumine the ways in which aesthetic values arise in this special field. There is a fair amount of agreement as to the core of the field and even as to the possible expansions of it, though the precise demarcation of the boundaries varies with each view. The chief difference among these views seems to lie in the way they distribute their value emphases within the field.

NATURALISTIC OR SCIENTIFIC APPROACHES TO AESTHETICS

Hedonism: the pleasure theory. The simplest and most liberal of these views is that which identifies the aesthet-

ic experience with some distinctive sort of pleasure, satisfaction, or liking. As a starting point for discussion, this theory has the advantage that it spreads out before the reader practically the whole field of the psychological data with which any sort of aesthetic theory will find itself concerned. Not all aesthetic subject matter is psychological, but a large proportion of it is—obviously all that has to do with aesthetic appreciation. There is no more direct way of initiating this survey than through this simple psychological approach, which merely says in principle that an aesthetic fact is a way of finding pleasures and satisfactions in things.

If pleasure is allowed to include satisfactions of any kind, this theory can properly be called the pleasure theory, or hedonism. It has a long history. It comes out of a naturalistic philosophical approach. Pleasure is equated with positive value and pain or unpleasantness with negative value. Aesthetic value is distinguished from other values, such as the ethical, by one or more special traits. In the broadest sense aesthetic value is taken as intrinsic pleasure or the liking of a thing for itself, as against liking it as a means to an end. Aesthetic values are immediate (direct) as opposed to mediate or practical values.

Element analysis of aesthetic value

This view lends itself easily to a typical mode of scientific analysis—that of element analysis such as one finds in chemistry, in which atoms combine into molecules and these into living cells and cells into organisms. Thus, aesthetic values can be conceived as building up from elementary sensory pleasures and likings, to combinations of these into aesthetic forms and modes of composition, and thence to the organizations of works of art, which in turn get gathered together into styles of art. This conception of aesthetic analysis accorded well with an important school of so-called structural psychology, which had been producing the most constructive introspective and physiological research from the time of the 17th-century Empiricist John Locke until the mid-20th century, so that the data and laboratory results of this school could be utilized for an analytical aesthetics.

One of the virtues of a naturalistic aesthetics is the emphasis it spontaneously gives to the simplest aesthetic delights.

Santayana's version of the pleasure theory. This emphasis comes out in *The Sense of Beauty* (1896), by George Santayana, a Spanish-born Harvard naturalist, in which he presented the first fully systematized aesthetics couched in hedonistic terms—and, in fact, the first such naturalistic theory. The book is a classic literary work of art in itself. Its analysis is divided into three parts: the materials of beauty, form, and expression.

Materials of beauty. The first sort of materials that Santayana mentions are those connected with man's vital functions. "They are loose," he says,

> and unlocalized, having no special organ, or one which is internal and hidden within the body. . . . Particularly important are they for the *value* of our experience. They constitute health, without which no pleasure can be pure.

Then he presents a whole section on the aesthetic importance of sex from both its direct and indirect expression. These passages read like a poem at the same time that they give a condensed psychological analysis of wide significance. The following passage may be quoted both for its beauty and its insight:

> Sex is not the only object of sexual passion. When love lacks its specific object, when it does not yet understand itself, or has been sacrificed to some other interest, we see the stifled fire bursting out in various directions. One is religious devotion, another is zealous philanthropy, a third is the fondling of pet animals, but not the least fortunate is the love of nature, and of art; for nature also is often a second mistress that consoles us for the loss of a first.

Pleasures of the senses

On turning next to the pleasures of the senses, Santayana admits that, as aesthetic materials, the lower senses—touch, taste, and smell—lack the capacities to combine into large works of art as sound and the visual materials can. For that reason the term beauty, as denoting aesthetic value in the highest (and perhaps most proper) sense, could be withheld from them (though many naturalistic aestheticians would not agree with this restriction). But the stress on the aesthetic value of pure simple sensuous pleasures is ever present in Santayana. He writes:

> Sensuous beauty is not the greatest or most important element of effect, but it is the most primitive and fundamental, and the most universal. . . . Taste, when it is spontaneous, always begins with the senses. . . . When sincerity is lost, and a snobbish ambition is substituted bad taste comes in. The essence of it is a substitution of non-aesthetic for aesthetic values.

Form. Aesthetic form comes when an aesthetic pleasure arises from a combination of elements that individually have little or no value: thus a triangle may be exciting when its individual lines are dead; and a musical chord can give a satisfaction far beyond what its component notes can yield separately. He distinguished between two sorts of form: compositional form and what he called types (see below).

Design and pattern

In later work in naturalistic aesthetics, two varieties of compositional form were distinguished, viz., design and pattern. The function of design is, negatively, to avoid monotony or aesthetic fatigue. Out of this come aesthetic principles or laws of contrast and of theme and variation. When a particular kind of aesthetic satisfaction begins to pall, interest in it can be revived by a contrasting pleasant stimulus. Theme and variation is even more effective in avoiding monotony and maintaining interest because it can continue longer. Some whole musical compositions are built on this principle only. An interesting theme or motive or tune is announced and then repeated with variations of rhythm or accompaniment or key or even of some of its notes. With such variations the theme can be repeated many times without loss of interest. And finally the original melody can be repeated, as it was first given, and it will come as something fresh and welcome. Contrast and theme and variation can cooperate with each other, as they do in the familiar three-part form of music—the first part developing a certain theme, followed by a contrasting part developing new material in a different key or mood, followed in turn by a repetition of the first part, which gives a natural and comfortable ending. These principles are equally effective when used simultaneously as in the visual arts. Sustained visual design depends greatly on their mutual cooperation. Architectural design makes impressive use of them.

Turning next to pattern, it is clear that the compositional function of pattern is, negatively, to avoid confusion—as the function of design was to avoid monotony. The pattern depends greatly on what the Chinese called "the rule of five," which refers to the limitations of the attention span. A viewer can take in five elements at a glance without counting. In fact, he can take in even a few more; but five is easy, and an artist can count on it with assurance. Aesthetic order (not mathematical order, which is quite different) depends entirely on this principle, unless some other principle has already bound the elements together. Thus aesthetic order can be obtained by groupings that fall within the range of the attention span—*i.e.*, by groups of groups of groups of not more than five or so. The stanzas of regular versification, for example, are groups of lines, which are groups of verse feet—little patterns of rarely more than two or three syllables with different accents or durations—which, in turn, are groups of uttered syllables. The verse feet are gathered into lines of rarely more than six or seven feet, and when they are that long there is generally a secondary break in the middle known as a caesura. Stanzas are often four lines long. If they are longer than that, their patterns are internally divided by rhymes or regular variations of lengths of line that keep them within the attention span and so aesthetically well-ordered. Large organizing patterns of this embracing sort or of other sorts can bring whole works of art with hundreds of details into transparent order. Where such order is missing there is confusion, unless other connections are also present to help produce an overall unity of pattern.

Santayana's notion of type

What Santayana called type is another such mode of aesthetic organization. Types, which are produced as a result of learning, are said to be the concepts that men

have developed in making adjustments to their social and physical environment. They are of many kinds. What may be called natural types are a person's means of recognizing types of objects and features of his natural environment—animals and plants, clouds and seas and mountains, and the characters of the men about him and their characteristic ways of acting (whether friendly or hostile). Aesthetically, these are the materials that make up men's recognition of representations of reality in pictures, novels, dramas, and the like. There are also types of utility consisting in their recognizing the uses of objects and how they ought to function for maximum utility. The appreciation of function in architecture comes from these types. And there are types of technique derived from men's knowledge of the skills needed for production or performance, particularly observed in the appreciation of the performing arts. A type may be described as the psychological concept of a group of features recognizable as a whole when presented for attention. The aesthetics of types is the psychology of recognition applied to the arts.

The importance of types for a naturalistic aesthetics lies partly in their organizing power; for they consist in acquired patterns of connected elements that can give unity to a work of art. A work of architecture, for example, can be largely unified by the transparent fulfillment of its function throughout—in plan, construction, and design. But, even more, it is valued as a specific source of the pleasure that it yields, viz., the satisfaction derived from the fulfillment of a type. For a type once stimulated operates like a purpose demanding fulfillment. And the satisfaction involved, particularly if the fulfillment is difficult and rare, can be very great. This experience can easily be appreciated in the perfection of performance achieved in music or acting. But it is equally present in supreme achievement in any work of art. Wherever there is a glow of admiration in the excellence of an aesthetic work, there the observer is showing his appreciation of fulfillment. Because there is a conceptual background for this sort of aesthetic valuing, it is sometimes called intellectual beauty.

Expression. Of Santayana's tripartite division for a naturalistic aesthetics into pleasurable materials, form, and expression, the pleasures of expression remain to be noted. In this area, he refers to the aesthetic contributions of symbols, in which the beauty is not so much in the symbol as in what it symbolizes. It is the aesthetics of meaning. All language is involved in this realm so that literature is the outstanding art of expression. But meaning saturates all of the arts. In religious art, this is particularly obvious, for it leads deeply into the aesthetics of the emotions, where soon the pleasure theorist finds that he has to deal with tragedy. For a pleasure theory, however, tragedy is a great paradox; for in tragedy the artist deliberately seeks out unpleasant, even horrible, subject matter. The paradox of the horrible as the beautiful in a theory in which beauty is based on pleasure is the more acute in that many of what are reputed to be the greatest works of art are tragic.

Symbols and meaning

Catharsis theory of tragedy. Santayana and other hedonists have offered many suggestions to account for this paradox, not the least of which is the theory of catharsis. This theory was originally put forward by Aristotle, who in the *Poetica* made a careful analysis of the art of tragedy having the works of Aeschylus, Sophocles, and Euripedes in mind. His statement about catharsis is brief:

> Tragedy, then, is an imitation of an action that is serious, complete, and of a certain magnitude; in language embellished with each kind of artistic ornament, the several kinds being found in separate parts of the play; in the form of action, not of narrative; through pity and fear effecting the proper purgation of these emotions.

This is unquestionably the most discussed passage in the history of aesthetics. There are dozens of interpretations of it.

Freudian interpretation of tragedy

One view that accords with the hedonistic approach and employs a recent development in psychology is the Freudian interpretation, which is essentially this: that in dealing with extreme mental conflicts and emotional sufferings, man is endowed with a protective capacity to inhibit them so that they do not have to rise into full consciousness. They nevertheless are not really forgotten but, lying in the back of the mind as complexes, constantly seek relief, often coming up in weird disguises in dreams. There is a satisfaction in such relief; and one of the ways of getting it—without having to face the full consciousness of a trauma held back by the inhibitions—is through what are called tragic works of art. In a roundabout way men enjoy the horrors depicted because, without being fully aware of why, they thereby obtain relief from similar experiences they have had themselves and have inhibited but that constantly tend to express themselves. Tragic art is thus, as Aristotle put it, like a purge for pent-up emotions.

A hedonistic aesthetics, as has been seen, is psychologically oriented. In Santayana the approach is by way of a structural method of element analysis. But as a psychological type of aesthetic theory, hedonism readily accepts new psychological developments. How easily it can absorb the Freudian data has just been shown. In fact, Freudian discoveries have contributed greatly to an understanding not only of the peculiar emotional satisfactions possible through the art of relief in contrast to an art of delight but also of many of the perplexities connected with aesthetic creativity.

Gestalt psychology: its amplification of naturalistic aesthetics. Yet another recent psychological movement that has been absorbed into hedonistic aesthetics is that of Gestalt psychology, a movement that began in violent opposition to the analytical methods of structural psychology on which Santayana and many other naturalistic aestheticians were learning. Actually, the two movements are not necessarily contrary to each other; it is better to say they are complementary.

The Gestalt movement was inaugurated by a group of German psychologists, Max Wertheimer, Wolfgang Köhler, and Kurt Koffka, whose laboratory experiments cast serious doubts on the structuralists' long-standing assumptions that simple sensations are the ultimate building stones of mental structures, that these elements get related into wholes by the laws of association, and that all complex wholes are thus acquired by associative learning. The Gestaltists presented evidence that there are instinctive unlearned patterns and that there are special Gestalt laws that cannot amalgamate with the traditional associative pattern laws. Gestalt is, in fact, the German term for pattern, and this term has been retained to distinguish the nonassociative patterns discovered by this school.

The Gestaltists demonstrated that many mental patterns, being self-contained with intrinsic internal relations, cannot properly be described as reducible to combinations of smaller elements. Moreover, perception in children does not begin with simple elements and work up to larger combinations; it begins with large, easily comprehensible patterns and may later analyze out internal features, which may or may not be able to stand as independent patterns. These matters were particularly manifest in the visual field. The principal aesthetic work so far written from the Gestalt viewpoint is *Art and Visual Perception* (1954), by Rudolf Arnheim, a noted psychologist of art. In it, the emphasis throughout is on visual wholes that hold together and visually keep intact in combination with other such wholes. The book demonstrates how somewhat unfinished wholes tend to complete themselves in perception by closure and calls attention to psychological tensions intrinsic to certain shapes and to the tendency toward simplicity of shapes, the pervasiveness of the figure–ground relationship, the internal demands of balance, and so on. It is not that those using structural psychology as a background were unaware of most of these things in their aesthetic analyses but that they failed to give them the aesthetic emphasis that they deserved.

Arnheim's *Art and Visual Perception*

It has been remarked that exclusive emphasis on the Gestalt features in turn covers up many aesthetic discriminations of the structuralists, notably the immediate subtle sensuous discriminations that run through Santa-

yana's *Sense of Beauty* and the works of D.W. Prall, another Harvard philosopher, Walter Pater, a late 19th-century art critic, and others. The Gestaltists are sometimes accused of putting so much emphasis on form that they fail to enjoy the simple materials. There is no necessary conflict, however, between the aesthetic contributions of men with the analytic approach of Santayana and those with the Gestalt approach of Arnheim. Both are dealing with intrinsic satisfactions—as against practical instrumental values; and both seek to explain them by psychological principles working on mental materials generally stimulated by external objects such as works of art. The Gestaltists merely forced the structuralists to liberalize the field of aesthetic materials. Though it may be true that simple sensations are the ultimate discriminable sense materials, they need not necessarily be the ultimate mental building blocks of aesthetic perceptions. They may come internally built into instinctive perceptual patterns.

Complementary theoretical approaches

In short, hedonistic aesthetics can welcome Gestaltists and Freudians as well as traditional structuralists, provided only that these schools are tolerant of one another. Several works of men who have contributed notably to the hedonistic psychological approach to aesthetics are cited in the bibliography.

Nonphilosophical aesthetic specialists. Mention must be made of a large number of men who, though not professed philosophers, have contributed enormously to the discrimination of data within the aesthetic field, viz., the musicologists, the art historians, and the literary historians. These men are aesthetic specialists—so specialized, in fact, that they are often naïve in each other's fields and even in the underlying aesthetic philosophy of their subject. Yet their aesthetic contributions are the most factually detailed and extensive materials available. The philosophical aestheticians turn to them when they want expert information about such things as musical scales, rules of harmony and counterpoint, recognized forms, historic styles of art, cultural influences, cycles of taste, techniques of composition, and production and performance.

Thomas Munro: culminating exponent of a scientific aesthetics. Through the work of these specialists, the analyses of psychologically inclined aestheticians, and some experimental work in psychological laboratories, a large quantity of factual material has accumulated through the last century, which needed only to be systematized to demonstrate that a distinct science of aesthetics actually exists today. Such a systematization was accomplished in a compendious volume entitled *Form and Style in the Arts* (1970), by the philosopher Thomas Munro, who, ever since his *Scientific Method in Aesthetics* (1928), has argued that aesthetics should be treated as a science and not as something opposed to a science.

Scientific systematization of aesthetics

Munro's influence has been widely felt. He was the founder of the American Society for Aesthetics and of *The Journal for Aesthetics and Art Criticism*, both of which were set up as scholarly and scientific undertakings. In his later work he produced what could be regarded as a model scientific text in the field. His main headings deal with "the psychological components of art" and "the modes and dimensions of organization."

His materials are taken directly from works of art themselves as empirical objects like plants and animals and the historical styles of art, and his book reads like a botanical treatise and seems almost to be value free and objective (in that limited provincial sense bruited about by many scientists). But he says explicitly of his book, "I do not claim that it is 'value-free.'" He believes only "that traditional aesthetics has suffered from too much haste in approaching evaluative problems without the necessary factual knowledge and without an adequate methodology."

Critics agree that Munro is correct in saying that the material of his book is not value free, that every bit of it consists of facts observably related to pleasures and satisfactions and other experiences of intrinsic value, since all of it is lifted out of works of art. What Munro calls his "naturalistic, functional definition of art," which controls his selection of material throughout, reads in part as follows:

> Art is skill in making or doing that which is socially used or intended as a stimulus and guide to satisfactory aesthetic experience . . . especially in such a way that the perceived stimuli, the meanings they suggest, or both, are felt as beautiful, pleasant, interesting, emotionally moving, or otherwise valuable as objects of direct experience.

Munro arises directly from the naturalistic, hedonistic (in the wide sense) tradition of aesthetics to which Santayana belongs. His work stands as one sort of culmination of it. It shows in a monumental way how aesthetics may be presented as an empirical science.

NONSCIENTIFIC APPROACHES TO AESTHETICS

Influence of Immanuel Kant. There are other views, however, with often a completely opposed tradition. By way of transition, Kant's *Kritik der Urtheilskraft* (1790; *Critique of Judgment*) comes to the fore. Strangely, in spite of some conclusions quite at variance with those of the typical hedonists, Kant can still be regarded as an aesthetic hedonist because he held that aesthetic value exhibits itself in a sort of pleasure.

His stress on superior nonscientific factors. For Kant, however, it was a very special sort of pleasure. In order to attain to beauty, the pleasure must be (1) disinterested, (2) universal, (3) necessary in a uniquely specified way, and (4) must give the effect of purposiveness without actually being the satisfaction of a purpose.

Most hedonists have distinguished aesthetic pleasure from pleasure in general. There has been wide agreement that it has to be an immediate pleasure found in the object, not the practical liking of a thing as a means to an end. This distinction was very nearly the same as Kant's disinterestedness. But many hedonists wanted to reserve the term beauty for a special higher sort of immediate pleasure, of a kind not associated, for instance, with the pleasures of the lower senses. In spite of Santayana's aspersions against those who disdained pure sensuous pleasures, he himself made a sharp distinction between what he called objectified pleasure, which alone he called beautiful, and others that were only agreeable. By objectified pleasure he meant such pleasure as occurred when a person was so absorbed in a piece of music or a picture that the feeling of pleasure seemed to be emerging from the piece and not coming out of the observer. "Beauty," he said,

Beauty as a higher type of pleasure

> is pleasure regarded as the quality of a thing. . . . It depends upon the degree of objectivity my feeling has attained at the moment whether I say "It pleases me," or "It is beautiful."

Kant had the same feeling that beauty was a value derived from pleasures far above the merely agreeable. He was particularly concerned about the demand people make for the universality of judgments of beauty to comport with the high prestige of the arts. This demand (he felt) was also made for morality, which, without it, seemed threatened with disintegration. Moreover, universality was very urgent for the stability of scientific knowledge in the avoidance of Skepticism.

As regards scientific knowledge, Kant preserved its universality and necessity by his revolutionary theory of the categories. David Hume, a Scottish Skeptic, had just given a devastating blow to the concept of causal necessity by an analysis of man's ideas as based in sense impressions. Hume could find no introspective evidence for necessary connections between any two impressions of which he was aware.

Universality and necessity

Kant reinstated the necessity and universality of causal connections by invoking the action of a mental faculty of Understanding (as he called it) common to all men, which Hume had not recognized. Understanding is the faculty of concepts. Among its leading concepts is the category of causality by which the mind molds unordered sense impressions into the order of nature discovered by the physical sciences. Thus, Newton's spectacular cosmic organization in terms of the laws of motion and gravitation could be universally justified.

Kant was convinced that a similar justification could be found for the widespread belief in the universality of judgments of moral and aesthetic values. He accepted the naturalistic view that aesthetic value is to be found in pleasure. But most pleasures are clearly subjective and do not yield to molding by the concepts of the Understanding. Accordingly, the universality of aesthetic pleasure could not be accounted for by the categories of the Understanding. His solution was that it is due to representations or impressions that set up a harmonious interplay between two whole faculties of the mind. Aesthetic pleasure arises when the faculty of Imagination comes into harmony with that of Understanding. Because these faculties are common to all minds, being the very structure of mind, the aesthetic judgment of the universality of aesthetic pleasure is automatically justified. For the same reason it is seen to be necessary. It is disinterested because practical purposive interests have to do solely with concepts of ends, which belong only to the Understanding. And it is not a satisfaction in the achievement of a purpose because, as has been shown, purposes are based on concepts. It contains a sort of purposiveness, however, because the manifold of material gathered up by the faculty of the Imagination is brought to conform harmoniously with the Understanding as the faculty of concepts.

The distinction of aesthetic pleasure as superior to all of the common pleasures of mere sensuous enjoyment, carnal indulgence, and entertainment is thus established by its universality, necessity, disinterestedness, and purposiveness without explicit purpose.

Worth and importance of Kant's Critique. Kant's theory in his *Critique of Judgment*, when presented in stark outline as above, has struck some critics as hardly plausible and even as fantastic or absurd. Nevertheless, it has been acclaimed as the first major work in aesthetics and as one of the greatest works in aesthetic history. Yet there were no prominent succeeding Kantians; no one now believes in faculties of the mind; and faculty psychology (a heritage from Plato) has long been dead. Moreover, practically no one now believes in Kant's a priori categories of the Understanding, and very few believe in any sort of a priori claims of necessity or certainty at all except perhaps in pure logic.

Significance of *The Critique*

It is reasonable, then, to question why it is so important a work. It is partly because it gathered together and assimilated the scattered aesthetic opinions of Kant's own generation and of many preceding ages; it made a drastic distinction between the activities of the sciences and those of the arts, which prepared the way for the distinction between facts and values; and it raised the possibility of two kinds of cognition—scientific, conceptual cognition and the insight of the genius into deeper values. But, perhaps most of all, Kant's theory of categories and the control furnished by strong guiding concepts in determining men's conceptions of the world gave a new turn to the whole scientific and philosophical enterprise. It is a recognition of Kant's categories, in fact, that gives order to the discussion on aesthetics in this article—except that these categories are not here presumed to be a priori. The presumption is merely that the different outstanding theories of aesthetics are distinguished by certain groups of categories in terms of which their findings are organized. These different sets of guiding categories operate to give alternative relatively adequate and consistent hypotheses about aesthetic experience and modes of evaluation.

Though Kant deserves much intensive consideration, it is necessary here to pass to other important aesthetic theories and their categories. Because the so-called contextualistic theory has some affinities with the hedonistic theory with which the discussion began, this theory is dealt with next. Here again Kant's influence is discernible in its claim that there are two sorts of cognition—the scientific and the intuitive.

Contextualistic contribution. It is necessary here to be somewhat critical of the idea that aesthetics can be a science of beauty, though it can still remain an orderly study of beauty—a study of theories about the special sort of values called aesthetic. Aesthetics then becomes a general term covering all of these aesthetic theories, including the theory that aesthetics is a special science dealing with aesthetic values as its subject matter.

In considering the contextualistic theory, it is notable that, when dealing with hedonistic aesthetics, attention was called earlier to the close connection between pleasure and the sensuous material in which the pleasure was taken. Of these two aspects, the hedonist emphasizes the pleasure whereas the contextualist emphasizes the intuited quality in which the pleasure is taken. The latter defines the aesthetic field as that of the quality of events: great beauty is great enhancement of quality. It is surprising what a great change of perspective develops from this change of emphasis.

The contextualistic view is the most recent systematic aesthetic theory to arise over the historical horizon. There were intimations of it in the past. Baumgarten's concept of confused cognition was one of them. The paraphase earlier offered for his definition of aesthetic perception is a contextualistic one. Aside from him, however, the French intuitionist Henri Bergson, a philosopher of biology, and the Italian Idealist Benedetto Croce were the earliest philosophers to give impetus to this new theory. Bergson's emphasis on intuition and instinct in his *Évolution créatrice* (1907) and his book *Le Rire* (1900; Eng. trans., *Laughter*, 1917) had many of the features of contextualistic aesthetics. He pronounced himself a Pragmatist, which was another name for contextualist.

Croce's aesthetic theory

Intuition of quality and fusion. It was Croce, however, who rather unintentionally had the most profound influence in disseminating the doctrine of aesthetic value as the intuition of quality. Croce's book *Estetica come scienza dell'espressione e linguistica generale* (1902; Eng. trans., *Aesthetic*, 1922) aroused tremendous interest during the early decades of this century. His view was, however, by no means a pure contextualism. Croce arose from the organistic Hegelian school (to be described presently) and his principal philosophical ideas reflected this origin. In aesthetics, however, his novel concept of intuition fed directly into contextualistic thought. He made an unusual identification of intuition with expression, which split his influence two ways: his emphasis on intuition as immediate qualitative sensitivity was highly contextualistic, while his emphasis on expression led to a quite different expression theory of aesthetics (which will be referred to later).

The close connection that Croce felt to exist between intuition and expression emerges from an observation that can be regarded as at least half true, viz., that a creative artist does not really know what the quality of his creation will be until he has fully expressed it. In this view, the intuition of the quality of his aesthetic object comes to light only in the process of giving it expression: a poet finds out what his poem is only as he makes it. He does not have to make it on paper, however; he can make it in his mind. But it is only in such expression of the poem that he realizes his intuition of it. And a reader in turn only gets the intuitive feel of the poem by a sort of re-expression of the poet's original expression. Croce goes on to draw many conclusions from this identification of intuition and expression, which constitute the subject matter of his *Aesthetic*. One of these conclusions is to reject all concepts from aesthetic intuition: concepts produce science, he holds, and intuition of immediate qualitative expression produces art. Thus any pure aesthetic intuition must be completely drained of concepts—a dichotomy reminiscent of Kant.

The mature contextualist in aesthetics does not go as far as this: he admits concepts into his intuitions of vivid quality, for even concepts have qualitative overtones, and they can help in connecting groups of qualities together. He seeks qualitative vividness in aesthetic intuition, however, not scientific analysis or prediction. So the contrast between scientific knowledge and the intuitive cognition of immediacy is retained. But the contextualist will welcome any means of increasing the

range and intensity of qualitative immediacy even to the utilization of concepts and analysis.

Stress on the quality of the whole in contextualism

Contextualism is unique among aesthetic theories not only in focussing on vividness of quality as the central character of beauty or aesthetic value but also in stressing fusions. It is the quality of the whole event or object that is emphasized—the total intuited quality of the picture, the poem, or the melody. What is beautiful is the whole picture, not the heap of its details. This means that in the aesthetic intuition the qualities of the details are fused into the quality of the whole.

The fact of fusion in man's everyday practical living is generally overlooked, even though it is omnipresent. In immediately recognizing a person's face, the observer does not put together a lot of details about the shapes and positions of the eyes, nose, and mouth, chin, forehead, and hair. He instantaneously intuits the character, the total quality of the face. All of the details count in the individuality of that face; and if one of them were much altered or omitted, he would notice it with the shock of a new quality. Similarly, with most of the objects that a man perceives, the details are fused in the comprehension of the whole. The fused quality, moreover, is different from any of the details even when the perceiver is taking up their qualities into the whole. The process and result is transparent in hearing any simple chord followed by the notes that compose it played in isolation: the quality of the whole is different from, yet clearly derived from, the qualities of the notes that are fused in the chord. The Pragmatist William James's famous example is the taste of lemonade: one can analyze out the tastes of the sugar, lemon, and water that go into it; but they are all fused into the taste of the mixture, which is distinctly different. Consequently, analysis is opposed to fusion.

Dangers to quality vividness and its value. In the process of analysis, the perceiver tends to undermine the felt quality of the whole and destroy it. This destructive tendency is what Croce noticed and is why he was inveigled into excluding concepts and analysis from aesthetic intuitions altogether. Another process that tends to be hostile to the vividness of quality is habit or regularity. A third is, as usual, practical problematic activity. Strangely enough, all three of these intrinsically hostile processes, however, can be used in certain ways to increase the vividness of quality.

Aesthetic value of conflict

The most interesting of these procedures is conflict, the source of most of man's practical activity. In contextualism, conflict is stressed as a positive aesthetic value up to the point at which it begins to precipitate overt practical action. No other aesthetic theory can be said to do this. The usual emphasis is continually on harmony. In contextualism with the emphasis on vivid quality, one of the dangers is the threat of monotony, excessive regularity, and the deadening results of habit. There is nothing so effective in counteracting these results, however, than a shock of conflict cutting across a habit or routine. But even when there is no danger of aesthetic fatigue, the contextualist can recommend the skillful use of conflict for positive aesthetic purposes, notably in an explanation of the high value of tragedy in art. Here, deeply moving drives are set in action such as ambition, love, jealousy, and fear and deliberately confronted with frustrations and conflict, up to the limit that a spectator can endure without an overt practical action (to close the book or leave the theatre). The aim is to increase the vividness of the depicted experience to the highest endurable intensity, for the greatest aesthetic value that it can yield. Tragedy as an art form produces no difficulties for the aesthetics of contextualism.

Aesthetic value of vividness

Having indicated the unique contributions made by contextualism, it may be well to close the discussion by briefly answering the question of the value of mere vividness of quality. The value must rest on something more than the pleasure or satisfaction to be found in it. One answer has been given in a contextualistic book, *Art and the Human Enterprise* (1958), by Iredell Jenkins of the United States. Jenkins argues that the value of vividness lies in its bearing on biological adaptation, on its human survival value: pleasure is subordinated to survival. Indeed, the ultimate human value of pleasure is its helpfulness to human adaptation, but the adaptive value of art in presenting vivid events and situations consists in its making man keenly aware of his environment and so preparing him to cope with it in emergencies and, indeed, in his everyday life as well. This service is most obvious in novels and drama. But all art makes men aware of themselves and their surroundings. As could be guessed, mere entertainment is disparaged in this approach.

Though Jenkins, as one of the latest of the contextualistic aestheticians, most clearly brings out the adaptive value of this approach, John Dewey in *Art as Experience* (1934) was by far the most influential contextualist aesthetician. In this book the social bearings of art are expatiated. All of the characteristic features of contextualism are found there expounded with the deep earnestness of the social reformer that Dewey was in all of his philosophy. But the purity of his contextualism is somewhat overlaid by strong, organistic ingredients (to be taken up presently).

Organistic contribution. Another important recent approach is that known as organicism, in which the chief value of art is found in the integration of experience. Integration also has adaptive value: personality psychology has exhibited the integrated personality as the mentally healthy one. Thus, many have found it tempting to combine an organistic approach with the contextualistic, and this, as just mentioned, is what Dewey did in his *Art as Experience*. A full-fledged organicist, however, concentrates entirely on the integrative function of art culminating in the concept of the organic whole.

Integrative function of art

An organic whole is a structure or form such that every detail in it is so intimately related to every other detail that the whole is destroyed or badly damaged by the loss or disturbance of any one of them. Thus an animal organism depends for its life and health on the mutual functioning of all of its organs together. If the heart, the liver, the lungs, or the brain gives out, the whole organism is injured if not destroyed. And, on this theory, so it is with any great work of art: every detail in it calls for every other detail; all must function together. Indeed, this is probably what Kant was calling attention to in his aesthetic requirement that a work of art should exhibit purposiveness without being an explicit purpose. In an organically structured work of art, every detail functions as a sort of purpose demanding satisfaction in the complementary functioning of the other details. Thus, in the well-balanced composition of a picture, each line and mass and colour reaches across the picture for its compensating mate to find there its own little purposive satisfaction. And so on all over the picture. The result is a cumulative satisfaction of these many little purposes finding their many satisfactions through the organic structure of the whole. There is a feeling of satisfied purposiveness provided internally throughout. And yet the work of art is not itself a purpose in pursuit of an external goal.

In this way a work of art yields a special sort of satisfaction not to be found except in an organic whole. Setting up an organic whole as the ideal of aesthetic organization, this sort of internal satisfaction—to be found only in such an organization of experience—may fittingly be called the aesthetic satisfaction. Practical satisfactions are automatically excluded. Loosely organized entertainment and crude isolated sensual enjoyments are also looked down upon. There are, to be sure, degrees of organicity. An organicist would hesitate, however, to call a work beautiful that was not rather highly integrated in the direction of an organic whole.

Art as a dynamic activity

A characteristic of this conception of the aesthetic experience is that it takes a certain stretch of time to fully realize, perceptually, an organic whole, especially if it is a work of even moderate complexity. The act of creating such a work is a dynamic activity. The artist has to feel his way through it to reach the total internal functioning of all the details that the whole is demanding. Similarly, an appreciative critic must imaginatively follow through the same process to attain the total satisfac-

tion potential in it. Thus it is said that the act of aesthetic appreciation is a re-creation of the artist's creative act; and criticism consists in observing how far the artist succeeded in realizing the organic demands of the details. If a shortcoming is discovered, the failure will be specifically indicated, showing just where the artist failed to satisfy a demand that he himself set up in the composition of his work.

The organistic approach has been steadily winning more and more adherents as time goes on. In its full development, it is a relatively recent aesthetics. Though the principle of the organic whole can be found in the writings of Plato and Aristotle and in other ancient writers, it is there conceived as a rather static sort of thing. Regarded as a dynamic activity with internal purposiveness as above described, it can hardly be said to have been realized before the advent of G.W.F. Hegel, perhaps the greatest of the German Idealists.

Formistic contribution. One of the oldest types of aesthetic theory is that of formism, more popularly known as the imitation theory. It begins with the idea that the artist's aim is to make a copy in some medium such as marble or bronze, paint on a smooth surface, or action and words as in a drama of existent objects and events in the environment.

Imitation theory in Plato and Aristotle. Plato presented the theory in a famous passage of *The Republic.* A picture is conceived as intended to be a faithful representation of its object, the closer the better—even to the point of being mistaken for the real thing. Having described the artist in these terms, Plato promptly degraded him as a socially superfluous person. Many scholars cannot believe that Plato was quite serious in this passage, beyond disparaging a type of illusionistic painting current at the time. Besides, aesthetics as a special study was not even thought of at that time.

Art as expressing the universal

Aristotle soon followed Plato and gave the imitation theory a new twist, which was developed and carried along through the succeeding centuries. He suggested that the artist might imitate the universal form or essence in which particular objects share rather than the physical particular. Aristotle made many other wise comments based on his observations of the arts, so that his complete aesthetic theory should not be identified with any one of them. But this suggestion—that the artist may, and for the noblest results should, imitate the universal form rather than the physical particular of a species—became a central principle of formistic aesthetics. By this means art acquired, as he once said, a universal cognitive role resembling science rather than history. The artist represents the form, not the particulars; he seeks, in this view, to look through the particular to the form. As a great painter brings out the character of his sitter in a portrait rather than a momentary appearance at a certain place, so he seeks out the essential form of a tiger, a lion, a horse, or even of a certain kind of chair, pairs of boots, a social scene, or modes of human action in comedy and tragedy.

Since Plato had already developed a theory of Forms, the general theory is often called Platonism. An important world theory emerged from Platonism, the force of which can be felt when trying to give serious thought to how to explain the kinds of similar objects that are found all about one. The problem is how to explain the relation of species to individuals in classifications of plants and animals. In a flock of sheep all of the same form and a herd of cows all of the same form, every particular instance partakes of the same appropriate form. Though particular animals come and go, the universal form remains and is thus the more stable reality. Plato held that the form is the basic reality, that it has, in fact, a sort of being distinct from that of particulars, which are only the appearances of forms in a lesser sort of being caught up in a flux of change. Aesthetically (when he was promulgating his imitation theory), Plato made the mistake of conceiving the artist as imitating the appearance of a particular. Aristotle corrected this by conceiving the artist as imitating the universal form as seen through the particular.

This insight of Aristotle's has been widely held and developed ever since. Among other attractive features of this theory for aesthetics is the fact that it furnishes a ground of objectivity for the aesthetic judgment and experience: for a form not only explains the relation of particular occurrences and appearances to universal types and laws of nature but also produces objective ideals of evaluation; the particular individuals of a species fulfill their forms with various degrees of completeness. A good specimen of a species is often hard to find. A collector of butterflies, for instance, will often have to discard many individual specimens before he gets a "perfect specimen" to include in his collection. A form sets up an ideal for its species.

Styles and social connections of art. The same principle carries over into the arts. Here also there are forms of art. These are easy to see in the crafts in terms of their technique in the service of norms of utility. The forms constitute ideals of perfection, which are sources for the production of styles of art. Formistic aesthetics has thus given a great incentive to the study of styles of art. It can be shown in detail how styles of art gradually grow and, in a sense, discover themselves and come to a culmination. The greatest works of art are presumed to be those produced at the culmination of a style, such as the Parthenon of Athens or the Cathedral of Amiens. Yet the innovators are not without praise, as well, in their insight into a new ideal to be aimed at, though their experience is still inadequate to attain it. Some formists offer evidence that the culminating works of a style exhibit the principle of the organic whole. This whole is conceived by them generally, however, as a static, passive, organic whole already subsisting in the norm—in contrast to the dynamic organic whole of the organicists.

Pioneering, growth, and culmination of styles

The formistic interest in styles of art leads naturally into an interest in the social connections of art; for a style of art tends to reflect a type of social organization as well. In architecture the mutual interplay of art forms and cultural pattern is particularly obvious. Such interrelationship permeates all of the arts, however, at least to some degree. This social phase of the aesthetics of formism is exemplified in the work *Philosophie de l'Art* (1865; Eng. trans., 1865) by Hippolyte-Adolphe Taine, a French deterministic psychologist. That he thought of himself as a Positivist—*i.e.*, as a purely scientific aesthetician—is just that much more interesting and to the credit of certain possibilities of the formistic approach. Taine was concerned with merely describing the types of art that exist, correlating them with their physical and social environments. And the outcome, as he abundantly disclosed, was the exhibition of the essence, the central form, not only of each style of art but of the individual superlative representative works done in that style. Great art, he held, emerges as an approach to perfection in the representation of the essence of a style.

The classic work on the aesthetics of formism, however, is Aristotle's *Poetica.* Probably no book has been so widely studied and so steadily influential as this one. It gives the deceptive impression of being just a series of reflections on the reasons for man's interest in the arts, particularly in drama and in the great tragedies of the period. But the whole philosophy of formism permeates it. In spite of vigorous criticism, the formistic theory of art is alive today. It is, for example, the official view of the Scholastics, represented by two of the foremost authorities on medieval philosophy, Étienne Gilson, in his *Painting and Reality* (1957), and Jacques Maritain, in his *Art et scholastique*, new ed. (1927; Eng. trans. 1930). In his later years, Santayana became a formist with a philosophy centred on essence. Though no exclusive treatment of aesthetics appeared during this phase of his thought, his writings on the "Realms of Being," including *Scepticism and Animal Faith* (1923), frequently refer to the aesthetic value of essence as immediately intuited.

Recent expressions of formism

Other contributions. Two other approaches to aesthetic value are those that proceed by way of emotional expression and mystical experience.

The expression theory. It was noted earlier that Croce's theory of the identification of Intuition and Ex-

pression split his successors two ways: one group stressing the intuition of quality, leading to the contextualistic aesthetic; and the other stressing expression, leading to a movement led by E.F. Carritt (*Theory of Beauty*, 1914) and R.G. Collingwood (*The Principles of Art*, 1938). The central doctrine of expressionism is that a work of art is an expression of the artist's emotion, which, if successful, can be communicated to the public or at least becomes capable of communication for those prepared to respond to it.

Emotional power of art

This is by no means a novel theory. The power of artists to arouse and communicate emotion and to embody it in works of art was noticed by Plato and Aristotle and by the Greek and Roman rhetoricians. What may be new is the construction of a whole aesthetic theory out of the observation. It was done, even before Croce's followers picked up the idea, by Leo Tolstoy, a Russian novelist and philosopher, in a much read book of his later years, *What is Art* (1898). Here Tolstoy pleaded eloquently for an art that elevated men with a deep moral and religious emotion free from worldly frivolity and carnal dissipation. In it he even repudiated his own great novels. A genuine work of art, he now held, should move men, by a sort of contagion with the emotion embodied by the artist in his work, toward faith in the universal religion of the brotherhood of man. His book *What is Religion* then became a companion piece to *What is Art*, showing the ultimate criterion of the value of art. The simple peasant by his closeness to nature, uncontaminated by the conventions and hypocrisies of the upper classes, becomes the only reliable critic of the essential sincerity of a work of art.

R.G. Collingwood, a correlator of philosophic and historical thought, has much the same theory—relieved, however, of Tolstoy's evangelism. In his view, the essential embodiment of sincere emotion and the importance of its communication with the work of art as the vehicle are both retained. Art becomes a medium of emotional communication on a level with the conceptual verbal communication of the sciences and of practical life—or, better, of commercial life: for nothing could be more practical than emotional communication when this is needed. And art can effectively communicate many things that are conceptually incommunicable.

Authenticity of emotions

The expressive theory of art is easy to explain in principle but leads to many confusing ramifications in detail. The heart of the theory is always an appeal to the genuineness of the emotion expressed. Superficial emotional expression or mere stimulation in entertainment is frowned upon. And insincere emotion is the ulcer of ugliness. The Existentialist term of an "authentic" emotion may be the most appropriate.

The problem is to describe or designate this crucial evaluative emotion and its expression. Tolstoy, as shown above, tied it in with his conception of a supposedly universal religious expression. Croce stressed its completeness of expression, a special sort of intuitive emotional clarity that can only disclose itself (even to the artist) by its fullness of expression. And he insisted on the exclusion of all conceptual or practical material.

Collingwood was not so exacting. He admitted intellectual material if it was sufficiently fused into the emotion. (Indeed, once in a while Croce did the same.) He had much to say about the creative activity of Imagination and sometimes came close to the organistic criterion of genuine aesthetic emotion in terms of an organic whole. His central opposition was that between the "corrupt" and the "uncorrupted" emotion—representing repressions, according to the evidences of the psychoanalysts, as a particularly insidious source of corruption. He allowed also for successful private expression of genuine emotion, so that communication is not essential; but some sort of embodiment of emotion is.

The mystic theory. When emotion is given so central a position in aesthetics, it is not far to go to the mystic theory of art based on the mystical experience as the immediate experience of God and ultimate Being. That mystical experiences do occur to many individuals and that they have the noetic (or knowledge) character ascribed to them—involving a conviction of an indubitable disclosure of the total significance of the universe in an ecstatic all-embracing intuition—is a well-attested fact. How far it may be credited as a true revelation is another matter. Moreover, the full experience—or some approximation to it—has inspired fine poetry and painting and music in man's cultural heritage. Artists as a group are fascinated by the theory. It is the dominant aesthetic view underlying a large part of Oriental theory and practice in the arts. With such an impetus behind the view, it is surprising that only one or two outstanding philosophers have espoused a mystic aesthetics in Occidental thought—the 3rd-century philosopher Plotinus, the foremost representative of Neoplatonism, and the German philosopher Arthur Schopenhauer, known for his pessimism. Moreover, both of them offered what amounts to a Platonic formist theory of aesthetic experience. This experience consists in the disinterested contemplation of the Platonic Forms in their calm detachment from particulars that are caught in the flux and turmoil of the world of appearance. The only mystic motive is that these Forms may act as symbols or rungs on the mystic ladder leading to communion with the unity and peace of ultimate Being.

The aesthetic and the Holy

Mystic aesthetics may be classified as a kind of emotive theory in which the criterion for the supreme experience is that of the mystic experience itself in complete ecstasy. Yet all mystics in the exposition of their aesthetic views seem to agree that the supreme experience itself is not an aesthetic experience. Thus Rudolf Otto, a German phenomenologist of religion, has set up, as a fundamental category, "the Holy," as distinguished from the aesthetic. It is as if the mystics feel that an identification of these two would be a sacrilege. Besides, the experiences of beauty in communion with nature and through the arts have been thought to be clearly distinguishable from the ultimate ecstasy that, when attained, absorbs all of these lesser experiences into its ineffable unity. The possibility of attributing a special high value to these lesser symbols of the ultimate Reality would appear to depend on their not being conceived as merged and lost in an ultimate ineffable One. Thus, there has been an inevitable tendency for mystical philosophers to borrow the details for the lesser levels of being from other world hypotheses.

The more simple religious mystics have borrowed profusely from the myths of animism, the view that natural objects are living and conscious. Their more sophisticated colleagues have borrowed from the more adequate world theories—particularly from Platonism and organicism. There are many organicists with strong mystical leanings, such as the Idealists F.H. Bradley and William Ernest Hocking; but none of them has shown much interest in aesthetics. So, again, Plotinus and Schopenhauer seem to be the most adequate examples of aesthetic mysticism. William Butler Yeats, Irish poet and dramatist, may be cited as a pure mystic who may almost be called a philosopher.

In mystical aesthetics beauty is found in the symbols of mystic peace and unity to be felt in nature and in works of art. For some appreciation of the efficacy of these symbols, one is best served by the poems and the paintings of the mystics themselves. In particular, classic Chinese painting is saturated with such mystical symbols. One of the most striking of these is the presence of great empty spaces in this art. When the viewer concentrates on these spaces in the context of a serene ink painting, for example, they cease to be mere vacancy. The mystic artist renders them alive in their emptiness: they are the symbols of the negation of all appearances and of union with the undisturbed unity of Nirvana.

LINGUISTIC APPROACHES TO AESTHETICS

The foregoing expressive emotive theories facilitate the transition to a vigorous new trend in aesthetics that goes under the general heading of the Linguistic movement. There are many facets to this movement; all are centred on questions of meaning and language, which, in turn, may be fairly said to be concentrated in the question of

Nature of an aesthetic judgment

what is involved in an aesthetic judgment. Answers to this question have led to close analyses of the words, sentences, and meanings used by critics and aestheticians in their discussions of art and aesthetic value.

The outcomes of these analyses often do not differ greatly from conclusions to be found in the theories already reviewed. There are two conclusions of Linguistic Analysis, however, that have been regarded as revolutionary in effect and have been very influential in English and American circles. One of these is the doctrine of the "naturalistic fallacy," and the other the emphasis on "the open question" and "the open textured" concept.

The Linguistic movement and the naturalistic fallacy. Though the naturalistic fallacy has had its chief impact on ethics, it is equally applicable to aesthetics and to value theory in general. It is primarily associated with an analysis of what can be meant by the term "good" developed in a book *Principia Ethica* (1903), by George Edward Moore, a careful pioneering Analyst in England. Briefly, his argument was as follows: the meaning of good cannot be identified with any natural experience such as pleasure or satisfaction of desire, for it makes sense to ask the question "Is pleasure good"; hence the proposition that good is equated with pleasure is either meaningless or false. The same argument would apply to any other natural entity—to satisfaction of desire or expression of authentic emotion, to harmonious integration of feeling and impulse, to perfection of form, or to mystic ecstasy. It is always meaningful to ask whether any of these is good. Hence "good" cannot mean the same as any one of these natural entities. The proposal or assumption that it can is "the naturalistic fallacy." Moore thought that the only way to escape this fallacy is to resolve that "good" means good and nothing else. One can have an undefinable "intellectual intuition" of the universal, formistic Platonic essence good itself. And this, according to Moore, is the basis of value.

It was soon pointed out that the identification of the meaning of "good" with a Platonic universal was also open to question by any philosopher who questioned the truth of the Platonic theory of universal Form. Moore himself had committed a naturalistic fallacy. Besides, the hypothesis that an intellectual intuition exists to be aware of this universal good had little evidence to support it.

Emotive theory of normative statements

But to many, Moore's linguistic analysis of "good" still seemed to have something in it. A Logical Positivist, A.J. Ayer, another English philosopher, in his *Language, Truth and Logic* (1936), proffered the idea that the naturalistic fallacy consists in thinking that a value judgment such as "Generosity is good" or "Lying is bad" may not be true or false like a scientific proposition or common declarative sentence. True, the word forms look like declarative sentences such as "The water is boiling" or "Diamonds cut glass," but actually value judgments are merely emotive expressions like uttering "Generosity, WOW!" "Lying Ouch!" In aesthetics, likewise, "The sunset is beautiful" really means only "Sunset, WOW"; and "A gangrenous leg is ugly" really means "Gangrene, OOF!" The upshot of this sort of analysis is to draw a sharp line between facts and values and to declare that a science of values or any study of values purporting to be true (or false) is impossible. Books on ethics and aesthetics are little more than expressions of likes and dislikes, wishes and dreads, demands and rejections. In technical terms they are made up of optative, imperative, and exclamatory sentences—which are neither true nor false—concealed under the appearance of true (or false) declarative sentences about matters of fact.

The emotive theory of value, including aesthetic value, appears to be the most skeptical theory of value ever promulgated, though this is not a reason for rejecting it.

Pluralistic nature of value

Many scholars now hold that the supposed naturalistic fallacy simply calls attention to the natural ambiguity of a very important word of ordinary language that is the general term for values of all sorts. There is no necessary need to identify the meaning of "good" with one kind of value alone and reject all other meanings—nor, indeed, to be led finally to reject all meanings, leaving the term apparently meaningless. The problem of value is rather to discriminate clearly the various meanings and kinds of good and the occasions for their appearance and application and to determine the relative priorities of these various values for each occasion according to the relevant evidence available. Whenever the evidence is not conclusive, the reasonable procedure is said to be to hold the various hypotheses of value priorities in suspense; *i.e.*, to hold them open pending additional evidence. As regards aesthetic value, one hypothesis gives priority to pleasure of some specified sort, another to vividness of quality, another to organic unity, and so on. But each recognizes that there is a contribution to aesthetic value in what the others hold in priority. The spectator, the critic, and the artist may all profit from taking each view seriously but not dogmatically. There may be biological or social conditions in which each of these values legitimately acquires priority in fact: under prosperous conditions when social pressure is low, pleasure may be the value that can safely be given priority over other aesthetic values; but under conditions of social stress, the adaptive value of a vivid feeling for the actual quality of events may gain a priority and pleasure might seem superficial. A reasonable conclusion may be to hold the hypotheses open for whatever relevant evidence may come.

The Linguistic movement and the open question. The most constructive contribution of the linguistic movement for aesthetics and other value disciplines may be its stress on the "open question." The trouble here was that even this could be carried too far. When the concept of the open question became a dogma, it ceased to remain open. It can be carried to such an extreme that aesthetic evaluations of better and worse in art become impossible. For a definition of aesthetic value or of a type of aesthetic value is the sole linguistic basis for any criterion of evaluation.

Definition of value as a standard

The question may be asked, for instance, how judges could decide on a prize dog or bull without a definition understood by them all of the "points" for the sort of dog or bull being judged. The same question may be asked of art juries selecting pictures for exhibitions and for aestheticians writing about ultimate aesthetic values. Their theories culminate in definitions of aesthetic value that constitute the ultimate linguistic standards of beauty from their point of view. These definitions, as has here been urged, are not to be taken as dogmatic but as hypothetical. Their adequacy depends on the evidence available to support them. They are descriptive definitions summarizing the conclusions of systematic studies in aesthetics.

If the open-question attitude, however, is carried to the extreme of discounting evaluations of art made from firmly formulated definitions of any sort, then the liberal intention deteriorates into a destructive dogma. An evaluative definition need not be loose and open-ended itself. If it is regarded as an hypothesis open to revision as new evidence may direct, it is still open. But it is at the same time firm and unambiguous in its evaluations.

Some linguists insist that the relevant concepts of art are all of the type called "family resemblance concepts." Ludwig Wittgenstein, a leading philosopher of language, brought this notion into prominence. Using the concept of "game" as his paradigm, he showed that a sharp boundary line cannot be drawn around the field of instances that all men would be willing to denominate "games," that there are no common traits characteristic of all games. All games have traits common to some of the others, but not to all of them. The resemblances overlap. Yet in common living men gather them all together into a single concept because they overlap so easily. Ordinary language is full of such concepts. This is therefore one particular way in which a concept may be open. In fact, by virtue of its very overlapping structure, such a concept cannot be closed.

Some aestheticians argue that all aesthetic concepts are, or should be, of this family-resemblance type. Many such concepts unquestionably are, especially in ordinary language. And there is a school of linguists who have

been saying that ordinary language concepts (except in the sciences) are the only correct concepts. Thus value concepts must be left open in the family-resemblance way. It is claimed that closed concepts would dam up the creative urge of artists, and it may generally be agreed that there is a modicum of truth in this view, because the established schools of art generally have developed clear standards of style, whereas the innovators are not yet fully aware of what the culmination of their new style will be. But, of course, any new style is actually seeking for its new standards, which will sometime become clarified. It still remains true that relatively adequate theories of aesthetics have been developed with clear, firm definitions of what constitutes excellence in art. Though closed in themselves, these definitions are best taken as hypotheses open to confirmation and revision in terms of any new available evidence. It is thus not necessary that aesthetic standards be kept deliberately vague and indecisive in order to be also free from dogmatization and open to revision and reconsideration.

Importance of definitions of aesthetics

It was stated earlier that a definition of value can act as a standard of value for the field of values that it defines. Some simple instances were shown. The point needs to be amplified a bit, however; and this can be done by summarizing the importance of firm, clear, closed definitions for a fully developed aesthetic theory. A definition acts as a standard of aesthetic value in two ways: first, it demarcates what are or are not objects of aesthetic value; and second, it determines the amount of aesthetic value that these objects have whenever the defining terms admit of quantitative differences. For instance, for the common hedonistic view that defines aesthetic value as experiences giving immediate pleasure, or as the liking of things in themselves, it would appear to follow that things liked as means to other things are not aesthetic values. Similarly, sentimental objects valued only for their associations, such as the pen used by Lincoln to sign the Emancipation Proclamation, are not aesthetic values. Such a definition is a powerful standard. It keeps many objects out of art museums and many musical scores from ever being played at a concert. But the definition also determines the amount of aesthetic value that an object has in terms of the amount of pleasure or liking that it gives.

This definition, as has been seen, is often regarded as too wide and has to be qualified in various ways—to distinguish, for instance, deep or superior beauty from mere entertainment. The justification of these added distinctions depends on the relevance of the evidence that can be brought up in support of the definitions. This is taken to show that the definitions are actually hypotheses about the place of aesthetic values in relation to other values and, indeed, to all of the other facts in the world.

If such definitions, which function as the standards of beauty and ugliness, are not firm and backed up with adequate evidence to justify their being used as they are in the arts, then there would appear to be no justifiable aesthetic standards at all. Some skeptical scholars have argued that this is in fact the case; the conclusion seems nonetheless improbable in view of the great body of constructive work that has been done to date in the field.

(S.C.P.)

ORIENTAL AESTHETICS

General seminal features of Oriental aesthetics. The distinction between the Orient and the Occident is often made on a simple, geographic basis, as in the division of the Earth into two equal parts. The terms Oriental art and Oriental aesthetics would then apply to all art and aesthetics produced in the Eastern Hemisphere. With advances in exploration and cartography, however, the inadequacy of that simple division for the study of human cultures was long ago disclosed. It was supplemented by the concept of Near Eastern, embracing the lands and cultures around the Nile, the Mediterranean, the Tigris–Euphrates, and sometimes even the Mohenjo-daro culture (about 3000 BC) of the lower Indus Valley. Islāmic influence in the arts later spread eastward through Iran, some of western India, and southern Spain. From the biogeographic point of view, the Orient is the land between the southern Himalayas and the western Malay Archipelago. The term Far Eastern usually includes the lands and cultures of India, Nepal, Ceylon, Indonesia, China, Korea, Tibet, and Japan.

Pragmatic and exotic terminology

Many unscientific terms, based on the inaccurate observations of travellers, were incorporated into discussions of the arts. In some cases, they served a useful purpose, as in classifying particular works and styles in art museums. It became a never-ending task, however, for aestheticians and historians to describe and compare the innumerable styles and movements in Far and Near Eastern art from Paleolithic Asia to the present time.

The concept of aesthetics eventually outgrew its former restriction to definitions and judgments of beauty in order to join in the larger task of discovering the nature and potency of art in a changing social world (see ART, PHILOSOPHY OF). Surmounting linguistic difficulties, modern scholars gradually appropriated foreign words from exotic languages, such as *zen*, *moribana*, *yoga*, and *rasa*, along with the ideas they signify until the foundations of an international aesthetic language had been laid. To some extent, this practice was a continuation of an earlier one in which, for example, Italian was the language of music and French that of diplomacy.

Modern civilization, with its desire to understand and control things by means of reason, had its beginnings in Egypt and Sumeria (in Mesopotamia). Early hints of a philosophy of beauty in Europe, before Pythagoras, a 6th-century-BC number philosopher, included so much mysticism in regard to mathematics as to suggest a previous influence from the Orient.

Religious foundations. As a factor in the social context of art in any moment of history, religious and philosophic thought is highly significant. It is necessary only to list the great, advanced religions of Oriental antiquity in order to realize how varied must have been their inspiration to artists of all sorts: specifically, the Brahman, Buddhist, Jain, and Hindu faiths; the Zoroastrian faith in Iran; the ascendancy of Hinduism in India as Buddhism shifted to the north; the importation of Judaism and Christianity from the Near East; new variants of Buddhism in Tibet and Japan; Shintō in Japan; Islāmic beliefs spreading from Arabia to the East in India and to the West in Spain. All of these religions were producers of art at certain times and places, with long or short florescences. Although the concept of an evolution of religion is controversial, numerous authorities have held that many of these religions went through a primitive stage of animism, magic, and realistic polytheism, each with its legacy of expressive imagery, before passing on to monotheism and pantheism. These last were increasingly devoid of vivid imagery.

Much Indian art and criticism obviously had a religious form and content, which is evident, first, in the countless myths and legends employed as represented subject matter, such as stories of the ancient hero Kṛṣṇa and the cowgirls; second, in the willingness of artists, rulers, and public to accept fantastic representations of the supernatural, as in the several arms of Śiva, a major Hindu deity; third, in the emphasis placed upon mystic symbolism in the arts, including dance and theatre.

On the whole, within an extensive culture such as the Greek or Indian, the arts tended to develop first partly for magical and religious purposes. Theoretical discussions of them—including instructions from priests and other patrons of the artist—came later. Philosophic discussions of their aims and standards of value, as in Aristotle's *Poetica,* tended to come relatively late. (Such a relative position in the evolutionary sequence is not, of course, the same as a date. At the present time, many social groups and individual writers are at relatively primitive stages in cultural development.)

Theism and naturalism

Though it has been said by some historians and denied by others that all Indian art is religious, it is true that most Indian art can be given a religious interpretation by persons of a strongly theistic attitude. This was not necessarily the intention of the artist or of his public. Religious interpretations can be applied to the most humble, utili-

tarian products as to the most magnificent palaces. A work of art can be appreciated on various levels by the educated observer, and one of these levels or attitudes may be supernaturalistic, another naturalistic. Many Indian works and their interpretations, which include ideal representations of gods and spirits, are clearly theistic. But all personifications of the gods can be regarded as avatars, or aspects, of the cosmic spirit, as explained in the Vedas (early religious poems), the *Upaniṣads*, and other sacred writings. Primitive polytheism could thus give way to what Western philosophers call Idealism, panpsychism, and pantheism.

Sensory, naturalistic, and humanistic expressions. Although many Indian theories of aesthetics disparage the realm of sensory experience as mere illusion, Indian artists continue to employ sensory materials and to display them for the enjoyment of others. (The same can be said of medieval Christian art and aesthetics.) In trying to explain the arts, supernaturalists tend to feel that they reflect a divine Creator, whereas naturalists—as in the poem *De rerum natura* ("On the Nature of Things") by Lucretius, an ancient Roman Atomist—regard them as reflecting man alone.

Neither India nor the Far East in general ever developed a strong, enduring naturalistic movement, such as might have led to empirical science. It had a brief one, the Cārvāka school of philosophy, which flourished about the time of the Greek naturalist Epicurus (died 270 BC), to whose philosophy it was similar. It was Materialistic in metaphysics (theory of the nature of Being) and hedonistic, or pleasure oriented, in ethics. But these and possibly other attempts of the sort were overwhelmed by the tide of mysticism that swept over the Far and Near East, holding sway until the 20th century. (Confucianism in China, though lacking a strong theistic basis, was consistent with a popular belief in ghosts and minor spirits.)

In the ancient military empires, a main purpose of the arts was to glorify the ruler and the noble, wealthy classes. This effort was restrained to some degree by priests and philosophers who urged that moderation, justice, and sacrifice were better ways to happiness in the next life than costly works of art and "vain oblations." In some times and places—particularly in China, which witnessed an increasing humanism and rationalism (though with ups and downs through the ages)—a clear-cut issue arose between the ethics of religious asceticism and that of humanistic art. Some kinds of art were said to be anagogic; *i.e.*, able to lead the mind upward to heavenly things—an aim similar to one of Dante's in *La divina commedia*, in which his guide, Beatrice, personifying philosophy, leads him heavenward.

Universal and mystic symbolism. One way in which art can perform this function, according to the ethics of supernaturalism, is by helping the student understand universal symbolism. Although monasticism flourished throughout most of the Orient, especially under Buddhism, it took various forms and prescribed different spiritual exercises, in which chants and rituals had a place. Mural paintings, scrolls, and stone or bronze sculptures helped to stimulate the desired attitude, as a means of reaching heaven or Nirvāṇa. Prolonged contemplation of an abstract design, such as one of interlacing triangles, could also help to induce a mystical attitude. Where the theory of reincarnation was accepted, many people thought that art—under the authority of priests and officials—could be a means of acquiring merit in this life, to assure a happier life in the next rebirth.

Symbolic religious figures

Another basic concept of Oriental aesthetics was that of mystic symbolism, also much studied in medieval Europe until well into the Renaissance. In its ordinary usage, the word symbolism refers to the practice of using a familiar image, such as a lion, to mean something very different, such as the abstract quality courage. In Christian art, the figure of a lamb is used to signify gentleness, meekness, innocence, and sacrifice—all as attributes of Christ; in India, the bronze figure of the dancing Śiva is well-known as a symbol of that god, a figure that signifies the cosmic rhythm of creation and destruction as symbolized by a drum—especially its destructive aspect through an emphasis on fire. Śiva, a favourite subject of Hindu sculpture, combines male and female attributes, such as those of Mars and Venus in Lucretius' poem.

Many early Christian artists and theologians accepted the doctrine of universal symbolism, attributed to St. Augustine and St. Clement of Alexandria, early Church Fathers. It taught that everything in the universe, especially important images in the Bible and other sacred writings, had not one meaning but many, as in the Book of Ezekiel and in Revelation. These meanings, it was thought, had been divinely established for man's guidance. Most of them are cryptic and hard to decipher. The process of doing so can be along naturalistic or mystical lines. In the Orient and in medieval Europe it was usually the latter.

Mystic symbolism refers not only to the cryptic meanings attributed to the symbol but also to the way in which the symbol-meaning combination is formed, grasped, and appreciated. In general, mystic experience is conceived as occurring not by sense perception but through a special, perhaps divine revelation, as in a trance or unsought vision. It is thought to open the observer's mind to some ineffable higher truth and level of reality. Works of art, it is thought, can be so perceived if the meaning is genuinely of divine origin.

In India and Tibet, various types of bodily and spiritual exercise called Yoga and Tantra were developed and are still used as a means of freeing the mind from unwanted desires and controlling inner experience in a positive way. The method called Tantric combines Hindu with older, prehistoric elements. It emphasizes the role of the female as a source of physical and spiritual energy. Some of the finest Indian sculpture shows Tantric influence. In Europe during the Council of Trent (1545–63), church authorities, noting the often farfetched attributed meanings with which the arts had become increasingly laden in medieval times, took steps to discourage the universal symbolism. From then on, this symbolism declined in Western art, although traces of it survive in the paintings—especially Flemish—of the early Renaissance. In the Orient, on the other hand, mystic symbolism remained a vital force in aesthetics and philosophy until the 20th century. Though it is now being gradually replaced by Rationalistic science, even those scholars who reject it as a mode of ascertaining truth may still value it as a source of aesthetic satisfaction on a high cultural level.

Specific cultural expressions of Oriental aesthetics. The principal cultures here reviewed are those of China, Japan, India, and contemporary Marxist lands.

Confucian and Taoist aesthetics

China. There is a distinct analogy between the aesthetic theories of Confucius (died 479 BC) and those of Plato (died 347 BC). Both sages discoursed on music and ritual as means of producing desired kinds of emotion, attitude, and character. They showed how young men could be educated to strengthen and harmonize the state. Both praised music of a stately and dignified sort, which helps to produce inner harmony. Confucius emphasized the value of traditional ritual in the development of emotional self-control, and his follower Hsün-tzu stressed the need for simplicity in the arts as leading to a well-ruled state. Both Plato and Confucius denounced the seductive, exciting effects of the "modern," complex music of their day.

Austere Confucian critics and officials condemned all novel writing as licentious, but popular novels, nonetheless, were written in China. In the long conflict between Confucian and Taoist schools of thought, animated arguments developed, which contributed vitality to this stage of aesthetic thinking. Lao-tzu, a founder of Taoism, disapproved all art as blinding the eye, deafening the ear, and cloying the palate. Rare treasures, he said, tempt men to do wrong. His severity toward art was extended to all attempts at changing conditions. Later Taoism became freer and encouraged the love of nature as well as the artistic depiction of deities and minor spirits. As against Confucianism, Taoism proposed a less formal, more intuitive approach to life in general. This approach was carried over into the arts and into theoretical discussions of them. On the whole, there is more humour and

lightness of touch in traditional Chinese than in Indian philosophy.

The movement called Ch'an in China and Zen in Japan denounced scientific technology for preventing a simple, direct acceptance of the world as it is. Though Zen has been interpreted in both a naturalistic and a mystic way, it has avoided the attempt to define its methods clearly.

In general, Chinese ideas on art and aesthetics were written in shorter, more epigrammatic rules and comments than those of Hindu thinkers. In India, aesthetic discussions sometimes formed parts of lengthy philosophic systems. In China around the turn of the 6th century, Liu Hsieh, a Buddhist scholar and critic, showed how literature has developed from the simple to the complex and ornate; how it expresses the spirit and socio-economic conditions of its time.

Japan. Although early Japanese art and aesthetic theory owed much to China, in later centuries more original features developed in Japan. One of the most striking is the great novel, *Genji monogatari* (*The Tale of Genji;* AD 1000), by Murasaki Shikibu, a lady-in-waiting to the Empress. It is great not only as a work of art but also for its theoretical discussions of good and bad features in various arts.

By the 18th century, many aesthetic problems were discussed in a sophisticated way, with recognition of the need for different methods. Appropriate words recorded the perceptive, emotional responses of sensitive observers to different kinds of art and nature, including human nature. They also provided a combination of descriptive and normative meanings, capable of use in characterizing a work of art and relating how an observer feels about it. The many value concepts of this sort, provided in Chinese and Japanese theory, contain a rich vocabulary for use in the criticism of various arts.

Descriptive and normative concepts

Many of these concepts were set forth by Zeami Motokiyo (died 1443), a Japanese playwright and actor-manager. He used the traditional Nō play as a symbolic theatre in which ideas and moods are suggested but not clearly represented. In the late 18th century, Moto-ori Norinaga, the leading scholar in Shintō and Japanese classics, emphasized a quality called *aware*, meaning gentle melancholy or sensitivity to the beautiful sadness of things. Other aesthetic qualities are *en* ("charming"), *okashi* ("cheerful," "amusing"), and *sabi* (having the beauty of old, faded, worn, or lovely things). These value concepts invite comparison with the Hindu *rasa* (flavour) and with such words as picturesque in European Romanticism.

The concept of *yūgen* ("mystery and depth") was developed by Zeami into a far-reaching principle, involving elements of several religions. Zeami assumed the animistic idea of a collective, cosmic mind, a kind of spiritual power underlying all parts of the Nō play and expressed in the work of art.

D.T. Suzuki, a present-day intrepreter of Zen, links these concepts to the Buddhist and Taoist absolute passivity in accepting things as they come. On the other hand, the popular art of the 18th and later centuries belongs to the so-called floating world of transitory phenomena. To the Buddhist, it symbolizes the ephemeral world of sensuous pleasures.

India. In India, the legends and myths of Kṛṣṇa, the great god who is also a mischievous child, a heroic warrior, a divine lover, and a religious teacher, fill many volumes. He is worshipped in countless rites, dramas, ballets, and folk festivals. The Kṛṣṇa legend as a whole is far more than a cycle of stories; it is a running thread through most of Indian civilization and a key to understanding that civilization at its best.

In the psychology of art, an integral part of modern Western aesthetics, the medieval Orient has much to offer, especially in its theory of *rasa*, or aesthetic flavour. Recent Western psychologists have so strongly emphasized Behaviorism and externally observable phenomena that they have almost ignored the inner world of individual subjective experience. Indian philosophers call attention to the importance of *rasa* in the total experience of creating and appreciating the arts, especially the theatre arts, and to the many kinds of *rasa* and ingredients in *rasa*, which, as they are felt and cultivated, are enhanced in value.

Theory of *rasa*: aesthetic flavour

The theory of *rasa* was first proclaimed by a mythical sage-priest, Bharata (*c.* AD 500), and developed by Abhinavagupta (*c.* AD 1000), a great rhetorician and philosopher. It was used in explaining the forms, techniques, and varieties of poetry and theatre arts. Bharata listed as the principal feelings of human nature: delight, laughter, sorrow, anger, heroism, fear, disgust, and astonishment. They are transformed by art into the *rasas*: erotic, comic, pathetic, furious, terrible, odious, marvellous, and quietistic—qualities into which ordinary feelings can be analyzed. Psychological studies of this sort were not purely mystical; but the development of aesthetic ability and sensitivity could be made a part of Rāja-Yoga, a kind of spiritual exercise, which rejected the supposed antagonism between sensuous and spiritual enjoyment. Bharata interpreted the power to feel and understand beauty (to taste *rasa*) as a reward for merit in a previous life.

On seeing the richly carved and painted ornamentation of Hindu temples, Western travellers are often puzzled by what they regard as obscenities, involving complete nudity and extremely erotic scenes carved and painted in full detail. They cannot understand the claim of Hindu scholars that such art is "religious" and "spiritual." The same may be said of erotic Indian literature, such as that of the *Kāma-sūtra*, written about AD 300 (Eng. trans., *The Kama Sutra of Vatsyayana*, 1883, by Sir Richard Burton). This distinguished treatise on love and pleasure was intended as a technical guide to sexual enjoyments and to the sensuous delights of perfume, music, and lyric poetry as auxiliary arts. It also presents a realistic account of amatory relations between the sexes in ancient India. Sensuous pleasure is not proposed as the highest good, nor is it morally disparaged. It is respected as a fitting element in the good life on a certain age level and in the institution of marriage.

Western art and aesthetics have recently tended to follow Oriental customs in approving greater freedom of sexual representation, but they seldom call it spiritual. Whatever term is used, it is a psychological and cultural fact that Orientals do not regard their erotic art as pornographic in the Western, popular sense. Sex as a means to love and joy is regarded as a basic fact of life, religious in that it carries on the divinely established rhythm of creation and destruction. It can be transformed into fine art by a capable artist.

Marxist lands. It may be asked whether the Soviet Union and China are now Oriental and whether they are productive in art and aesthetics. Briefly, it can be answered that, geographically, both nations occupy large areas of Oriental territory. Culturally, China has inherited much from ancient Oriental traditions; and Confucianism, which was a major influence until recent years, has affected all of the arts as well as philosophy and ethics.

Western influence in the U.S.S.R.

The Soviet Union, instead, has inherited much of western European civilization, especially its arts. With this aid, it has, at times, led the world in film and ballet. The Soviet Union has also inherited much of German philosophy and British economic liberalism. Indeed, the tradition of cultural evolution, deriving from G.W.F. Hegel, the foremost Idealist of the 19th century, led directly to the modern conception of aesthetics as a branch of philosophy, distinct from art and from particularized art criticism. But, whereas Hegel's philosophy was Idealistic, Karl Marx has transformed it into a kind of Materialism. In many respects, Marxism has been the opposite of Oriental mysticism, subjectivism, and Taoist laissez-faire. Hence, its influence on art and aesthetics has not tended to follow Oriental lines.

The dominant Marxisms of the Soviet Union and China, however, have had aesthetic implications in their own right. Briefly summarized, these are that one main aim and standard of value in the arts is to reinforce and strengthen the revolution along Marxist lines and that another is to enrich and improve the cultural life of the workers. Toward these ends, the arts have been frankly employed for indoctrination.

The arts as reflecting and subserving social conditions and aims

While acknowledging their debt to the past, Marxist theoreticians emphasize that they aim to create a new culture—not merely to admire and follow the old. In both Communist countries, there has been a long period of competition between the old and the new, with disagreement on the extent to which any departure from orthodox Marxism (any revisionism) is to be allowed. The newer bases for cultural advance, especially in Maoist China, tend to reflect an emphasis on local needs and the development of technical skills through practical education. Both countries encourage folk arts on a local basis, as well as urban performances on a high level of proficiency. Both use the arts to glorify the conception of the worker and other aspects of Communist ideology. Marxist aesthetics has stressed the need for art (especially for music and drama) that will appeal to the masses and inspire them to revolutionary attitudes, as opposed to artificial formalism. Socialist realism can be a means to that end.

Such issues have led to prolonged discussions among Soviet aestheticians—as, for example, in judging from a Marxist point of view the merits of the novelists Leo Tolstoy, Honoré de Balzac, and Voltaire; the composer Ludwig von Beethoven; and the painter Honoré Daumier. They have given moderate praise to past artists who were regarded as revolutionists or fellow travellers before their time. But they have also insisted that all art, including that of radical artists in other ages, is much influenced by the social conditions and tastes of the time. In the Soviet Union, much scholarly writing is devoted to working out the details of this hypothesis and to attacking contrary views. (Th.M.)

CONCLUSION AND EVALUATION

Whether aesthetics is only a science

A glance cast back over the preceding survey shows that a noncommittal definition describing aesthetics as the study of beauty and ugliness was about as fair as might be found. When one comes to closer terms with the field, however, it is discovered that there is an issue blocking the desire to be more definite—the issue as to whether, or to what extent, aesthetics may be regarded as a science.

If the narrow conception of science as restricted to the exact sciences (such as physics) is set aside, there is no question but that aesthetics is a developing science. Indeed, only two or three centuries ago, that is all that could be said for physics. If one merely considers the development of the naturalistic school of aesthetics from Santayana to Thomas Munro and includes the detailed studies of the musicologists and other aesthetic specialists, he finds a rather extensive, systematized body of conceptual knowledge about the arts and their materials and modes of composition, and about the psychological responses and perceptions of them. The issue is no longer whether aesthetics constitutes a special scientific field; it is whether it does not include something else besides. And it clearly does have to include other nonscientific factors.

An inclusive descriptive definition of the field of aesthetics today would, accordingly, be spread out something like the following: (1) On the conceptual side, aesthetics is a special science of which the subject matter is the appreciation of the fine arts and other similar acts of appreciation. For some writers aesthetic appreciation extends very far and is allowed to take in all immediate liking and disliking whatsoever, excluding only instrumental liking of things as means to an end. Not only objects of nature acquire aesthetic value in their view but all sensuous pleasures and displeasures from smell and taste and sex to games and puzzles do so. Other writers draw the line at some natural juncture, as Santayana did with the requirement that pleasure be "objectified." (2) To this body of data conceptually organized in the manner of a special natural science, the subject of aesthetics adds a number of nonscientific modes of cognition. Among these modes are the contextualistic intuition of the vivid quality of an event and the formistic intuition of the essence of things as distinct from their appearance. Also there is the organicist's awareness of an integration of feelings and the expressionist's recognition of authentic (in contrast to corrupt) emotions embodied in works of art. These are all forms of nonscientific cognition. To the writers who stress these cognitions, they are regarded as the heart of aesthetic experience; and the scientific conceptual treatment is peripheral and inferential. (3) To complete the series, one must add sheerly felt emotions devoid of any cognitive ingredient, scientific or nonscientific. These must be interposed to satisfy the exponents of the emotive judgment theories. The scientific aestheticians regard these as data, of course, for their aesthetic systems—as a zoologist could study a cat's fear or a dog's belligerence. In doing this, the emotions are designated and conceptually related to one another through conceptual correlations and laws of contrast and gradation for compositions of painting or music. But the pure emotionist wants to say that value judgments are simply emotional expressions of Ah!, Oh!, Ooo!, Ouch!, or Whoopee!, with aesthetic emotion distinguished from the moral by not being directed upon acts of persons pro and con.

This series of three sorts of items seems to cover the aesthetic field as it is being worked over today. Any further restriction would represent a bias of some sort.

Objective and subjective vantage points

The major contrast, however, is that between the scientific conceptualized treatment of group (1) and the nonscientific, nonconceptual treatments of (2) and (3). There need not be any insurmountable conflict between these two treatments. The data could be regarded as the same set of data in both cases. The scientific aestheticians treat them conceptually as by observers from the outside. The nonscientific aestheticians, on the other hand, treat them intuitively as they feel them immediately from the inside. It just happens that in the science of aesthetics (in contrast to physics) the facts being conceptually described as "out there" (in the picture or in the music) are also capable of being immediately felt and intuited by the observer. A physicist can describe an electron with great accuracy in technical conceptual units, but he cannot feel it from the inside. An aesthetician, however, cannot only describe the composition of a picture in explanatory conceptual terms from the outside with considerable precision, but he can also feel the composition intuitively and immediately from the inside. These two different modes of aesthetic cognition can, moreover, complement each other. The conceptual description can benefit from the intuited feeling and vice versa.

With this insight in mind, a condensed definition can perhaps, without too much distortion, be given of aesthetics somewhat as follows: aesthetics is the study of immediate experience and its objects when valued for its own sake, either described conceptually as a special science observing it from without or reported intuitively as it is felt from within. (S.C.P.)

BIBLIOGRAPHY

Histories of aesthetics: The classic history in English is BERNARD BOSANQUET, *A History of Aesthetic* (1892; 4th ed., 1917), an Hegelian, organistic interpretation. KATHERINE EVERETT GILBERT and HELMUT KUHN, *A History of Esthetics*, rev. ed. (1953), is the most frequently used standard text. An excellent up-to-date treatment is MONROE C. BEARDSLEY, *Aesthetics from Classical Greece to the Present* (1966). WLADYSLAW TATARKIEWICZ, *Historia estetyki*, 2 vol. (1960; Eng. trans., *History of Aesthetics*, 2 vol., 1971), is the most comprehensive scholarly history; each section is followed by salient quotations from the original language with parallel English translations.

Anthologies of contemporary aesthetics: ELISEO VIVAS and MURRAY KRIEGER, (eds.), *The Problems of Aesthetics* (1953); JOHN HOSPERS (comp.), *Introductory Readings in Aesthetics* (1969).

Critical studies: MONROE C. BEARDSLEY, *Aesthetics: Problems in the Philosophy of Criticism* (1958), is a most detailed scholarly critical book on modern men and movements in contemporary aesthetics. A unique treatment of art as a form of emotional symbolism is SUSANNE K. LANGER, *Feeling and Form* (1953), which combines features of symbolic logic and emotional expressionism (stimulating and controversial). NELSON GOODMAN, *Languages of Art* (1968), presents a critical interpretation of such concepts as "imitation" and "expression" in terms of symbolic logic (highly original and controversial). See also MORRIS WEITZ, *Philosophy of the Arts*

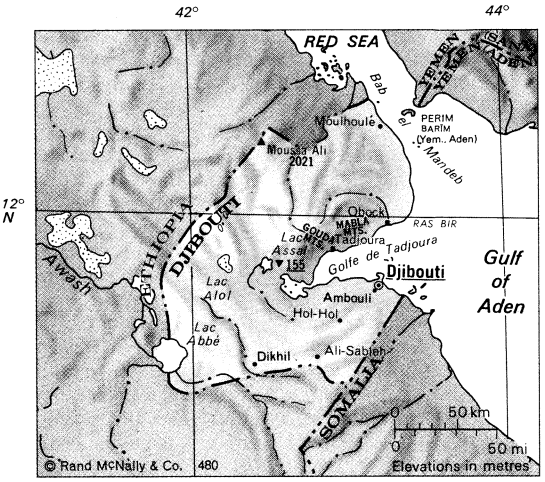
(1950), by a strong exponent of linguistic aesthetics and the open texture concept; and JACQUES MARITAIN, *Art et scholastique*, new ed. (1927; Eng. trans., *Art and Scholasticism, with Other Essays*, 1930), a formistic, Thomistic, interpretation.

Schools of thought in aesthetics: Many of the most important works of the various schools are cited in the text; in addition, the following may be listed. (*Hedonistic school*): CURT J. DUCASSE, *The Philosophy of Art* (1929), probably the most rigorous analytical account to be found; DEWITT H. PARKER, *The Principles of Aesthetics* (1920; 2nd ed., 1946; repr., 1976), describes materials of composition in the arts; STEPHEN C. PEPPER, *Principles of Art Appreciation* (1949), a systematic development consistently employing element analysis; DAVID W. PRALL, *Aesthetic Judgment* (1929) and *Aesthetic Analysis* (1936), careful analyses of aesthetic value, with sensitive illustrations of aesthetic discrimination. (*Contextualistic school*): One of the most deliberately consistent expositions is STEPHEN C. PEPPER, *Aesthetic Quality* (1937); also IRWIN EDMAN, *Arts and the Man* (1939). See also LEO STEIN, *A-B-C of Aesthetics* (1927), perhaps the earliest clear statement of contextualism; historically remarkable for its originality of insight and its reflection of *avant garde* influences. (*Organistic school*): One of the best condensed statements is BERNARD BOSANQUET, *Three Lectures on Aesthetic* (1915). Prominent recent exponents of the theory are BERTRAM MORRIS, *The Aesthetic Process* (1943); T.M. GREENE, *The Arts and the Art of Criticism* (1940); HAROLD OSBORNE, *Aesthetics and Criticism* (1955) and *Aesthetics and Art Theory* (1970). (*Formistic school*): HIPPOLYTE ADOLPHE TAINE'S two theoretical books are *Philosophie de l'art* (1865; Eng. trans., 1865) and *De l'Idéal dans l'art* (1869; Eng. trans., 1869); but his principal work is his *Histoire de la littérature anglaise*, 4 vol. (1863–64; Eng. trans., 1873). From a non-Scholastic background, one of the most systematic developments is JAMES K. FEIBLEMAN, *Aesthetics* (1949) and *In Praise of Comedy* (1939).

Oriental aesthetics: WING-TSIT CHAN (comp. and trans.), *A Source Book in Chinese Philosophy* (1963; paperback, 1969), a monumental history, based on original sources, tracing the entire panorama of Chinese philosophy; A.K. COOMARASWAMY, *The Dance of Śiva*, rev. ed. (1957), authoritative essays treating Hindu and Buddhist painting and music with insight, and interpreting the religious symbolism and profound mysticism of Indian art; SHERMAN E. LEE, *A History of Far Eastern Art* (1964), a thorough, clearly-stated treatise, lavishly illustrated, explaining the social, religious, philosophical, and visual aspects; RADHAKAMAL MUKERJEE, *The Culture and Art of India* (1959), a comprehensive work that stresses the great variety of styles and focusses upon the spread of Buddhism to China, the Golden Age of gupta culture, and the Tantric renaissance; THOMAS MUNRO, *Oriental Aesthetics* (1965), a far-reaching critical study with comparison of Eastern and Western attitudes and beliefs (with many bibliographic notes); MILTON B. SINGER (ed.), *Krishna: Myths, Rites, and Attitudes* (1966), a treatment of legends that form a thread running through Indian civilization and provide a key to the understanding of it at its best; MAKOTO UEDA, *Literary and Art Theories in Japan* (1966), essays by specialists in each of the arts bringing out its essential forms, ideas, aims, and values; VATSYAYANA, *The Kāma-sūtra*, ed. by W.G. ARCHER (1963), a distinguished guide to sexual enjoyments and the sensuous delights of perfume, music, and lyric poetry.

(S.C.P./Th.M.)

Afars and Issas (Djibouti)



Afars and Issas—since 1977 the Republic of Djibouti—is a small nation on the east coast of Africa, facing the Strait of Bab el-Mandeb between the Red Sea and the Gulf of Aden. It is bordered by Ethiopia to the north, west, and southwest, and by Somalia to the south. It covers an area of 8,880 square miles (23,000 square kilometres), and its coastline, deeply indented by the Gulf of Tadjoura, runs some 500 miles (800 kilometres) from north to south. The population in the early 1980s was about 300,000. The capital is the city of Djibouti; other towns are Ali-Sabieh and Dikhil in the south, and Tadjoura and Obock in the northeast.

Strategic importance

A French colony known as French Somaliland until 1967 and an overseas territory of France from 1967 to 1977, Djibouti is both a desert land of nomads and traders and a busy commercial entrepôt on the Red Sea. Its natural resources are poor, and its landscape and climate forbidding. Its location at the southern end of the Red Sea, however, lends it strategic value. The city of Djibouti is the only seaport to which neighbouring Ethiopia is connected by rail. The nomadic tribes cross into both Ethiopia and Somalia. (For historical aspects see EAST AFRICA, HISTORY OF.)

The landscape. Djibouti consists mostly of slightly elevated, volcanic plateaus that are bordered in places by sunken plains and lakes, some of which (Lakes Assal and Alol) are below sea level. Mountain ranges north of the Gulf of Tadjoura reach 6,630 feet (2,021 metres) at Moussa Ali. Drainage runs either to the coast or the lakes, but few streams flow above ground except after rain.

The climate is extremely hot during most of the year; temperatures average 86° F (30° C) at Djibouti city. A relatively cool season extends from November to April. Humidity is high near the coast but decreases notably in the interior. The scarce and irregular precipitation averages less than five inches annually along the coast and about 20 inches in the mountains. Except for the few permanent wooded areas on the Mabla and Gouda mountains, the vegetation consists chiefly of scrub bush. Animal life is similar to that of Ethiopia and Somalia and includes hyenas, jackals, antelopes, and gazelles.

AFARS AND ISSAS (DJIBOUTI)

The people. The two major ethnic groups of Djibouti are the Afars (or Danakil) and the Issas. Both share a common Hamitic origin and language, both are largely nomadic, and both adhere at least nominally to Islām. The Afars are concentrated in the north and west and the Issas, related to peoples in Somalia, in the south. In the most recent enumeration of 1967, the population numbered 125,000, of whom 40,000 were nomads. By the 1980s, the population was estimated to exceed 300,000, excluding some 30,000 Ethiopian and Somali refugees, predominantly Issas, who created a danger of upsetting the country's uneasy ethnic balance.

The Afars, who numbered about 90,000 in the late 1970s, are part of a larger group, the majority of which lives in Ethiopia. Those in Djibouti are divided into two main groups—the Adoyammaras and the Asahyammaras—which in turn are subdivided into several tribes and subtribes. All belong to three feudal-type sultanates, of which only that of Tadjoura is wholly within the country. The sultan, who is traditionally chosen alternately from one of two families, shares his power with a vizier and a tribal council.

The Issas numbered about 96,000 in the late 1970s. They are divided into three main groups—the Abgals, the Dalols, and the Wardiqs; they, too, are divided into several tribes. Their society is not as rigidly hierarchical as that of the Afars, although it has pariah castes. The supreme chief, the *ougaz*, is elected for life from the Wardiqs and lives in Ethiopia.

There are more than 12,000 Arabs and more than 10,000 Europeans and *assimilés* (persons not of European or African origin) in the country, most of whom live in Djibouti city. Established by the French in 1892, Djibouti city accounts for about half of the country's population. There is also an unstable population of Indian traders,

Sudanese fishermen, and Somali and Ethiopian labourers. The Europeans are chiefly French, Greek, and Italian.

Djibouti, Area and Population

	area		population

Total Djibouti	8,880	23,000	103,000	226,000*

*Total includes 10,000 Europeans.
Source: Official government figures.

The economy. Agriculture is limited to the small-scale production of dates, other fruits, and vegetables. Most cultivation is at Ambouli and Dikhil; the produce is generally sold at Djibouti city.

There are an estimated 20,000 camels, 100,000 sheep, 600,000 goats, and 20,000 cattle. In the late 1970s the administration conducted a pilot well-drilling and irrigation program for growing vegetables and new fodder crops. Limited fishing is practiced by individuals along the coast.

In addition to salt, there are deposits of iron, copper, and other ores in small quantities. None of the ores had been exploited by the early 1980s, and the salt trade was discontinued in the mid-1950s. Feasibility studies have been conducted for the construction of a power plant to exploit the geothermal resources of Lake Assal.

Internal trade is negligible. The economy rests almost entirely on services and external trade. Imports are mainly textiles and other manufactured consumer goods, coal, and cement. Exports include local products such as hides and skins, Ethiopia's transshipments of coffee and livestock, goods unloaded for transshipment, and shipping supplies. Djibouti was severely affected by the closing of the Suez Canal in 1967–75, during which time traffic declined by about 75 percent. Although canal traffic had not recovered its pre-1967 levels by 1980, Djibouti was being used by new transshippers, such as Uganda, and there was the prospect of increased containerized-shipping trade.

Port facilities

Transport and communications. Djibouti city is equipped with some 7,800 feet of quays, nine piers, a refrigeration plant, water reservoirs, and a fuel-storage tank. The port is connected to Addis Ababa, Ethiopia, by rail.

There are more than 150 miles of paved roads and about 66 miles of railroad track. The Djibouti airport serves international air routes to France, Ethiopia and other East African countries, Madagascar, and Egypt. Several small airfields are mostly used by military aircraft. There are daily radiobroadcasts in French, Afar, Issa, and Arabic, and there is a television station.

Government. The republic is governed by a president elected by the 65-member national assembly; a prime minister heads the Cabinet. Both legislative organs are structured to preserve the political balance between the Afars and the Issas. In March 1979, the ruling political party was restructured and renamed the *Rassemblement populaire pour le progrès* (RPP; Popular Assembly for Progress). The legal system is based on a mixture of traditional practices, Islāmic law, and French civil practice. Local government consists of five districts, or *cercles*; provision has been made for the creation of municipalities within the districts. Djibouti is a member of the United Nations, Organization of African Unity, and Arab League.

The labour force

Social conditions. The labour force contains many who are only temporarily or seasonally employed. Most of the wage-earning population is employed at the port and railway in Djibouti. Other labour markets are the administration, the construction and public-works industries, and the trading companies.

The main hospital at Djibouti is equipped with some 670 beds. In the interior of the country, there are several multipurpose dispensaries and medical posts.

Education, which is free but not compulsory, is provided by both religious and secular institutions. Public primary education is financed by the government, and mission schools (most of which are Roman Catholic) receive financial aid. There are about 10,000 primary school students and more than 1,600 lycée (state-run secondary school) students.

Cultural life. The country's limited cultural life is centred in Djibouti city. The Djibouti-based Société d'Études de l'Afrique Orientale (East African Studies Association) publishes a quarterly magazine, *Pount*, dealing with a variety of subjects pertaining to the country. A weekly newspaper, *Le Réveil de Djibouti*, is issued by the government.

BIBLIOGRAPHY. V.M. THOMPSON and R. ADLOFF, *Djibouti and the Horn of Africa* (1968), a well-documented study of the territory; A. TEUILIERES, *L'Outre-Mer français: hier, aujourd'hui, demain* (1970), a general work on the economic and human problems of French overseas territories; lengthy surveys of the country were published in *Marchés tropicaux et méditéranéens* (May 17, 1974) and the *Revue française d'études politiques africaines* (no. 124, April 1976), the latter containing a lengthy chronology; W.S. CLARKE, *A Developmental Bibliography for the Republic of Djibouti* (1979).

(M.B.P./Ed.)

Afghanistan

Afghanistan is located in the heart of south central Asia. Previously an absolute monarchy, it became a constitutional monarchy in 1964, a republic in 1973, and a people's republic in 1978. It has an area of about 252,100 square miles (653,000 square kilometres) and a population estimated in 1979 to number about 15,488,000. It is completely landlocked, the nearest coast lying along the Arabian Sea, 300 miles to the south. Its longest border of 1,125 miles (1,810 kilometres) is with Pakistan to the east and south. Slightly shorter is the 1,050-mile border with the Soviet Union in the north. The 510-mile border in the west separates Afghanistan from Iran, and there is a 200-mile border with the part of Jammu and Kashmir claimed by Pakistan. The shortest border—of 50 miles—is with the Sinkiang Uighur Autonomous Region of the People's Republic of China, at the end of a long, narrow corridor in the extreme northeast. The capital of Afghanistan is Kābul.

The boundaries of Afghanistan were established in the late 19th century, mainly as a result of the rivalry between imperial Britain and imperial Russia. In the 20th century, Afghanistan became a pawn in a struggle of political ideologies and a search for commercial influence. It is still economically backward and lacks the social and economic institutions necessary for development. The geographic location of this rugged, mountainous country with a limited network of roads further handicaps its economic progress, although some advances have been made. (For associated physical features, see HINDU KUSH [MOUNTAINS] and PAMIR MOUNTAIN AREA; for historical aspects, see AFGHANISTAN, HISTORY OF.)

THE LANDSCAPE

The Hindu Kush

The natural environment. *Relief.* Afghanistan's shape has been compared to a leaf, of which the Vākhān (Wākhān Corridor) forms the stem. The outstanding geographic feature of Afghanistan is its towering mountain range, the Hindu Kush (in Afghanistan, Hendu Kosh). This formidable range is a barrier between the comparatively rich, fertile northern provinces and the rest of the country, and creates the major pitch of Afghanistan from northeast to southwest. The mountain range, when it reaches a point some 100 miles north of Kābul, spreads out like a fan and continues westward under the names of Kūh-e Bābā, Band-e Bāyan, Safīd Kūh, and others, each section in turn sending spurs in different directions. One of these spurs is the Band-e Torkestān, which extends northwestward. Other important ranges include the Kasa Murgh, south of the Harīrūd (Harī River); the Kūh-e Hesār, which extends northward; and two formidable

ranges, the Kūh-e Mazar and Koh-i-Khurd, extending in a general southwestern direction. On the eastern frontier, several mountain ranges effectively protect the country from the rain-laden winds that blow from the Indian Ocean, accounting for the dryness of the climate.

Geographic regions

The Hindu Kush and subsidiary ranges divide Afghanistan into three distinct geographic regions, which roughly could be designated as the Central Highlands, the Northern Plains, and the Southwestern Plateau. The Central Highlands, actually a part of the Himalayan chain, includes the main Hindu Kush range. Its area of about 160,000 square miles (400,000 square kilometres) is a region of deep, narrow valleys and lofty mountains, some peaks rising above 21,000 feet (6,400 metres).

The Northern Plains, north of the Central Highlands, extends from the Iranian border to the foothills of the Pamirs. It is a 40,000-square-mile region of plains and fertile foothills sloping gently toward the Amu Darya (the ancient Oxus River). This area is a part of the much larger Central Asian steppe, from which it is separated by the Amu Darya. The average elevation is about 2,000 feet. The Northern Plains region is intensively cultivated and densely populated. In addition to fertile, loess-covered soils, the region possesses rich mineral resources, particularly deposits of natural gas.

The Southwestern Plateau, south of the Central Highlands, is a region of high plateaus, sandy deserts, and semideserts. The average altitude is about 3,000 feet. The Southwestern Plateau covers about 50,000 square miles, one-fourth of which forms the Rīgestān Desert. Several large rivers cross the Southwestern Plateau; among them are the Daryā-ye Helmand (Helmand River) and its major tributary, the Daryā-ye Arghandāb.

The Sīstān depression

Most of Afghanistan lies between 2,000 and 10,000 feet in elevation. Along the Amu Darya in the north and the delta of the Daryā-ye Helmand in the southwest, the altitude is about 2,000 feet. The Sīstān depression of the Southwestern Plateau, 1,500 to 1,700 feet in elevation, was the seat of a flourishing ancient civilization that was ended in the 14th century by Timur (Tamerlane).

Drainage. Practically the entire drainage system of Afghanistan is enclosed within the country. Only the rivers in the east, which drain an area of 32,000 square miles, reach the sea. The Kābul River, the major eastern stream, flows into the Indus River, which empties into the Arabian Sea of the Indian Ocean. Almost all the other important rivers of the country originate in the Central Highlands region and empty into inland lakes or dry up in sandy deserts. The major drainage systems are those of the Amu Darya, Helmand, Kābul, and Harīrūd.

The Amu Darya, a 1,578-mile-long river originating in the glaciers of the Pamirs, drains an area of approximately 93,000 square miles in the northeastern (Badakhshan) and northern (Khānābād and Mazār-e Sharīf) parts of the country. It forms the frontier between the Soviet Union and Afghanistan for 600 miles of its upper course. Two of its major Afghan tributaries, the Kowkcheh and the Qondūz, rise in the mountains of Badakhshan and Qondūz provinces, respectively. The Amu Darya becomes navigable from its confluence with the Kowkcheh, 60 miles west of the city of Feyzābād. The Amu Darya empties into the Aral Sea in the Soviet Union.

The northwestern drainage system is dominated by the Harīrūd, originating on the western slopes of the Kūh-e Bābā range, at an altitude of 9,000 feet. The river flows westward, just south of Herāt and across the broad Herāt Valley. After irrigating the fertile lands of the valley, the Harīrūd turns north about 80 miles west of Herāt and forms the border between Afghanistan and Iran for a distance of 65 miles. It then crosses into Soviet Central Asia and disappears in the Kara-Kum Desert.

The Helmand River

The principal river in the southwest is the 900-mile-long Helmand, which rises in the Kūh-e Bābā Mountains, about 50 miles west of Kābul. With its many tributaries, mainly the Arghandāb, it drains more than 100,000 square miles. The river empties into Hāmūn-e Ṣāberī, an inland lake. In its course through the southern region of the country, the Helmand flows north of the Rīgestān Desert and then crosses the Dasht-e Mārgow (Mārgow Desert) until it reaches the lakes region of the Sīstān depression. Three other rivers are part of the Helmand drainage system. They are the Farāh Rūd, the Khāsh Rūd, and the Hārūt Rūd.

The largest drainage system in the southeastern region is that of the Daryā-ye Kābul, which flows eastward from the slopes of the Kūh-e Mazar range to join the Indus River at Attock, Pakistan. Its major tributary in the south is the Lowgar.

Afghanistan has few lakes of any considerable size. The two most important are the Hāmūn-e Ṣāberī and the Āb-e Īstādeh-ye Moqor, situated 60 miles south of Ghaznī. There are five small lakes in the central highland of Hazārajāt known as the Band-e Amīr; they are known for their unusual shades of colour, from milky white to dark green, caused by the underlying bedrock.

Climate. In general, Afghanistan has extremely cold winters and hot summers, typical of a semiarid steppe climate. There are many regional variations, however. While the mountain regions of the northeast are dominated by a subarctic climate with dry and cold winters, the mountainous areas on the border of Pakistan are influenced by the Indian monsoons, usually coming between July and September and bringing maritime tropical air masses with humidity and rains. In addition, humid air masses entering from the Persian Gulf bring showers and thunderstorms in the southwest during the summer.

Local variation is also produced by differences in altitude. The weather in winter and early spring is strongly influenced by cold air masses from the north and the Atlantic low depression from the northwest; these two air masses bring snowfall and severe cold in the highlands and rain in the lower altitudes.

Afghanistan has a wide range of temperatures. High temperatures over 95° F (35° C) have been recorded in the drought-ridden Southwestern Plateau region. In Jalālābād, considered to be one of the hottest localities in the country, the highest temperature of 120° F (49° C) has been recorded in July. January temperatures may drop to 5° F (-15° C) in the high mountain areas, while at the city of Kābul, located at an altitude of 6,000 feet, the lowest temperature has been recorded at −24° F (−31° C).

Annual precipitation, again, reflects regional diversity. In the mountains, for example, the annual mean precipitation increases from west to east; there, as in the southwestern monsoon region, it averages 15.8 inches (401 millimetres). The extremes of precipitation have been recorded in the Sālang Pass of the Hindu Kush, with the highest annual precipitation of 53 inches, and in the arid region of Farāh in the west, with only 3 inches a year.

Climate of Kābul

Among the important cities in Afghanistan, Kābul has the highest annual precipitation (14 inches) and the lowest annual mean temperature (52° F). Most of the country's precipitation occurs from December to April; in the highlands snow falls from December to March, while in the lowlands, it rains intermittently from December to April or May. The summer months are hot, dry, and cloudless everywhere but in the monsoon region.

Vegetation and animal life. Vegetation is sparse and scanty in the southern part of the country, particularly toward the west, where dry regions and sand deserts predominate. Trees are almost nonexistent, and only in the rainy season of early spring is the soil covered with flowering grasses and herbs. The plant cover becomes more dense toward the north, where precipitation is more abundant; and at higher altitudes the plants are almost luxuriant, particularly in the mountainous region north of Jalālābād, where the climate is influenced by the monsoons. The high mountains abound in large forest trees, among which conifers, such as pine and fir, predominate. Some of these trees are 180 feet high. The average altitude for the fir line is over 10,000 feet. At lower altitudes, somewhere between 5,500 and 7,200 feet, cedar is abundant, and below the fir and cedar lines, oak, walnut, alder, ash, and juniper trees can be found. There are also shrubs, several varieties of roses, honeysuckle, hawthorn, and currant and gooseberry bushes.

Most of the wild animals of the subtropical temperate zone inhabit Afghanistan. Large mammals, although for-

merly abundant, are now greatly reduced in numbers, however. The Siberian tiger, which inhabited the banks of the Amu Darya, has all but disappeared, as have the tigers that inhabited the southeastern region. There is still a great variety of wild animals roaming the mountains and foothills, including wolves, foxes, hyenas, and jackals. Gazelles, wild dogs, and wild cats are widespread. Wild goats, including the markhor (prized for its long, twisted horns) and the ibex (with long, backward-curving horns), can be found in the ranges of the Pamirs, and wild sheep, including the urial and argali (or Marco Polo sheep), in the Pamirs and the Hindu Kush. Bears are found in the mountains and forests. Smaller animals such as mongooses, moles, shrews, hedgehogs, bats, and several species of kangaroo rat (jerboas) may be found in the many isolated, sparsely populated areas.

The bird kingdom is well represented by birds of prey, especially vultures, which occur in great numbers, and eagles. Migratory birds abound during the spring and fall seasons. There are also many pheasant, quail, cranes, pelicans, snipe, partridge, and crows.

There are many varieties of freshwater fish in the rivers, streams, and lakes, but their numbers are not great except on the northern slopes of the Hindu Kush, where the rivers are well stocked with brown trout.

Traditional regions. The Hindu Kush divides the coun-

The designer as an employee of an agency

The upshot of this development is that the advertising designer has virtually become a staff employee and team colleague of the agency. His freedom as an independent creative designer is thus restricted to the extent that he must subordinate his gifts to the advertising conception elaborated by the marketing experts. Depending on his talents, he will be employed in a variety of capacities or as a specialist in one particular line—for example, as an illustrator, letterer, draftsman, filmmaker, or display designer. In most cases his work remains outwardly anonymous and is integrated with the overall output of the agency. Actually, his work is identified by the layout man, who sees to the rough draft of the advertisement and prepares sketches showing how the separate units are to be integrated into a whole. The designer also works in close collaboration with the copywriter and the contact man who is in touch with the agency's client.

KINDS OF MEDIA

Graphic or printed, drawn, and painted media. These include advertisements in periodicals, posters, brochures, leaflets, pamphlets, buttons, and the like. Frequently they contain a "device," "trademark," or "trade name" used to denote the maker or supplier of the product or service. The device or trademark represents the most concise graphic form that a particular subject can be given. It should be simple, unmistakable, applicable, and timeless. The trade word has the advantage over the device in that it can be read at once, whereas the meaning of the device must first be made known. Its disadvantages, of course, are that it contains more formal elements (depending on the length of the name) and that the designer's freedom to shape it at will is limited by the demands of legibility; it thus usually has a weaker impact.

The special characteristics of each medium

Each medium has its own demands. Whereas a poster designed to produce an effect at a distance, for instance, must be drawn and coloured on a generous scale, a newspaper advertisement has to be worked out with greater attention to details. In any case, the idea is to achieve the maximum of clarity and impact with the minimum resources of colour and form. The illustrative poster, for example, presents the theme or object with an atmospheric appeal; the realistic poster supplies objective information through its copy and the truthful depiction of the object; the constructivist poster arranges its pictorial elements in accordance with their thematic importance. The experimental poster surprises the viewer by the novel way in which it presents a problem or by the new techniques it employs.

Kinetic or moving media. Television commercials and other kinds of films afford the advertising designer a variety of interesting opportunities. If the film or tape consists of live action, then titles, subtitles, possibly functional diagrams, statistics, movie sets, and so on have to be designed. If the film consists of an animated cartoon, then the designer's imagination is given almost unlimited scope; every type of drawing can be used, from fairy-tale illustration to surrealistic montage, and every kind of style can be employed—naturalism, simplified and stylized presentation, abstract symbolism, and so on. But, in any event, it is important that the designer depict his pictorial ideas clearly and simply, that they do not change too quickly, and that he not present more than one or two ideas in the picture at the same time. He must consider colours and their sequences with the same care. In all types of films, lettering, image, word, and sound must complement one another, and thus the designer must collaborate closely with the producer, the copywriter, and the cameraman to make sure that the various components work together to enhance the total impact. The eye and mind of the viewer must be captured amid the multitudinous visual impressions.

In parades and demonstrations there are posters, transparencies, banners, and boards, but, unlike most ordinary posters, they are continually in motion and must be visible from various angles. Lettering and images must be recognizable and legible at a distance.

Identifying and directional signs. One of the most interesting jobs in advertising design is the creation of a uniform "image" for a business or organization. All advertising aids from visiting cards through commercial forms and newspaper advertisements to outdoor signboards should be given an unmistakable character with regard to graphic form, typography, and colour, so that each element is seen as part of an overall conception. All these different impressions must have a family resemblance, so that their effect is cumulative and produces a clear image in the eye of the beholder. Uniform advertising is a powerful aid in the creation of a firm's image.

Creating the "image" of the firm

In comparing lettered signs on doors, windows, buildings, factories, and so on, the advertising designer is confronted by three specific problems: the lettering must be visible at a certain distance; it must make an impact by reason of its formal originality; and it must be integrated with the architecture in size, form, colour, and material. If the lettering is to be visible at night, the designer can make his choice between neon lettering and spotlighted lettering. If he chooses neon lettering, he must adapt the shape of his letters to technical or engineering requirements.

In composing lettered signs on delivery vans, trucks, and so on, the designer must take the factor of movement into account: the letters must be somewhat spaced out so that they will not run together when read on the moving vehicle. Similar care is also needed in selecting colours; as a rule dark colours are more suitable because they produce more contrast.

Although not always thought of as part of advertising, directional signs and other communication systems, if well designed, help to promote a firm's good public relations. These are the signs that figure importantly at airports, railway stations, administrative buildings, and other places where large numbers of people have to be directed to their destination by the shortest route in the shortest possible time. The signs and lettering must be uniform in design, clear and factual, and somehow correspond to the organization's advertising design or image. Large airlines, for instance, have recognized that uniform liveries for their employees and uniform lettering for their check-in counters, passageways, and so on are important for advertisement as well as for directional signals, and they have engaged graphic artists to design them.

Promotional items. There is an enormous variety of items that an advertiser can distribute in order to attract the attention of the public it addresses. These include calendars, matchbooks, glassware, ashtrays, notebooks, writing instruments, playthings, and decorative items of all sorts. Such items may be distributed year-round or be used as holiday gifts.

How long an object will continue to attract attention depends on the quality of the material, its workmanship, and the timelessness of its form or colour arrangement. The designer must be guided by aesthetic considerations in affixing the name of the firm, which may be stamped or printed on the object, attached to it on a label, or cast in its interior if the material is transparent. A decorative version of the name may be a factor in determining the form of the object, but often it is placed discretely on the underside.

HISTORICAL DEVELOPMENT

Origins. Advertising is as old as humanity itself. Advertising tries to do what every man wants to do: to influence others, to win their suffrage, and to convince them. First of all there was the word, which expressed man's thoughts and feelings; then followed the picture, which gave his ideas lasting form; and finally came writing, which perpetuated the spoken word beyond the moment of its utterance.

Ancient designs and posters

In the ancient civilizations of China, Mesopotamia, Egypt, Greece, and Rome, tradesman and merchant became recognized callings. They used books of account, business deeds, contracts, written powers of attorney, and—most important here—stamps for making their products, marks to denote the ownership of their livestock, and seals that were recognized and protected by the law as pictorial "signatures." These were the prede-

cessors of today's trademarks. In Rome there were a number of marketplaces and streets reserved for particular craftsmen and tradesmen or their goods and bearing their names. Professional "poster painters" inscribed election manifestos and advertisements on walls (*dipinti* and *graffiti*), and some 1,600 of these announcements have been found in Pompeii alone. Frescoes painted on the houses of tradesmen publicized their products or their work.

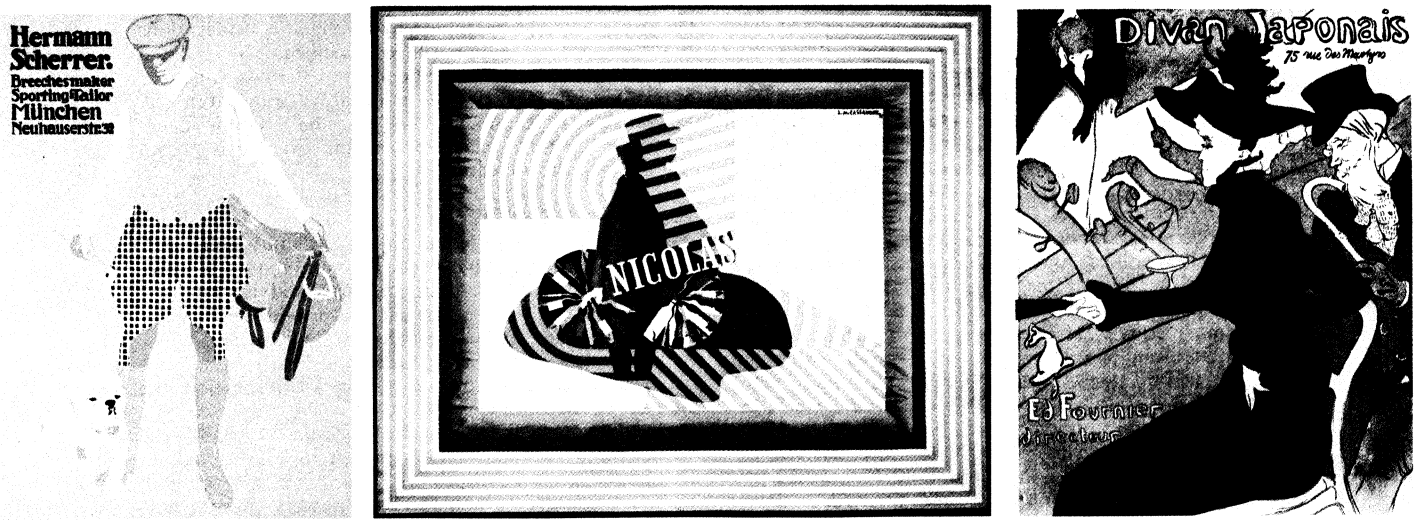
The next most crucial development was the invention of printing in the 15th century. Printing with movable letters allowed the distribution of an unlimited number of copies of an item. In the following three centuries, from the 15th to the 18th, there appeared an ever expanding number of books, calendars, leaflets, travel guides, exhibition guides, book catalogs, playing cards, chronicles, newspapers, advertising sheets, weeklies, letterheads, certificates, labels, business cards, maps, and posters. The prosperous condition of the printing trade gave rise to printer's marks, watermarks, bookplates, monograms, trademarks, and devices, and encouraged the development of various type fonts. Printers and type designers cut letters that bear their names and are still in use today, being frequently employed by the advertising designer. Claude Garamond cut his type in 1544, William Caslon in 1722, John Baskerville in 1757, Firmin Didot in 1783, and Giambattista Bodoni in 1788. François-Ambroise Didot invented the typographical point system, which has become indispensable for establishing type sizes. The printed picture also received attention. At first the primary function of the illustration was to support the text, but later it became an attractive means of visual communication in its own right, reaching its peak in the 19th-century poster.

19th and early 20th centuries. The industrialization of the West in the 19th century and the explosive development of the economy gave impetus to the graphic arts. Advertising began to make a more deliberate use of means of visual communication. Government authorities, publishers, business firms, industrialists, and politicians harnessed newspapers, magazines, posters, and pamphlets to their purposes. Interest was shown in the design of letterheads, packages, wrapping paper, and shop signs.

Development of lithography and photography

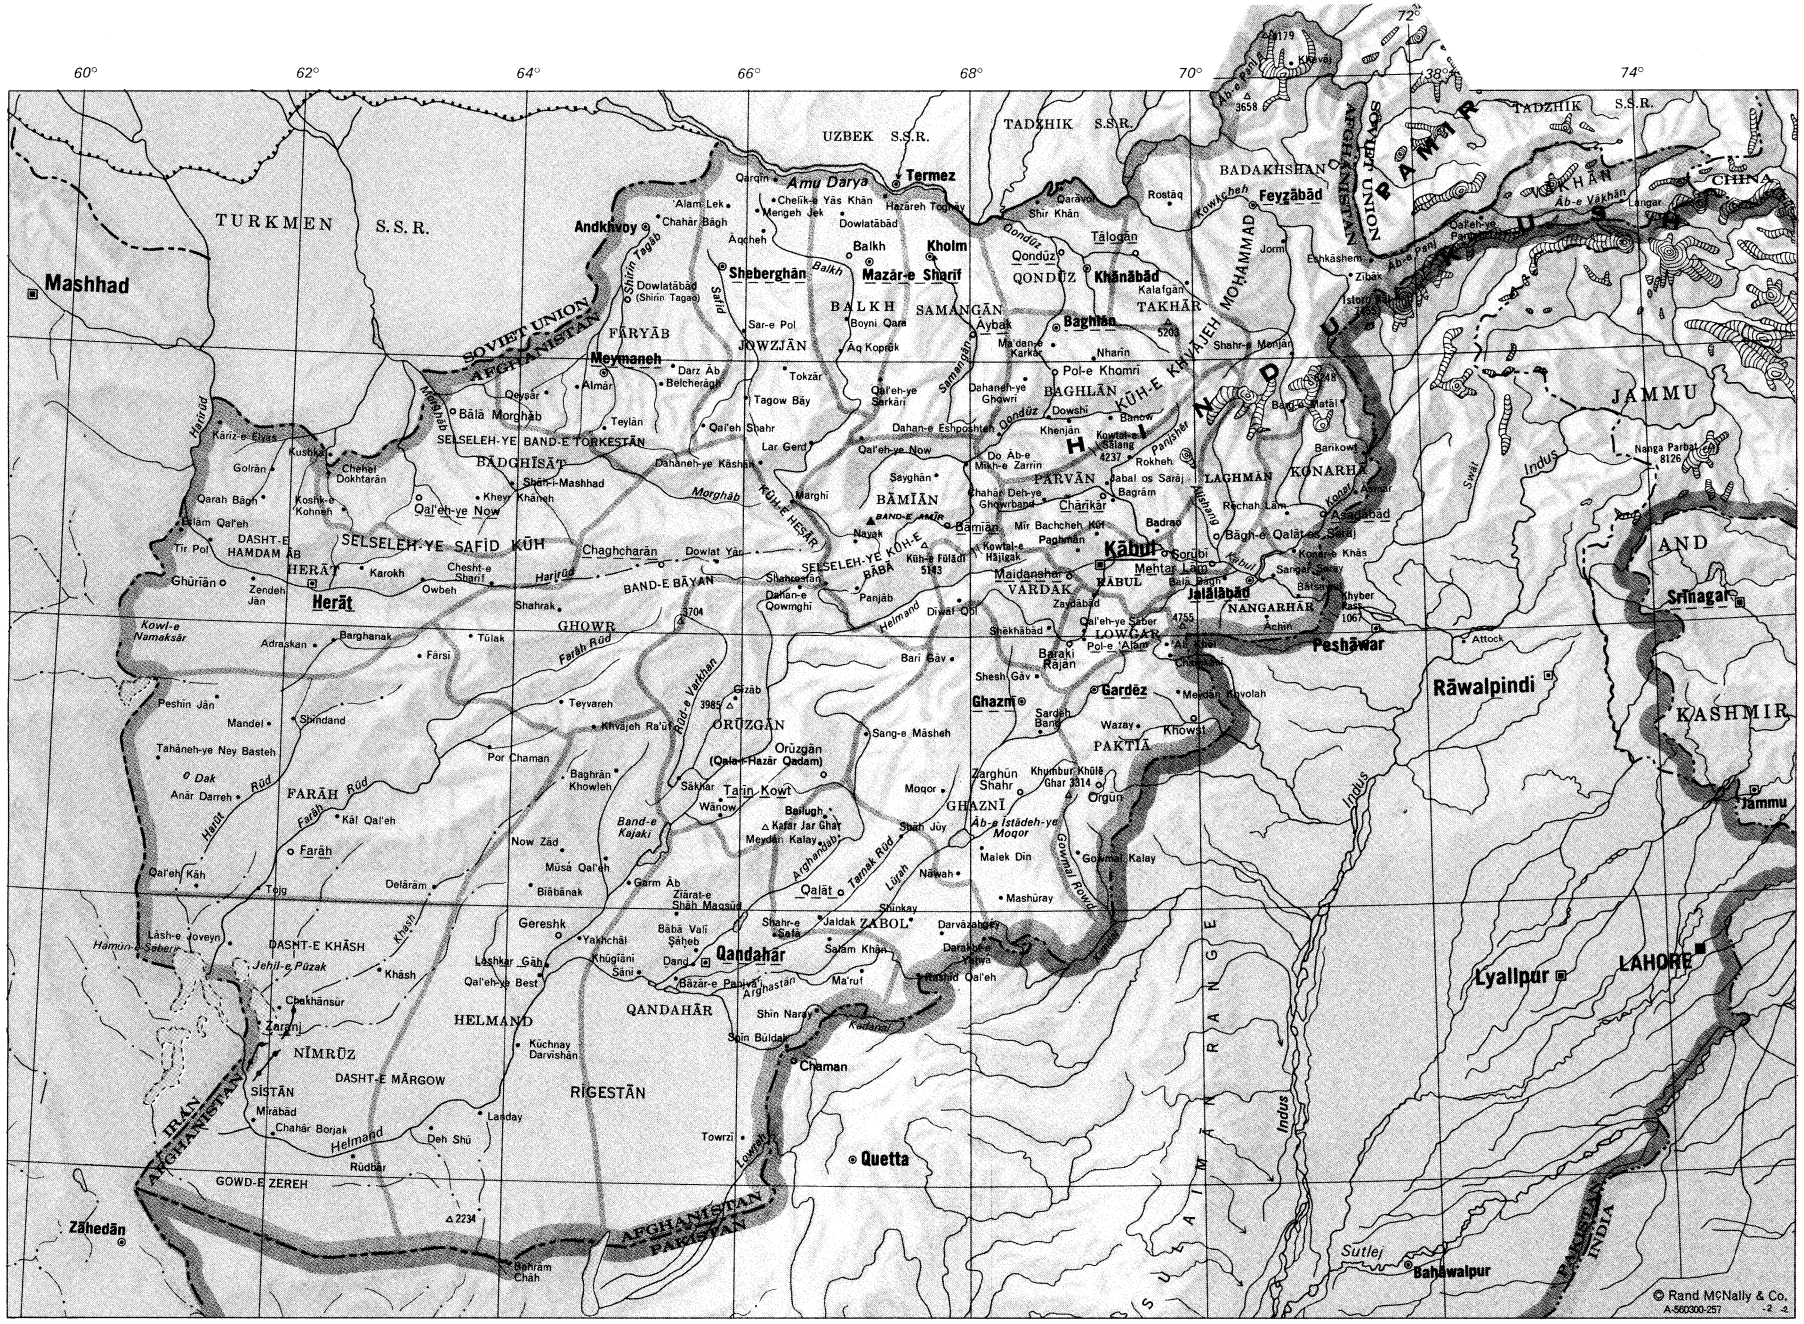
The invention of lithography, or chemical printing from stone, in 1795–98 greatly widened the scope of reproduction and printing. It allowed the finest lines to be printed and at the same time was simpler and cheaper than letterpress printing. In 1827 it was followed by colour lithography. The negative aspect of this invention was that a large number of new fonts appeared which were suitable for the lithographic technique but which were generally inferior aesthetically. Among the exceptions were "Egyptian," designed by Vincent Figgins, and the "Display Sans Serif," developed by the Berthold type foundry in Berlin and Vienna. Since World War II this latter face has been enjoying a renaissance in Europe.

In 1826, Joseph-Nicéphore Niepce succeeded in producing an image on a metal plate coated with light-sensitive asphaltum and thus invented photography. Louis-Jacques Daguerre improved the process with his daguerrotype, with which it was possible to make a usable negative. In 1903, the newspaper *Le Matin* printed the first half-tone block from a photograph. In the same year Louis Lumière invented colour photography. Concurrently, "moving" photography, or motion pictures, was being developed. Science, industry, process engraving, and advertising soon found that photography and films had become indispensable mediums of information. In the latter part of the 19th century, Jules Chéret, Toulouse-Lautrec, T.A. Steinlen, Pierre Bonnard, and others, influenced by the coloured woodcut of Japan, brought the lithographic poster to an artistic peak, which at the same time marked the birth of the modern poster. In the early 20th century, Max Klinger, Ludwig Hohlwein, and other artists working in Germany produced the realistic picture poster, which displays the subject or theme starkly and vividly. About the same time there appeared the first Constructivist posters by Peter Behrens (in Berlin) and J. Hoffmann and Joseph Olbrich (in Vienna), in which the picture is built up architecturally and geometrically.



In the mid-19th century, advertising agencies appeared in Germany and thereafter engaged in the design and placing of advertisements in newspapers, periodicals, and catalogs. Well into the 20th century, however, the artistic quality of their output often was poor.

From the 1920s to the present. After World War I there was an efflorescence of intellectual and creative activity in all fields of design. Soviet Constructivism offered Cubist and geometric themes; Italian Futurism presented the idea of the machine with an almost photographic vision; the de Stijl movement in Holland espoused rectangular forms and primary colours; Dadaism and Surrealism in Switzerland, Germany, France, and the U.S., offered fantasy, humour, and near animation. Among the most renowned advertising designers of this period between two wars was A.M. Cassandre, whose witty and formally sophisticated posters dominated the billboards in France.



Bauhaus influence

The Bauhaus, the art school founded by Walter Gropius in 1919, became the centre of modern design. Fundamentally, it sought to end the old schism between the artist and the technically expert craftsman by training

try into northern and southern regions, which can be further subdivided on the basis of topography, national and ethnolinguistic settlement patterns, or historical tradition. Northern Afghanistan, for example, may be subdivided into the Badakhshan–Vākhān region in the east and the Balkh–Meymaneh region in the west. The east, which is mainly a conglomeration of mountains and high plateaus, is inhabited chiefly by Tadzhiks (Tajiks), while the west, which is mostly plains of comparatively low altitude, contains a mixture of peoples in which Uzbeks and Turkmens of Turkic origin predominate.

Southern Afghanistan

Southern Afghanistan can be subdivided into four subregions—those of Kābul, Qandahār, Herāt, and Hazārajāt. The Kābul region combines the area drained by the Daryā-ye Kābul and the high plateau of eastern Afghanistan, bounded in the south by the Gowmal Rowd (Gumal River). This region is inhabited by Pashtuns (Pathans), Tadzhiks, and Nuristanis (formerly called Kafirs, a pejorative term since the 1890s). This region is the main corridor connecting the other regions and their peoples.

The Qandahār region consists of the sparsely populated southern part of Afghanistan. The people inhabiting this region belong principally to the Durrānī branch of the Pashtuns. In addition, there is a small number of Baluch and Brahui peoples. The city of Qandahār, former capital of the country, is located in a fertile oasis near the Daryā-ye Arghandāb.

The region of Herāt, or western Afghanistan, is inhabited by a mixture of Tadzhiks, Pashtuns, and Chahar Aimaks. The life of the region revolves around the city of Herāt.

The mountainous region of Hazārajāt occupies the central part of the country and is inhabited principally by the Ḥazāras. Although Hazārajāt is located in the heart of the country, its high mountains and poor communication facilities make it the most isolated part of Afghanistan.

Settlement patterns. In 1979, about 13 percent of the people of Afghanistan were urban dwellers. Most urban settlements have grown along the major circular road of the country that runs from Kābul southwestward to Qandahār, then northwest to Herāt, northeast to Mazār-e Sharīf, and south back to Kābul. The rural population of farmers, semi-sedentary farmers, and nomads is distributed unevenly over the rest of the country, mainly concentrated along the rivers. The most heavily populated part of the country is between the cities of Kābul and Chārīkār. Other concentrations of people can be found in the Herāt oasis of the northwest, in the valley of the Harīrūd, and in the valley of the Daryā-ye Qondūz in the northeast. The high mountains of the central part of the country and the deserts in the south and southwest are sparsely populated or uninhabited.

Rural settlement. Sedentary farmers usually live in small villages, most of them scattered near irrigated land in the valleys of major rivers. These villages, as a rule, are built in the form of small forts. Each fort-village contains several mud houses, inhabited by closely connected families who form a defensive community.

The semi-sedentary farmers, who breed livestock and raise a few crops, live in the high alpine valleys. Since cultivable land there is scarce, they live in scattered isolated hamlets. Each household owns a few head of livestock, which are moved in summer to the highland pastures and are returned in the winter. Usually, the people divide themselves into two groups in summer: one group remains in the hamlet to tend the crops, while the other accompanies the livestock to the highlands.

The nomads are mainly Pashtun herdsmen; there are also several thousand Baluch and Kirgiz nomads. They move in groups (tribes or clans) from summer to winter pasturages and back again, living in tents and, while on the move, packing their belongings, together with their small children, on the backs of camels, donkeys, and cattle. Of an estimated total population of more than 15,000,000, between 2,500,000 and 3,000,000 people in Afghanistan are nomads. Since 1977, however, some nomads have been settled in the plains north of the Hindu Kush or in the area of the Helmand Valley Project.

Major cities

Cities. The major cities of Afghanistan are Kābul, Qandahār, Herāt, Baghlān, Tagāb, Qondūz, Chārīkār, and Mazār-e Sharīf. Kābul is the administrative capital of the country, located south of the Hindu Kush at the crossroads of the trade routes between the Indian subcontinent and Central Asia and between the Near and Far East. It is a city of almost 900,000 people (1979 estimate), built on both sides of the Daryā-ye Kābul and covering an area of 53 square miles (137 square kilometres). It is also the main centre of economic and cultural activity. All banking institutions and most of the important commercial enterprises are located there. In addition, a new industrial area was being developed in the late 1970s east of the city. The capital boasts cultural institutions including theatres, concert halls, and libraries. It is a fast growing city with modern buildings, wide avenues, and bustling bazaars.

Qandahār is second to Kābul in the size of its population, estimated in 1979 at 245,000. It is located on the Asian Highway, halfway between Kābul and Herāt. Qandahār became the first capital of modern Afghanistan in 1747 under Aḥmad Shāh Durrānī.

The city of Herāt had an estimated population of 171,000 in 1979. Of the other major cities, Baghlān had an estimated 1975 population of 110,900. Qondūz had 108,000, Tagāb 106,800, and Chārīkār 100,400. The rapidly growing trade and industrial city of Mazār-e Sharīf had a population of more than 100,000 in 1979.

PEOPLE AND POPULATION

The people. *Linguistic groups.* The people of Afghanistan form an intricate mosaic of ethnic and linguistic groups. Two major language families—the Indo-European and the Altaic—have gradually developed in the country. Pashto (Pushtu) and Dari, a dialect of Persian (Fārsī), are Indo-European languages; they are the official languages of the county. About half of the population speaks Pashto, the language of the Pashtuns, while about a third of the population speaks Dari, the language of the Tadzhik (Tajik), Ḥazāra, Chahar Aimak, and Kizilbash peoples. Other Indo-European languages, spoken by smaller groups, include Western Dardic (Nuristani or Kafiri), Baluchi, and a number of Indic and Pamiri languages spoken principally in isolated valleys in the northeast.

The subfamily of Altaic languages in Afghanistan is that of the Turkic languages. They are spoken by the Uzbek and Turkmen peoples, the most recent settlers, who are related to peoples from the steppes of Central Asia, now within the borders of the Soviet Union. The Turkic languages are closely connected with each other; within Afghanistan they include Uzbek, Turkmen, and Kirgiz, the last spoken by a small group in the extreme northeast.

Ethnic groups. The present population of Afghanistan contains a number of elements, which, in the course of history and as a result of large-scale migration and conquests, have been superimposed upon each other. Dravidians, Indo-Aryans, Greeks, Scythians, Arabs, Turks, and Mongols have, at different times, inhabited the country and have influenced its culture and ethnography. The great majority of people belong to two main linguistic groups—the Pashtuns and Tadzhiks, who speak Indo-European languages, and the Uzbeks and Turkmens, who speak Turkic languages. Intermixture of these two groups is evident in such peoples as the Ḥazāras and Chahar Aimaks, who speak Indo-European languages but have pronounced Mongoloid physical characteristics and cultural traits usually associated with Central Asia.

The Pashtuns

The 6,214,000 Pashtuns of Afghanistan principally inhabit the southern and eastern parts of the country, but are also well represented in the west and north. They are divided into a number of tribes, some sedentary and others nomadic. The traditional homeland of the Pashtuns lies in an area east, south, and southwest of Kābul, with a large segment of their numbers in contiguous territory of Pakistan. The two most important groups of the Pashtun tribal confederation are the Durrānīs, who live in the area around the city of Qandahār, and the Ghilzays, who inhabit the region between Kābul and Qandahār. The Durrānīs formed the traditional nucleus of Afghanistan's social and political elite.

The Tadzhiks, mostly farmers and artisans, number more than 3,600,000 and live in the Kābul and Badakh-

*No census has ever been taken. †Detail does not add to totals given because of rounding. ‡Total includes an estimated number of nomads for whom no provincial breakdown was available.
Source: Official government figures.

shan areas of the northeast and the Herāt region in the west; there are also pockets of Tadzhiks in other areas. They are sedentary in the plains and semi-sedentary in the higher valleys. They are not divided into clear-cut tribal groups.

The Nuristanis, who speak Western Dardic, number about 66,000 and inhabit an area of some 5,000 square miles in Laghmān and Nangarhār provinces, north and east of Kābul. The Ḥazāras traditionally occupy the central mountainous region of Hazārajāt. Because of the scarcity of land and pressure of population, however, they have migrated in large numbers to other parts of the country. The Ḥazāras speak a Dari dialect that contains a number of Turkish and Mongolian words. No definite figures for the number of Ḥazāras are available, and estimates range between 500,000 and 2,000,000.

The Chahar Aimaks are probably of Turkic or Turco-Mongolian origin, judging by their Mongoloid physical appearance and their housing of Mongolian-style yurts. They are located mostly in the western part of the central mountain region; their numbers range between 300,000 and 830,000. The Uzbeks and Turkmens inhabit a region north of the Hindu Kush, and there are small numbers of Kirgiz in the Vākhān in the extreme northeast. The Uzbeks are usually farmers, while the Turkmens and Kirgiz are mainly semi-nomadic herdsmen. The Uzbeks, numbering 1,346,000, are the largest Turkic-speaking group in Afghanistan. The Turkmens number approximately 400,000, while the Kirgiz number no more than 36,000 (the majority of the Kirgiz live in the neighbouring parts of the Soviet Union). There are other smaller Turco-Mongolian groups in the country.

The Uzbeks and Turkmens

Very small ethnic groups of Dravidian and Semitic speakers should also be mentioned. Dravidian languages are spoken by about 19,000 Brahuis, residing in the extreme south of Afghanistan. There is also a small number of Jews, most of whom speak Dari in their daily lives, but use Hebrew for their religious ceremonies.

Religion. About 99 percent of the people of Afghanistan are Muslims, of whom 80 to 85 percent are members of the Sunnī sect (Ḥanafī branch). The others, particularly the Ḥazāras, Kizilbash, and a few Ismāʿīlīs, follow Shīʿah Islām. The Nuristanis are descendants of a large ethnic group, the Kafirs, who were forcibly converted to Islām in 1895; the name of their region was then changed from Kafiristan (Land of the Infidels) to Nuristan (Land of Light). There are also a few thousand Hindus and Sikhs.

Demography. No comprehensive census had been taken in Afghanistan by 1980. A growth rate of 2.2 percent a year has been tentatively accepted, however, and the total population in 1979 was estimated to be about 15,488,000.

The average density of population is about 61 persons per square mile (24 per square kilometre). In general, the river valleys, with their fertile land and irrigated plains, are more densely populated than the unproductive mountains or sandy deserts. The estimated population density ranges from seven persons per square mile in Nīmrūz province to 795 persons in Kābul province. The most densely populated provinces are Kābul, Nangarhār, Qondūz, Parvān, Laghmān, Lowgar, Balkh, Takhar, Paktiā, and Vardak. The most sparsely populated provinces are Nīmrūz, Farāh, Ghor, and Helmand.

THE NATIONAL ECONOMY

When Afghanistan began to plan the development of its economy in the mid-1950s, it lacked not only the necessary social organization and institutions for modern economic activities but also the essential managerial and technical skills. On the whole, the country was at a much lower stage of economic development than most of its neighbours. Since 1956, however, the country's economic growth has been guided by several five-year plans and a seven-year plan (1976–83), and aided by extensive foreign assistance in the form of loans and grants. Roads, dams, power plants, and factories have been constructed, irrigation projects carried out, and education broadened. Especially important in this country of traditional Muslim conservatism have been the steps taken to give women equal rights with men and to abolish polygamy.

Resources. *Mineral resources.* Extensive surveys have revealed the existence of a number of minerals of economic importance. The most important discovery has been that of natural gas, with large reserves near Shibarghān in Jowzjān province, near the Soviet border, about 75 miles west of Mazār-e Sharīf. These major natural gas deposits are estimated to total about 67,000,000,000 cubic metres. The Khvājeh Gūgerdak and Yatīm Taq fields are major producers, with storage and refining facilities. A pipeline delivers natural gas to the Soviet Union, and a second pipeline delivers natural gas to a thermal power plant and chemical fertilizer plant in Mazār-e Sharīf.

Natural gas

Oil resources so far have proved to be insignificant. Many coal deposits have been found in the northern slopes of the Hindu Kush, and it is estimated that all known deposits possess between 300,000,000 and 500,000,000 tons of various grades of coal. Coal is mined from the three major fields of Karkar and Eshposhteh, in Baghlān province, and Qalʿeh-ye Sarkārī, the largest of the three, in Balkh province. Qalʿeh-ye Sarkārī is estimated to have more than 60,000,000 tons of coal, Karkar about 4,000,000 tons, and the old Eshposhteh deposit, now nearing exhaustion, some 350,000 tons. Reserves of about 20,000,000 tons of coal at Masjid-Chabi, 96 miles northeast of Herāt, are not consistently mined.

High-grade iron ore, with an iron content of 62–63 percent, has been discovered at Ḥājīgak, 60 miles northwest of Kābul. This deposit contains reserves of some 2,000,000,000 tons of ore, but is mined in small quantities. There are also deposits of copper, lead, and zinc near Qondūz; beryllium in Konar-e Khāṣ; and the semiprecious stone lapis lazuli in Badakhshan. Afghanistan has sufficient deposits of rock salt, the production of which, however, is hampered by the lack of roads; the Tāloqān mine, about 30 miles east of Qondūz, produces some 21,000 tons of salt annually. Another rock salt deposit is at Kalafgān, about 28 miles from Tāloqān, and large quantities of salt are collected from a salt lake, 50 miles southeast of Andkhvoy.

Biological resources. Afghanistan is essentially a pastoral country. Only 6 percent of the total area is planted annually. The remaining area consists of fallow cultivable land (6 percent) or steppes and mountains that are seasonally covered by flowering grasses and herbs and serve as pastureland. In addition, a large area is desert.

Forests cover about 7,300 square miles; they are found mainly in the eastern part of the country and on the southern slopes of the Hindu Kush. Those in the east consist mainly of conifers, providing timber for the building industry as well as some wild nuts for export. Other trees, especially oaks, are used as fuel. North of the Hindu Kush are pistachio trees, the nuts of which are exported. The gum resin asafetida, obtained mainly from the *Ferula foetida* plant, is exported to India.

Power resources. Afghanistan is potentially rich in hydroelectric resources. The seasonal flow of the country's many streams and waterfalls, however—torrential in spring, when the snow melts in the mountains, but negligible in summer—necessitates the costly construction of dams and reservoirs in remote areas. The nation's negligible demand for electricity renders such projects unprofitable except near large cities or industrial centres.

The potential of hydroelectricity has so far been tapped substantially only in the Kābul-Jalālābād region. Nevertheless, the total electric power capacity has grown steadily from 18,534 kilowatts in 1956 to 335,000 kilowatts by 1978. More than 70 percent of the installed capacity is hydroelectric, while diesel and thermal (natural gas or coal) stations account for the balance.

Sources of national income. The annual gross national product of Afghanistan in the late 1970s was about 160,000,000,000 afghanis (45 afghanis = $1 U.S.). Per capita national income was about 10,800 afghanis in 1978.

Agriculture and animal husbandry. Agriculture and animal husbandry are by far the most important items of the national product, accounting for about 50 percent of its total value. The total arable area has been calculated to be 19,892,000 acres (8,050,000 hectares). Since much of the land is arid or semi-arid, about half of the cultivated land is irrigated. The area under irrigation is being gradually increased.

Irrigation projects

Almost 90 percent of the cultivated land is planted with cereals. Of these, wheat is the chief crop and the staple food of the population. The other food grains are corn (maize), barley, and rice. Cotton is also important, both for the domestic textile industry and for export. The annual production of wheat is estimated at about 2,830,000 tons, while that of barley is 415,000 tons, corn 800,000 tons, and rice 448,000 tons. The area used for the production of fruits and nuts has been increasing steadily. Fruits and nuts are important items of export. Fruit production is about 680,000 tons annually.

Animal husbandry produces meat and dairy products for local consumption; skins, especially the famous karakul, and wool (both for export and for domestic carpet weaving) are also important products. There are about 22,556,000 sheep, 3,866,000 cattle, 3,000,000 goats, 1,291,000 donkeys, 392,000 horses, 290,000 camels, 37,000 buffalo, and 28,000 mules. About 70 percent of the annual milk production is from cows, the rest from sheep and goats.

Industry. Modern industry is just beginning and is based mainly on agricultural and pastoral raw materials. Most important is the cotton textile industry, which has a yearly production of 243,000,000 feet. In addition, the country produces 92,000,000 feet of rayon and acetate fibres. Among the other industrial products are cement, sugar, vegetable oil, and woolen textiles. An important nitrogenous fertilizer plant, based on natural gas, was constructed in Mazār-e Sharīf in the 1970s, and phosphate fertilizers are also produced. Afghanistan also has a number of traditional handicrafts, which account for a fair proportion of the country's export earnings.

Tourism. A large proportion of foreign exchange earnings was provided by tourism; tourist visas were readily granted and several luxurious tourist hotels constructed, especially the one in Kābul. As a result, the number of foreign visitors increased 10-fold in the 1960s, and in 1977, more than 100,000 tourists visited Afghanistan. The number of foreign tourists sharply declined thereafter, however, because of political upheavals.

Management of the economy. *The private and public sectors.* Theoretically, the government is committed to developing a mixed, guided economy by means of a series of five-year plans. In practice, the effectiveness of such a policy is limited by the paucity of government resources and by a cumbersome bureaucracy. Of the first five-year plan of 1956–61, 75 percent was provided by foreign assistance. The main emphasis under this plan was to begin road construction, especially of roads to neighbouring countries; air communication was initiated with the formation of Ariana Afghan Airlines. The second five-year plan of 1962–67 emphasized development of natural resources (natural gas, oil, and coal) and provided funds for the continued construction of roads. The third five-year plan of 1968–72 assisted in the further industrialization of the country, expansion of irrigation systems, and exploration for natural resources. The much-delayed fourth five-year plan of 1973–77 and the seven-year plan of 1976–83 concentrated on large-scale, long-maturing programs.

Five-year plans

Before the Soviet invasion, the government budget was divided into two parts, ordinary and development. The former covered administrative activities and the latter investment expenditures, incorporated into the national plans of development. Total domestic revenue was usually exceeded by expenditures; the difference was covered through deficit financing and foreign loans and grants.

Total annual imports consistently exceed exports, resulting in an adverse balance of trade that is covered partly by invisibles, but mainly by foreign assistance. In 1979, Afghanistan's imports exceeded exports by 24 percent. Roughly two-thirds of Afghanistan's exports go to the Soviet Union, and one-fifth to India and Pakistan. Other export recipients are the U.K., West Germany, and the U.S. The Soviet Union is also the leading source of imports, followed by Japan, Iran, West Germany, India, and the People's Republic of China.

The private sector engages primarily in agriculture and livestock breeding. There was a mixed pattern of small, medium, and large landholdings, but this system underwent drastic change, particularly after 1978. The bulk of the trade and transport and most manufacturing have been in the hands of private entrepreneurs. Public enterprise was confined to a section of the foreign trade, to mining, and to some industries. This system was also in the process of change in the late 1970s.

Taxation. Before the Soviet invasion, there were direct and indirect taxes. Direct taxes include those on personal income, on land, on livestock, and on company income. Indirect taxes, mainly import but also export duties, in the 1970s accounted for about 50 percent of total domestic revenue. Land revenue, at one time the main source of government income, represented less than 2 percent of total revenue in the 1970s.

Foreign aid. Much of Afghanistan's development in the 1960s and early 1970s was achieved through foreign assistance, mainly from the United States, the Soviet Union, West Germany, and the People's Republic of China. In addition, substantial aid came from the United Kingdom, France, Japan, India, and several countries of eastern Europe.

Soviet and U.S. aid

In general, the Soviet grants subsidized highway construction and education programs. U.S. grants went for the same purposes and for supplying food. The Soviet Union, by the end of the 1970s, provided about $228,000,000, mainly for the construction of oil storage tanks, improved river ports, asphalt roads, electrical transmission lines, and the Shibarghān natural gas pipeline to the Soviet Union; an additional $81,000,000 was provided for petroleum-oil lubricant equipment. Further loans from the Soviet government provided for industrial, irrigation, and other programs. U.S.-assisted projects included transportation programs, the Helmand Valley Project, various education and government management programs, and development of agriculture, mining, and industry.

Trade unions. After the promulgation of the 1964 constitution, which guaranteed the right of association, some agitation occurred among the workers for better wages and working conditions. Since about 80 percent of the population is engaged in agriculture, however, the industrial labour force is insignificant and labour unions have failed to develop. Traditional loyalties to families and tribes are stronger than those to workers' organizations,

and the government, in the past, discouraged the formation of any professional organization that could develop into a political force.

Problems and prospects. Although Afghanistan has made a major developmental effort, it is still faced by many difficult problems, particularly the political instability that began in 1978. The rate of population growth is increasing and is estimated to be around 2.2 percent per year. Because of this, the country, which formerly was self-sufficient in food, imported 5 to 10 percent of its food in the 1970s. The economy stagnated in the late 1970s and unemployment was widespread. On the other hand, it appeared that the farmers had at last accepted modern agricultural methods and that food imports might again be abandoned.

Transportation. Being a landlocked country, Afghanistan is entirely dependent on transit facilities from its neighbours for its international trade. Lacking railways and with few navigable rivers, it relies on roads as the mainstay of its transport system. These factors put a heavy burden on the country's economy in the form of higher transport costs; they also add to the difficulty of integrating the transport system of the country with those of its neighbours. During the first two five-year plans, covering the period from 1956 to 1967, efforts were directed toward upgrading the highway system and to connecting the main trading centres of the country with each other, as well as with the railheads or road networks of neighbouring countries. At the same time, the road network was integrated into the plan of the United Nations Economic Commission for Asia and the Far East (ECAFE) for the construction of the Asian Highway, to run from Istanbul to Saigon (Ho Chi Minh City).

The new road network of Afghanistan, which connects Soviet railheads in Kushka and Termez with those at Chaman and Peshāwar, Pakistan, respectively, opens the way for direct overland transit between the Soviet Union and the Indo-Pakistani subcontinent. The most important Afghan highways are those connecting Kābul with Shīr Khān, on the Soviet border in the north, and with Peshāwar in Pakistan. Other paved roads link Qandahār, Herāt, and Mazār-e Sharīf with Kābul and with frontier towns of Pakistan, Iran, and the Soviet Union. The total length of modern, paved roads is 1,770 miles. In addition, there are about 8,700 miles of secondary roads, mostly unsurfaced, and more than 1,100 miles of feeder roads, which are principally trails.

Major highways

Despite the rapid development of motor transport, camels and donkeys are still commonly used as draft animals. In the countryside, many have not abandoned their cherished horses, which are important for prestige.

Civil aviation has been increasing in importance. Almost all provincial centres possess at least a seasonally operable airport, while there are international airports at Kābul and Qandahār.

ADMINISTRATION AND SOCIAL CONDITIONS

The structure of government. *The constitutional framework.* Before the late 20th century, Afghanistan was ruled by the supreme power of the king and the royal family. Two constitutions were promulgated in 1923 and 1931, both affirming the power of the absolute, hereditary monarchy. The constitution of 1964, however, provided for a constitutional monarchy, based on the separation of executive, legislative, and judicial authorities. A military coup in 1973 overthrew the monarchy and established the Republic of Afghanistan, with Gen. Sardar Mohammed Daud Khan, leader of the coup, as president. Another coup, led by Nur Mohammed Taraki in 1978, established the People's Republic of Afghanistan, governed by a Revolutionary Council. Political turmoil continued, marked by a third coup led by Hafizullah Amin in September 1979 and a massive invasion of troops from the Soviet Union and the installation of Babrak Karmal as the head of government in December 1979.

Political instability

Regional and local government. Afghanistan has a centralized system of government. For administrative purposes the country is divided into 27 provinces, each administered by a governor. Local administration in the towns and cities was vested in elected city councils, each headed by a mayor who was also elected.

The political process. Under the 1964 constitution, elections were held every four years on the basis of adult suffrage. Women acquired the right to vote in 1964, but this right was seldom exercised outside the chief cities. Although a political party law was enacted by the legislature, it was never promulgated, and no recognized legal parties existed. Several groups that functioned somewhat like political organizations, however, formed around newspapers of different shades of ideology. The Khalq (People's) Party gradually emerged and, since the changes in government in 1978–79, it has become the only legal party in the country.

The judiciary. Under the 1964 constitution and an amendment of 1967, the judiciary was an independent organ of the state; it was composed of a Supreme Court, provincial courts, and primary courts. The Supreme Court consisted of a chief judge and eight members, whose terms of office were renewable only after a period of 10 years. Since 1978, the law has been determined by the Revolutionary Council.

Armed forces. Until 1973, the king was the supreme commander of the army. With the coups of 1978–79, the Revolutionary Council and its leaders have controlled the army and the nation. Regular army officers have been trained in a military school in Kābul. There is a small air force, equipped with modern Soviet aircraft and with bases at Bagrām and Shīndand. Before 1978, there was also a corps of gendarmes, under the Ministry of the Interior, responsible for internal security and for the supervision of the frontiers. The police force, also attached to the Ministry of the Interior, was responsible for the maintenance of law and order and for the protection of the life and property of the people.

Education. Education is free at all levels, and elementary education is compulsory wherever it is provided by the state. There are primary schools throughout the country, attended by about 29 percent of all school-age children. Secondary schools exist only in the provincial and some district centres. By 1978, only 12 percent of the population was literate. The ratio of boys and girls attending schools is about six to one. Kābul University (Kābul Pohantoon) was founded in 1946 by the incorporation of a number of faculties, the oldest of which was the faculty of medicine, established in 1932. The University of Nangarhār was formed in Jalālābād in 1963.

Public health. Smallpox has been virtually eradicated through systematic campaigns supported by the World Health Organization of the United Nations. Apparently good progress has been made against cholera, typhoid fever, and typhus. Attempts to eradicate malaria in the 1960s and 1970s, however, had failed. The child mortality rate is high, especially among the nomads and in the poor mountain regions, and there is a high incidence of tuberculosis, venereal diseases, and gastrointestinal infections such as bacillary and amoebic dysentery. Syphilis and trachoma occur especially in the western regions. Hazārajāt is still plagued by leprosy. There are only about 700 doctors and 55 hospitals in Afghanistan and, as a result, medical service is minimal. Most of the doctors are located in Kābul. The Afghan Red Crescent Society, founded in 1951, provides assistance in case of earthquakes, floods, and epidemics, and it runs a number of welfare houses for the elderly and the crippled.

Social conditions. *Wages and cost of living.* In 1979, there were about 195,500 workers employed in industry and an additional 50,800 in construction work. The law does not provide for a minimum wage, but protection is extended to wage earners against arbitrary dismissal or in the event of work accidents. The general world trend in the rising cost of living is also evident in Afghanistan; the price index for consumer goods doubled during the 1960s and rose 42 percent between 1970 and 1978.

Social and economic divisions. The bulk of the population in the rural areas consists of small farmers exploiting their tiny plots of land. It is estimated that about 80 percent of the labour force are farmers and herdsmen. The majority of the city and town dwellers are artisans,

small traders, or government employees. The industrial labour force, though small, is steadily growing. There is also a business community of merchants and industrialists, and a new community of entrepreneurs is forming.

Role of women

A woman's welfare society is centred in Kābul, with branches in important cities. Its activities were enhanced with the guarantee of equal rights for women in the constitution of 1977. Since the 1960s the wearing of a veil has been voluntary, women have found employment in offices and shops, and some Afghan women have received a university education.

Cultural life and institutions. The country has a rich cultural heritage, covering more than 5,000 years. Because of almost complete isolation from the outside world, however, little in art, literature, or architecture was produced between the 16th and early 20th centuries. Because most Afghans live outside the cities, their mode of living can be described as that of a peasant tribal society. Kinship is the basis of social life and determines the patriarchal character of the community. Religion, as a rule, plays a very significant role.

Cultural activities and institutions. Archaeological research carried out since 1922 has uncovered many fine works of art of the pre-Islāmic and Islāmic periods. A revival of these arts and an interest in new forms of expression have given a new dynamism to artistic creation. Of the new painters, some draw direct inspiration from the Herāt school of the 15th-century Timurid period; others are influenced by Western styles. Through government initiative, some of the old monuments of architectural value are being restored and redecorated. An arts college, Maktab-i-Sanai Nafisa, was established in Kābul in the 1930s. In architecture, the traditional Timurid techniques are preserved, particularly in the design of the exterior walls of mosques or tombs. Handicrafts include Afghan carpets and copper utensils.

The theatre, as known in the West, has flourished only since about 1960. Adaptations of European classics were introduced at first, but the present trend favours the didactic treatment of themes from everyday Afghan life. In addition to city theatres, such as those in Kābul, Herāt, or Qandahār, there are travelling companies that take plays to provincial centres or country fairs.

In music and dance, a revival of traditional folksinging has gone hand in hand with the imitation of modern Western and Indian music. Afghan music is different from Western music in many ways, particularly in its scales, note intervals, pitch, and rhythm, but it is closer to Western than to Asian music. Afghans celebrate their religious or national feast days, and particularly weddings, by public dancing. The performance of the *attan* dance in the open air has long been a feature of Afghan life. It is the national dance of the Pashtuns and now of the nation.

The *attan* dance

The Afghan Historical Society is devoted to disseminating information on Afghan history. It publishes *Aryana*, a monthly, in Pashto and Dari. The society also arranges for the publication of research works on Afghan history, manuscripts, and historical sites and monuments. The Pashto Society is working for the development of Pashto literature and for its promotion among the non-Pashto-speaking population. It publishes the monthly *Kābul* and arranges for the publication of old Pashto manuscripts and works on Pashto linguistics and literature.

Press and radio. In the 1970s, a number of dailies, weeklies, and magazines were published by the Press Department and other government agencies. These publications had a limited total circulation, however, because of the high rate of illiteracy. Radio Afghanistan, in operation since 1941, broadcasts from Kābul. Most of the programs are produced locally for domestic transmission in either Pashto or Dari. There were an estimated 130,000 radio receivers in the country in 1981. There is no television broadcasting, but it is possible that some people in the border areas possess television sets and listen to foreign programs. Motion picture production has concentrated mostly on documentary films.

Prospects for the future. Although the overthrow of the monarchy in 1973 cast doubt on the nation's future, later events indicated that Afghanistan might combine democracy with political stability. This trend was curtailed in 1978–79 by political eruptions and the Soviet invasion, which halted democratic processes and ended the nation's attempt to maintain its traditional neutrality.

BIBLIOGRAPHY. JAMAL-UD-DIN AHMAD and MUHAMMAD ABDUL AZIZ, *Afghanistan: A Brief Survey* (1934), contains important information on the geography, history, and government of the country. JOHANNES HUMLUM, *La Géographie de l'Afghanistan* (1959), is a comprehensive geography. Social life and customs are discussed in MOHAMMED ALI, *The Afghans* (1965); MARY LOUISE CLIFFORD, *The Land and People of Afghanistan* (1962); and DONALD N. WILBER *et al.*, *Afghanistan: Its People, Its Society, Its Culture* (1962). See also MOHAMMED ALI, *A Cultural History of Afghanistan* (1964); and BENJAMIN ROWLAND, *Ancient Art from Afghanistan: Treasures from the Kabul Museum* (1966). MOUNTSTUART ELPHINSTONE, *An Account of the Kingdom of Caubul and Its Dependencies in Persia, Tartary, and India* (1842), is the first detailed account of Afghanistan by an English observer. More recent travel books and guides, which contain contemporary descriptions, include: MARY BRADLEY WATKINS, *Afghanistan: Land in Transition* (1963); SOHRAB K. KATRAK, *Through Amanullah's Afghanistan*, 2nd ed. (1963); ROSANNE KLASS, *Land of the High Flags: A Travel-Memoir of Afghanistan* (1964); CAROLA BURKNER, *Afghanistan*, 2nd ed. (1970), in German; and ROLAND MICHAUD, *Afghanistan* (1970), in French. ARNOLD FLETCHER, *Afghanistan: Highway of Conquest* (1965), is a well-documented account based on collections of the India Office library and the British Museum, manuscripts and materials available in Afghanistan, and discussions with Afghan leaders. (V.P.P.)

Afghanistan, History of

Variations on the word "Afghan" may go back as early as a 3rd-century-AD Sāsānian reference to "Abgan." The earliest reference to the Afghans in a Muslim source probably dates 982 AD, but tribes related to those of the modern Afghans have lived unrecorded in the region for many generations. For millennia, the land now called Afghanistan has been the meeting place of four cultural and ecological areas: the Middle East, Central Asia, South Asia, and the Far East.

The Afghans proper (also called Pashtuns, Pushtuns, or Pukhtuns, depending on the dialect spoken) speak an Indo-European language, Pashto. They are centred in eastern Afghanistan and northwestern Pakistan, from just north of Jalālābād to Farāh and Shīndand (Sabzevār), to the Indus River in Northwest Frontier Province, Pakistan, and as far south as Quetta, Pakistan. They dominate both sides of the Durand Line, the boundary drawn between Afghanistan and the former British territories of Pakistan in 1893.

Several empires, such as those of the Ghaznavids and the Durrānīs, spread out from the classic Pashtun area, but large-scale Pashtun migration into non-Pashtun regions dominated by such peoples as the Tadzhiks, Ḥazāras, and Uzbeks did not occur until the late 19th century.

PREHISTORY

Paleolithic peoples probably roamed Afghanistan as early as 100,000 BC, if not earlier. The earliest definite evidence of human occupation was found in the cave of Darra-i-Kur in Badakhshān, Afghanistan, where a transitional Neanderthal skull fragment in association with Mousterian-type tools was discovered; the remains are of the Middle Paleolithic, dating about 30,000 years ago. Caves near Āq Koprūk yielded evidence of an early Neolithic culture (*c.* 9000–6000 BC) based on domesticated

animals. Archaeological research since World War II has revealed a number of Bronze Age sites, dating both before and after the Indus Valley (or Harappān) civilization of the 3rd to the 2nd millennium BC. There was trade with Bronze Age Mesopotamia and Egypt, the main item of export from the Afghan area being lapis lazuli from the mines of Badakhshān. In addition, a site with definite links to the Harappān civilization has been excavated at Shortugai near the Amu Darya (the ancient Oxus River), northeast of Qondūz.

HISTORICAL BEGINNINGS (TO THE 7TH CENTURY AD)

The Achaemenians and the Greeks. In the 6th century BC, the Persian Achaemenian ruler Cyrus II the Great established his authority over the area. Darius I the Great (ruled 522–486 BC) consolidated Achaemenian rule of the region through the provinces, or satrapies, of Aria (in the region of modern Herāt), Bactria (Balkh), Sattagydia (Ghaznī to the Indus River), Arachosia (Qandahār), and Drangiana (Seistan).

Alexander the Great

Between 336 and 330 BC, Alexander III the Great of Macedonia destroyed the Achaemenians and conquered the Afghan satrapies. An outpost Greek city was then founded at the confluence of the Amu and Kowkcheh rivers, where the modern village of Ai Khanoum sits in the vicinity of Shortugai. Alexander left the Afghan area in 327 BC and, after his death in 323 BC, the eastern satrapies passed to the Seleucid dynasty that ruled from the Baghdad area. About 304 BC, the territory south of the Hindu Kush was ceded to the Maurya dynasty of northern India. Bilingual rock inscriptions in Greek and Aramaic (the official language of the Achaemenians) found at Qandahār and Laghmān (in eastern Afghanistan) date from the reign of Aśoka (*c.* 265–238 BC, or *c.* 273–232 BC), the Maurya dynasty's most renowned emperor. Diodotus, a local Greco-Bactrian governor, declared the Afghan plain of the Amu Darya independent in 250 BC; Greco-Bactrian conquerors moved south *c.* 180 BC and established their rule at Kābul and in the Punjab. The Parthians of eastern Iran also broke away from the Seleucids, establishing control over Seistan and Qandahār in the south.

The Kushāns. About 135 BC, a loose confederation of five Central Asian nomadic tribes known as the Yüeh-chih wrested Bactria from the Bactrian Greeks. These tribes united under the banner of the Kushān (Kuṣāṇa), one of the five tribes, and conquered the Afghan area. The zenith of Kushān power was reached in the 2nd century AD under King Kaniṣka (*c.* AD 78–144), whose empire stretched from Mathurā in north central India beyond Bactria as far as the frontiers of China in Central Asia.

Kushān art

The Kushāns were patrons of the arts and of religion, and Buddhist Gandhāra art flourished during this period. Evidence of the trade and cultural achievement of the period has been recovered at the Kushān summer capital of Bagrām, north of Kābul; it includes painted glass from Alexandria; plaster matrixes, bronzes, porphyries, and alabasters from Rome; carved ivories from India; and lacquers from China. Also, a massive Kushān city at Delbarjin, north of Balkh, and a major gold hoard of superb artistry near Sheberghān, west of Balkh, have been excavated. A major branch of the famed Silk Route carrying luxury goods and ideas between Rome, India, and China passed through Afghanistan, where a transshipment centre existed at Balkh.

The Sāsānians and Hephthalites. The Kushān Empire did not long survive Kaniṣka, though for centuries Kushān princes continued to rule in various provinces. Persian Sāsānians established control over parts of Afghanistan, including Bagrām, in AD 241. In AD 400, a new wave of Central Asian nomads under the Hephthalites took control, only to be defeated in AD 565 by a coalition of Sāsānians and Western Turks. From the 5th through the 7th century, many Chinese Buddhist pilgrims travelled through Afghanistan. The pilgrim Hsüan-tsang (Xüan-zang) wrote an important account of his travels, and several of the religious centres he visited, including Hadda, Ghazna, Qondūz, Bāmīān, Shotorak, and Bagrām, have been excavated.

MEDIEVAL PERIOD (7TH–18TH CENTURY)

Under the Hephthalites and Sāsānians, many of the Afghan princedoms were influenced by Hinduism. The Hindu kings (Shāhī) were concentrated in the Kābul and Ghaznī areas. Excavated sites of the period include a major Hindu Shāhī temple north of Kābul and a chapel with both Buddhist and Hindu statuary, indicating the mingling of these two religions, in Ghaznī.

The first Muslim dynasties. Islāmic armies defeated the Sāsānians in AD 642 and moved on to the Afghan area, but their initial incursions were ephemeral; cities submitted, only to rise in revolt, and the hastily converted returned to their old beliefs once the armies had passed. The 9th and 10th centuries witnessed the rise of numerous local Islāmic dynasties. One of the earliest was the Ṭāhirids of Khorāsān, whose kingdom included Balkh and Herāt; they established virtual independence from the ʿAbbāsid caliphate in AD 820. The Tāhirids were succeeded in 867–869 by a native dynasty from Seistan, the Ṣaffārids, one of whom, Yaʿqūb ebn Leyš aṣ-Ṣaffār, made a series of whirlwind campaigns throughout Afghanistan. In the north, soon after, the local princes became feudatories of the powerful Sāmānids, under whose rule of the region from 872 to 999 Bukhara, Samarkand, and Balkh enjoyed a golden age. (L.Du./N.H.D.)

The Ghaznavids. In the middle of the 10th century, a former Turkish slave named Alptegin seized Ghazna (Ghaznī). He was succeeded by another former slave, Subüktigin, who extended the conquests to Kābul and the Indus. His son was the great Maḥmūd of Ghazna, who came to the throne in 998. Maḥmūd conquered the Punjab and Multan and carried his raids into the heart of India. The hitherto obscure town of Ghazna became a splendid city, as did the second capital at Bust (Lashkar Gāh).

Maḥmūd of Ghazna

The Ghūrids. Maḥmūd's descendants continued to rule from Ghazna over a gradually diminishing empire until 1150, when ʿAlāʾ-ud-Dīn Ḥusayn of Ghūr, a mountain-locked region in central Afghanistan, descended upon the city, sacked it, and drove the last Ghaznavid out to India. ʿAlāʾ-ud-Dīn's nephew, Muʿizz-ud-Dīn Muḥammad, known as Muḥammad of Ghūr, invaded India in 1775. After his death in 1206, his general, Quṭb-ud-Dīn Aybak, became the first sultan of Delhi.

The Khwārezm-Shāhs. Shortly after Muḥammad of Ghūr's death, the Ghurīd Empire fell apart, and Afghanistan was occupied by Sultan ʿAlāʾ ad-Dīn Muḥammad, the Khwārezm-Shāh. The territories of the Khwārezm-Shāh dynasty extended from Chinese Turkistan in the east to the borders of Iraq in the west. (F.R.Al.)

The Mongol invasion. Genghis Khan invaded the eastern part of ʿAlāʾ ad-Dīn's empire in 1219. Avoiding a battle, ʿAlāʾ ad-Dīn retreated to a small, deserted island in the Caspian Sea, where he died shortly afterward (1220). Soon after ʿAlāʾ ad-Dīn's death, his energetic son Jalāl ad-Dīn Mingburnu rallied the Afghan highlanders at Parwan (modern Jabal os Sarāj), near Kābul, and inflicted a crushing defeat on the Mongols under Kutikonian. Genghis Khan, who was then at Herāt, hastened to avenge the defeat and laid siege to Bāmīān. There Mutugen, the Khān's grandson, was killed, an event so infuriating to Genghis Khan that when he captured the citadel he ordered that no living being be spared. The beautiful city of Bāmīān was utterly destroyed. Advancing on Ghazna, Genghis won a great victory over Jalāl ad-Dīn, who then fell back toward the Indus (1221), where he made a final but unsuccessful stand.

Later medieval dynasties. After his death in 1227, Genghis Khan's vast empire fell to pieces. In Afghanistan some local chiefs succeeded in establishing independent principalities and others acknowledged Mongol princes as suzerains. This state of affairs continued until the end of the 14th century, when Timur (Tamerlane) conquered a large part of the country.

Timur's successors, the Timurids, were great patrons of learning and the arts who enriched their capital city of Herāt with fine buildings. Under their rule (1404–1507) Afghanistan enjoyed peace and prosperity.

The Mughals

Early in the 16th century the Uzbeks, a Turkic people, rose to power in Central Asia under Muḥammad Shaybānī, who triumphantly entered Herāt in 1507. Bābur, a direct descendant of Genghis and Timur and the founder of the Mughal dynasty in India, made Kābul the capital of an independent principality in 1504. In December 1510, the Ṣafavid *shāh* Esmāʿīl, to avenge an insult, attacked Shaybānī, besieged him in Merv, and slew him in an ambush. Bābur took Qandahār in 1522 and then turned his attention toward India. In 1526 he marched on Delhi. He defeated Ibrāhīm, the last of the Lōdī Afghan kings of India, at Pānīpat, 80 miles (129 kilometres) north of Delhi, and established the Mughal Empire, which lasted until the middle of the 19th century. Bābur made Āgra his capital, and all eastern Afghanistan up to the Hindu Kush became a part of the empire. When Bābur died in 1530 his body, as he had wished, was taken from Āgra to Kābul to be buried in his favourite garden.

During the next 200 years Afghanistan had no political identity and was parcelled between the Mughals of India and the Ṣafavids of Persia—the former holding Kābul north to the Hindu Kush and the latter Herāt and Farāh. Qandahār was for many years in dispute.

LAST AFGHAN EMPIRE (18TH CENTURY TO 1973)

Overthrow of foreign rule. Periodic indigenous attempts were made to gain independence. In 1709, Mīr Veys Khān, an influential leader of the Hotaki Ghilzay tribe, led a successful rising against Gorgīn Khān, the Persian governor of Qandahār.

The Hotakis. Mīr Veys Khān governed Qandahār until his death in 1715. In 1716 the Abdālīs of Herāt, encouraged by his example, took up arms against the Persians and under their leader, Asadullāh Khān, succeeded in liberating their province.

Maḥmūd, Mīr Veys's young son and successor, was not content with holding Qandahār, and in 1722 he led about 20,000 men against Isfahan; the Ṣafavid government surrendered after a six-month siege.

Shāh Ashraf

Maḥmūd immediately set out to reorganize the Persian administration and economy, but he died in 1725. His young cousin Ashraf, who succeeded him, came to power at a critical time: the Afghans in Persia were threatened on all sides, the Russians were advancing from the north, and the Ottoman Turks seized part of western Persia. Internal strife and jealousy among the Afghan chiefs made the situation worse. Shāh Ashraf halted the Russian advance at Darband and in 1726 inflicted a crushing defeat on the Turks, who were marching on the capital. Meanwhile, news was brought to him that a brigand chief, Nāder Qolī Beg, had attacked Ṭūs and was on his way to take Meshed and Herāt. Collecting all available troops Ashraf hastened northward to meet him but was defeated at Dāmghān on October 2, 1729. The Afghan position in Persia was thereafter untenable, and during the retreat Ashraf himself was murdered, probably on orders from his cousin, who was then holding Qandahār.

Nāder Shāh. After consolidating his position in Persia, Nāder Qolī Beg marched against Herāt in 1732. The besieged fought desperately, but dissension forced them to sue for peace. Impressed by their valour, Nāder treated them with courtesy and recruited many of them into his own army. He was elected *shāh* of Persia, with the name Nāder Shāh, in 1736.

In 1737 Nāder Shāh advanced with an army of 80,000 men against Qandahār. The city fell after a year's siege, and Nāder then came into conflict with the Mughal Empire of India. He seized Ghazna and Kābul and, advancing into India, defeated the Mughals at Karnāl, north of Delhi, in 1739. Then, having seized the jewels and treasure of the capital, including the Koh-i-noor diamond and the famous peacock throne, he returned to Persia. He was assassinated at Khabushan in 1747.

The Durrānī dynasty. The empire disintegrated after the death of Nāder Shāh. His personal bodyguard of 4,000 Afghans, commanded by Aḥmad Khān Abdālī, returned to Qandahār, where Aḥmad Khān was elected king (*shāh*) by a tribal council. He adopted the title of Durrānī ("Pearl of Pearls") and was henceforth known as Aḥmad Shāh Durrānī. A highly personable and charismatic leader, Aḥmad Shāh gained the respect of the tribal leaders and succeeded in establishing his authority throughout the Afghan area. He also extended Afghan rule from Meshed to Kashmir and Delhi, from the Amu Darya to the Arabian Sea. Next to the Ottoman Empire, that of the Durrānī was the greatest Muslim empire in the second half of the 18th century. Aḥmad Shāh's popularity, coupled with his indomitable courage and martial virtues, won him the title of *bābā* ("father," implying "father of the nation").

Aḥmad Shāh Durrānī

When Aḥmad Shāh died in 1772, he was succeeded by his son, Tīmūr Shāh, who received but nominal homage from the tribal chieftains. Much of Tīmūr's reign was spent in quelling their rebellions. Because of this tribal opposition, Tīmūr shifted his capital from Qandahār to Kābul in 1776.

Zamān Shāh (1793–1800). After the death of Tīmūr in 1793, his fifth son, Zamān, seized the throne with the help of Sardār Pāyenda Khān, an influential chief of the Bārakzay. Zamān then turned to India with the object of repeating the exploits of Aḥmad Shāh. The move alarmed the British, who induced Fatḥ ʿAlī Shāh of Persia to bring pressure upon the Afghan king and to divert his attention from India. The *shāh* went a step further, helping Maḥmūd, governor of Herat and a brother of Zamān, with men and money and encouraging him to advance on Qandahār. Maḥmūd, assisted by his vizier, Fatḥ Khān Bārakzay, eldest son of Sardar Pāyenda Khān, and by Fatḥ ʿAlī Shāh, took Qandahār and then pushed on toward Kābul. Zamān, in India, hurried back to Afghanistan. There, after various vicissitudes, he was handed over to Maḥmūd, blinded, and imprisoned in the Bala Hissar fort at Kābul (1800). The Durrānī Empire had begun to disintegrate after 1798, when Zamān Shāh appointed a Sikh, Ranjit Singh, as governor of Lahore.

Shāh Maḥmūd (1800–03; 1809–18). Shāh Maḥmūd took little interest in the welfare of the country and left the affairs of state in the hands of Fatḥ Khān. Some of the chiefs who had grievances against the King or his ministers joined forces and invited Shāh Shojāʿ, a full brother of Zamān, to Kābul. The intrigue was successful. Shāh Shojāʿ occupied the capital, and Maḥmūd sued for peace.

Shāh Shojāʿ (1803–09; 1839–42). The new king, Shāh Shojāʿ, ascended the throne in 1803. The chiefs had become powerful and unruly, and the outlying provinces were asserting their independence. The Sikhs of the Punjab were encroaching upon Afghan territories from the east, while the Persians were threatening from the west.

At this time Napoleon was at the zenith of his power in Europe. He proposed to Alexander I of Russia a combined invasion of India. A British mission, headed by Mountstuart Elphinstone, met Shāh Shojāʿ at Peshāwar to discuss mutual defense against this threat, which never developed. A treaty of friendship was concluded (June 7, 1809), the *shāh* promising to oppose the passage of foreign troops through his dominions. Hardly had the mission left Peshāwar, however, when news was received that Kābul had been occupied by the forces of Maḥmūd and Fatḥ Khān. Shāh Shojāʿ's troops were routed, and Shāh Shojāʿ withdrew from Afghanistan and found asylum with the British at Ludhiāna in 1815.

Treaty with the British

The rise of the Bārakzay. The Bārakzay were now dominant. This situation incited the jealousy of Kāmrān, Maḥmūd's eldest son, who seized and blinded Fatḥ Khān. Later, Shāh Maḥmūd had him cut to pieces.

Dōst Moḥammad (1826–39; 1843–63). Advancing from Kashmir in 1818, Dōst Moḥammad, younger brother of Fatḥ Khān, took Peshāwar and Kābul and drove the *shāh* and Kāmrān from all their possessions except Herāt, where they maintained a precarious footing for a few years. Balkh was seized by the ruler of Bukhara; the trans-Indus Afghan districts were occupied by the Sikhs; the outlying provinces of Sind and Baluchistan assumed independence. Ghazna, Kābul, and Jalālābād fell to Dōst Moḥammad.

Dōst Moḥammad established the Bārakzay (or Moḥammadzai) dynasty. His position secure after he assumed the

title of *amīr* in 1826 at Kābul, he decided to recover Peshāwar by force from the Sikhs. Declaring a *jihād*, or Islāmic holy war, in 1836, he advanced on Peshāwar. The shrewd Sikh leader, Ranjit Singh, however, sowed dissension in Dōst Moḥammad's camp, the invading army melted away, and Peshāwar was permanently lost to the Afghans.

In November 1837, Moḥammad Shāh of Persia laid siege to Herāt, which was looked upon by the British as the key to India. The Russians supported the Persians; and the British, fearful that Persia was falling completely under Russian influence, determined to stem the tide by entering into alliances with the rulers of Herāt, Kābul, and Qandahār. A British mission to Kābul under Capt. (later Sir) Alexander Burnes in 1837 was welcomed by Dōst Moḥammad, who hoped the British would help him recover Peshāwar. Burnes, however, could not give him the required assurances; and when a Russian agent appeared in Kābul, the British left for India.

With the failure of Burnes's mission, the governor general of India, Lord Auckland, ordered an invasion of Afghanistan, with the object of restoring Shāh Shojāʿ to the throne. In April 1839, after suffering great privations, the British Army entered Qandahār; Shāh Shojāʿ was then crowned *shāh*. Ghazna was captured in the following July, and in August Shāh Shojāʿ was installed at Kābul. Dōst Moḥammad escaped first to Balkh, then to Bukhara, where he was arrested. The Afghans, however, could tolerate neither a foreign occupation nor a king imposed on them by a foreign power, and insurrections broke out. Dōst Moḥammad escaped from prison and returned to Afghanistan to lead his partisans against the British. In a battle at Parwan on November 2, 1840, Dōst Moḥammad had the upper hand; but the next day he surrendered to the British in Kābul. He was deported to India with the greater part of his family.

First Anglo-Afghan War, 1839–42

Outbreaks continued all over the country, and the British eventually found their position untenable. Terms for their withdrawal were discussed with Akbar Khān, Dōst Moḥammad's son, but Sir William Hay Macnaghten, the British political agent, was killed during a parlay with the Afghans. On January 6, 1842, about 4,500 British and Indian troops, with 12,000 camp followers, marched out of Kābul. Bands of Afghans swarmed around them, and the retreat ended in a massacre. Shāh Shojāʿ was killed after the British left Kābul.

Though in the summer of the same year British forces reoccupied Kābul, the new governor general, Lord Ellenborough, decided on the evacuation of Afghanistan. In 1843 Dōst Moḥammad returned to Kabūl. During the next 20 years, Dōst Moḥammad consolidated his rule by occupying Qandahār (1855), Balkh and the northern Khanates (1859), and Herāt (1863), the last less than a month before his death in June 1863.

Shīr ʿAlī (1863–66; 1868–79). Shīr ʿAlī Khān, Dōst Moḥammad's third son, then became *amīr*, but his two elder brothers took the throne from him in May 1866. Shīr ʿAlī regained his throne in September 1868. Shīr ʿAlī's reception of a Russian mission at Kābul and his refusal to receive a British one, on British terms, led directly to the war of 1878–80. Shīr ʿAlī, leaving his son, Yaʿqūb Khān, as his regent in Kābul, sought help from the Russians, but they advised him to make peace. Shīr ʿAlī died in Mazār-e Sharīf on February 21, 1879.

Second Anglo-Afghan War, 1878–80

Yaʿqūb Khān (1879). The Treaty of Gandamak (Gandomak; May 26, 1879) recognized Yaʿqūb Khān as *amīr*. He agreed to receive a permanent British embassy at Kābul and to conduct his foreign relations with other states in accordance "with the wishes and advice" of the British government. This British triumph, however, was short-lived. On September 3, 1879, the British envoy and his escort were murdered in Kābul. British forces were again dispatched, and before the end of October they occupied Kābul. Yaʿqūb abdicated and was given exile in India, where he died in 1923. (M.Al./L.Du./N.H.D.)

ʿAbdor Raḥmān Khān (1880–1901). The British finally withdrew from Qandahār in April 1881. In 1880, ʿAbdor Raḥmān Khān, a cousin of Shīr ʿAlī, had returned from exile in Central Asia and proclaimed himself *amīr* of Kābul. During the reign of ʿAbdor Raḥmān, the boundaries of modern Afghanistan were drawn by the British and the Russians. The Durand Line of 1893 divided zones of responsibility for the maintenance of law and order between British India and the kingdom of Afghanistan; it was never intended as a *de jure* international boundary. Afghanistan, therefore, although never dominated by a European imperial government, became a buffer between Tsarist Russia and British India.

Domestically, ʿAbdor Raḥmān exerted his influence, if not actual control, over the various ethnolinguistic groups inside Afghanistan, fighting about 20 small wars to convince them that a strong central government existed in Kābul. ʿAbdor Raḥmān was so successful that, at his death, his designated successor and eldest son, Ḥabībollāh Khān, succeeded to the throne as Ḥabībollāh I without the usual fratricidal fighting. ʿAbdor Raḥmān can be considered the founder of modern Afghanistan.

Ḥabībollāh Khān (1901–19). The introduction of modern European technology begun by ʿAbdor Raḥmān was furthered by Ḥabībollāh. Western ideals and styles penetrated the Afghan royal court and upper classes. An Afghan nationalist, Maḥmūd Beg Ṭarzī, published (1911–18) the periodical *Serāj ol-Akbār* ("Torch of the News"), which had political influence far beyond the boundaries of Afghanistan.

Ḥabībollāh Khān visited British India in 1907 as guest of the viceroy of India, Gilbert Elliot, 4th earl of Minto. Impressed with British power, Ḥabībollāh resisted pressures from Ṭarzī, Amānollāh (Ḥabībollāh's third son, who had married Soraya, a daughter of Ṭarzī), and others to enter World War I on the side of the Central Powers (Germany, Austria-Hungary, the Ottoman Empire, and Bulgaria). The peace ending World War I brought death to Ḥabībollāh; he was murdered on February 20, 1919, by persons associated with the anti-British movement, and Amānollāh seized power.

Amānollāh (1919–29). Amānollāh launched the inconclusive Third Anglo-Afghan War in May 1919. The month-long war gained the Afghans the right to conduct their own foreign affairs. The Treaty of Rāwalpindi was signed on August 8, 1919, and amended in 1921. Before signing the final document with the British, the Afghans concluded a treaty of friendship with the new Bolshevik regime in the Soviet Union; Afghanistan thereby became the first nation to recognize the Soviet government, and a "special relationship" evolved and lasted until December 1979.

Third Anglo-Afghan War, 1919

Amānollāh changed his title from *amir* to *padshah* ("king") in 1923 and inaugurated a decade of disastrous reforms, including constitutional and administrative reform, advocating removal of the veil from women, and founding coeducational schools, that offended conservative religious and tribal leaders.

Civil war broke out in November 1928, and a Tadzhik folk hero called Baccheh Saqow (Bacha Saqqao; "son of a water carrier") invested Kābul. Amānollāh abdicated on January 14, 1929, in favour of his elder brother, Inayatollāh, but Bacha Saqqao proclaimed himself Ḥabībollāh Ghāzī (or Ḥabībollāh II), *amīr* of Afghanistan. Amānollāh failed to retrieve his throne and went into exile in Italy. He died in 1960 in Zürich.

Moḥammad Nāder Shāh (1929–33). Ḥabībollāh II was driven from the throne by Moḥammad Nāder Khān, a distant cousin of Amānollāh, and Moḥammad's brothers. On October 10, 1929, Ḥabībollāh II was executed along with 17 of his followers. A tribal assembly elected Nāder Khān as king, and the opposition was bloodily persecuted.

Nāder Shāh produced a new constitution in 1931 that was modelled on Amānollāh's constitution of 1923, but was more conservatively oriented to appease Islāmic religious leaders. The national economy thrust ahead in the 1930s under the leadership of several entrepreneurs, who launched small-scale industrial projects. Nāder Shāh was assassinated on November 8, 1933, and the 19-year-old crown prince, Zahir, succeeded his father.

Mohammad Zahir Shah (1933–73). The first 20 years of Zahir Shah's reign were characterized by cautious policies

of national consolidation, an expansion of foreign relations, and internal development using Afghan funds alone. The war brought about a slowdown in development processes, but Afghanistan maintained its traditional neutrality. The "Pashtunistan" problem regarding the political status of those Pashtun living on the British (Pakistani) side of the Durand Line developed after the independence of Pakistan in 1947.

The Pashtunistan problem

Shah Mahmud, prime minister from 1946 to 1953, sanctioned free elections and a relatively free press, and the so-called Liberal Parliament functioned from 1949 to 1952. Conservatives in government, however, encouraged by religious leaders, supported the seizure of power in 1953 by Lieut. Gen. Mohammad Daud Khan.

Prime Minister Daud Khan (1953–63) took a stronger line on "Pashtunistan," and Pakistan reacted by temporarily closing its border with Afghanistan several times before 1963. To the surprise of many, Daud Khan turned to the Soviet Union for economic and military assistance. The Soviets ultimately became Afghanistan's major aid and trade partner. The Afghans refused to take sides in the Cold War, and Afghanistan became an "economic Korea," testing the Western (particularly U.S.) will and capability to compete with the Soviet bloc in a nonaligned country. Daud Khan introduced several far-reaching educational and social reforms, such as the voluntary removal of the veil from women and the abolition of purdah (the practice of secluding women from public view), which theoretically increased the labour force by about 50 percent. The regime remained politically repressive, however, and tolerated no direct opposition.

The "Pashtunistan" issue precipitated Daud Khan's downfall. In retaliation for Afghan agitation, Pakistan closed the border with Afghanistan in August 1961. A prolongation of the closure led to Afghan dependence on the Soviet Union for trade and in-transit facilities. To reverse the trend, Daud Khan resigned in March 1963, and the border was reopened in May. The "Pashtunistan" problem still existed, however.

Zahir Shah and his advisers instituted an experiment in constitutional monarchy. In 1964, the Loya Jirgah (Great National Assembly of Notables) approved a new constitution, under which the Wolesi Jirgah (House of the People) was to have 216 elected members, and the Meshrano Jirgah (House of the Elders) was to have 84 members, one-third elected by the people, one-third appointed by the king, and one-third elected indirectly by new provincial assemblies.

Constitutional monarchy

Elections for both houses of the legislature were held in 1965 and 1969. Several unofficial parties ran candidates with beliefs ranging from fundamentalist Islām to the extreme left. National politics became increasingly polarized, a situation reflected in the appointment by the King of five successive prime ministers between September 1965 and December 1972. The King refused to promulgate the Political Parties Act, the Provincial Councils Act, and the Municipal Councils Act, thereby effectively blocking the institutionalization of the political processes guaranteed in the constitution. Struggles for power developed between the legislative and the executive branches, and an independent Supreme Court, as called for in the 1964 constitution, was never appointed.

Mohammad Daud Khan, the former prime minister and a brother-in-law and first cousin of Zahir Shah, sensed the stagnation of the constitutional processes and seized power on July 17, 1973, in a virtually bloodless coup. Leftist military officers and civil servants of the Parcham (Banner) Party assisted in the overthrow. Daud Khan abolished the constitution of 1964 and established the Republic of Afghanistan, with himself as chairman of the Central Committee of the Republic and prime minister.

THE REPUBLIC OF AFGHANISTAN (1973–78)

During Daud Khan's second tenure as prime minister, he attempted to introduce socioeconomic reforms, to write a new constitution, and to effect a gradual movement away from the socialist ideals his regime initially espoused. Afghanistan broadened and intensified its relationships with other Muslim countries, trying to move away from its dependency on the Soviet Union and the U.S. In addition, Daud Khan and Zulfikar Ali Bhutto, the prime minister of Pakistan, reached tentative agreement on a solution to the "Pashtunistan" problem.

Second tenure of Daud Khan

The turning point, however, occurred after Daud Khan received approval in 1977 of his new constitution from the Loya Jirgah, which wrote in several new articles and amended others. In March 1977, Daud Khan, then president of Afghanistan, appointed a new Cabinet composed of sycophants, friends, sons of friends, and even collateral members of the royal family. The two major leftist organizations, the Khalq (Masses) and Parcham parties, then reunited against Daud Khan after a 10-year separation. There followed a series of political assassinations, massive anti-government demonstrations, and the arrests of major leftist leaders. Before his arrest, Hafizullah Amin, a U.S.-educated Khalqi leader, contacted party members in the armed forces and devised a makeshift, but successful, coup. Daud Khan and most of his family were killed, and the Democratic Republic of Afghanistan was born on April 27, 1978.

THE DEMOCRATIC REPUBLIC OF AFGHANISTAN (FROM 1978)

Nur Mohammad Taraki was elected president of the Revolutionary Council, prime minister of the country, and secretary general of the combined People's Democratic Party of Afghanistan (PDPA). Babrak Karmal, a leader of the Parcham faction, and Hafizullah Amin were elected deputy prime ministers. The leaders of the new government insisted that they were not controlled by the Soviet Union and proclaimed their policies to be based on Afghan nationalism, Islāmic principles, socioeconomic justice, nonalignment in foreign affairs, and respect for all agreements and treaties signed by previous Afghan governments.

Nur Mohammad Taraki

Unity between the Khalq and Parcham factions rapidly faded as the Khalqis emerged dominant, particularly because their major base of power was in the military. Karmal and other selected Parcham leaders were sent abroad as ambassadors, and there were systematic purges of any Parcham members or others who might oppose the regime.

The Taraki regime announced its reform programs, including the elimination of usury, equal rights for women, land reforms, and administrative decrees in classic Marxist-Leninist rhetoric. The people in the countryside, familiar with Marxist broadcasts from Soviet Central Asia, assumed that the Khalqis were Communist and pro-Soviet. The reform program—which threatened to undermine basic Afghan cultural patterns—and political repression antagonized large segments of the population, but major violent responses did not occur until the uprising in Nūrestān late in the summer of 1978. Other revolts, largely uncoordinated, spread throughout all of Afghanistan's provinces, and periodic explosions rocked Kābul and other major cities. On February 14, 1979, U.S. Ambassador Adolph Dubs was killed, and the elimination of U.S. assistance to Afghanistan was guaranteed.

Hafizullah Amin became prime minister on March 28, 1979, although Taraki retained his posts as president of the Revolutionary Council and secretary general of the PDPA. The expanding revolts in the countryside, however, continued, and the Afghan Army collapsed. The Amin regime asked for and received more Soviet military advisers, weapons, and supplies.

Hafizullah Amin

Taraki was killed in an armed confrontation between Taraki and Amin supporters on September 14, 1979. Amin then tried to broaden his internal base of support and to again interest Pakistan and the U.S. in Afghan security. Despite his efforts, on the night of December 24, 1979, the Soviets began their invasion of Afghanistan, and Amin and many of his followers were killed on December 27. Babrak Karmal returned to Afghanistan from the Soviet Union and became prime minister, president of the Revolutionary Council, and secretary general of the PDPA. Opposition to the Soviets and Karmal spread rapidly, urban demonstrations and violence increased throughout 1980, and resistance escalated in all regions.

Four major struggles developed in and around Afghani-

stan: the uncoordinated, generalized war against the regime and the Soviets; the internal struggle for power between the dominant Parchamis and the surviving Khalqis; the fight for publicity, followers, and Arab money by several religious leaders in Peshāwar; and the consolidation by local leaders of regionally oriented bases of power inside Afghanistan. At the end of 1980, several regional groups had united inside Afghanistan to resist the Soviet invaders. At least 1,400,000 Afghan refugees had fled to Pakistan, and another 200,000 to 300,000 to Iran.

(L.Du./N.H.D.)

Africa

Africa is the second largest continent in the world, being smaller only than Asia. It has a population of more than 482,000,000, and its area—11,700,000 square miles (30,300,000 square kilometres)—covers about one-fifth of the total land surface of the world. The continent is bounded on the north by the Mediterranean Sea, on the west by the Atlantic Ocean, on the east by the Red Sea and the Indian Ocean, and on the south by the mingling waters of the Atlantic and Indian oceans. Africa measures about 5,000 miles (8,000 kilometres) from north to south and about 4,600 miles from east to west. Its northern extremity is Ras ben Sekka, near ar-Ra's al-Abyaḍ (Cap Blanc), Tunisia; its southern extremity is Cape Agulhas, South Africa; its farthest point east is Ras Hafun, near Cape Guardafui in Somalia; its western extremity is Pointe des Almadies, on Cap Vert (Cape Verde), Senegal. In the northeast Africa was joined to Asia by the Sinai Peninsula until the construction of the Suez Canal.

Paradoxically, the coastline of Africa—18,950 miles in length—is shorter than that of Europe, because there are few inlets and few large bays or gulfs.

Africa's islands

Off the coasts of Africa a number of islands are associated with the continent. These include Madagascar, one of the largest islands in the world, the Comoros, Mauritius, Réunion, and other islands to the southeast; the Seychelles, Socotra, and other islands to the east; the Azores, Madeira Islands, and the Canary Islands to the northwest; Cape Verde, the Bijagós Islands, Bioko, and São Tomé and Príncipe to the west; and Ascension, St. Helena, and Tristan da Cunha to the southwest.

From north to south, the continent is cut almost equally in two by the Equator, so that most of Africa lies within the tropical region, bounded by the Tropic of Cancer (23°28′ N) and the Tropic of Capricorn (23°28′ S). Because of the bulge formed by West Africa, the greater part of Africa's territory lies north of the Equator. Africa is crossed from north to south by the prime meridian of Greenwich (0° longitude), which passes a short distance to the east of Accra in Ghana.

In antiquity, the Greeks are said to have called the continent Libya and the Romans to have called it Africa, perhaps from the Latin *aprica* ("sunny"), or the Greek *aphrike* ("without cold"). The name Africa, however, was chiefly applied to the northern coast of the continent, which was, in effect, regarded as a southern extension of Europe. The Romans, who for a time ruled the North African coast, are also said to have called the area south of their settlements Afriga, or the Land of the Afrigs—the name of a Berber community south of Carthage. Another explanation occasionally offered is that the name applied to a productive region of what is now Tunisia and meant Ears of Corn. The word Ifriqiyah is apparently the Arabic form of Africa.

The whole of Africa can be considered as a vast plateau rising steeply from narrow coastal strips and consisting of very ancient crystalline rocks. The plateau's surface is higher in the southeast and tilts downward toward the northeast. In general, the plateau may be divided into a southeastern portion and a northwestern portion. The northwestern part, which includes the Sahara (desert) and that part of North Africa known as the Maghrib, has two mountainous regions—the Atlas mountain system in North Africa, believed to be part of a system that extends into southern Europe, and the Ahaggar (Hoggar) plateau in the Sahara. The southeastern part includes the Ethiopian Highlands, the East African Plateau, and—in the eastern part of South Africa, where the plateau edge falls downward in a scarp—the Drakensberg Mountains.

According to a widely accepted theory, Africa, South America, peninsular India, Australia, and Antarctica were joined together millions of years ago to form a continent called Gondwanaland; after the breakup of Gondwanaland, the fragments drifted apart. Part of the evidence in support of the theory is that the African and Brazilian plateaus have similar geological formations.

The continent has a number of volcanoes, some of which are now extinct; they include the cones of Kilimanjaro, Mt. Kenya, and Elgon, as well as the Virunga range, in the east, and Mt. Cameroon, in the west.

The Rift Valley

One of the most remarkable features in the geological structure of Africa is the East African Rift System, or Great Rift Valley, which lies between 30° and 40° E. The rift itself begins beyond the continent's limits, in Syria to the north, from where it travels down the Jordan Valley, runs along the length of the Red Sea and enters the African plateau near Ethiopia. It continues southward through Kenya to Tanzania, where it virtually disappears below the surface. This constitutes the eastern branch of the Rift Valley; it contains a series of lakes, including Lake Rudolf (also called Lake Turkana) and Lake Nyasa (Lake Malawi). The western branch of the rift, which describes an arc along the eastern border of Zaire, contains Lakes Albert, Edward, Kivu, and Tanganyika. A short branch of the rift, extending southwest from the northern end of Lake Tanganyika, includes the valley of the Luangwa and part of the Zambezi Valley.

The African plateau includes a number of basins, surrounded by divides. These include the basin surrounding Lake Chad, to the northeast of Nigeria; the Congo Basin; and the Baḥr al-Ghazāl Basin in The Sudan.

In tropical Africa, where rainfall is heavy, many rivers empty into the sea. The four longest are the Nile (which

flows northward beyond tropical latitudes), the Congo, the Niger, and the Zambezi. In the course of their lengthy journeys to the sea, they encounter cataracts as they break through the plateau region down to the narrow coastal plain, incising deep gorges in the process. Although often navigable for sections of their courses, African rivers in general cannot be compared for navigability to their counterparts on other continents—a circumstance that helped to delay the development of the continent.

The climates are dominated by Africa's position astride the Equator. Temperatures are high for most of the year in the northern and southern tropical zones. The northern tropical zone is hottest between March and September and the south between September and March. At high altitudes in parts of the interior, however, temperatures are modified by the height of the mountains. This is especially so in the mountains of East Africa, Ethiopia, and parts of Central and southern Africa. The northern zone and the southern coastal zone, which lie outside the tropics, have more moderate temperatures and a milder climate. The climate of the continent is further modified by the influence of ocean currents, such as the cooling Benguela Current, which flows north from the Cape of Good Hope toward the Congo, and the warming Mozambique Current, which passes through the channel between Madagascar and the southeast coast of Africa.

Although it is the second largest continent, Africa contains only about 10 percent of the total world population and can therefore be described as underpopulated. This fact is due, in part, to the large expanses of desert. The Sahara alone—the largest desert in the world—covers one-quarter of the entire continent.

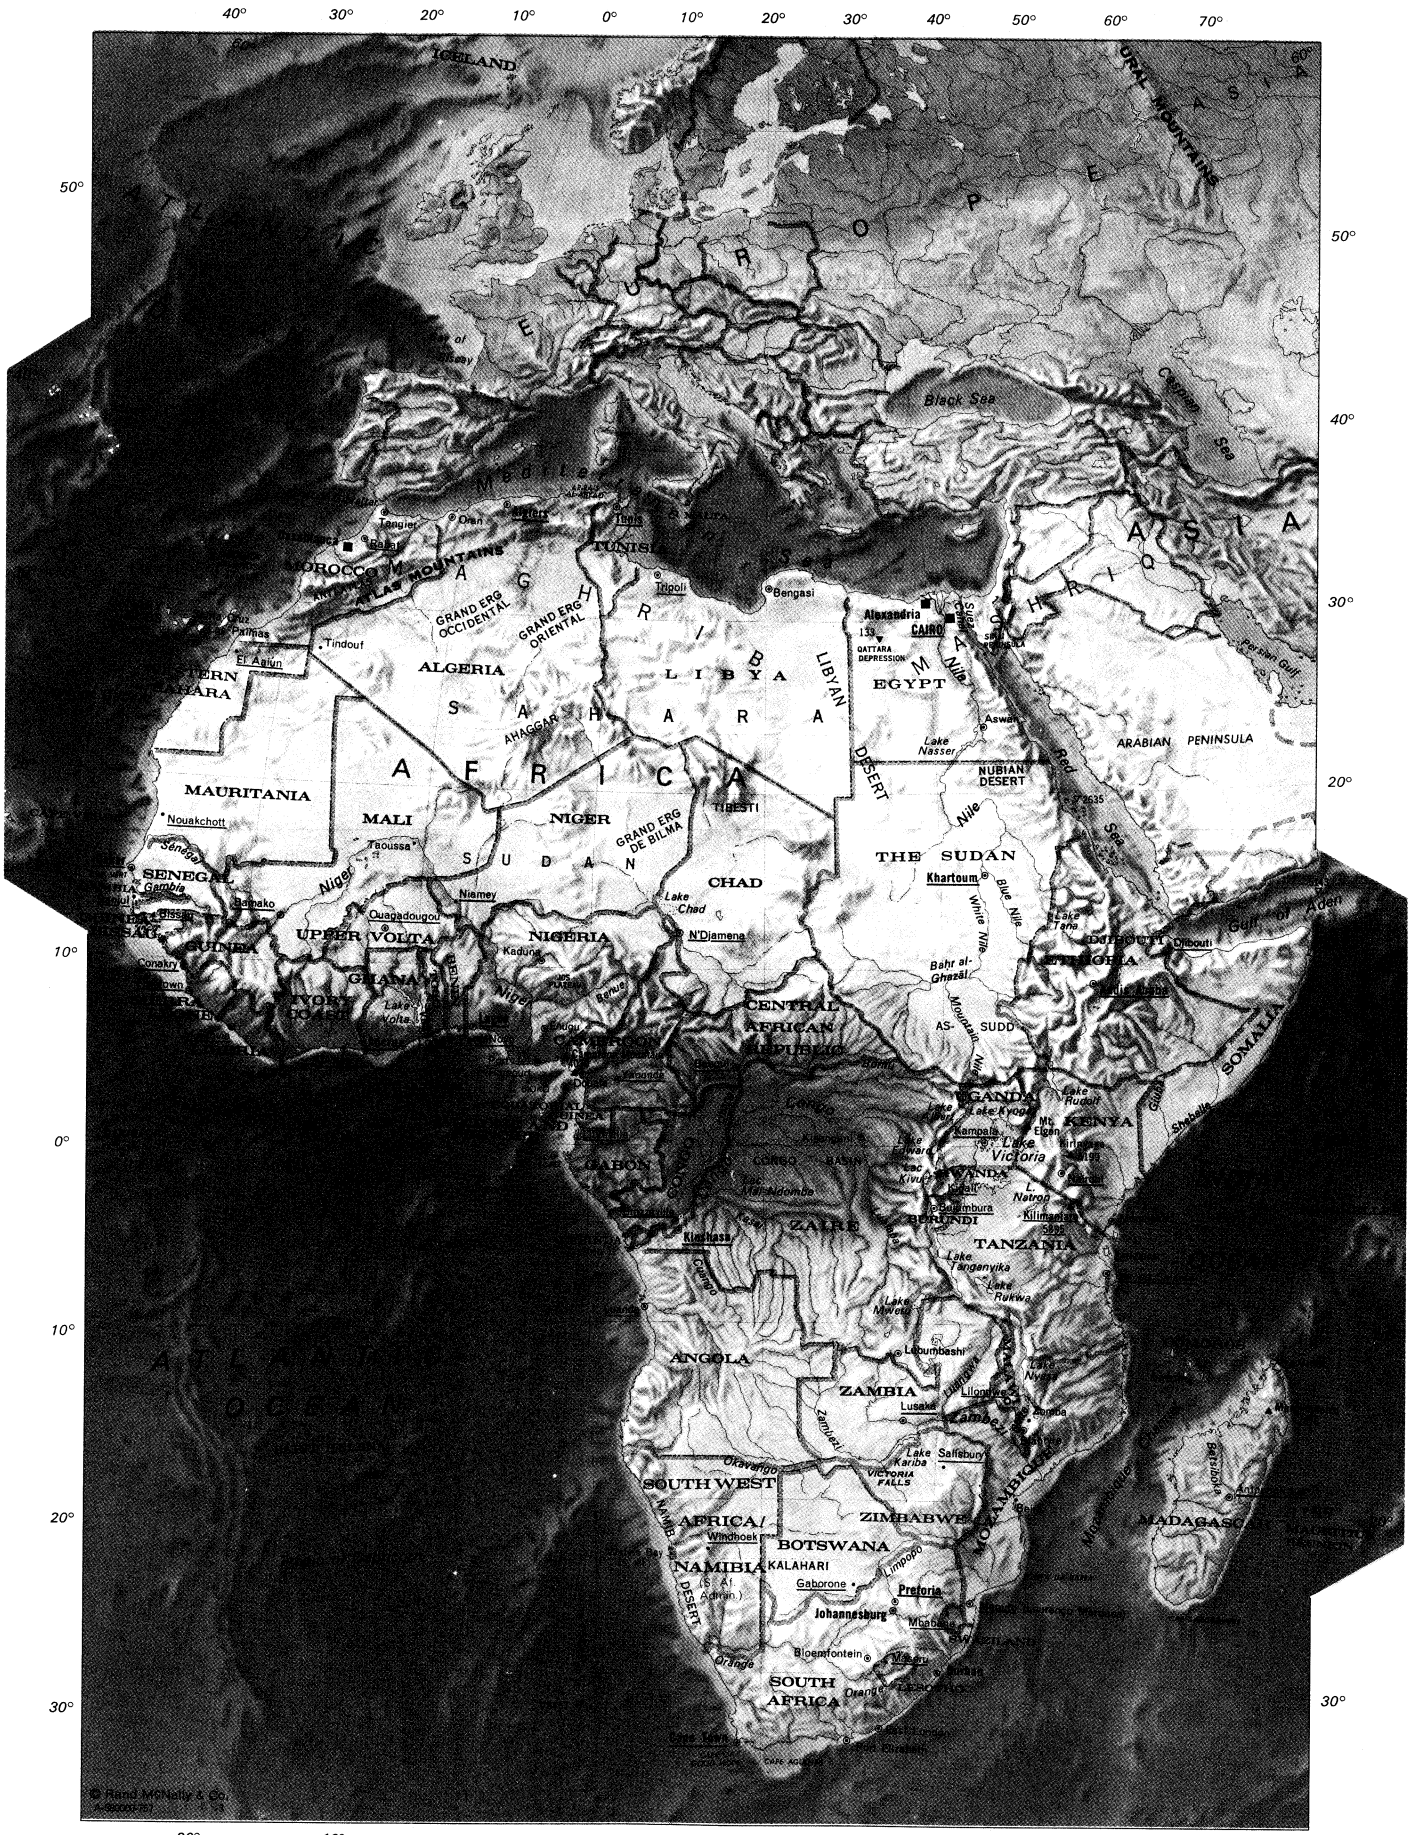
The greatest concentrations of population are found in Nigeria and around the shores of the East African lakes. Nigeria, with a population of about 77,000,000 in 1980, is the most populous of the African states, followed by Egypt (44,000,000) and Ethiopia (31,000,000).

Africa's historical legacy, formed of a variety of influences of varying strengths, has shaped its culture and its patterns of religious affiliation. Herodotus, the Greek historian of the 5th century BC, reported that in about 600 BC the Phoenicians sailed around the African continent. Even earlier, more than 1,000 years before Christ, they had established trading posts in northern Africa. Later influences included those of the Greeks and of the Romans. Climatic and other factors have exerted considerable influence on the patterns of human settlement in Africa. While the greater part of the continent has always been inhabited by black peoples, there have also occurred major immigrations from both Asia and Europe. The extensive movement of Arabs into North Africa began in the 7th century AD, while a more limited settlement along the East African coast began in the following century. The extreme northern and southern regions of the continent, and certain highland parts of East Africa, because of their moderate climatic conditions, were later to attract settlers from Europe, such as the Dutch in South Africa from the 17th century onward and the French in Algeria as well as the British in Central and South Africa in the 19th century. In the colonial period the demand for labour, for such enterprises as the railways in East Africa and the sugar plantations in Natal, also led to the importation on a large scale of workers from the Indian subcontinent. Because of the humid nature of its climate, West Africa alone remained largely unaffected by migrations from outside the continent. Of all such foreign settlements in Africa, that of the Arabs made the greatest impact. The Islāmic religion, which the Arabs carried with them, spread from North Africa into many areas south of the Sahara, so that West African peoples such as the Hausa, Kanuri, Songhai, and Malinke (Mandingo) are now largely Islāmized. Although most of North Africa and much of West Africa is thus Muslim in religion, the one area that is an exception is that of Ethiopia in the northeast, where many follow the Christian Coptic religion. There are also some Coptic communities in Egypt.

While the northern third of Africa is populated for the most part by people of Arab stock superimposed upon an older Berber substratum, people of black stock dominate the greater part of the remainder of the continent. Apart from the Islāmized peoples of West Africa and the growing Christian communities to be found especially near the coast, traditional animistic forms of religion survive. In black Africa important kingdoms arose, such as those of Ghana, Kanem-Bornu, Mali, and Songhai—all of which flourished between the 8th and the 16th centuries—or the later states such as Dahomey, Ashanti, and Buganda, which remained independent until their conquest by the colonial powers at the end of the 19th century. It was also black Africa that became centrally involved in the slave trade with the Americas and the Caribbean. While Arab and European writers had often been impressed by the degree of social and political advancement in the old kingdoms of black Africa, the institution of slavery gradually led to the categorization of black peoples everywhere as "backward" and "inferior." This concept survived the abolition of the slave trade between Africa and Europe and the Americas in the 19th century and is only now disappearing through black activism, the influence of liberal thinkers, and the political influence of independent black African states.

The southern third of Africa, inhabited by Bantu-speakers and other peoples, was used by Europeans as a way station on the route from Europe to Asia around the Cape. This part of Africa still contains the majority of the people of European descent living on the continent, although they are far outnumbered by the black population.

African agriculture



The agricultural produce of tropical Africa, which includes such commodities as palm oil, peanuts (groundnuts), cocoa, cotton, and rubber, has long been in demand among the industrial nations of Europe and the Americas. The era of colonization, which extended throughout much of the 19th century and lasted until about 1960, led to the division of most of the continent into European-ruled colonies or areas of influence. Since then, most African territories have become independent. Their exports, however, still remain largely agricultural, and the prices that they obtain for their goods are determined to a large extent by the developed nations.

The mineral resources of Africa are equally important. Among the most important mineral regions are the gold- and diamond-mining areas and the platinum and chromium regions of South Africa, the Zambian copper belt, and the mineral-rich Shaba (formerly Katanga) area of Zaire. Other major mineral reserves are to be found in Ghana, Sierra Leone, Liberia, and Mauritania. Since the 1950s oil reserves have been located in many parts of Africa; the most important are found in Algeria, Libya, Angola, Nigeria, and Gabon.

The great rivers of Africa have been harnessed to provide power for industrial development or to irrigate large areas. Thus, large dams, such as the Kariba Dam on the Zambezi River, the Aswān High Dam on the Nile, the Akosombo Dam on the Volta River in Ghana, and the Owen Falls Dam where the Nile issues from Lake Victoria, have been constructed, and more are envisaged.

The continent is well known for its wild animals. Big game animals are found roaming the savanna (grassy parkland) regions of southern and eastern Africa and, to a lesser extent, in the savanna areas north of the West African coastal belt. Game reserves have been established in such countries as Kenya, Uganda, Tanzania, Zambia, and South Africa; apart from helping to maintain the ecological balance, they also constitute tourist attractions.

Profound political changes occurred in Africa during the 1960s, at the conclusion of which most of Africa had attained political independence. Territories of mainland Africa that still remained in a state of dependency by 1970 included the Portuguese-held territories, Rhodesia (Zimbabwe; though it had unilaterally proclaimed its independence from Britain), South West Africa (Namibia), the Spanish (Western) Sahara, and some smaller territories, such as the French-administered territory of the Afars and Issas (Djibouti) and, in the Indian Ocean, the French-administered Comoro Islands and Réunion. By the early 1980s most of these territories had achieved independence. Exceptions were South West Africa (Namibia),

0 400 800km

0 200 400 600 800mi

administered by South Africa; the Western Sahara; Réunion; and Mayotte, one of the Comoro Islands that did not seek independence.

Africa's trade, which in the past, because of geographical proximity, had primarily been in Europe, is now also being channelled toward Asia and the Americas. While different degrees of political stability prevail in the African states, a desire for democratic government can often be discerned. African states, in foreign policy, are largely nonaligned, avoiding involvement in East–West conflicts, although they occasionally receive aid from both sides.

This article covers, in general terms, the physical and human geography of the African continent. There are separate articles on the major geographical features of Africa, as well as on contemporary African countries and cities. Linguistic patterns are described in the articles AFRICAN LANGUAGES and HAMITO-SEMITIC LANGUAGES. Ethnic and cultural patterns are discussed in the article AFRICAN PEOPLES AND CULTURES. For historical aspects, see CENTRAL AFRICA, HISTORY OF; COLONIALISM; EAST AFRICA, HISTORY OF; EGYPT, HISTORY OF; ETHIOPIA, HISTORY OF; MADAGASCAR, HISTORY OF; NILOTIC SUDAN, HISTORY OF THE; NORTH AFRICA, HISTORY OF; SOUTHERN AFRICA, HISTORY OF; TIMBUKTU; WEST AFRICA, HISTORY OF. For cultural aspects, see AFRICAN PEOPLES, ARTS OF. See also CONTINENTS, DEVELOPMENT OF. (D.S.H.W.N.)

I. Geological history

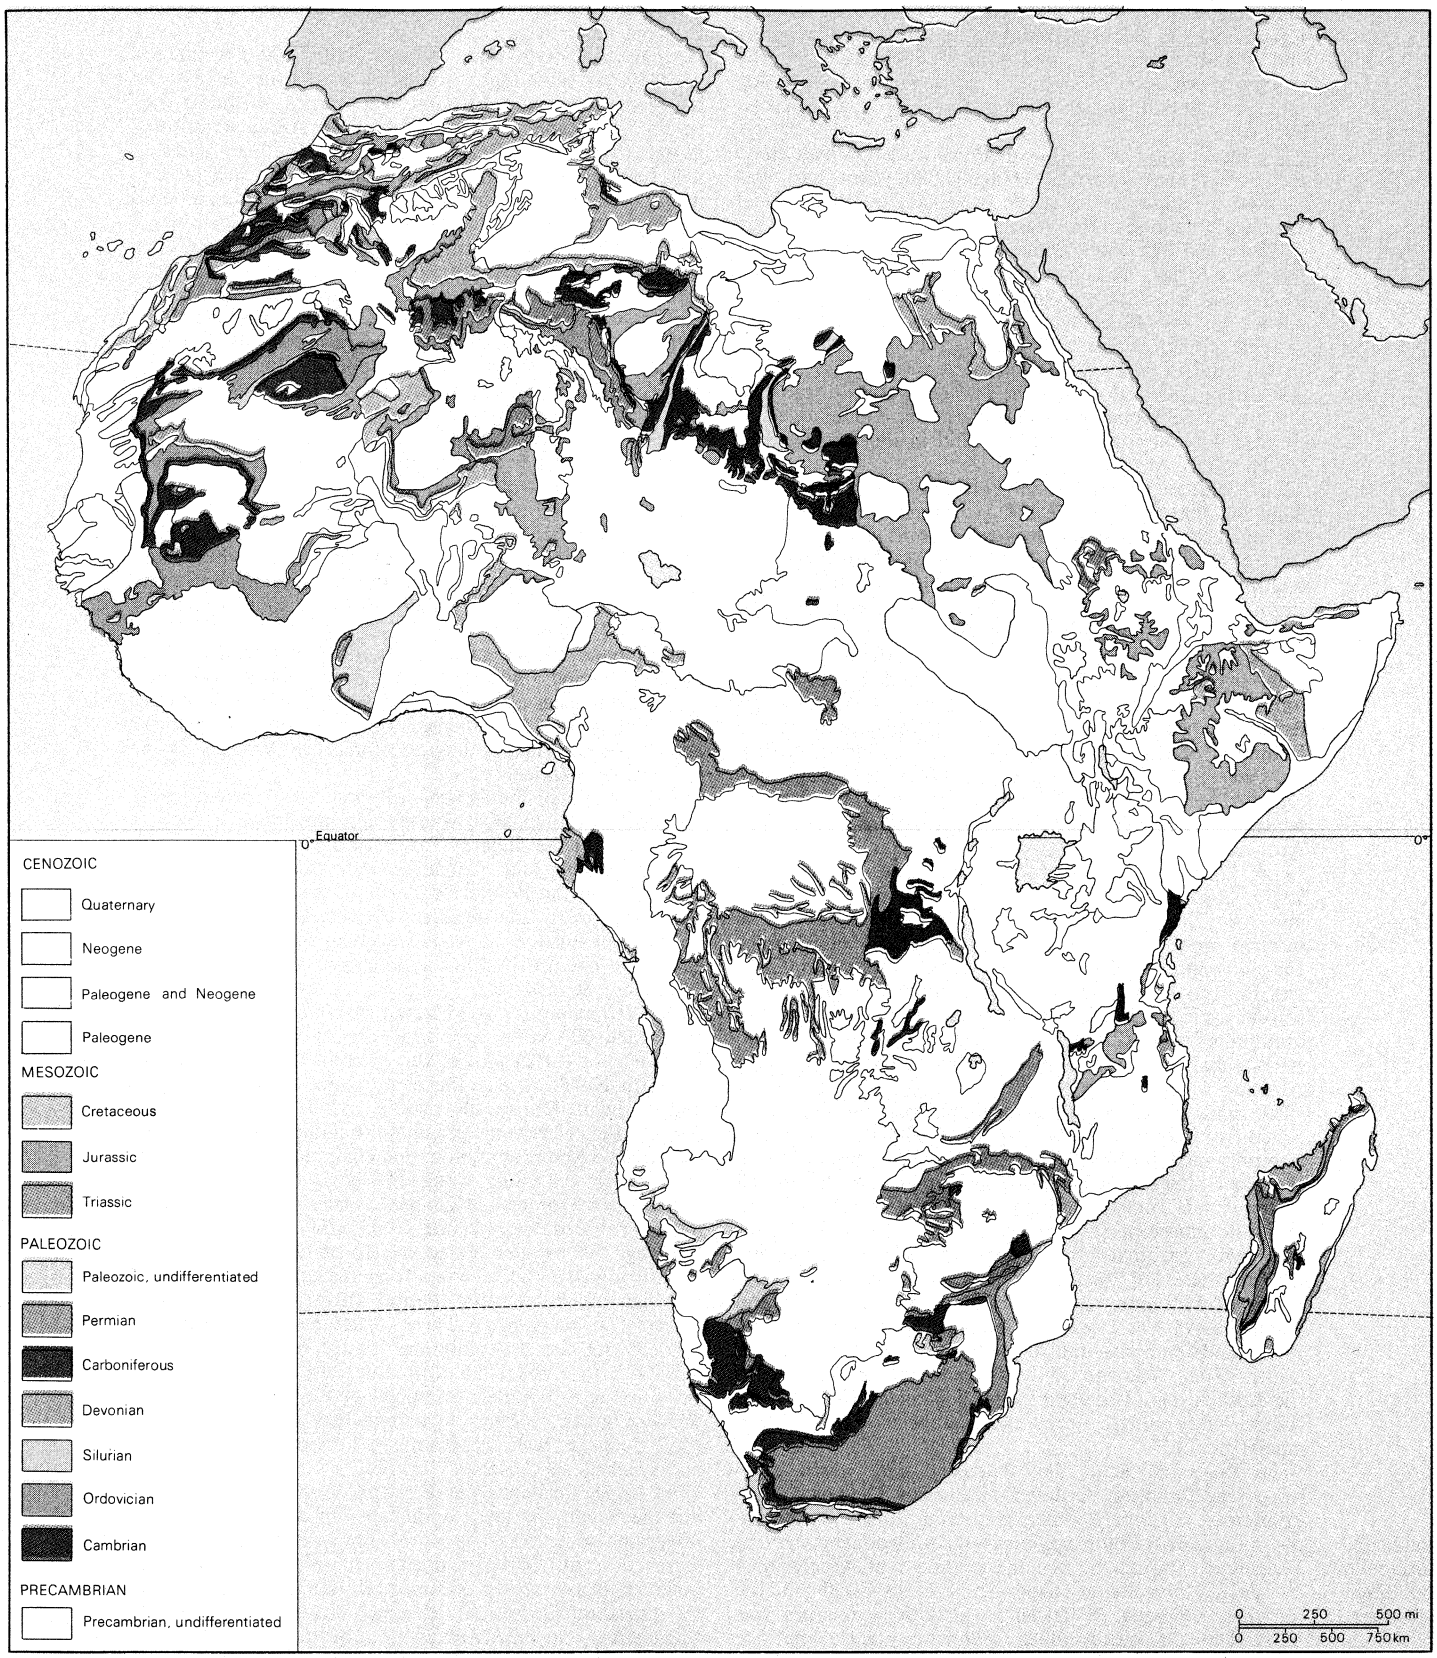
The African continent essentially consists of an ancient Precambrian Shield (formed between 4,000,000,000 and 570,000,000 years ago) that has since been folded, metamorphosed (altered in composition or structure by heat and pressure), and granitized. As a result of later erosion, Precambrian rock outcrops appear on 57 percent of the surface.

The Precambrian Shield

An examination of the shield leads to three preliminary observations. Firstly, geologically the continent of Africa includes the Arabian Peninsula, which was closely linked to it until the appearance of the Red Sea Trough. Secondly, North Africa (contemporary Morocco, Algeria, and Tunisia) belongs to the Mediterranean and Alpine area; it emerged and became joined to Africa only quite recently in geological time. Thirdly, the Precambrian Shield shows numerous traces of life. These are found, for example, in the microorganisms of the Fig Tree System of rocks in South Africa, which are 3,200,000,000 years old; in the Bulawayo series, which are 2,700,000,000 years old; in the Ivory Coast series, which are 2,500,000,000 years old; in the Gabon series, which are 1,700,000,000 years old; and in all of Africa in formations that are between 600,000,000 and 1,000,000,000 years old.



Geological analysis is simpler after the end of the Precambrian because of the existence of this enormous shield. There are no traces of geosynclines (large linear troughs, in which sediments accumulated over geological time cause the trough itself to sag deeper) or of orogenic (mountain-building) processes comparable to those of other continents. On the western rim of the continent, however, there are very eroded traces of ancient mountains that have been called the Mauritanids; these thrust from the west toward the east. If, however, they were associated with a geosynclinal trough, this was situated further west in the Atlantic Ocean.

The relative geological stability that characterized the continent did not, however, hold true in the north. The Tethys Sea, a sea ancestral to the Mediterranean, ran along the northern edge of the Sahara, and a geosynclinal depression covered the region; from this depression the Alpine chain of the Atlas Tellien (Tell Atlas) and Atlas Saharien (Saharan Atlas) later arose during the Tertiary Period (65,000,000 to 2,500,000 years ago).

Seas of the Paleozoic Era (from 570,000,000 to 225,000,000 years ago) covered northwestern Africa, extending first from the Mediterranean to the Gulf of Guinea, and then to South Africa. At the end of the era, during the Permian Period (from 280,000,000 to 225,000,000 years ago), the Permian Sea advanced as far as the Mozambique Channel.

The Mesozoic Era (from 225,000,000 to 65,000,000 years ago) is represented by marine deposits of the Jurassic Period (from 190,000,000 to 136,000,000 years ago) in the Western Sahara, Senegal, and on the Indian Ocean coast. Marine deposits of the Lower Cretaceous Period (from about 136,000,000 to 100,000,000 years ago) occur on all African coasts, while deposits of the Upper Cretaceous Period (from 100,000,000 to 65,000,000 years ago) are located in the Sahara and on the coasts of the Atlantic and Indian oceans. During the Tertiary Period, North Africa emerged, and the rift valley of the Red Sea subsided, isolating Arabia from the continent.

A quick glance at any geological map of Africa reveals firstly the distinctive effects of the great rifts,

Geological structure of Africa.

running northwest to southeast and northeast to southwest, and secondly the volcanic activity that took place both in the Tertiary and in the Quaternary periods (up to 2,500,000 years ago).

STRATIGRAPHY AND STRUCTURE

The Precambrian. The Precambrian landmass in Africa comprises four groups of interconnected cratons (immobile parts of the Earth, usually of large size). These are firstly, the West African Craton, which became stable about 2,000,000,000 years ago and which today comprises the states of Mauritania, Mali, Guinea, Liberia, the Ivory Coast, Ghana, and the western Ahaggar (Hoggar) mountain region of southern Algeria; secondly, the Arabo-Nubian Shield, which includes the eastern Ahaggar mountains of Algeria, the Tibesti moun-

The African cratons

tain region (extending into Chad, Niger, and Libya), Egypt, and the Arabian Peninsula; thirdly, the Congolese and Kalahari cratons; and fourthly, Madagascar, the eastward extension of which is unknown, as it subsided into the Indian Ocean during the Upper Cretaceous Period.

The final period of the Lower Precambrian (which came to an end approximately 3,000,000,000 years ago) was marked by important orogenic processes, traces of which are clearly defined in the West Nile System on the borders of Zaire and The Sudan, and in the Swaziland System of southern Africa. Still later mountain building at the end of this era is visible in West Africa (in Liberia), in East Africa (in the Bulawayan, Dodomian, and Sebakwian systems, found in Tanzania, Kenya, and Uganda respectively), and in Madagascar (in the Androyan System). It was during this period that the first discoverable traces of life are to be found in the fossilized unicellular algae of the Fig Tree Series in Swaziland and in the Orange Free State, South Africa.

The Middle Precambrian, which lasted from about 3,000,000,000 to 2,000,000,000 years ago, was characterized by orogenic activity that was manifested in such series as the Amsaga and Ghallaman of Mauritania, the Kambui of Sierra Leone, the Zadinian of the Congo Basin, the Dibayan of South West Africa/Namibia, the Kavirondian of East Africa, the Great Dyke of Zimbabwe, the Transvaal System of South Africa, and the Vohibory of Madagascar. The period ended with a new mountain-building episode, the widespread continental effects of which may be seen in such formations as the Berberids of the Anti-Atlas Mountains in North Africa, the West African Birrimian Formation, the Buganda–Kibali–Toro Formation of East Africa, and the Witwatersrand, Bushveld, and Limpopo formations in southern Africa.

The Upper Precambrian, which lasted from about 2,000,000,000 to 1,000,000,000 years ago, may be divided into two orogenic cycles. The first of these cycles is marked by the uplifting of the Anti-Atlas Mountains of Morocco and of such formations as the Tarkwaian (Ghana), Francevillian (Gabon), and Mayumbian (Congo). The second cycle consisted of the rise of the western Kibarian mountain chain (Zaire), the Irumian chain in Central Africa, and the Waterberg and Matsap chains of South Africa.

The final, or terminal, stage of the Precambrian, which lasted from about 1,000,000,000 to 570,000,000 years ago, is represented throughout the continent by several thousand feet of sandstone, schist (medium- or coarse-grained metamorphic rock containing micaceous materials), and dolomite limestone (limestone rich in magnesium carbonate) with stromatoliths (fossilized calcareous algae). Among these are such formations as the Adoundounian Series of Morocco, the Adrar Series of Mauritania and Mali, the Western Congo System, the Katangan Series of Zaire and Zambia, and the Damara–Otavi System of South Africa. The end of the Precambrian, at which time the Lufilian and Katangan orogenies occurred in Central Africa, is separated from the Cambrian Period by a glacial period.

The Paleozoic Era. The Paleozoic Era, which comprises the Cambrian, Ordovician, Silurian, Devonian, Carboniferous, and the Permian periods, includes two principal mountain-building episodes—the Caledonian and the Hercynian. During this era the continent of African may be said to have taken shape—the cratons fused and the landmass emerged. A glacial period during this era was marked by deposition tillites (sedimentary rocks that are composed of cemented clay and rock), which may be seen in southern Morocco, throughout West Africa and subequatorial Africa as far as South West Africa/Namibia. The tillite is considered as marking the break between the end of the Precambrian and the beginning of the Cambrian Period (which lasted from 570,000,000 to 500,000,000 years ago).

Paleozoic mountain-building episodes

Marine fossils of the Cambrian Period are found in Southern Morocco, the Western and Mauritanian Sahara, and South West Africa/Namibia. In Egypt and Arabia their presence has been revealed by drilling. Elsewhere they remain unknown.

During the Ordovician Period (from 500,000,000 to 430,000,000 years ago) fossiliferous marine sandstone completely covered North and West Africa, including the Sahara. The table sandstones of South Africa constitute its only other trace. This period is, in addition, remarkable for the tectonics (forces or conditions causing movements of the Earth's crust) of the Caledonian mountain-building episode. Although no great folds resembling those of Europe and North America occurred, the episode was marked by at least two important epeirogenic (continent-forming) movements, which raised the continental table of the central and western Sahara by approximately 5,000 feet (1,500 metres). Each emergence resulted in the creation of valleys that became flooded when the continent subsided. It is known that toward the end of the period the Sahara became glaciated, and tillites and sandstones filled the valleys.

Although no major folding took place, except in local instances, granites were rejuvenated. Many authentic Precambrian granites show ages of between 45,000,000 and 550,000,000 years old. These are not new granites, for nowhere do they pierce the covering of Cambrian or Ordovician sediments. They constitute a phenomenon that is found from the central Sahara to as far south as South Africa and Madagascar.

A complete change of sedimentation characterized the Silurian Period, which lasted from 430,000,000 to 395,000,000 years ago; this is indicated by the deposits of graptolitic schists (containing fossils of colonies of extinct animals of uncertain zoological affinity) in Arabia and in northwestern Africa.

Marine fossils of the Devonian Period, which lasted from 395,000,000 to 345,000,000 years ago, are found in North Africa and in the Sahara. Traces also remain in parts of Guinea, Ghana, and Arabia, as well as in Gabon; they also occur in the Bokkeveld Series of South Africa. Fossils of vegetation that includes *Archaeosigillaria* (fossils of ancient club mosses) may be traced in formations of the earlier Devonian Period in the Sahara and in South Africa (Witteberg Series).

The Carboniferous Period

The Carboniferous Period lasted from about 345,000,000 to 280,000,000 years ago. Evidence of marine life that existed in the earlier part of this period comes from fossils found in North Africa, the central and western Sahara, and in Egypt. During the middle and later parts of this period, the Hercynian mountain-building episodes occurred. The Mauritanid mountain chain appeared, running from north to south along the edge of northwestern Africa from Morocco to Guinea. Ancient sediments were metamorphosed and pushed from west to east, locally covering the tabular Paleozoic formations. Elsewhere, great swellings or subsidences took place, continuing until the end of the Triassic Period (from 225,000,000 to 190,000,000 years ago). These structures were synclinal (folded with the strata dipping inward toward a central axis) in form in the Tindouf area of western Algeria, dorsal (forming a mountainous spine) at Reguibat in eastern Western Sahara, basinal (forming a basin) at Taoudeni in Mali, dorsal at Kinshasa (formerly Léopoldville) in Zaire, and synclinal in Ghana.

The Upper Carboniferous Period is represented throughout the Sahara by layer upon layer of fossilized vegetation, and sometimes—as in Morocco and Algeria—by seams of coal. Different phenomena may be observed, however, in the region of subequatorial Africa, including the important Dwyka Tillite, which covers South Africa, Madagascar, an extensive portion of the Congo Basin, and Gabon. At several places in South Africa, these Dwyka strata are covered by thin marine layers that serve to demarcate the transition from the Carboniferous to the Permian periods and that form the beginning of the great Karroo System.

Marine fossils of the Permian period are visible in southern Tunisia (in the Jabal aṭ-Ṭabaqah region), in Egypt (at the Abū Daraj Wadī), in the Arabian Peninsula (southwest of Riyadh), on the coasts of Tanzania, and in the Mozambique Channel.

Everywhere else, the traces of the Permian Period are of continental rather than marine origin and are included in the Karroo System in South Africa. There, the Lower Permian strata are known as the Ecca Series and are divided into three groups—the Lower Ecca, containing almost 1,000 feet of clay-bearing schists; the Middle Ecca, containing 1,650 feet of sandstone, seams of coal, and fossilized vegetation; and the Upper Ecca, containing 660 feet of clay-bearing schists.

The Upper Permian is represented by the lower part of the Beaufort Series (which was also formed during the Lower Triassic period), which is almost 10,000 feet thick and which is famous for its amphibian and reptile fossils, a similar series of which are also found in the southern Soviet Union. Other Permian formations, not as rich in coal, are found in Zaire, Tanzania, Kenya, Uganda, Zambia, Zimbabwe, Mozambique, and Madagascar.

The absence of primary marine formations throughout southern Africa should be emphasized; it is not yet known whether this absence is due to a hiatus in deposition or to erosion.

The Mesozoic Era. Comprising three periods—the Triassic, Jurassic, and Cretaceous—the Mesozoic Era is remarkable for the overflowing of ancient seas and for the emergence of massive land formations containing interesting fossil remains.

Marine formations. During the Triassic period ancient seas left deposits in North Africa, the southern Sahara, Egypt, Arabia, and parts of Tanzania and northern Madagascar. Jurassic deposits extended to the Atlantic basins of Río de Oro and Senegal. In the middle of the Jurassic Period a great transgression of the Indian Ocean extended over Somalia and Ethiopia as far as Eritrea. In the Cretaceous Period this was followed by a series of transgressions including one on the coast of equatorial Africa at the time that the present Atlantic and Indian Ocean coasts took shape; one that totally invaded the Sahara and Egypt as far as The Sudan; and one that covered the same places once more, as well as western Arabia and the east coast of Madagascar.

Continental formations. In north equatorial Africa, including Arabia, the continental formations took the shape of an interlocked landmass. During the Triassic Period the Saharan Zarzaïtine Series, containing dinosaur and reptilian fossil remains, was laid down. During the Jurassic Period the Saharan Taouratine Series, containing fossils of vegetation and great reptilian fossils, was formed. In the Upper Karroo System of subequatorial Africa, formed during the Lower Triassic Period, the Beaufort Series contains fossils of fish, amphibians, and reptiles. The final stages of the Triassic and Lower Jurassic periods were characterized by the folding of the Cape mountain chain, by the rise of the Karroo Basin, by fracturing, and by widespread upwelling of basaltic lavas through fissures, creating formations from 3,000 to 6,000 feet thick, such as the Drakensberg range in South Africa.

During the Jurassic and the Cretaceous periods layers similar to those of the interlocked landmasses of the north were formed; they contained fossil vegetation, dinosaurs, and reptiles. During the Cretaceous Period certain eruptions of a particular type occurred, resulting in the creation of the Kimberlite diamond pipes (such a pipe being a cylindrical rock body, usually approximately vertical).

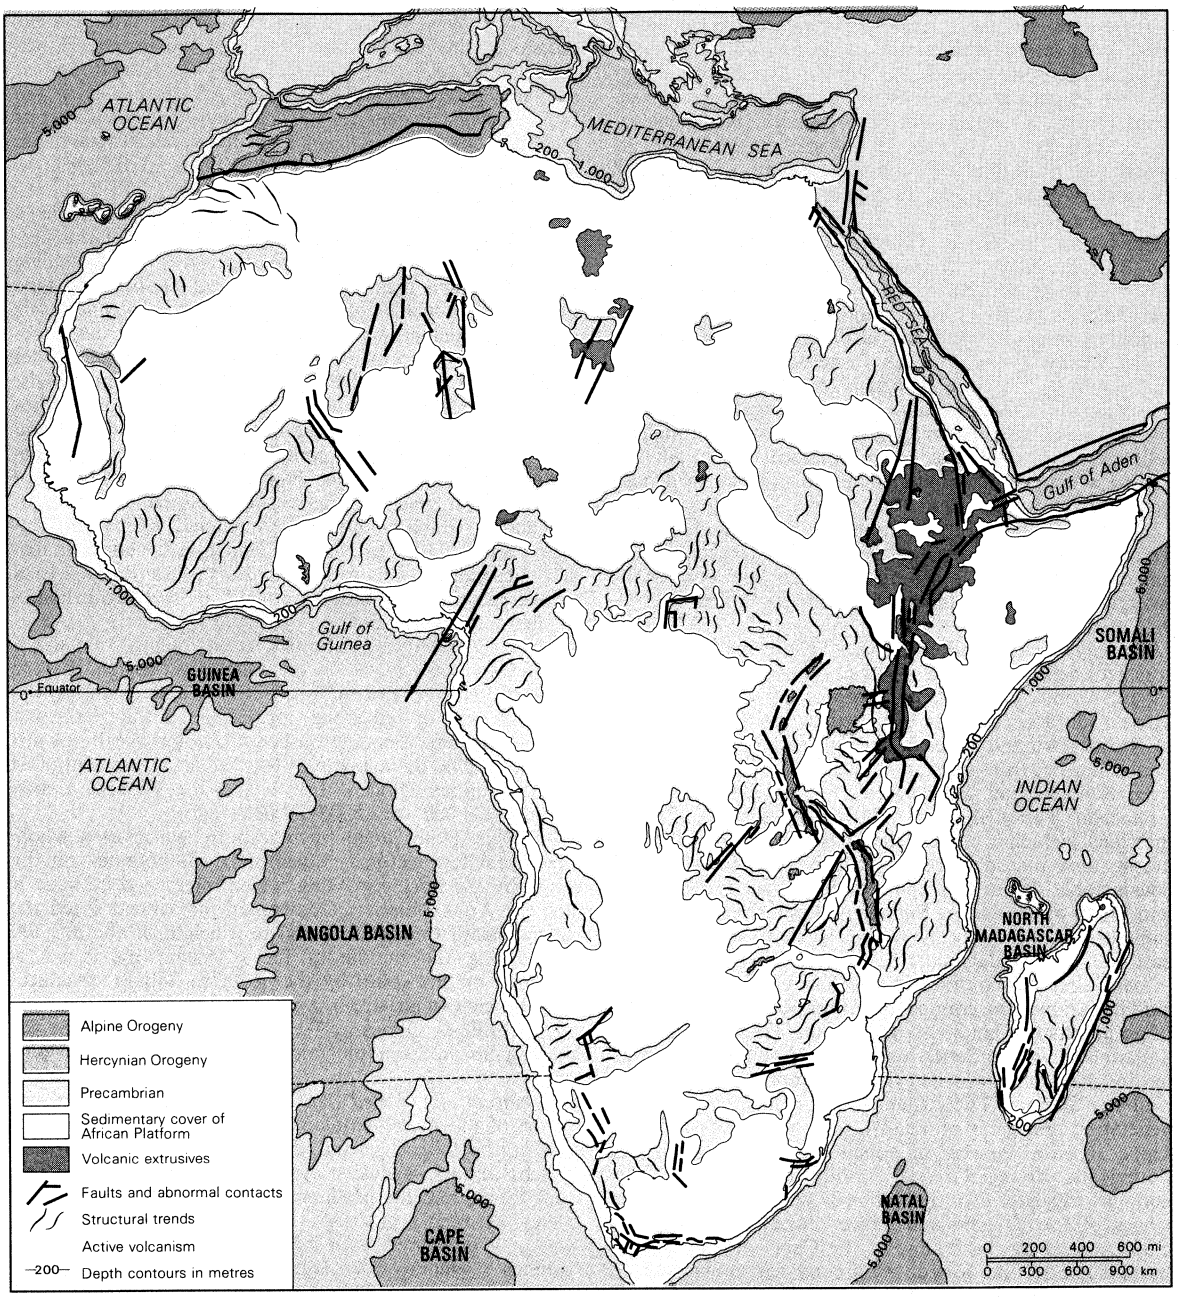
The Tertiary Period. The Tertiary Period of the Cenozoic Era (which has lasted from 65,000,000 years ago to the present) is remarkable for its great tectonic movements, which resulted in the Alpine mountain-building episode during which the North African mountains were uplifted. It is also remarkable for the creation of the Red Sea Rift Valley and for the volcanism and rifting that took place during its later stages.

Marine formations. The Paleocene Epoch (which occurred from 65,000,000 to 54,000,000 years ago) is important for its animal fossils, which include nummulites (a large kind of foraminifera, which are unicellular animals of macroscopic size), nautiloids (shelled cephalopods, which are mollusks with tentacles attached to their heads), and echinoids (sea urchins); all these are found in North and West Africa and in the Sahara. With the exception of the Sahara, nummulites of the Eocene Epoch (from 54,000,000 to 38,000,000 years ago) are found in the same places, as well as on the African coasts of the Indian Ocean, as also are lepidocyclines (foraminiferas) of the Oligocene Epoch (from 38,000,000 to 26,000,000 years ago) and the Miocene Epoch (from 26,000,000 to 7,000,000 years ago).

Continental formations. Several levels may sometimes be distinguished in the continental formations of the Tertiary Period. They include lower Eocene levels containing *Pseudoceratodes* (gastropod genus) and *Dyrosaurus* (type of reptile), as well as upper Eocene and Oligocene levels containing silicated woods and fossilized fish, turtles, crocodiles, snakes, and mammals. In Egypt the Oligocene deposits found in the al-Fayyūm area contain mammals, birds, turtles, and crocodiles. The levels of the lower Miocene, which are found on the banks of Lakes Rudolf and Victoria in East Africa, contain mastodon (a large elephant-like mammal) and *Proconsul africanus* (a large ape). Central Asian hipparions (three-toed ancestors of the horse), which simultaneously entered Africa and Europe during the upper Miocene Epoch, also left their fossilized remains in this region, as did the *Kenyapithecus* of Kenya (possibly the oldest hominid, or manlike primate) at about the same time.

Mammalian fossils of the lower Miocene

Tectonic movements. The first great foldings of the Atlas Tellien took place in the Oligocene Epoch. In the Miocene, North African flyschs (thick and extensive deposits, largely of sandstone) formed layers that, from the Rif to northern Tunisia, pushed from the north toward the south. The movements of the Tellian layers continued into the upper Miocene Epoch and the Pliocene Epoch (from 7,000,000 to 2,500,000 years ago).



The High Plains area, further south, which as a whole underwent few tectonic movements, was bounded on the south by the northern Atlas, which intervened between it and the Atlas Saharien. Continental movements lifted the Aurès Massif (mountain mass) to a height of about 3,300 feet during the middle of the Miocene; the Aurès is bounded on the south by the northern Sahara structural line, which extends from Agadir in Morocco in the west to the Gulf of Gabes in Tunisia in the east, dividing the African Shield from the folded Mediterranean or Alpine zone.

Formation of the Red Sea. Tectonic movements in the region of the Arabo-Nubian Shield that took place at the end of the Oligocene and the beginning of the Miocene epochs almost separated Arabia from Africa. A trough sank down, and the Mediterranean Sea swept into the rift valley, forming a gulf that extended to Yemen. The gulf was only prevented from joining the Indian Ocean by an isthmus stretching from Djibouti to Aden.

At the end of the Miocene Epoch the Isthmus of Suez was formed, and the gulf became a saline lake at the bottom of which thick evaporites (sediments formed as a result of evaporation) were laid down. The isthmus permitted Asian animal life to pass into Africa during part of the Pliocene Epoch. The sinking of the Djibouti–Aden isthmus, also during the Pliocene Epoch, allowed the Indian Ocean to flow into the Red Sea as far as the Isthmus of Suez.

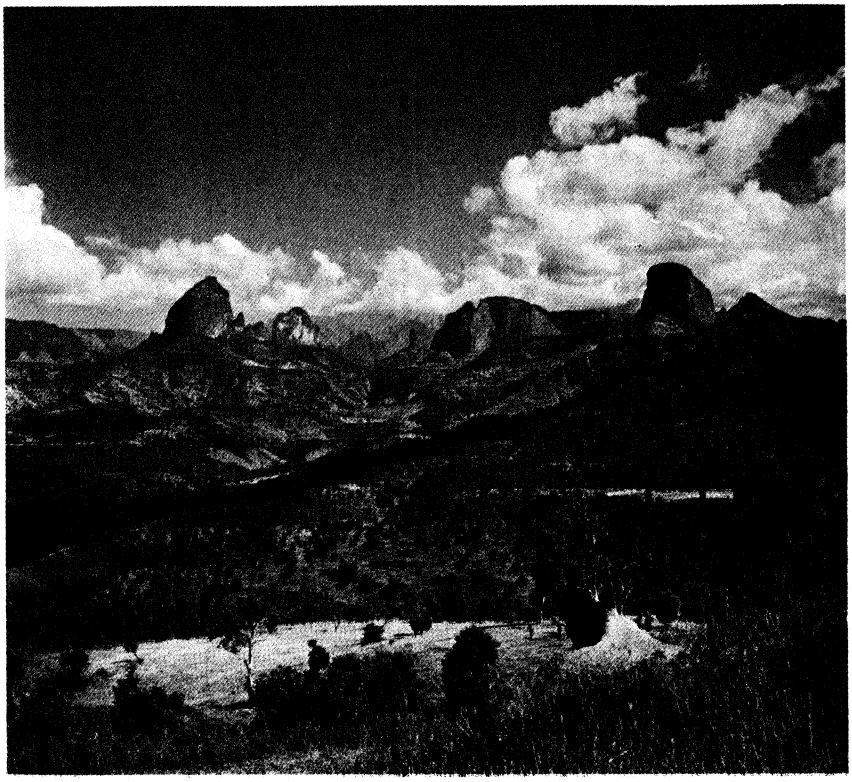
Volcanism and rifting. Tectonic movements in the Miocene and Pliocene scored the continent with a network of northeast to southwest and northwest to southeast faults. Volcanic eruptions and basaltic upwellings accompanied fracturing in the Ahaggar area of southern Algeria, in the Tibesti area of Libya and Chad, in Ethiopia, throughout East Africa, and in Cameroon, as well as in the islands of Bioko (for long Fernando Po) and São Tomé and Príncipe in the Gulf of Guinea.

The Quaternary Period. The Quaternary Period is divided into the Pleistocene Epoch (from 2,500,000 to 10,000 years ago) and the Recent epoch (up to 10,000 years ago). It represented a phase of continuing volcanic activity that caused the basement rocks of the Ahaggar and Tibesti mountains of the Sahara to rise. The activity manifested itself in eruptions and in the deepening of the Saharan valleys—sometimes to a depth of about 660

Structural features of Africa.
Adapted from *Carte tectonique de l'Afrique* (1968); UNESCO/ASGA

feet—as well as in the welling up of basalt. Although the marine deposits of the Quaternary Period as a whole are of no particular interest, continental deposits of this period bear witness to a human chronology and to human activities that parallel those of Europe.

During the cold humid periods called pluvials, which correspond to the glacial phases of the Northern Hemisphere, the glaciers that covered the high mountains of East Africa were from 3,000 to 5,000 feet thicker than they are today. Elsewhere, the desert zones of the Sahara and of the Kalahari were alternately subjected first to humid and then to dry and arid phases that expanded the desert surface at the expense of adjacent forested zones.



The oldest levels at which hominids are to be found, known as the Villafranchian–Kaguerian Series and recognized in Ethiopia and Kenya, date back approximately 3,000,000 to 4,000,000 years and are characterized by ancient forms of animal life, including in particular some ancient hominids.

Primitive hominids

These primitive hominids, called Australopithecines, may be classified in two main groups—*Australopithecus africanus* and *Australopithecus robustus*. Both groups left traces of stone and bone implements.

The Kaguerian–Kamasian Interpluvial levels, which date back to a period approximately 500,000 years ago, contain the Pithecanthropoids (a new primitive kind of human) of Olduvai Gorge (Tanzania), Ternifine (Algeria), and Chad. The Kamasian, or Second, Pluvial of the middle Pleistocene Epoch corresponds to the Mindel in Europe and also contains the remains of *Dinotherium* (which has been described as a large mammal with tusks on its lower jaw). A dry but not a desert climate is implied by the Kamasian–Kanjeran Interpluvial levels at Olduvai Gorge. The Kanjeran, or Third, Pluvial, which occurred during the middle Pleistocene Epoch and which corresponds to the Riss Pluvial in Europe, bears traces of a number of animals such as the elephant, the giraffe, and the hippopotamus.

An arid phase, which greatly reduced the area of forest, is revealed in the Kanjeran–Gamblian Interpluvial levels, which were laid down between about 60,000 and 55,000 BC. This period corresponds to an important tectonic phase marked by undulations in North Africa and activity along all the faults, in particular those in East Africa; it was at this time that East Africa assumed its present topographical aspect.

Simen Massif, which rises above the Ethiopian Plateau in the western region of Ethiopia, near Adi Arkay.
Photo Almasy

During the Gamblian, or Fourth, Pluvial, which occurred from approximately 30,000 to 15,000 BC, three distinct humid phases are separated by drier intervals. During these phases the dimensions of Lake Chad and of the glaciers of Mt. Kenya and Mt. Kilimanjaro diminished rapidly. The postpluvial phase that followed this period, equivalent to the postglacial phase of the Northern Hemisphere, was marked by a succession of alternately dry and humid stages, in which traces of Mesolithic (a transitional period of the Stone Age) and Neolithic (New Stone Age) civilizations occur, and by the desertization of both the Sahara and the Kalahari, a process which began about 3000 BC.

PRESENT GEOLOGICAL STRUCTURES AND RELIEF

Africa represents a magnificent example of the relation of geological structure to relief. In the north the chains of the Atlas Mountains, extending from west to east, evoke the orogenesis of the Alpine episode and are separated from the Sahara basement rock by the great interrupted line of the southern Atlas. Egypt, by contrast, exposes the magnitude of the Cretaceous and Tertiary marine transgressions. Between the southern Atlas and the Ahaggar Massif, the lower Sahara Basin, up to 30,000 feet in depth, contains a wide, water-bearing fossiliferous substratum and is partly covered by the great sand dunes of the Western and Eastern Ergs (Grand Ergs Oriental and Occidental). Encircling the Ahaggar, the Tassili plateaus are edged by cliffs that bound accumulations of Paleozoic deposits.

The West African landmass

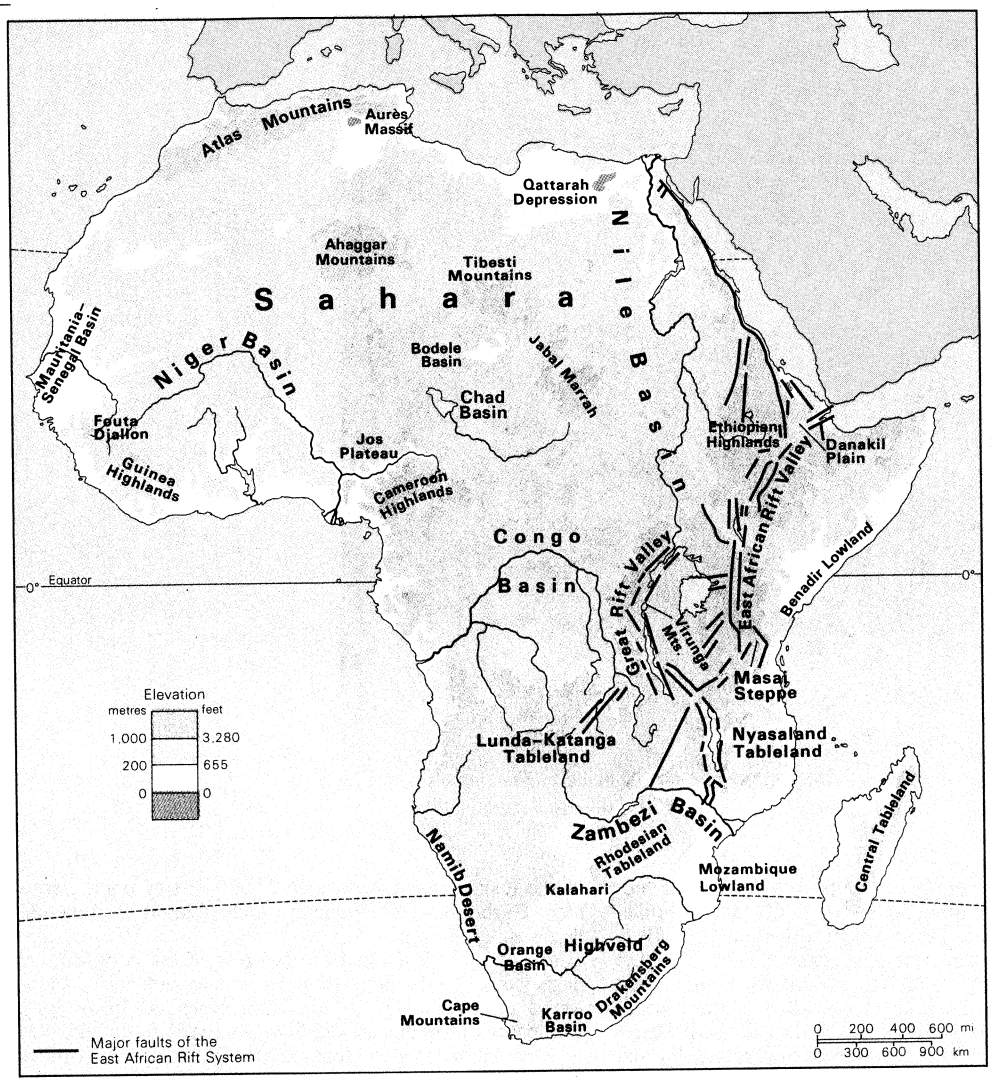
The West African landmass comprises the Taoudeni syncline, the average diameter of which is more than 620 miles. The syncline is situated between the Ahaggar mountains in the east and the Mauritania-Sénégal Basin in the west and between Reguibat in the north and Kinshasa in the south. The east-to-west crystalline dorsal formations running from Cameroon through the Ubangi (Oubangui) region to The Sudan completely separate northern from subequatorial Africa. Karroo and continental deposits fill the Congo Basin, which is surrounded by Precambrian rock formations dating from all periods of that era.

In southern Africa the Kalahari Basin and the plateaus of the Karroo System provide 23,000 feet of undifferentiated Carboniferous, Permian, and Triassic continental deposits.

East Africa is isolated from the rest of the continent by huge tectonic rift valleys that have been volcanized (subjected to volcanic heat) and that extended from Syria southward through the Red Sea and the Rift Valley lakes to Mozambique. The Mozambique Channel, which dates from the Permian Period, bounds Madagascar on the west, while on its eastern periphery a great fault dates from the Upper Cretaceous Period.

Along the coasts of Africa a number of basins disappear beneath the sea—off Western Sahara; Senegal; Ivory Coast and Ghana; Benin, Nigeria, and Cameroon; Gabon; the Congo; Angola; Mozambique; Tanzania; and Somalia.

Africa's geological structure as a whole may thus be said to express its geomorphology.



(R.L.C.F.)

II. Physical geography

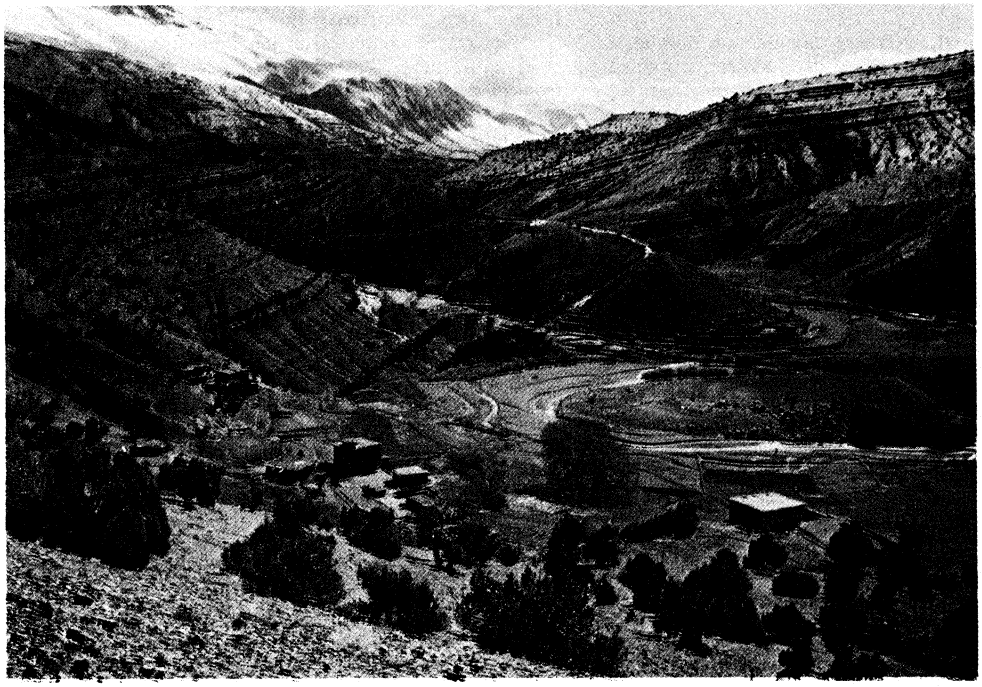
RELIEF

The physiography of Africa is largely a reflection of the geological history and geology that was described in the previous section. The continent, largely composed of a vast rigid block of ancient rocks, has geologically young mountains at its extremities in the highlands of the Atlas Mountains in the north and Cape ranges in the south. Between these mountainous areas is a series of plateau surfaces, with huge areas that are level or slightly undulating, above which stand occasional harder and more resistant rock masses. Surrounding these plateaus is a zone of plateau slopes below which are narrow coastal belts widening along the Mediterranean coast, the coastlands of Tanzania and Mozambique, a narrow belt between the Niger and Kunene (Cunene) rivers, and an area northward of the Gambia and Sénégal rivers.

Mt. Kilimanjaro (19,340 feet) is the highest point on the continent; the lowest is Lake Assal (502 feet below sea level) in Djibouti. In proportion to its size, Africa has fewer high mountains and fewer lowland plains than any other continent. The limited areas above 8,000 feet are

Physiographic regions of Africa.

either volcanic peaks or resistant massifs. All the land below 500 feet occurs within 500 miles of the coast, except for two small basins in the Sahara.



The higher areas of the south and east are in marked contrast to the considerably lower elevation of the western and northern parts of the continents. South of a line drawn from near the mouth of the Congo River to the Gulf of Aden, most of the land lies 1,000 feet or more above sea level, and much of it exceeds 3,000 and even 4,000 feet. North of the line there is relatively little land above 3,000 feet, most of the area being between 500 and 1,000 feet above sea level; there are also broad coastal lowlands, except in the northwest and in the east beyond the Nile.

The highest extensive areas are to be found in Ethiopia, parts of which exceed 15,000 feet. Southward the East African Plateau is highest in Kenya, where it is often 8,000 feet or more above sea level; there are occasional volcanic peaks that are much higher, such as Kilimanjaro, Mt. Kenya (17,058 feet), Meru (14,979 feet), and Elgon (14,178 feet). The Ruwenzori Range, or the Mountains of the Moon, which reach their highest elevation at Margherita Peak (16,763 feet), on the borders of Zaire and Uganda, are not volcanic in origin. From East Africa the plateau extends southward, often with a well-defined, though not continuous, escarpment particularly noticeable in the Drakensberg of southern Africa, where Thabaṇa Ntlenyana, or Thabantshonyana, is 11,425 feet and Mont aux Sources is 10,822 feet. There, the plateau edges are especially marked, because the rock formations are hard and horizontal, whereas in Ethiopia they are conspicuous because of faulting. Where the rocks are softer and less resistant, the escarpment is not so pronounced and so forms less of a barrier to climatic influences and to human movement.

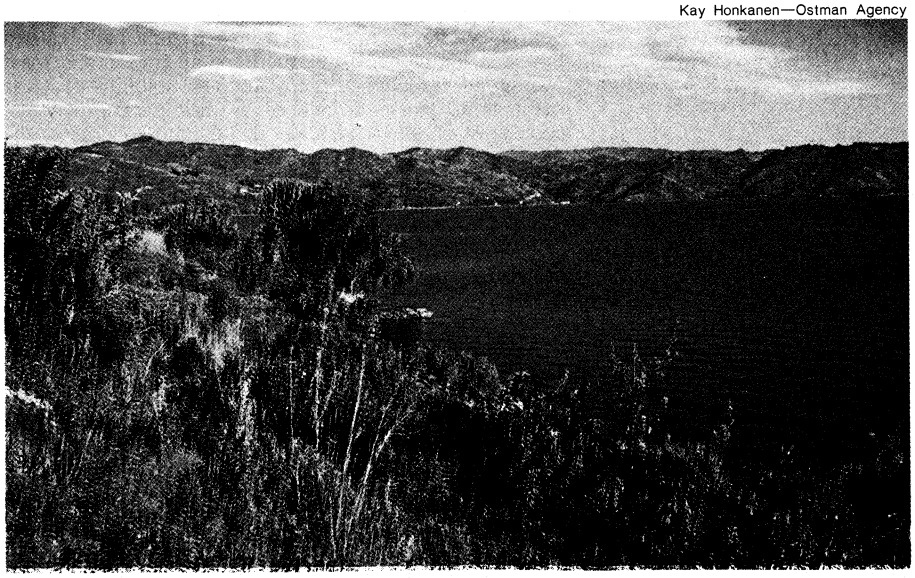
To the northward and westward of the plateau area of the southern parts of the continent there is a general descent to the lower areas of the basins of the Congo, Niger, and Nile rivers. The only large areas that extend above 3,000 feet are in the folded ranges of the Atlas Mountains and in the central Sahara, where resistant granites form the massifs of Ahaggar and Tibesti. The interior uplands of West Africa and of Cameroon consist of ancient crystalline rocks, reaching considerable heights only in the Fouta Djallon plateau in Guinea; in the Guinea Highlands, which also extend over the borders of Sierra Leone and Liberia; in the Jos Plateau in Nigeria; in the Adamawa region of Nigeria and Cameroon; and in the Cameroon Highlands. There are extensive low-lying areas near the coast and in the basins of the Sénégal, Gambia, Volta, and Niger–Benue rivers. The high areas of Darfur in The Sudan (more than 10,000 feet) and of Mt. Cameroon (13,353 feet) are volcanic in origin and are evidence of the same tensions that have resulted in rifting and volcanism in East Africa.

Volcanic activity

The East African Rift System constitutes the most striking and distinctive relief feature of the continent. Associated with its formation was the volcanic activity responsible for most of the higher peaks of East Africa, including Kilimanjaro, which is always snowcapped despite its nearness to the Equator. Seismic and volcanic disturbances are still recorded in the western portions of the rift valley system. In the Virunga Mountains, northeast of Lake Kivu, there are periodic outbursts (about every 10 or 12 years) that have created a series of lava flows. One of these volcanoes dammed the rift valley and converted a

Ouzirhlmt Valley in the Haut Atlas, Morocco.
Victor Englebert—Photo Researchers

large area, formerly drained by a tributary of the Nile, into Lake Kivu.



The rift valley extends for about 4,000 miles, its course being clearly marked out by many of the lakes of East Africa as well as by the adjacent volcanic peaks. From the Gulf of Aqaba it can be traced southward along the Red Sea and into the Ethiopian Highlands to lakes Rudolf, Naivasha, and Magadi in Kenya. Further south, through Tanzania, the line of the rift is not quite so obvious. The walls that constitute the eastern rim have been more easily eroded, while the lakes of this area are generally smaller and not in line, and some of them are only waterless salt beds. The largest of these lakes are Natron and Manyara, with Eyasi in a side branch of the main rift. The edges are obvious enough to the south in Malaŵi, where a huge crusted block collapsed along the parallel faults that constitute the steeply rising slopes of Lake Nyasa. The lake is 360 miles long but never more than 50 miles wide; it has a maximum depth of 2,316 feet. The rift then follows the line of the Shire Valley to reach the Indian Ocean near Beira, Mozambique.

The western branch, or Western Rift Valley, extends from the northern end of Lake Nyasa in a great arc, taking in Lakes Rukwa, Tanganyika (after Lake Baikal in Siberia the deepest lake in the world, with a sounding of 5,315 feet), Kivu, Edward, and Albert. Subsidiary branches of this valley include the basins in which lie lakes Mweru and Upemba.

Most of the lakes that occur along the course of the rift valley lie well below the general level of the plateau, ranging from about 1,300 to 3,000 feet above sea level. They are generally very deep and bear a striking resemblance to fjords; some have floors that are below sea level, even though their surfaces are hundreds of feet above sea level.

In complete contrast is Lake Victoria, the largest of all African lakes, which occupies a shallow depression on a plateau 3,720 feet above sea level between the major branches of the rift valley. Its greatest depth is only 270 feet, but with an area of 26,828 square miles, it is the third largest of the world's great lakes, after the Caspian Sea and Lake Superior. (Ro.W.St.)

CLIMATE

Factors influencing the African climate. A number of factors influence the climate of the African continent. Firstly, most of the continent—which extends from latitude 35° S to about latitude 37° N—lies within the tropical zone. Secondly, the near bisection of the continent by the Equator results in a largely symmetrical arrangement of climatic zones on either side. This symmetry is, however, imperfect because of a third factor—the great east-to-west extent of the continent north of the Equator, in contrast to its narrow width to the south. In consequence, the influence of the sea extends further inland in southern Africa. Moreover, true low pressure zones develop in the heart of northern Africa, while in southern Africa the belt of high pressure on land weakens during the time of high sun (the season when the Sun is overhead—in December and January). A fourth influence is constituted by the cool ocean currents, which chill the winds that blow over them and thereby influence the climate of the neighbouring shores. Fifthly, because of the extensive plateau surfaces of the continent and the absence of high and long mountain ranges comparable to, for example, the Andes of South America or the Himalayas in Asia, climatic zones in Africa tend to shade into one another, rather than to change abruptly from place to place. Finally, the high mountains have climatic zones of their own that vary with altitude.

While these factors help to account for the broad climatic patterns of the African continent, there are, nevertheless, numerous local variations to be found from place to place within the same climatic zone. Towns, for example, have their own climates, although in Africa the relevant data are not yet available to permit a detailed study of urban climates.

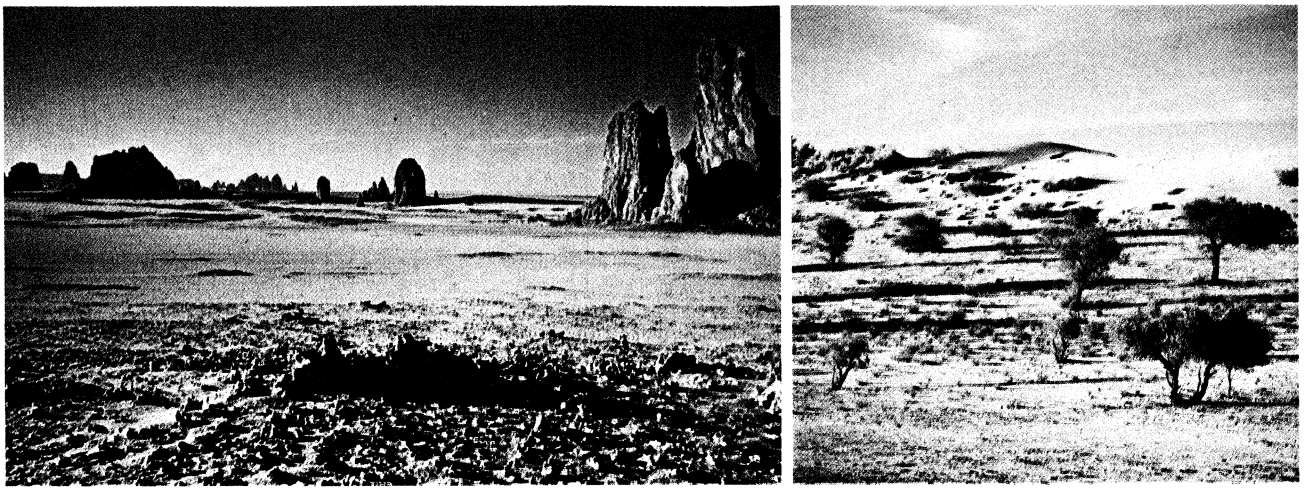
Average annual precipitation for Africa.

The air masses

The most important differentiating climatic element is rainfall; this, together with other climatic elements, depends upon the characteristics and incidence of air masses. The air masses of relevance to the African climate may be broadly classified as tropical maritime, equatorial maritime, tropical continental, polar maritime, and polar continental. Of these, the least important are the polar continental air masses, which may occasionally bring intense cold to lower Egypt in December and January, and the polar maritime air masses, which are associated with rain-bringing depressions over the northern and southern extremities of the continent during the winter. With the exception of these, the continent is affected both by the tropical continental air mass to the north and by the tropical maritime and equatorial maritime air masses to the south. These northern and southern air masses meet at the Intertropical Convergence Zone. The hot, dry tropical continental air mass, which is present the entire year in the upper levels of the atmosphere, descends to the ground only at the convergence zone. Less hot than the tropical continental are the tropical maritime and equatorial maritime air masses, which originate from the Indian and South Atlantic Oceans, respectively; they differ from each other only in that the equatorial maritime air mass is unstable and brings rain, while the tropical maritime air mass, when fully developed, is stable and will not normally bring rain unless it is forced to rise by a high mountain.

In July the Intertropical Convergence Zone moves northward toward the area of low pressure over the Sahara; there, the maritime and tropical continental air masses converge, with the maritime air masses swinging inland from the sea. There is no rainfall on the northern side of the convergence zone, since the region is completely under the dry tropical continental air mass. Conversely, on the southern side rainfall increases with distance away from the convergence zone as the maritime air masses become thicker. South of the Equator, at yet greater distance from the convergence zone, the maritime air masses are so thick and stable that they bring hardly any rainfall, except over some of the East African highlands. Only the southern tip of South Africa receives rainfall at this time, from winter cyclones.

During the period of low sun in the Northern Hemisphere (from December to January, when the Sun has moved to its southern limit), the situation described above is reversed. The convergence zone moves southward, dipping into southern Africa, while its western section hovers along the West African coast. At this season the whole of northern Africa (except the Atlas region) is under the dry tropical continental air mass, while southern Africa receives rainfall except in the Cape region and on the southwest coast, where the maritime air mass remains stable offshore over the cool Benguela Current.



The eight climatic regions

Climatic regions. When considered in detail, the movement of air masses and their effects provide the basis for a division of the continent into eight climatic regions. These are the hot desert, semiarid, tropical wet-and-dry, equatorial (tropical wet), Mediterranean, humid subtropical marine, warm temperate upland, and mountain regions.

The hot desert region comprises the Sahara and Kalahari deserts, which are always under the influence of dry tropical continental air masses, and the northern Kenya–Somali desert, the aridity of which is principally caused by the stable nature of the maritime air masses that pass over it all throughout the year. The stability of these maritime air masses is induced by their passing over the cool body of water offshore. In addition to aridity, the desert climate is characterized by high mean monthly temperatures; the diurnal (daily) temperature range is, however, greater than the annual range of the mean monthly temperature.

Semiarid climatic regions fringe the desert areas and include the greater part of the land south of the Zambezi River. They differ from true desert regions in being just within reach of the Intertropical Convergence Zone and therefore receiving more rainfall. Temperatures are about the same as in the desert regions.

The tropical wet-and-dry region is often called the savanna climatic region; this implies, incorrectly, that all areas with savanna vegetation have this type of climate. This region covers a little less than half of the total surface area of the continent, extending toward the Equator from the semiarid areas. The great distinguishing feature of this climatic region is the seasonal character of its rainfall. During the period of high sun the maritime air masses produce up to six months of rainfall—the length of the rainy season depending on nearness to the Equator. The

African deserts.

(Left) Emil Schulthess—Black Star, (right) Gerald Cubitt

rest of the year is dry. In a few places, for example, on the coast of Mauritania and Senegal, there is also a little rainfall in the period of low sun. As in the desert and semiarid climatic zones, mean monthly temperatures show less variation than daily temperatures. In West Africa lower than normal temperatures in December and January characterize what is known as the harmattan season (the harmattan is a warm, dry, northeasterly or easterly wind) and are caused by the relative coolness of the tropical continental air mass.

Regions with the equatorial, or tropical wet, type of climate, or variants thereof, are the wettest in Africa. There are two peak periods of rainfall from the equatorial maritime air mass during the year; these occur shortly before the Sun reaches the Tropics of Cancer and Capricorn and shortly after it recrosses the Equator. The first rainy season is often more important than the second, although there are years or places in which the second rainy season is the more important. Because areas with an equatorial climate are constantly covered by warm maritime air masses, variations in their monthly and daily temperatures are less pronounced than in the tropical wet-and-dry region.

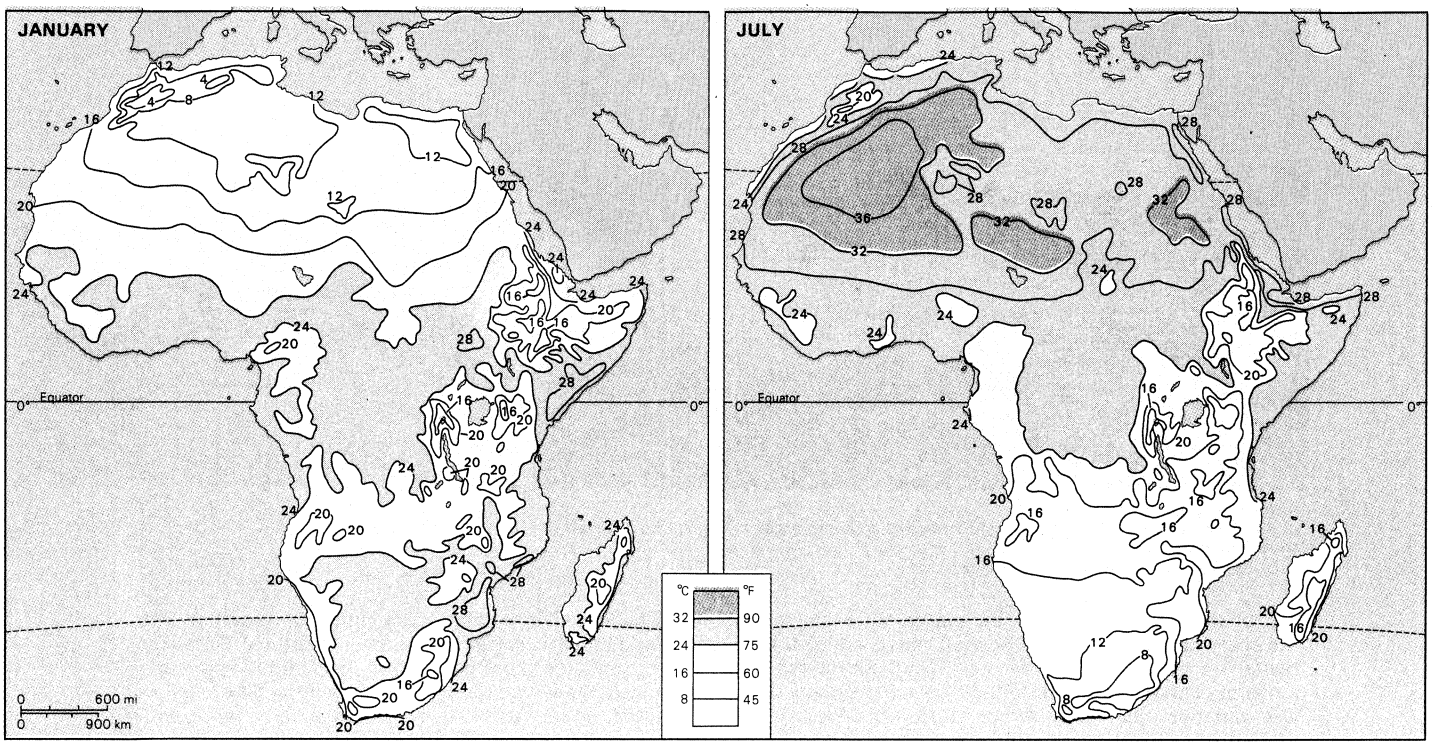
Marked variations in the rhythm of equatorial climate sometimes occur; for example, the rainfall may be monsoonal (characterized by rain-bearing winds), and the second rainy season may be all but nonexistent. But the most notable anomaly is that to be observed on the West African coast from around Cape Three Points, Ghana, eastward to Benin, where, although the two-peak regime prevails, the total annual rainfall is less than 40 inches (1,000 millimetres). Among the explanations that have been suggested are that the presence of a cold body of water offshore chills the lower layers of the maritime air mass and makes it stable; that the body of cold air that forms offshore diverts the incoming air streams to the west and east of the anomalously dry area; that there is a strong tendency for the winds to blow parallel to the shore during the rainy seasons; and that the absence of high mountains deprives the region of orographic (mountain) rainfall.

The Mediterranean climatic zone

In the northern and southern extremities of the continent there is a dry summer subtropical, or Mediterranean, type of climate. Rain falls only in winter (December–January in North Africa, June–July in southern Africa), although in some localities it may fall in autumn (September in North Africa, April in southern Africa). Mean monthly temperatures are lower than in tropical climates, dropping to about 50° F (10° C) in winter, while summer (June–July in North Africa, and December–January in southern Africa) temperatures may sometimes exceed those of tropical climates. Clear blue skies are characteristic.

The humid subtropical marine climatic region is restricted to the southeast coast of southern Africa. This region is characterized by rainfall throughout the year but with heavier rainfall occurring in summer. South of Natal the winter rainfall is more pronounced, and the temperatures are a little lower than they are to the north. Thus, at Port Elizabeth, South Africa, there are six months when temperatures are below 62° F (17° C), while at Durban, South Africa, mean monthly temperatures do not fall below 64° F (18° C).

The warm temperate upland climatic region is found on the Highveld of southern Africa. Its rainfall regime is similar to that of the tropical wet-and-dry climate, but temperatures are greatly modified by the altitude; frost, for example, occasionally occurs in Lesotho. Toward the coast the climate shows maritime characteristics, and there is a tendency toward winter rainfall.



The mountain climatic region includes the high mountain areas of Ethiopia and the lake region of East Africa. In some respects the climate is similar to the warm, temperate upland climate, except that temperatures are even lower and snow occurs on the tops of the highest peaks, such as Kilimanjaro. The rainfall regime is similar to that of the adjacent lowland areas.

DRAINAGE

The uplifting and warping of the surface of the African continent that occurred during the Pliocene and Pleistocene epochs produced a number of structural basins; these are now either individually occupied by, or are linked up with, drainage systems. With the exception of the Chad Basin, all the major drainage basins have outlets to the sea. In addition, minor drainage basins, similar to that of Lake Chad, are situated in the East African rift valleys. Some, again like Lake Chad, constitute the focus of centripetal drainage (drainage directed toward the centre), while others are linked to river systems. Although the East African lakes are climatically and economically important, relatively little is known of their hydrological characteristics.

Climate, geology, and the history of land movements have imparted certain common characteristics to African rivers. Spatial variations in the incidence and amount of rainfall are reflected in their hydrological regimes. In areas that have one rainfall season, for example, and have pronounced drought throughout the rest of the year, the rivers flood in the rainy season and shrink in the dry season.

Whatever their regimes, all the important African rivers are interrupted by rapids, cataracts, and waterfalls. This is explained by several factors. One of the most important of these was the land movements that caused ridges to be formed across the courses of the rivers. Waterfalls are often found where the rivers are still engaged in cutting downward as they flow across these ridges; Cabora-Bassa (falls) on the Zambezi and the Augrabies Falls on the

Average temperatures for (left) January and (right) July in ° C for Africa.

Orange River are examples. Another factor that contributes to the creation of rapids or falls is the incidence of bands of rock that have proved resistant to the erosive effect of the rivers' flow. (Tropical rivers do not generally carry large quantities of stone or rock; instead, they have a tendency to carry loads of fine silt, produced by chemical weathering.)

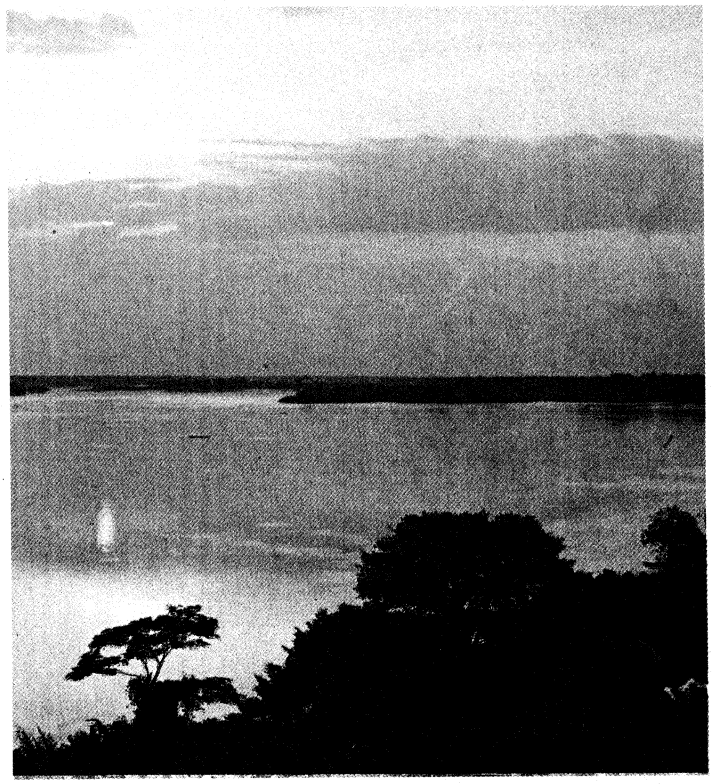
Although the Nile, the Zambezi, and the Niger rivers have large deltas, their size does not compare with that of, for example, the Ganges–Brahmaputra deltas. In Africa their generally poor development is due mainly to the restricted extent of the coastal plain, together with the relatively narrow continental shelf, which provides neither sufficient room nor shallow enough water for the deposition of delta-forming material. The great speed with which most of the rivers flow into the sea is another factor inhibiting delta formation.

Major drainage basins

The major drainage basins of Africa are those of the Nile, the Niger, the Congo, the Zambezi, and the Orange rivers, and of Lake Chad.

The Nile Basin. There are two theories concerning the development of the Nile, which, it appears, originally consisted of two sections. The first theory is that the Lower Nile had its source at about latitude 20° N, whence it flowed directly into the sea, while the Upper Nile, issuing from Lake Victoria, flowed into an inland lake that covered the Sudd region (as-Sudd) in what is now The Sudan. The lake became filled with water, which then spilled over at its northern end and flowed into what is now the Upper Nile. According to the second theory, the upper section originally flowed into a vast lake between Jabal as-Silsilah (near Luxor, in Egypt) and what is now Aswān; this was tapped by the lower section of the Nile after the so-called Sebile erosion (which takes its name from the fact that the break-through by the lower Nile was identified at Sebile).

The Nile, which is about 4,132 miles long, is the longest river in the world. From Lake Victoria it flows, as the Victoria Nile, into Lake Albert, from which it emerges as the Albert Nile. Further north it is known as the Bahr el-Jebel. Thereafter, having received several tributaries, it becomes the White Nile, and finally the Nile, emptying at last into the Mediterranean. Its major tributaries are the Baḥr al-Ghazāl (the largest left-bank tributary), and the Sobat, Blue Nile, and ʿAṭbarah (on the right bank). Because of the numerous rapids and waterfalls, the Nile descends fairly rapidly from source to mouth, as do its major right-bank tributaries. This is especially true of the Blue Nile, which, after issuing from Lake Tana in the Ethiopian Highlands at a height of approximately 6,000 feet, flows for most of its length through a steep gorge. Swamps also interrupt the river's course. Of these the largest is the Sudd, a vast area of floating swamp reeds, mostly papyrus.



The river's regime is now controlled by a series of dams situated on the Nile itself or on one of its various tributaries; of these, the largest is the Aswān High Dam on the main Nile.

The Niger Basin. The Niger Basin is the largest West African river basin. The Niger River, which rises in the mountains of Guinea, enters the sea through its delta in Nigeria; it is about 2,600 miles in length. Rapids interrupt its course at several points, for example, below Bamako and at Bussa.

The Niger receives its largest tributary, the Benue, which flows in from its left bank, in Nigeria. The valleys of both the Niger downstream from Taoussa and of the Benue appear to be faulted troughs dating from the Lower Cretaceous Period. Originally, the Middle Niger was separate from the Upper Niger, which flowed into an inland lake, the remnants of which now form the inland Niger Delta. The Middle Niger flowed southeastward to the sea; its valley eroded toward its headwaters, eventually tapping the inland lake and linking the Middle with the Upper Niger.

The Congo Basin. With a total area of about 1,335,000 square miles, the Congo Basin consists of a vast shallow depression that rises by a series of giant steps to an almost circular rim of highlands through which the river has cut a narrow exit into the Atlantic Ocean. The present exit is comparatively recent, the previous exit being to the north of the present one.

The Congo River is 2,900 miles in length. Its many waterfalls and rapids cause its valley, like that of the Nile, to lose height quickly. The river's course is often constricted by gorges. The best known are the Stanley (or Boyoma) Falls at Kisangani, where the river swings through an arc to flow westward; in fact, the Stanley Falls are no more than a series of unevenly spaced rapids at no great height, extending along a 60-mile stretch of the river. Downstream from Kisangani, the Congo is joined first by the Ubangi from the right and then by the Kasai—which ri-

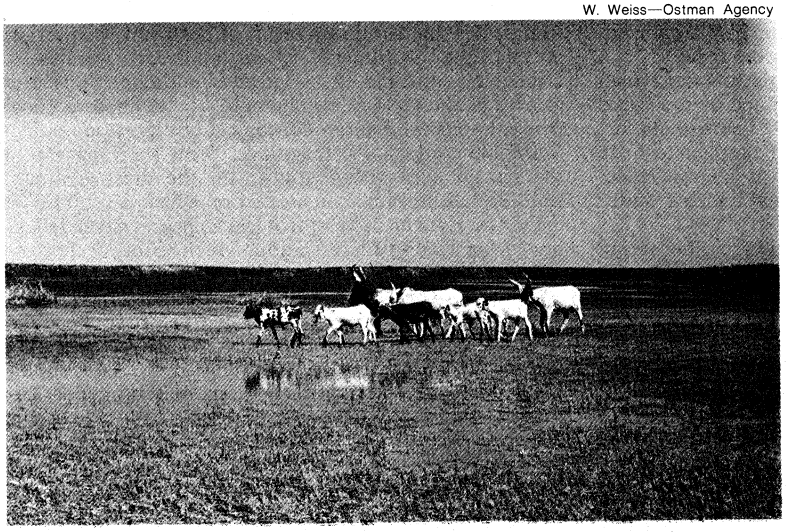
Evening on the Congo River, in Zaire.
Emil Schulthess—Black Star

vals the Ubangi in the size of its drainage basin—from the left. Below its confluence with the Kasai, the main river cuts through the Cristal Mountains (Monts de Cristal) in a deep gorge, which at one point expands into Stanley Pool (Malebo Pool in Zaire), a shallow lake measuring 22 miles in length and 14 miles in width. The Congo enters the sea through a swampy estuary that is about six miles wide at its mouth.

The Zambezi Basin. The Zambezi River is about 2,200 miles in length; it occupies a basin with an approximate area of 514,000 square miles. Originally, there were two rivers, corresponding to the upper and lower courses of the present river; the valley of the lower section eroded toward the headwaters until it captured the waters of the upper section. Although there are stretches of the river where the gradient is very gentle—a drop of only about three inches to the mile—the valley as a whole has a fairly steep gradient. There are numerous waterfalls, the most spectacular of which is the Victoria Falls. After these falls, the river winds through a number of deep gorges cut out of basalt and, after flowing through a broad valley, enters Kariba Gorge, which is more than 16 miles in length and is cut through paragneiss (a gneiss, or coarse-grained rock, in which bands rich in granular minerals alternate with bands containing schistose minerals, formed out of sedimentary rock). The Kafue and the Luangwa, the two main tributaries, which both flow through gorges, join the Zambezi on its left bank downstream from Kariba. At the mouth of the main river is a delta about 37 miles wide.

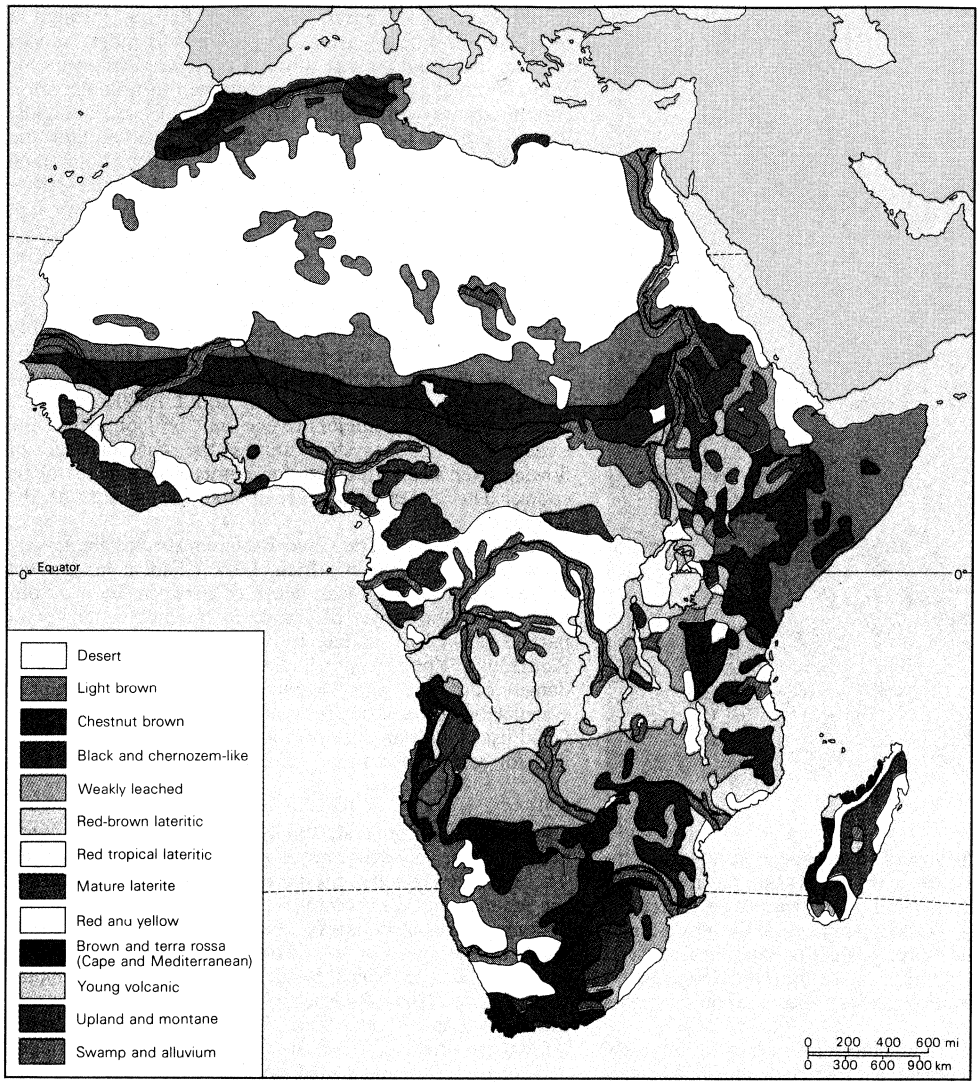
The Orange Basin. The Orange River is the longest in South Africa. Flowing across almost the entire width of the country, it makes its way from the highlands in the east through the Kalahari depression in the west to empty into the South Atlantic Ocean. Its major tributary, the Vaal, is one of its northern headwaters; the two rivers together have a combined length of about 1,300 miles. Together with other major rivers on the continent, the Orange–Vaal river system shares the characteristic of flowing over steep gradients for numerous stretches of its course. The largest drop (about 400 feet) occurs at the Augrabies Falls.

The Chad Basin. The Chad Basin constitutes the largest inland drainage area in Africa. Lake Chad, a large sheet of freshwater with a mean depth of between 3½ and four feet, lies at the centre of the basin but not in its lowest part. Lake Chad is fed by three major streams, the Komadugu Yobe, Logone, and Chari, but these are in danger of having their waters claimed by the drainage systems of rivers that flow in opposite directions. Lake Chad itself, with an area of only some 5,000 square miles, was formerly much more extensive.



SOILS

Soil types. In general, soil types on the African continent may be divided into five or six broad categories. There are desert soils; chestnut-brown soils, which border the deserts; and chernozem-like soils (very black soils rich in humus and carbonates), which are found immediately south of the chestnut soils from The Sudan westward to just beyond the Niger Bend (the bend in the middle course of the Niger River), and pockets of which are also found in East Africa, Zambia, Zimbabwe, and South Africa. In addition, there are black soils (often grouped with chernozems and found on the Accra Plains in Ghana); red tropical soils and laterites (leached red iron-bearing soils), which occur in the tropical wet-and-dry and equatorial climatic zones; and Mediterranean soils, found in the Atlas Mountains of North Africa and the Cape region of South Africa.



Factors affecting soil formation

The most important factors that affect soil formation are climate, geology, relief, drainage, vegetation cover, and the passage of time. Where the land has been generally stable and fairly flat for prolonged periods, as in Africa, the climate becomes the major determinant of the soil

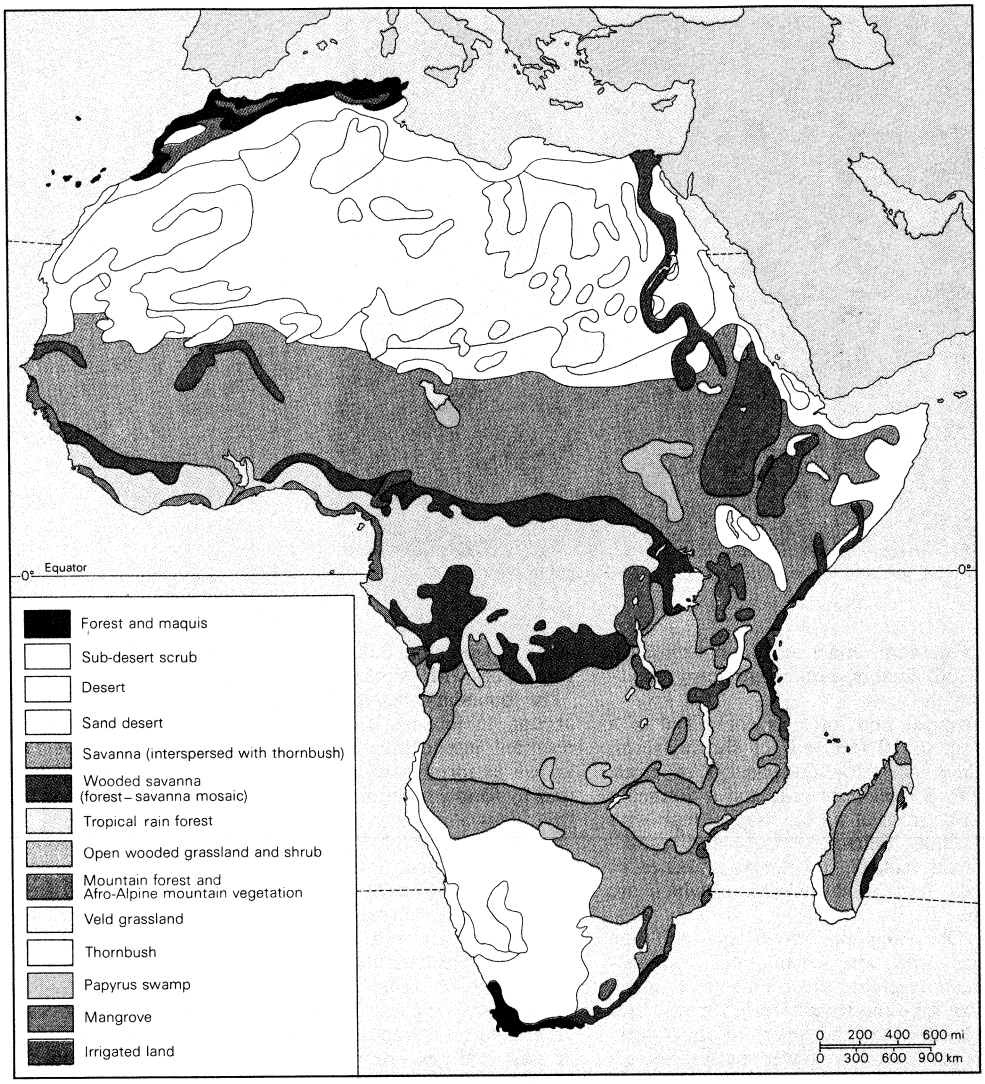
W. Weiss—Ostman Agency

Zebu cattle grazing in the northern region of Lake Chad near Nguigmi, Niger.

Soils of Africa.
After S.J. Schokalskaja, reproduced by permission of UNESCO

groups. The different rocks are deeply weathered and are broken down into their common component elements to produce broadly similar soils under the same climatic conditions. Given sufficient time under a tropical climate, the differences in humus content of the great soil groups, which are introduced by vegetation types, are minimized. But within these groups there will naturally be differences in soil types as a function of local differences in physical factors.

Desert soils. These soils are characterized by the insignificance of their organic content; by the types of rock reflected in them, the chemical breaking down of which has been inhibited by the lack of water; and by the crusts or concretions of soluble salts on or just below their surface. While these crusts are in general thought to have been formed as a result of evaporation, it is nevertheless possible that they may have been formed under a wetter climate during the Pleistocene epoch.



Chestnut-brown soils. In the semi-arid areas bordering the desert, increased rainfall makes grass vegetation more plentiful, results in rocks becoming more weathered than in the desert, and produces better developed soils with a higher humus content. It is the humus content that, according to the amount present, gives the chestnut soils their characteristic dark or light brown colour. Chestnut soils also differ from desert soils because they receive enough water to wash out some of the salt accumulations either on the surface or immediately below it.

Chernozem-like and black soils. An unfailing characteristic of the chernozem is the presence of a subsurface zone of calcium carbonate, sometimes accompanied by calcium sulfate, which is left behind after all the soluble salts have been washed out. Grouped with them are the black soils, which should, perhaps, be differently classified, for their black colour is not necessarily due to high humus content but rather to the presence of certain minerals, as in the black soils of the Accra Plains, in Ghana.

Red tropical soils and laterites. The majority of tropical soils have shades of colour varying from yellow and brown to red. The reddish colour reflects the presence of iron oxides that form as a result of chemical weathering. At one time, all tropical red earths or soils were indiscriminately referred to as laterites, although it is now clear that the term laterite should be confined to those tropical soils with large concentrations of sesquioxides (insoluble compounds) that have formed a hard pan at the surface or a little below it. At the most advanced state of laterization, bauxite, from which aluminum is extracted, is formed. Most tropical soils are, nevertheless, in varying stages of laterization, which is to say they are at various stages of accumulating insoluble compounds as the soluble elements are washed out. The compounds accumulate more readily in areas with a pronounced dry season and where the water table is not too far below the surface. If the top horizons (layers) of the soils should erode, the subsurface concentrations of sesquioxides are then exposed to the atmosphere, whereupon they crystallize irreversibly to form true laterite concretions.

Laterization of soils

Mediterranean soils. Mediterranean soils are generally deficient in humus not so much because of sparse vegetation cover as because of the slowness of the chemical processes that convert the vegetable matter to humus.

Vegetation zones of Africa.

Low rainfall, occurring when temperatures are lowest, retards chemical decay. The uneven surface relief of the regions where these soils occur also makes it difficult for mature soils to develop, since the land, except in the valley bottoms, is not sufficiently flat over wide enough areas to allow the soil-forming (parent) materials to remain *in situ* and thus to be thoroughly weathered.

Soil problems. Soil is the foundation of Africa's economic life, and as such its detailed study is most important. Failure to appreciate the physical and chemical properties of the soils has led to disastrous results for several projects for agricultural improvement (one example of this was the failure of the East African Groundnut Scheme in the late 1940s).

In studying the soils of Africa, it is essential not to lose sight of the importance of such social factors as the ability or inability of mostly uneducated farmers to judge the quality of the soil. Thus, schemes for transforming traditional systems of farming that are based on soil classification but that do not take into account local perception may have little chance of success.

For desert soils to be productive, they should be irrigated, as they are on the desert margins of North Africa; their excessive salinity or alkalinity should also be reduced. Compared to desert soils, the chestnut-brown soils are easier to work and are more productive under irrigation. Black soils tend to have a markedly crumbly structure and are sometimes difficult to plow. In the wet season, the black soils of the Accra Plains swell and become slippery, while in the dry season they shrink once more and crack to such an extent that they are said to plow themselves.

Red tropical soils need careful handling. Despite their luxuriant vegetation cover, high temperatures coupled with humidity promote the rapid decay of organic matter and keep the humus content low. Erosion is a constant threat if the soils are exposed to the elements for any length of time; the soils will only remain cultivable if the sesquioxides remain below the surface.

In the Atlas and Cape regions, there is a clearer relationship between soil characteristics and parent material than in the humid tropical areas. Over expanses of limestone, for example, the soils contain large amounts of calcium compounds, some of which must be washed away or neutralized before the soils can become fully productive. (K.B.D.)

III. Vegetation and animal life

VEGETATION

African vegetation develops in direct response to the interacting effects of rainfall, temperature, topography, and type of soil; it is further modified by the incidence of fire, human agriculture, and depasturing by livestock.

Vegetational zones. With few exceptions, it may be divided into zones of decreasing humidity. The main zones are the tropical rain forest, mountain forest, woodland or wooded savanna, wooded grassland, thornbush, subdesert scrub, and desert zones.

Tropical rain forest. This vegetation develops in tropical climates wherever the rainfall exceeds 50 inches a year, with at least two inches of rain falling in any month. The wetter and warmer the climate, the more luxuriant the forest, although excessive rainfall, cloud cover, and relatively low temperatures may discourage growth. Rain

Baobab trees, native to Africa, growing in the savanna regions of Senegal in West Africa.
K. Scholz—Shostal

forest is the natural vegetation under such conditions, except where edaphic (soil) factors, notably swampy conditions, inhibit tree growth.

Characteristically, tropical rain forest is composed of a ground story, from six to 10 feet tall, of shrubs, ferns, and mosses; a middle story (or understory) of trees, palms, and lianas 20 to 60 feet in height; and a dominant top canopy consisting of trees of up to 150 feet high with straight unbranched trunks, buttressed roots, and spreading crowns of perennial leafage, the large branches of which support orchids, ferns, and mosses, or which are festooned with lianas.

Mountain forests. Occurring on the slopes of high mountains in Ethiopia, Cameroon, Angola, and East Africa, the mountain forests resemble those that grow at sea level in Cape Province. Like the tropical rain forests, they are characterized by a shrub ground layer, an understory, and emergent dominants. They have fewer species, however, and are usually less tall and luxuriant. Local variations may be discerned by the dominance of particular trees, which may include primitive conifers absent from true tropical rain forests. Mountain forests are usually isolated by large tracts of more xerophytic (drought-resistant) vegetation, but occasionally—as in Cameroon and in western Ethiopia—they may merge in unbroken altitudinal succession with lowland tropical rain forest.

Dominance of various trees

Woodland or wooded savanna. This type of vegetation covers huge lowland tracts from latitudes 10° to 15° north and south of the Equator, receiving 40 to 55 inches of annual rainfall, but with a dry season of at least four months. In the equatorial Intertropical Convergence Zone, 4° north and south of the Equator, such woodlands also occur where 35 to 45 inches of annual rainfall is received. The Guinea savannas to the north of the Equator strikingly resemble the woodlands to the south, with wooded ridges of sandy loam alternating with swampy clay-based valley grasslands.

Such woodlands typically include a ground layer of grass and fire-resistant shrubs from four to six feet tall, the luxuriance of which varies according to the density of the canopy of deciduous fire-resistant trees, which rise from it to heights of from 30 to 50 feet. These trees shed their leaves in the dry season to spread them again just before the rains break. In the southern woodlands, *Brachystegia* (a leguminous hardwood tree, the bark of which is used for making cloth and roofing huts) and *Julbernardia* (a spreading leguminous tree which may grow to heights of from 40 to 50 feet) cover vast tracts with uniform vegetation, as do *Isoberlinia* (a tree resembling *Julbernardia* in many of its characteristics), *Daniellia* (a leguminous tree with white bark which reaches heights of from 50 to 70 feet), and *Lophira* (a spindly tree with fissured bark and simple strap-shaped leaves) in the northern savannas. In areas of lower rainfall, *Combretum* and *Terminalia* (hardwood trees with simple leaves and winged seeds) dominate.

The boundary between forest and savanna is usually abrupt. In forested areas receiving marginal rainfall, the resultant interlocking fingers of savanna and forest are known as forest-savanna mosaic and are often characterized by forests along the watercourses and by savannas on the ridges.

Wooded grassland. A gradual transition to wooded grassland, or acacia savanna, occurs as the rainfall decreases from 30 to 20 inches a year. Small (20 to 30 feet) deciduous or fine-leaved trees (mainly acacia) occur at intervals, rising from a continuous sheet of perennial grass two to four feet tall that also contains a few small shrubs.

Thornbush vegetation. Occurring in areas with an annual rainfall of 12 to 20 inches, thornbush, or bushveld, vegetation is characterized by the reduction of perennial grasses and the predominance of xerophytic, thorny, sometimes succulent or semisucculent trees, such as acacia, *Commiphora* (the myrrh tree), or *Boscia* (an evergreen hard-leaved tree). The baobab in these areas reaches heights of up to 100 feet. A relatively luxuriant shrub layer, often forming dense thickets, is admixed with succulents, such as aloes, *Sansevieria* (a fibrous succulent species), and *Adenium*, or Desert Rose (a succulent shrub with smooth grey bark, a huge water-storing base, and beautiful red or pink flowers), and smaller euphorbias. This type of vegetation covers vast tracts in East Africa, Somalia, Botswana, The Sudan, and West Africa.

Subdesert scrub. In areas where annual rainfall decreases from 12 to five inches, tree growth and perennial grass—surviving in narrow strips along watercourses—separate much larger areas of sparse annual grasses and scattered low (four to six feet) shrubs, often mainly acacias. Shrubs may often be salt-tolerant. While shrubs may die as a result of inadequate, erratic rainfall, they are little affected by the rare fires that occur. This type of vegetation covers huge areas on the southern edge of the Sahara, in the Horn of Africa, and in the Kalahari of South Africa and Botswana.

Salt-tolerant and fire-resistant shrubs

Desert vegetation. More than a fourth of Africa has less than five inches of rainfall and is thus typified by the absence or extreme sparsity of vegetation, except where water that has run off the surface and has collected in depressions encourages the growth of small trees such as acacia. Desert vegetation consists of two main types: perennials with huge root systems and sparse aerial parts, often protected by waxy cuticles, thorns, or hairs; and ephemerals, with slight root systems and little foliage but with the ability to flower profusely immediately after occasional storms and then to seed quickly and abundantly. The seed remains dormant until the next storm, for years if necessary.

Other vegetational types. Special types of vegetation, not necessarily controlled by the rainfall pattern, include sudd, edaphic valley grasslands, macchia, and Afro-Alpine mountain vegetation.

Sudd consists of an association of such sedges as papyrus with reeds and other water plants, such as the floating Nile cabbage (*Pistia stratiotes*); this mass of vegetation usually floats and is almost totally unproductive.

Edaphic valley grasslands consist of associations of tall grasses, which occur in seasonally inundated areas of larger river valleys. They are partly maintained by intense dry-season fires, which burn off the dead grass and promote renewal; they constitute true edaphic climax vegetation (that is to say, they represent a predominant type resulting more from soil than from climate) and, unlike the sudd, are intensely productive of food for both domestic and wild animals.

Macchia, a dense growth of xerophytic or sclerophyllous shrubs (foliage hardened so as to retain water) and small trees, often fire-resistant, occurs in northwestern (Mediterranean) Africa and at the Cape. Mediterranean macchia includes *Quercus* (a genus of hardwood trees and shrubs, often evergreen, including typical oaks), merging gradually on mountain slopes with pines and cedars. South African macchia is florally much richer and is the remnant of a once much larger tract of similar vegetation. Ericaceous plants (a family that comprises the heaths) abound, and many indigenous families occur. Giant heath (*Erica arborea*) is common to both areas. To the north, beyond the mountains, southern Africa macchia merges into the subdesert scrub of the Karroo region, which is characterized by small shrubs and by *Salsola* (the Russian thistle).

Heath and scrub

Afro-Alpine mountain vegetation occurs on Ethiopian and East African mountains at elevations above 10,000 feet, where nightly frosts occur. This vegetational type is made up of associations of mainly ericaceous plants together with tussock grasses and sedges; superficially, these associations are similar to macchia. A unique feature is the profusion of giant *Senecio* (groundsel or ragwort) and *Lobelia* species (plants with a basal rosette of smooth, soft leaves, from which emerges a tall spike of flower), often specific to particular mountains. *Helichrysum* (a large genus of African and Australian plants with long-lasting flowers) are equally characteristic but are individually more widespread. Vegetation dies out at about 15,000 feet on East African mountains and at 13,500 feet on those of Ethiopia.

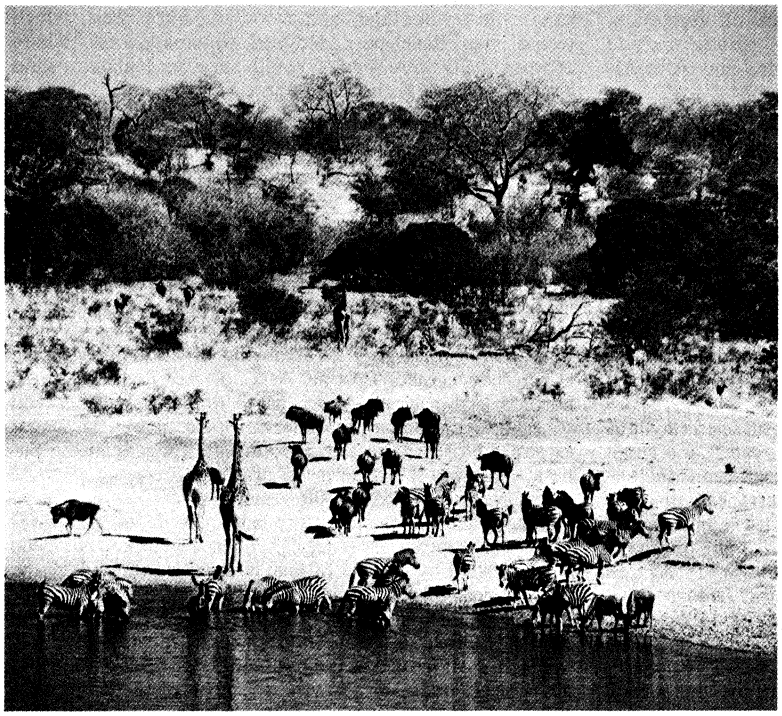
Influences on vegetation. Though they may have been modified by climatic changes, movements of the Earth's crust, and the varying position of the caloric Equator, the vegetational zones of Africa have probably existed in approximately the same climatically controlled series and with the same characteristically developed plant and animal life for a long period of time. The main features of vegetational distribution are adequately explained by climatic changes that took place during the last 1,000,000 years when the zones expanded and contracted at least four times. Successive glacial advances in the Northern Hemisphere were probably associated with wet (pluvial) periods in the African tropics, while glacial retreat conversely corresponded to increased aridity and warmth.

Climatic influences. If, as is assumed, the rainfall over much of Africa in the last pluvial, which ended about 10,000 to 15,000 years ago, was 140 to 150 percent that of the present day, the mean annual temperature would have been depressed by about 9° F (5° C), and glaciers would have descended to about 10,000 feet on the East African mountains. The upper vegetational limit would then have been depressed to about 9,000 feet, Afro-Alpine vegetation would have covered huge tracts of present-day savannas on plateaus at heights between 5,000 and 6,000 feet, and continuous forest would have extended from Senegal to Tanzania and from Ethiopia to South West Africa/Namibia.

Conversely, during warmer, drier interpluvials, mountain vegetation would have retreated to higher levels, to die out altogether on isolated mountains of less than 6,000 to 7,000 feet high. With rainfall perhaps half of the present amount, acacia steppe (treeless plains) would have advanced into woodland, and woodland into forest, which would then have been reduced to small areas where comparatively few species could survive. Kalahari sand appears to have been blowing in eastern Angola 11,000 to 13,000 years ago, with arid conditions extending to the Zambezi. Much of the present *Brachystegia* woodland was acacia steppe, and the woodland itself occupied much of the present-day equatorial forest areas. In interpluvials, arid tracts coalesced in Central and East Africa, permitting the north-to-south spread of adapted species.

The historical expanse of Kalahari sand

During the pluvials forest separated the northern savannas from the southern, isolating related forms and encouraging increased speciation. Savanna vegetation, with flowing rivers, advanced northward across the Sahara to meet Palearctic vegetation (*i.e.*, belonging to the biogeographic region that includes Europe, Asia north of the Himalayas, northern Arabia, and Africa north of the Sahara) forced southward by glaciation. The European lime—no longer extant in North Africa—was found at Ahaggar in the Sahara. The whole western Sahara has probably become desert within the last 5,000 years.



Influences of humans. In the last 2,000 years, and within the last century especially, African vegetation has been impoverished by the use of fire, by cultivation, and by the introduction and depasturing of livestock. From perhaps 350,000 years ago, when primitive people first acquired the use of fire, its previously sporadic effects intensified, for then as now a few hunters could burn disproportionately large tracts of growth. In most of Africa human cultivation has become catastrophic in its effect only within the last 50 years, the process being greatly accelerated by the trebling of the population since 1900 and the provision of better tools. Great tracts of savanna have in consequence been impoverished, and in forested zones a type of man-made savanna—derived savanna—now covers large areas. Many mountain forests have been almost totally destroyed.

Destruction caused by population increases

In the main, the depredations of livestock have adversely affected the vegetation of semiarid areas close to permanent water and free from the deadly tsetse fly. These effects have been accelerated by the effective control of epizootic diseases (those affecting many animals simultaneously) and by continuing bad management (grazing of too many livestock, excessive use of fire, and failure to use selection to improve stock when breeding). Typically, by eating down the grass, cattle and sheep reduce inflammable material and so diminish the frequency and intensity of fires to such an extent that uneatable shrubs and bush gain ascendancy. The animals continue to graze until the grass is completely suppressed and the ground is covered with tall unpalatable thickets. Browsing livestock (goats and camels) then tend to replace the grazers, or the tsetse fly may invade the area and exclude them all. The overgrazing effect is worsened by the fact that the bare soil under trees no longer absorbs so much moisture, and the amount of runoff is increased.

The ecological balance. Where relatively unaltered vegetation still exists, it shows close adaptation to topography, soil type, and drainage. Where temperature and rainfall are relatively constant in wide belts of savanna, a succession of gently rolling ridges and valleys is covered with broad-leaved woods on sandy ridge soils, while swampy grassland is covered with more xerophytic acacias on valley clays. In a small area of higher rainfall of only a few square miles, there may be a visible succession from actual swamp with papyrus, through swampy grassland and broad-leaved savanna to a patch of forest on rich hillside soil, and finally to succulents and xerophytes on a nearly naked rock summit. These effects, not explained by climatic variation, demonstrate that, even in the absence of humans and livestock, the African countryside maintained a mosaic of natural habitats.

Other influences. In response to climatic and other influences, the fluctuation and varying extent of African vegetational types have led both to the diversification of and to the emergence of distinct species of native plants and animals; at the same time, such variations have largely controlled or affected the activities of humans. Where the tsetse fly, which is associated with forest or

Watering hole in the Veld region of Transvaal, South Africa.
John Rushmer—Ostman Agency

well-watered savanna, effectively excludes livestock, Africans must fall back on fire and agriculture. In semiarid areas where crop cultivation becomes impossible, residents affect the vegetation through fire and livestock. Some 50,000,000 pastoralists thus live in three-fifths of the continent.

ANIMAL LIFE

Zoogeographical regions

Africa includes parts of two main zoogeographical regions: the Ethiopian region, which comprises the continent south of the Sahara and part of Arabia, as well as Madagascar; and North and northwestern Africa south to the Tropic of Cancer.

Genera and distribution. Of all the continents, Africa is the richest in large ungulates (hoofed mammals) and freshwater fish. There are some 90 species of ungulates and 60 of Carnivora (the order of flesh-eating mammals). Among ungulates of the order Artiodactyla (composed of mammals with an even number of toes), several families, including giraffes and hippopotamuses, are now endemic (peculiar to a locality). Some families of Carnivora, such as civets (catlike carnivorous mammals of the Viverridae family) and their relations the genets, which are small carnivores, as well as hyenas are chiefly African. The rodent family of jumping hares (Pedetidae) is endemic, and one order, the aardvark (Tubulidentata), a large nocturnal burrowing mammal, with one species, is exclusively African.

The primates include some 45 species of Old World monkeys, as well as the world's largest ape, the gorilla. Presimian primates—such as pottos (African lemurs) and galagos (bush babies, or small arboreal lemurs), as well as Lorisidae (a family of arboreal lemurs, moving with a slow, delicate crawl), are mainly small and nocturnal, but in Madagascar, where there are no true monkeys, a varied animal life of large and small diurnal and nocturnal presimian lemurs survives. Madagascar also has a remarkable insect-eating family, the tenrecs (animals with long pointed snouts, some of whom are spiny and tailless). Saltwater aquatic mammals include one Mediterranean and one South African seal, and two Sirenia (an order of aquatic, herbivorous mammals)—the dugong and the manatee.

South of the Sahara the birdlife includes some 1,480 resident species, to which must be added another 275 species that are either resident in northwestern Africa or else are Palearctic winter migrants; these migrants total perhaps 2,000,000,000. Birds are mainly of Old World families, but of those that are endemic, the most noteworthy are perhaps the ostrich, shoebill, hammerkop (a brown heronlike bird), secretary bird (a large longlegged predatory bird), and the touracos (brightly coloured birds, some with helmetlike crests). Other families, such as bustards, sand grouse, honey guides (small dull-coloured birds, some species of which are noted for leading people to honeybees' nests, in order to feed on them after the nests have been broken), and larks are predominantly African.

Reptiles, of which there are few endemic families, have mainly Old World affinities. Those most likely to be seen include lizards of the agamid family, skinks (a family of lizards characterized by smooth overlapping scales), crocodiles, and tortoises. Endemic reptiles include girdle-tailed and plated lizards. Lizards of the iguana family and boa constrictors occur only in Madagascar. Large vipers are abundant and varied. A wealth of both colubrine snakes (with fangs at the posterior end of the upper jaw) and elapine snakes (with fixed poison fangs at the front of the upper jaw) include such highly venomous elapine species as mambas.

Amphibians mainly belong to Old World groups. Salamanders and hylid tree frogs (having teeth in the upper jaw) are confined to the Palearctic northwest. Abundant commoner frogs and toads include such oddities as the so-called hairy frog of Cameroon, whose hairs are auxiliary respiratory organs. The frog family Phrynomeridae is exclusively African.

Freshwater fish, of which there are altogether some 2,000 species, include both remarkable archaic forms and examples of sudden recent evolution. The coelacanth, an archaic marine form, believed extinct for 70,000,000 years, was rediscovered in 1938, since which time others have been found. Other ancient freshwater forms, such as lungfish (*Protopterus*), bichirs or lobefins (*Polypterus*), and reedfish (*Calamoichthys*), can all breathe air—a property that certain catfish (Clariidae), which are able to travel overland for some distance in wet weather, also possess.

Archaic fish species

A rich and varied invertebrate animal life on the east and west coasts includes marine organisms typical of the Indo-Pacific and Atlantic oceans. Coral reefs and associated organisms are mainly eastern, while the southwest coast, washed by the cold Benguela Current, abounds in fish. Among arthropods (a grouping that includes insects

and other segmented invertebrates) are to be found large butterflies of the *Charaxes* (brush-footed) and *Papilio* (swallow-tailed) genera, stick insects, and mantises, grasshoppers, driver ants (tropical ants that travel in vast swarms), termites, and dung beetles. Spiders and scorpions also abound. At one time most African fauna was thought to derive from elsewhere. There is no doubt, however, that as little as 15,000 years ago an amelioration of the present Saharan climate enabled such typical Ethiopian forms as clariid catfish to reach the river systems of North Africa. Likewise, Palearctic animal life and vegetation appear to have extended far south into the Sahara, and the white rhinoceros apparently lived beside elklike, typically Palearctic deer.

Within the Ethiopian region, repeated climatically controlled expansion and contraction of vegetational zones resulted firstly in organisms establishing themselves in numerous ecological communities (niches) of plants and animals, and secondly in the proliferation of those species that successfully adapted themselves to the prevailing conditions. The spreading of forests during the pluvials, separating northern and southern savannas, led to the evolution of such closely related northern and southern species of antelope as the kob and puku, the Nile and common lechwe, as well as of the northern and southern races of white rhinoceros.

Some subfamilies of Bovidae (the ox family), like the spiral-horned antelopes (Tragelaphinae), have adapted to almost every ecological environment—forest, savanna, and Afro-Alpine zones, and even to papyrus swamp. Others, like the hartebeests (Alcelaphinae), which inhabit savannas and grasslands, are less adaptable.

Freshwater fishes demonstrate the existence of the relation to one another of former river systems and lakes. Large rivers containing Ethiopian fish evidently existed quite recently in the northern Sahara. The fish life of the now isolated Lake Rudolf, in East Africa, demonstrates that the lake was once connected to the Nile, though Lake Victoria, the present source of the White Nile, was not. Lake Kivu, too, was formerly connected with the Nile, but as a result of volcanic activity is now part of the Congo drainage system.

In earlier periods the animal life was even more remarkable than today. Fossil deposits reveal sheep as big as present-day buffalo, huge hippopotamuses, giant baboons, and other types similar to existing species. These huge types probably lived in pluvial periods, dying out as aridity increased. Smaller types survived.

The effects of humans. Until the introduction of firearms, humans had relatively little effect on the animal life. Within the last century, however, and particularly since 1940, direct or indirect human wastage of Africa's animal life has been intense. The antelope known as the Zambian black lechwe, for example, believed to number 1,000,000 in 1900, has been reduced to less than 8,000.

Though European hunters and colonists were rightly blamed for much of the early decline, hunting, destruction, or the disturbance of habitats by Africans has become more important. Rinderpest, an acute, and usually fatal, infectious disease of livestock, entering Africa with domestic stock in the 1890s, decimated many indigenous antelopes; the accelerated spread of agriculture and stock raising involving the destruction of forests, and excessive grazing and burning of vegetation eliminated large animals from wide tracts. In the southern Sudan, for example, political strife and warfare in the 1960s have entirely eliminated wildlife from some areas. The demand for fancy leather and fur also endangers the Nile crocodile and the leopard.

Humans, however, have been of benefit to many smaller species. Dams and irrigation schemes benefit waterfowl, frogs, and fish, and the spread of grain crops encourages certain pests. Even the patchy cultivation of forests results in the development of a mosaic of habitats.

Complementary grazing systems

Ecology. There are still sufficiently large tracts of relatively unspoiled country in which animal life may be studied in its environment. The complementary roles of wild ungulates, for example, show that in any area inhabited by a wide variety of species, the grass is grazed in regular succession and at different stages of growth—for example, by zebra, wildebeest, hartebeest, and gazelle—while specific adaptations enable a still greater variety to survive. A much smaller variety of domestic stock cannot duplicate such effects. Overpopulation by domestic or wild species may upset the delicate natural balance, as may be seen by the example of elephant overpopulation in Kabarega (formerly Murchison Falls) National Park, Uganda, and in Tsavo National Park, Kenya; whether the elephants survive or not they have ineradicably altered the environment to the detriment of many other typical species.

Animal life of particular interest. Animal life of particular interest includes four main groups that are not mutually exclusive. They are: (1) species potentially or actually useful to humans as food (large ungulates); (2) dangerous or pest species that may have to be controlled or eliminated (locusts, tsetse flies, *Quelea* finches or black-faced diochs, which do immense damage to grain crops, and some ungulates or carnivores); (3) species that provide a spectacle and bring economic benefit (elephants, the larger plains ungulates, primates, or carnivores); and (4) endangered, rare, or unique species.

Intensive studies, associated with human behaviour and psychology, have been made of such primates as baboons; the Ethiopian gelada, to which baboons are related; and especially of the chimpanzee and the gorilla. Studies of such primitive primates as the lemurs of Madagascar show them to be threatened by the destruction of their habitat, and reveal that the forest lemurs, including the largest (*Indri*), are especially in danger. The unique aye-aye (*Daubentonia*), a nocturnal lemur feeding on insects and fruit, has been shown to be nearly extinct, not only because of habitat destruction but also because it is killed for superstitious reasons.

Other studies show that, in areas made inaccessible to domestic stock by the tsetse fly, controlled populations of wild ungulates may help to compensate for the chronic protein shortage among African peoples. Studies of predators, such as the lion, have shown that they do not generally control the numbers of ungulates as do disease or starvation. It also has been established that the hyena is as much a potent predator as a scavenger. Since about 1960 the territorial behaviour of many antelopes also has been revealed. Such pest species as the desert locust, tsetse, mosquito, and *Quelea* finch have been intensively studied as a first step in their control.

Conservation. Many countries have now set aside large tracts as national parks, game reserves, or forest reserves. Of these parks, only some are large enough to be self-contained ecosystems, and most have been set aside for large mammals. In East Africa there are also sanctuaries for birds and marine organisms. The conservation of vegetation is undertaken mainly in forest reserves but also in national parks.

The oldest and best known national park is the Kruger National Park in South Africa, where representative populations of most savanna species are maintained. The Kalahari Gemsbok National Park, which South Africa shares with Botswana, conserves a tract of arid country with such associated types of antelope as springbok and gemsbok; smaller reserves and parks conserve particular species. Only one large mammal species, the blaubok (or blaauwbok), has become extinct, though several subspecies have nearly disappeared; one such subspecies, the quagga, a race of zebra, has vanished.

East and Central African countries have large national parks, which have been expanded in size or have increased in number as a result of the economic benefits of tourism. Kenya's parks include Tsavo, one of the largest, with an area of 8,000 square miles, Lake Nakuru National Park for flamingos, montane national parks, and a marine park. Uganda has three large national parks; Tanzania has the famous Serengeti National Park, with its unrivalled populations of plains ungulates, and the parks of Ngorongoro, Lake Manyara, Arusha, and others. Zambia has the Kafue National Park and the Luangwa Valley Parks; Zimbabwe has Wankie; Mozambique has the Gorongoza; Botswana has the Chobe Game Reserve and the

Central Kalahari Game Reserve; South West Africa/Namibia has the Namib Desert Park; and Malawi has the Kasunga National Park. All these parks preserve representative woodland, savanna, or thornbush species.

Depletion of wildlife

Elsewhere the situation is less satisfactory. In Zaire national parks were all seriously depleted after independence. Zaire now has six major national parks, including the Virunga National Park. Though The Sudan is one of the countries with the largest numbers of remaining ungulates, little of it is known, and it is not conserved by an adequate park network. Ethiopia has parks largely on paper, and Somalia has only a rudimentary system consisting mostly of game reserves and one area (Luc Badana) nominally a national park, but failing to meet UN criteria for such parks. The "W" park is shared between Upper Volta, Niger, and Benin, but most West African countries have only small national parks if any at all.

Animals not protected in parks are not necessarily threatened. Many large species are still plentiful in forest or game reserves or in controlled hunting areas. Well-managed forest reserves in particular provide secure habitats for many smaller unprotected forms.

Animals affecting land usage. Historically, the abundance of large ungulates may have stimulated some individuals—notably Europeans in southern Africa—to occupy certain areas. Trade routes were established and early hunter-explorers were influenced by the availability of elephants, whose ivory tusks slaves could carry.

Large or small animals now may affect humans by competing with them or with their livestock. They may prey on people or on livestock or carry diseases affecting either. The bilharzia snail and the *Simulium* fly (host to an organism causing blindness), the tsetse fly, and the mosquito collectively affect human beings and their livestock far more than do such individually large or formidable species as lions or elephants.

The larger ungulates may compete with domestic livestock for forage but they are more keenly resented and hunted by agriculturists, whose crops they may eat. Pastoralists are much more concerned about lions that occasionally kill cattle than they are about locusts or rats, which, by depleting forage, indirectly cause the death of much livestock.

Danger to humans from large animals, carnivorous or otherwise, has been greatly exaggerated, but disease carried by living organisms is still a serious problem. Indigenous African ungulates are resistant to the diseases (such as trypanosomiasis, a parasitic organism that causes sleeping sickness) carried by tsetse, but domestic livestock, none of which has been in Africa much more than 4,000 years, is not. Despite tremendous efforts to eradicate tsetse, the insect still occupies more than 2,000,000 square miles of forest and savanna, from which most of it cannot economically be cleared. (L.H.B.)

IV. Natural resources

MINERAL RESOURCES

Africa's mineral wealth

Africa's known mineral wealth places it among the world's richest continents. It has a very large share of the world's mineral resources that includes coal (5 percent), petroleum (9 percent), natural gas (10 percent), uranium (25 percent), radium (the chief source), low cost thorium (a grayish-white, lustrous, radioactive metal; 4 percent), iron ores (3 percent), chromium (almost the entire world reserve), cobalt (68 percent), copper (14 percent), lead (7 percent), zinc (9 percent), tin (7 percent), bauxite (36 percent), titanium (the deposit at Sherbro, in Sierra Leone, is one of the largest in the world), antimony (about 7 percent), gold (54 percent), platinum (more than 85 percent), tantalum (a gray, hard, rare metallic element; 70 percent), germanium (a scarce, metallic, grayish-white element; about half of world reserves), lithium (a soft, silver-white metal; 11 percent), phosphates (two-thirds), and diamonds (the bulk of world reserves).

Mineral fuels. Information about Africa's more important mineral fuels is often fragmentary in character. Moreover, any assessment of mineral resources is necessarily valid only for a short span of time, as old mines are depleted and new ones discovered.

Coal. Major deposits are confined to three groups of coal basins. The largest is in southern Africa, with a total of about 200,000,000,000 tons of proven reserves and estimated resources; South Africa has much of this total (65,000,000,000 tons), and Botswana contains an even larger proportion (114,000,000,000 tons). There are other deposits in Zimbabwe (7,200,000,000 tons), Madagascar (about 500,000,000 tons), Malawi (13,000,000 tons), Mozambique (430,000,000 tons), Tanzania (1,900,000,000 tons), Zambia (130,000,000 tons), Zaire (660,000,000 tons), and Swaziland (5,300,000,000 tons).

The second group of coal deposits is in North Africa, and contains less than 1,500,000,000 tons. They consist of a number of large basins extending from Algeria into Morocco. The third potential source of coal is in West Africa, particularly in Nigeria, where reserves and estimated resources total 1,000,000,000 tons.

Petroleum. Proven petroleum reserves (1978) in North Africa occur in Libya (3,300,000,000 tons), Algeria (1,100,000,000 tons), Egypt (440,000,000 tons), and Tunisia (180,000,000 tons). So far, exploration has been concentrated north of the Aïr-Ahaggar massifs; there may also be major Saharan reserves to the south. The other major oil reserves are in the West African coastal basin. Nigerian basins contain 2,500,000,000 tons, with the Gabon Basin containing 270,000,000 tons, the Congo 43,000,000 tons, and Angola 150,000,000 tons.

Natural gas. Africa's natural-gas reserves are concentrated in basins of North and West Africa. Algeria has the lion's share (250,000,000,000,000 cubic feet, or 7,000,000,000,000 cubic metres, in 1978) and ranks among the world's largest. The other countries with the most commercially promising reserves are Nigeria (42,000,000,000,000 cubic feet), Libya (24,400,000,000,000 cubic feet), Tunisia (4,800,000,000,000 cubic feet), Egypt (3,000,000,000,000 cubic feet), Gabon (2,400,000,000,000 cubic feet), and the Congo (2,200,000,000,000 cubic feet).

An unusual source of natural gas lies in Central Africa, where the waters of Lake Kivu, shared by Rwanda and Zaire, contain in solution about 2,100,000,000,000 cubic feet of methane gas. There is also an important source of low-grade oil, estimated at 15,000,000,000 tons, in the bituminous tar sands and oil shales that are widespread in southern Africa, particularly in Angola, Zaire, and Mozambique.

Uranium and fissionable elements. Southern Africa is said to be one of the world's seven major uranium provinces. In South Africa the unusual degree of knowledge of reserves derives from the joint occurrence of uranium with gold, a condition that also decreases the cost of production. Reasonably assured resources amount to 430,000 tons, with a further 153,000 tons possible. In Zaire uraninite veins are associated primarily with cobalt and nickel occurrences at Shinkolobwe-Kasolo and at Kalongwe, in reserves totalling about 2,000 tons of low-cost uranium. Elsewhere in Africa the mineral occurs in unusually high concentrations with phosphates. Deposits occur in Morocco; in Algeria (31,000 tons); at Thiès, in Senegal; at Bakouma, in the Central African Republic (about 20,000 tons); in Niger (176,000 tons); and in South West Africa/Namibia (146,000 tons).

Uranium deposits

There are deposits of major international significance in Central and West Africa. At Mounana and at Oklo, in Gabon, reserves of 37,000 tons of uranium are known, and, in Niger, ores in sandstone are thought to contain 160,000 tons. In Somalia exploration of the Bur region has revealed the Alio Ghelle deposits known to include 6,600 tons of uranium.

Africa is thought to contain about 300,000 tons of thorium. So far, however, exploration for this element has been limited. The chief ore mineral is monazite, in which thorium is contained in varying proportions. The primary ore is found in South Africa, Malawi, Burundi, Kenya, Niger, and Nigeria. Elsewhere, secondary concentrations of monazite are found in Ivory Coast, in the beach sands of Madagascar, and in the black sands of the Nile Delta in Egypt.

Zaire has the world's chief source of radium—located in the uranium ores of the Shinkolobwe-Kasolo area.

Metallic deposits. *Iron and iron ores.* Although iron ore reserves are known to be widespread, knowledge of the deposits is somewhat limited.

In North Africa reserves of iron ore are concentrated in the Atlas and western Sahara. Egypt, however, has 200,000,000 tons of medium-grade reserves, of which the most important are in the al-Kāḥāt al-Babrīyah. The ore deposits in Morocco and Tunisia, which were of considerable importance in the past, have been severely depleted. Algeria has proven reserves of about 586,000,000 tons. The largest deposit of North Africa is at Gara Djebilet, Algeria, with estimated reserves of 2,000,000,000 tons of medium-grade ore. Large deposits at Djebel Bou Ari in Batna *wilaya* (governorate) were discovered in 1975. Africa's most significant iron reserves, however, are to be found in West and southern Africa. Potential lateritic ores are widespread in Ghana (iron ore reserves estimated at 150,000,000 tons), in Nigeria (86,000,000 tons), and in Guinea, where the laterities of the Presqu'île de Camayenne have iron-ore content. Madagascar's lateritic crusts also have high iron content.

West African iron-ore deposits

It is the sedimentary Precambrian rocks themselves, however, particularly in West Africa, that have proved the basis of Africa's role as a major world producer of iron ore. The most significant deposits are in Liberia, with 700,000,000 tons of contained iron in the Bomi Hills, Bong and Nimba ranges, and the Mano Valley deposits; in the extension into Guinea of the Nimba–Simandou ranges, where 1,500,000,000 tons of hematites have been located; in Mauritania (400,000,000 tons of low-grade ore); in Zaire, where vast reserves are present; and in Gabon (1,000,000,000 tons). Weathering of such formations has produced the Cassinga ores of Angola (more than 100,000,000 tons of high-grade hematite), while the massive parent rock is assumed to contain further supplies.

In southern Africa most iron-ore reserves lie in South Africa itself, having total reserves of 1,200,000,000 tons of contained iron. The chief deposits are at Postmasburg, in the Bushveld Complex, which has at least 200,000,000 tons in the eastern and northern Transvaal, at Thabazimbi, and in the vast, low-grade deposits of Pretoria. There are also substantial reserves in Zimbabwe, which has 200,000,000 tons of ore near Que Que, as well as more than 200,000,000 tons elsewhere in the country.

While this outline completes known reserves of international importance, it excludes those that may be only of national significance on account of inaccessibility or low grade. There are considerable Zambian reserves; more than 90,000,000 tons of potential ore in Uganda; 78,000,000 tons in Tanzania; and outcrops of banded ironstones in Kenya, Cameroon, and the Central African Republic; as well as the unevaluated reserves of the Congo.

Ferroalloy metals. Africa's reserves of minerals used as ferroalloys in the steel industry are even more striking than its vast share of world iron-ore reserves. This is particularly true of chromium. Almost the entire world reserve of chromium is found in southern and, to a much lesser extent, in West and northeastern Africa. The highest concentrations are found in Zimbabwe, where the Great Dyke contains reserves estimated at 1,000,000,000 tons. South Africa contains the largest deposits of chromite, estimated at 4,000,000,000 tons. As compared with these two sources, reserves elsewhere in Africa are relatively small.

Manganese reserves

Manganese reserves are considerable. In South Africa reserves of about 800,000,000 tons of contained manganese are found in the Kalahari Manganese Field and elsewhere. The Mouanda deposit in Gabon is thought to be one of the largest in the non-Communist countries and has been assessed at 80,000,000 tons of manganese content. Ghana is another important source of manganese, having both low-grade and high-grade reserves of about 6,500,000 tons of contained metal.

Elsewhere in West Africa, manganese deposits are situated in Upper Volta (about 10,000,000 tons) and Ivory Coast (about 1,500,000,000 tons), as well as in Zaire (5,000,000 tons) and Cameroon. In North Africa manganese is found in Morocco (470,000 tons) and in Algeria.

Africa's contribution to world resources of other ferroalloys is, by comparison, insignificant. Nickel is of some importance, occurring in other metalliferous ores in southern Africa.

There are only two important reserves of tungsten on the continent, although wolframite ore (an important ore of tungsten) occurs in Zimbabwe, South Africa, and fairly extensively in East Africa. Economic reserves are concentrated at Mokama, Zaire, and at Gifurwe, Rwanda.

Deposits of vanadium (a rare element used to toughen steel and to increase its shock resistance) are widespread in southern Africa, but the concentrations are rarely sufficient to make them commercial, except in South Africa.

Africa is seriously deficient in reserves of molybdenum, a metal needed in the production of steel; some is found in Morocco and in South Africa.

Nonferrous base metals. Most of Africa's copper is contained in the Central African Copperbelt, stretching across Zambia and into the Shaba area of Zaire. In the late 1970s Zambia was estimated to have 36,000,000 tons and Zaire 26,000,000 tons of contained copper, out of a total for African reserves of almost 76,000,000 tons. Accompanying minerals vary with the geological layer, but cobalt dominates.

Outside the copper belt a number of countries have lesser but still significant reserves of copper. Elsewhere in southern Africa, Zimbabwe has 660,000 tons of copper, South Africa has known reserves of about 5,000,000 tons of copper, and in South West Africa/Namibia reserves of 2,200,000 tons of copper are associated with the lead-zinc ores of Tsumeb. Botswana also has 530,000 tons of copper metal reserves, while, to the north, Mauritania has the largest reserves of West Africa, 740,000 tons of copper metal. In East Africa Uganda has a reserve of more than 200,000 tons of metal. In North Africa the ore is found in Algeria, Morocco, and the Niger Sahara. Only Nigeria and Zaire contain tin reserves of any significance.

Lead and zinc

Although it is difficult to consider Africa's reserves of lead and zinc separately, of the two, lead ores are considerably more widespread. Total lead reserves are about 1,000,000,000 tons. North Africa is the largest traditional producing region. Most Moroccan ores are approaching exhaustion, but two additional ore bodies were discoverd during the 1970s in the Oued Moulouya River Basin that contains 630,000 tons of ore reserves. Algeria has more than 400,000 tons, but reserves in Tunisia appear to be largely exhausted. South of the Sahara, the largest reserve is in South West Africa/Namibia at Tsumeb.

African reserves of zinc metal are estimated at 16,500,000 tons; they are located along the Moroccan-Algerian frontier, in the copper belt of Zaire, in Nigeria, in Zambia, and in South West Africa/Namibia.

Africa has about one-third of the world's reserves of bauxite, the chief aluminum ore. Virtually all of this occurs in a major belt of tropical laterite stretching 1,200 miles from Guinea to Togo. The largest reserves are in Guinea (6,500,000,000 tons of bauxite); Cameroon, with about 1,000,000,000 tons, has the second largest reserve in Africa. The other major West African reserves, small by comparison, are those of Ghana (570,000,000 tons) and Sierra Leone (about 130,000,000 tons). There are also reserves in Mali and in Malaŵi.

One-half of the world reserves of cobalt can be found in Zaire, where an estimated 1,300,000 tons of cobalt metal are located. A continuation of the geological formation into Zambia gives the country a reserve estimated at 400,000 tons of cobalt content. The only other deposit of any importance is found in Morocco, with reserves of 50,000 tons.

The titanium ores, ilmenite and rutile, are widely distributed in Africa but are rarely considered as minable reserves. A major source is the Sherbro deposit in Sierra Leone, where 1,800,000 tons of demonstrated and 16,000,000 tons of probable rutile ore containing titanium are present. Elsewhere along the West African coast, ilmenite is found in the black sands at the mouth of the River Saloum, Senegal, and near Grand Lahou, Ivory Coast (400,000 tons). In South Africa demonstrated re-

serves of titanium are 36,200,000 tons and additional probable resources are about 117,000,000 tons. Other reserves include those of the Nile Delta and on the Somalia and Madagascar coasts.

Almost all of Africa's antimony resources lie in the Murchison Range, South Africa, where demonstrated reserves of 350,000 tons of metal are the second largest (after Bolivia) of any non-Communist country. The major concentrations of beryllium are in Madagascar, Mozambique, Zaire, Zimbabwe, Rwanda, Uganda, and South Africa. The principal sources of cadmium are in South West Africa/Namibia and Zaire. Deposits of mercury are restricted to North Africa, notably to Tunisia and, more particularly, Algeria.

Gold reserves

Precious metals. Gold and allied metals are widely disseminated, reaching their greatest concentrations in South Africa, where reserves of 530,000,000 troy ounces (16,500,000 kilograms) of gold probably constitute about one-half of the world total. Gold is also found in Zimbabwe, in the Zaire belt, and in Ghana. There are numerous alluvial sources of gold in Burundi, Ivory Coast, and Gabon.

South Africa has the most important deposit of platinum of the world's market economies, amounting to an estimated 450,000,000 troy ounces of metal. Silver reserves of the continent are not important, amounting to about 2 percent of the world's reserves, and are significant only through their association with other commercially valuable minerals. The major sources are in Zaire, South West Africa/Namibia, Morocco, and South Africa.

Africa contains a major share of world reserves of tantalum (70 percent), consisting of 50,000 tons of metal. Zaire has more than 80 percent of the African reserves, with further reserves located in Nigeria and Kenya. African reserves of columbium or niobium (a steel-gray metallic element resembling tantalum in its chemical properties and used in alloys) are relatively small. Nigeria, however, with almost 70 percent of the 100,000 tons of African reserves, is an important world producer.

One of Africa's many sources of zirconium (a metallic element resembling titanium chemically) is the Jos Complex, Nigeria. Greater reserves, however, are contained on the Senegal coast; on the east coast of South Africa; in Madagascar; at Sherbro, Sierra Leone; and in the Nile Delta.

Another rare metal of which Africa contains a majority of world reserves is germanium, concentrated in Zaire and South West Africa/Namibia. Africa has large deposits of lithium; the largest deposits are found in Zaire.

Nonmetallic deposits. *Clay minerals.* Clays are widespread and are found in North Africa, where brick and pottery clays occur in Algeria and in Morocco; in West and Central Africa, where clays are located in Togo (ceramic); in the Central African Republic; in Ivory Coast (ceramic); and in East and southern Africa.

Kaolin (china clay) occurs in Algeria. Outside North Africa it is widespread. In West Africa it occurs most notably in Nigeria's Jos Plateau, as well as in Mali, in Ghana, and in Guinea. Similar deposits occur in Central and East Africa, as well as in southern Africa.

Bentonite (a clay formed from decomposed volcanic ash, which is able to absorb large quantities of water and to expand to several times its usual size) is found in the Moroccan Atlas, in Tanzania, in Kenya, and in South Africa. The continent's principal reserve of fuller's earth (an absorbent clay) is in Morocco.

Economic mica deposits occur primarily in southern Africa (South Africa, Zimbabwe, and Tanzania) and in Madagascar.

Sulfur and salt. Africa has none of the world's major reserves of sulfur. It reaches economic concentrations only in South Africa's Witwatersrand, in Zambia's Copperbelt, and in Morocco. Large quantities of sodium deposits remain to be evaluated. Sodium chloride is the principal salt, the largest deposit being in the Danakil depression of Ethiopia. The principal sources of salt in Africa, however, are inland or coastal basins, from which it is extracted by evaporation. Major coastal reserves of this type lie along the North African Mediterranean coast and along Red Sea and Indian Ocean coasts of East Africa and Madagascar. Inland, the chief reserves are in the Oran *sebkha* ("salt pan"), in Algeria; in Botswana around Lake Makarikari; and in Uganda.

Natron deposits

The second sodium mineral is natron, or sodium carbonate. This is more limited in occurrence, but Africa contains several significant deposits. It is found in Lake Magadi, Kenya, and in Lake Natron, Tanzania, as well as in West Africa, where beds have been deposited from the waters of Lake Chad.

Phosphates and potash. North Africa has been a traditional exporter of phosphates, and West Africa has large reserves. Morocco and Western Sahara together have the vast reserves of 20,000,000,000 tons of phosphate.The Río de Oro region in Western Sahara contains huge deposits, and a major development at Bru-Craa has been established. Algeria and Tunisia together have a further 12,000,000,000 tons. To the east, phosphate-bearing sediments outcrop on the Red Sea coast. Egyptian reserves total about 660,000,000 tons. Togo has about 60,000,000 tons and Senegal 140,000,000 tons. The Thiès deposit in Senegal is of particular interest in constituting the world's only source of aluminum (as opposed to calcium) phosphate, of which it is estimated there are about 100,000,000 tons. Other phosphate deposits occur in Tanzania (10,000,000 tons), Uganda (180,000,000 tons), and Malaŵi (18,000,000 tons).

The potash deposits in the Congo are the largest in Africa. The other large reserve (150,000,000 tons of ore) is in Ethiopia.

Refractory substances. Madagascar has the world's largest known accumulation of flake graphite deposits. Continuations of these deposits in Mozambique and southeastern Kenya contain further reserves of graphite; 15,000 tons are also known to exist in Malaŵi.

While deposits of low-grade sand suitable for construction and engineering work are widely distributed, reserves of sands with a sufficiently high silica content for glass manufacture are more localized. There are deposits in West Africa (Ivory Coast, Liberia, Nigeria, and Ghana), East Africa (Uganda and Tanzania), and South Africa. Glass sands are also found in Egypt.

Kyanite (cyanite), a mineral aluminum silicate, used as a refractory, occurs most typically in southern Africa. Apart from South African reserves, there are deposits in Kenya, Malaŵi, Ghana, Cameroon, and Liberia.

Abrasive substances. Of the abrasive substances, industrial diamonds are most closely associated with Africa. The continent contains about 95 percent of the total Western-world reserves. The stones are found in a number of major belts south of the Sahara. The principal known reserves of diamonds in their primary form are in the South African Vaal belt. Elsewhere in Africa, primary deposits are found in Tanzania, Botswana, and Lesotho.

Industrial diamonds

Another major belt of diamondiferous rocks encircles the Congo Basin and includes the world's largest deposit, located in Zaire, which contains the majority of Western reserves of industrial diamonds. The same belt has secondary deposits that occur elsewhere in that country, as well as in the Central African Republic and Angola. In West Africa known reserves are located primarily in alluvial gravel fields. They are found in Sierra Leone, Guinea, Ivory Coast, Liberia, and Ghana.

A considerable proportion of the world reserves of corundum (a common mineral, aluminum oxide, notable for its hardness) is located in southern Africa. The principal deposits are in Zimbabwe, South Africa, Mozambique, Madagascar, and Malaŵi.

Pumice is found in areas of volcanic activity such as the Atlantic islands, the coastal Atlas of northeastern Morocco, and in the East African Rift System, notably in Kenya, Tanzania, and Malaŵi. Joint reserves constitute, however, only a small percentage of the world total.

Building materials. Reserves of building materials are characterized by their wide distribution to such an extent that the commercial status of such deposits depends more on their location relative to areas of development than on their extent and quality. While almost all African countries have reserves of building materials, knowledge of

such reserves is strictly related to the country's level of development, and no meaningful estimate of the size of reserves can be made.

Granite is located in Morocco and Nigeria, and there are vast reserves in Upper Volta. Quartzite (a granular rock, consisting essentially of quartz) is important as a building stone in Uganda and Zaire. Dolerite (a coarse-grained basalt) is produced in South Africa, and basalt, which is crushed for use in road construction, in Senegal. Marble is found in Mali, Togo, Nigeria, and South Africa.

Limestone is important because of its use in the cement industry, and deposits are fairly widespread. North Africa is a particularly important source. In West Africa a belt of limestone runs from the Central African Republic to the Atlantic coasts, with major outcrops in northern Nigeria, Niger, Upper Volta, and Mali. Elsewhere there are deposits in Togo and Ghana. East African deposits include those in Kenya, Tanzania, Uganda, and Zambia; there are also deposits in South Africa.

Gypsum deposits

North Africa has major reserves of gypsum on the Mediterranean coast, as well as in outcrops along the Gulf of Suez and the Red Sea. Somalia has a reserve of 30,000,000 tons—one of the largest known deposits. East Africa and Madagascar have further reserves, and in southern and West Africa superficial deposits are particularly important—for instance, north of Nouakchott, Mauritania.

Gem minerals. Many of the major deposits of the most important commercial gem mineral, the diamond, have already been described in the discussion of industrial diamonds (see above *Abrasive substances*). One major deposit, that of South West Africa/Namibia, however, consists almost entirely of gem diamonds.

There is no other gem mineral in Africa of comparable importance to these diamond reserves. Deposits of a number of such stones are found, however, especially in southern and East Africa, where diamond fields contain beryl, garnets, amethyst, rose quartz, topaz, opal, jasper, emeralds, and other stones. Madagascar contains a large deposit of garnet. Tourmaline is found in Madagascar and South West Africa/Namibia. Agate is particularly associated with the volcanic areas of East and southern Africa, and malachites with the Shaba Copperbelt, while sapphires are found with diamonds in Ghana.

Miscellaneous deposits. Africa contains no major world deposits of talc, but the mineral is found in Morocco, The Sudan, Zimbabwe, and South Africa. Reserves of asbestos are much more important, and southern Africa has a number of deposits of world significance.

Major deposits of fluorite or fluorspar (a common mineral, calcium fluoride, used as a flux in metallurgy), constituting about 40 percent of world reserves, are particularly associated with deposits of lead and zinc. In South Africa the chief deposit is in the Transvaal. North African reserves lie primarily in Tunisia and Morocco.

Africa produces a very small share of the world supply of diatomite (a fine siliceous earth, used as an abrasive). The most important deposit is in Kenya.

WATER RESOURCES

Freshwater derives firstly from rainfall that has run off the land to collect on the surface in rivers and lakes, and secondly from groundwater that results from rainfall infiltrating through and then collecting in the soil. In general, the seasonal distribution of river flow reflects the seasonal rainfall pattern; the amount of groundwater entering the river channels during the dry season is comparatively small. Important modifications in the flow of some rivers are caused by the presence of large lakes and swamps, which act as natural storage reservoirs.

Natural storage reservoirs

Surface water. Although the surface area of Africa is about 21 percent of the Earth's land surface, the combined annual flow of African rivers is only about 7 percent of the world's river flow reaching the oceans.

North Africa's few perennial rivers originate in the mountains of the Maghrib; their water is used extensively for irrigation. The large number of wadis, or watercourses, to be found throughout the Sahara and the eastern Mediterranean coastal lands become filled with water as a result of the rare and erratic storms that occur over mountainous areas; otherwise they remain dry.

From the relatively well-watered areas of western and equatorial Africa, the Sénégal, the Niger, the Logone–Chari, and the Nile rivers flow through the drier inland zones. Of these, the Niger River, originating in the Fouta Djallon, in Guinea, is retarded in the lake and swamp area south of Timbuktu in Mali, and the Logone–Chari feeds Lake Chad.

The Nile, the world's longest river, receives more than 60 percent of its water from the highlands of Ethiopia, although its source is much farther south in the mountains of Burundi. Since the completion of the Aswān High Dam (opened 1970), only a small proportion of the total river flow reaching Egypt enters the Mediterranean Sea.

A number of rivers flowing in a more or less southerly direction into the Atlantic Ocean drain the southern part of West Africa. Many flow rapidly over bedrock before entering the coastal plains, draining into the system of lagoons and creeks along the coast. During the dry season the upper reaches of these rivers are without water; but in Guinea, Sierra Leone, and Liberia, where the dry season is fairly short, the rivers flow throughout the year.

In the well-watered western part of equatorial Africa the total average annual flow of the Congo River is 42,300,000,000,000 cubic feet. River flow at the lower end of the basin has two maxima: one that corresponds with the rainy season north of the Equator, the other with the rainy season that occurs when it is summer in the Southern Hemisphere. The waters in the lower reaches of the river are slightly acid after traversing the large swamps situated in the centre of the basin.

Great Rift Valley lakes

East Africa's many lakes stretch along the Great Rift Valley from the Red Sea to the mouth of the Zambezi. Evaporation from most of them exceeds their surface rainfall, and in consequence their outflow is less than the quantities brought in annually by their tributaries. They often govern river flow by acting as natural storage reservoirs—decreasing the flood flow and increasing the dry-season flow. A number of the rift valley lakes are situated in closed basins and contain high percentages of dissolved salts. The largest of these are Lakes Rudolf, Natron, and Eyasi.

Rainfall over much of southern Africa is small, and the majority of the rivers originating there have an intermittent flow. Some large perennial rivers (*e.g.*, the Okavango, the Zambezi, and the Orange) flow from areas of abundant rainfall into the drier zones.

Groundwater. The conditions under which groundwater is found and the quantity and quality of groundwater reserves are closely related to geological structure. Large inland depressions in Africa's basement rock, having been filled with sedimentary layers of continental origin, sometimes form important groundwater reservoirs, notably those in the Taoudeni–Niger region, in the central Sahara between the Atlas and Ahaggar mountains, in the Libyan Desert, and in Chad, the Congo Basin, the Karroo area of South Africa, and the Kalahari.

The East African plateaus usually contain little or no quantities of groundwater, and aquifers (geological formations containing water)—generally of local importance—are found only in humid areas where the crystalline rock is weathered or fractured.

The chalky shales (rocks of laminated structure formed by the consolidation of clays) and dolomitic limestones (those containing calcium magnesium carbonate), which sporadically cover the basement rock, may contain important aquifers; those in Zambia and South Africa are major sources of water.

In the Sahara a rock stratum called the Continental Intercalary, which dates to the Cretaceous Period and which includes Nubian Sandstones, is the most important water-bearing layer. It extends over very large areas and reaches a thickness of more than 3,000 feet; in Egypt and Algeria it provides artesian water. In The Sudan it sometimes lies directly on the Precambrian rock and contains underground water layers of local importance. Overlaying the Continental Intercalary, but generally separated from it by a thick marine deposit, is a layer called the Continen-

Great Fish River Canyon in the Namaqualand region of South West Africa/Namibia.
John Rushmer—Ostman Agency

"Fossil" water layers

tal Terminal, which is the second largest aquifer in this area. Both these layers contain "fossil" water or, water that entered the layers when rainfall in and around the Sahara was much more abundant than today. Near the surface, aquifers are found in such recent deposits as alluvial deposits and sand dunes.

In the coastal areas of Senegal, Ivory Coast, Ghana, Togo, Benin, Nigeria, Cameroon, Gabon, the Congo, Angola, Mozambique, East Africa, and Madagascar, aquifers are found in sandstone, limestone, and sand and gravel sediments. Intensive exploitation, however, may result in saltwater intrusions.

The Jurassic limestones of the mountainous area of the Maghrib are much more abundant in water sources than are dolomitic limestones. Around the cape in South Africa, sandstones and limestones contain very little water.

Yields from aquifers with good porosity, such as coastal sedimentary rocks or alluvial deposits, vary from a few cubic feet per hour in the fine-grained sands found in many parts of the continent to 35,000 cubic feet per hour in the coarse gravels of the Nile Delta. The capacity of wells in the Continental Terminal is generally somewhat lower, although 280 cubic feet per hour have been reported. The Continental Intercalary and the Karroo formations can also deliver moderate to high yields.

In North Africa limestones containing many cracks and fissures may yield hundreds of cubic metres of water per hour, while, in Zaire, Zambia, and South Africa, large yields are drawn from dolomitic limestones.

The harder sandstones, sandy shale, and quartzites of Precambrian and Paleozoic age are not generally very porous, and water is obtained only from fractured or weathered deposits. West African, Angolan, and Tanzanian wells in these formations produce only a few cubic feet per hour. Crystalline and metamorphic rocks are almost impermeable except where fractured or weathered. Volcanic rock, especially the basalts, may yield up to 1,060 cubic feet per hour.

Densities of mineral solutions

Most of the exploited groundwater is generally fit for consumption because the dissolved minerals in water from shallow wells, particularly in the sandy aquifers of West Africa, are quite low. Groundwater from deeper marine layers, however, such as occurs in parts of North Africa, Mozambique, Ethiopia, and South Africa, may have a high content of dissolved salts. In moist tropical countries, water from Precambrian rocks generally contains only small amounts of dissolved solids. In the volcanic areas of East Africa, groundwater may have so high a content of fluorine as to make it unfit for human consumption. There and elsewhere in Africa, hot (possibly medicinal) springs with high mineral contents occur.

Availability for human use. The pronounced seasonal character of rainfall and the fact that many rivers stop flowing during the dry season necessitate the development of groundwater for human use, whether for husbandry or industrial development.

Large-scale irrigation prior to the early 1970s was practiced mainly in North Africa, Egypt, The Sudan, South Africa, Mali, Zimbabwe, and Mozambique. Medium-scale irrigation projects are operated in Madagascar, Senegal, Somalia, and Ethiopia. In Ivory Coast, Upper Volta, Kenya, Nigeria, Ghana, and Zambia, medium- to small-scale projects have been constructed.

More than 50 river basins are shared by two or more countries, and the development of their resources requires the cooperation of the basin states and several intergovernmental agencies—such as the Organization for the Development of the Sénégal River, the Niger River Commission, and the Chad Basin Commission.

Several large reservoirs were built in the 1960s and 1970s, such as the Aswān High Dam, Roseires, and Khashm al-Qirbah reservoirs in the Nile Basin, Kainji on the Niger, Akosombo on the Volta, Kariba on the Zambezi, Cabora Bassa on the Zambezi in Mozambique, Kossou on the Bandama in Ivory Coast, and Kafue on the Kafue in Zambia. The Inga on the Congo River is under construction. At a number of man-made lakes, research centres have been set up to study resettlement problems, the full use of ecological conditions, and the control of health hazards that sometimes occur.

BIOLOGICAL RESOURCES

The biological resources of Africa consist of an immensely varied vegetational cover, a vast insect life, and a diverse

animal life that populates a wide variety of ecological environments, including the biological resources like bacteria, earthworms, and termites that influence soil and soil fertility. Hydrobiological resources include the fisheries of lakes and rivers, as well as the oceans surrounding the continents.

Botanical resources. Out of the total land area of the continent, forests cover about 20 percent, savannas about 40 percent, and deserts about 40 percent.

The forested area cannot be ascertained exactly, as original forests are progressively being converted to farming areas, and few governments have undertaken comprehensive land-use surveys. The tropical forests consist of both rain forests of virtual evergreen trees (found in the equatorial belt in areas with an annual rainfall of more than 100 inches, as well as at high altitudes) and tropical moist semideciduous forests (in which many species of trees shed their leaves at some time of the year) in areas with less than 70–100 inches of annual rainfall. Forests of this description, in the rainfall range between 50 and 150 inches, are mainly found in the equatorial belt. The tropical high forests contain most tree species commercially in demand.

A large proportion of the land surface of Africa bears vegetation in which grass is an essential feature. Grasses occur only rarely in forest environments, where they are usually tall and fibrous and seldom very palatable to livestock. In certain savanna areas, however, fire, flooding, or soil conditions may produce open grasslands free from woody vegetation. The broad physiognomic vegetation types and their grass cover may be divided into six groups: (1) forest, dense, woody growth with virtually no grass cover; (2) woodland, woody growth of varying density with some grass cover; (3) savanna, woody growth of varying density and conspicuous grass cover; (4) grassland, good, dense grass cover, the absence of woody growth or its confinement to watercourses; (5) steppe, very open, scattered woody growth with sparse grass cover and including desert conditions; and (6) undifferentiated types, variable grass cover, much of it ungrazeable for climatic or topographical reasons.

Vegetation types

Natural vegetation, especially grasses—which are basic to the well-being of domesticated livestock as well as to ruminant game species—are of particular importance in those parts of the continent where livestock is economically important. Better management of pastures is required in much of Africa where indiscriminate burning and widespread overgrazing and undergrazing are rife.

The savannas, of which there are some 30 types in Africa, cover more than 5,000,000 square miles and stretch latitudinally across the continent in two broad zones north and south of the Equator, where they are divided by the tropical forests of West Africa and the Congo but join each other in the east. Savanna in North Africa is represented in the Atlas Mountains and foothills.

Arable land and land under permanent crops occupies about 6 percent of Africa's total land area. Agriculture is largely confined to subsistence farming and is considerably dependent on the inefficient system of shifting cultivation, in which land is temporarily cultivated and then abandoned for a time. Over most of Africa, where arable land is generally allocated through tribal affiliation and not through individually acquired title, the intensity of arable production tends to be low. A number of countries have made efforts to raise productive levels by selecting better varieties of seeds and planting materials or by increasing the use of mineral fertilizers and insecticides. Such measures, however, are still relatively limited. In areas of cash crop production, land has become private rather than community property, and cultivation is intensive.

Individual sites for arable cultivation are usually chosen because they have well-drained soils, because their soils are easy to work with hand tools and are free from large stones, and because they are reasonably near to the homestead.

The importance of the Albida acacia tree

The Albida acacia tree of the orchard savannas of West Africa is of economic importance. Unlike almost all other dry savanna woodland trees, whose leaf shedding normally occurs at the onset of the dry season, it appears to have a period of partial dormancy during the rainy season and springs to life only at the beginning of the dry season. At such periods its foliage is abundant and—being a palatable leguminous species—is much prized as browse for sheep, goats, and cattle. The smaller leafy branches are frequently fed to stock. The tree flowers and produces fruits, which are harvested, dried, and fed as a protein concentrate to stock at the height of the dry season.

Another plant of particular interest is genetically improved corn (maize). Corn is not in itself a balanced food, being deficient in some amino acids. A scientific breakthrough, resulting in an increase of the amino acid called lysine in certain new varieties of corn, has the potential to improve the value of diets in Africa, which consist mainly of corn preparations.

Animal resources. *Draft animals.* Although water buffalo, oxen, horses, mules, donkeys, and camels are used primarily as draft, pack, or riding animals in Africa, they also provide milk, meat, hides, or skins.

The water buffalo is an offshoot of the Asiatic buffalo (*Bubalus bubalis*); it arrived in Africa in relatively recent times and is now found almost exclusively in Egypt, where it numbers about 2,400,000. The domesticated African water buffalo is used to cultivate irrigated land (mainly in the Nile Delta) and to provide milk and meat.

Because of its intractability and wild nature, the African elephant, unlike the Asian elephant, is not used for draft or haulage purposes.

Horses and ponies are principally found in Morocco, Algeria, Tunisia, Chad, Ethiopia, Mali, Niger, Nigeria, Senegal, Upper Volta, Egypt, South Africa, and Lesotho; in the early 1980s they were estimated to number approximately 3,800,000 head. Horses are largely used as riding or pack animals and in a number of areas are bred to produce mules. Few are kept in areas where the tsetse fly, deadly to livestock, is present.

In Africa five main types of horses have been defined: the Darfur pony, the Dongola horse, the Ethiopian-Galla horse, the Somalia pony, and the South African horse (a type that includes the Basuto pony). In North Africa types also have evolved as a result of selection and crossing with exotic Arab, Barb (Barbary), and Thoroughbred horses. Arab and Thoroughbred influence may also be noted in southern Africa.

The distribution of the ass roughly corresponds to that of the horse, except that it also extends into the livestock areas of East and Central Africa.

Mules may be observed in Algeria, Ethiopia, Morocco, Somalia, South Africa, and Tunisia. In Africa as a whole, mules numbered about 2,100,000 by the early 1980s. They provide farm draft power and are used as pack animals and for riding. The ability of mules to perform work in hot, dry climates is superior to that of most other farm animals.

Camels

The camel, or one-humped dromedary, is widely dispersed in the drier regions of North and northeastern Africa. The camel is also found frequently in Ethiopia, Egypt, Algeria, Libya, Mauritania, Mali, Niger, northern Kenya, Morocco, Chad, The Sudan, Somalia, Tunisia, and Western Sahara. In the early 1980s the total camel population of Africa was estimated to be about 12,000,000. Although used principally as a pack animal, it also is used for land cultivation, water pumping, and riding. The dromedary is essentially a bush browser and, if reasonably well fed and watered, may produce about 11 to 13 pounds (five to six kilograms) of milk daily, in addition to that fed to the calf. The milk is prized by the camel herders and their families. Camel meat and camel hides find a ready market among Muslim communities.

Oxen are widely used in Africa for agricultural purposes, especially for plowing and cultivation; they are also trained to thresh grain, pump water, and act as pack animals. Bullock (male, castrated oxen) plowing is well developed in the countries of North Africa, in Ethiopia and The Sudan, and further west in Chad, in northern Nigeria, and in the savanna climatic zone of West Africa. Plowing and cultivation by oxen is also well developed in tsetse-free areas of East and southern Africa. Females used for work may also be milked. Work oxen are often used for meat and to provide hides.

Game animals and wildfowl. The main group of herbivores—which includes the principal game animals—are the African antelopes, which belong to four subfamilies of the ox family (Bovidae). The first subfamily is the ox-like Bovinae, which are further subdivided into the African buffalo and the twisthorned antelope, including the eland (the largest of all antelopes), kudu, nyala, and bushbuck. The second subfamily is the duiker, a small, primitive bovid that lives in thickets, bush, and forest. Thirdly, there is the "horse antelope," further divided into sabre-horned sable, roan, and oryx antelope; the "deer antelope," kongonis, hartebeest, topi, gnu, and blesbok, all mostly inhabitants of the open plains; and the "marsh antelope," waterbuck, lechwe, kob, puku, and reedbuck. The fourth subfamily is the antelope proper, divided into two distinct tribes, the first of which includes royal, dik-dik, klipspringer, oribi, steenbok, and grysbok and the second, gazelle, impala, springbok, and gerenuk.

Predators and scavengers that are important in maintaining the ecological equilibrium are the lion, leopard, cheetah, wild dog, hyena, serval (a long-limbed African cat), wildcat, jackal, fox, civet, mongoose, eagle, vulture, and marabou (a large stork).

Other vertebrates include birds, reptiles, amphibia, and small mammals. There are also many invertebrates.

African wildfowl are too numerous to list in detail, but they include pheasants, of which there are two subfamilies in Africa, and various genera that include peafowl, quail, francolin, partridge, guinea fowl, sandgrouse, duck, goose, snipe, and many others.

Sources of animal products. Cattle provide hides, and sheep, goats, and pigs provide skins. Skins of the Maradi, Sokoto, and Kano red goats from Niger and Nigeria are greatly prized by the Morocco leather trade.

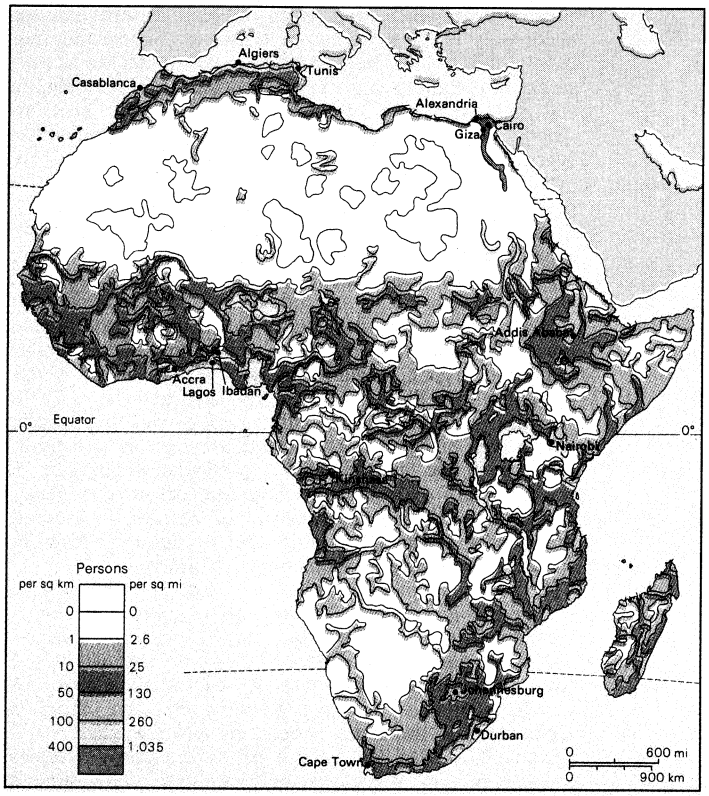
North and south of the tropics, African sheep are covered with wool, but in the tropics they are hairy. In elevated areas, such as Ethiopia, where temperatures are modified by altitude, some sheep may be partially woolled, at least on the back and buttocks. The woolled sheep of North Africa are largely of the woolly Barbary type, which was originally introduced to Africa from the Middle East.

Many countries are attempting to conserve wildlife by refusing export licenses for certain kinds of skins, especially those of the leopard, cheetah, and zebra.

Fish and other aquatic animals. The most useful fish found in the African waters include many species of freshwater fish. Important among the marine fish are flounder, halibut, sole, redfish, bass, conger, jack, mullet, herring, sardine, and anchovy. Crustaceans are important for local consumption and for export.

Other economically important aquatic animals and plants include the Cape fur seal, turtles, porpoises, and dolphins, as well as various whales, oysters (for pearls), trochus shells, corals, and sponges.

(R.K.A.G.)



V. Human resources

THE HUMAN ECOLOGY

The pattern of settlement. The basic pattern of settlement in Africa may be described as follows. Africa north of the Sahara is inhabited primarily by peoples who speak languages that belong to the Afro-Asian group. These peoples include, for example, the Berber of Morocco, Algeria, and Tunisia; many are light-skinned people with dark hair, thin noses, and non-everted lips. In several regions, as a result of culture contact and of intermarriage, the Berber have become largely assimilated into the Semitic-speaking Arabs who migrated into North Africa from Arabia in a number of waves, the first of which occurred in the 7th century AD. The distinctive nature of Maghribian, or western, Arab culture resulted from this admixture. In the Sahara, such Arab peoples as the Shuwa live side by side with such Berber peoples as the Tuareg. In the region of West Africa that lies south of the desert, known as the Western and Central Sudan, the pastoral Fulani show in their physical characteristics clear evidence of the infusion of lighter-skinned elements into a basic black stock.

On the East African coast, contact and intermarriage between Arab settlers and local Bantu gave rise to the distinctive Swahili culture. Ethiopia and Somaliland are populated by members of the Cushitic branch of the Hamitic-speaking peoples. The movement of Semitic-speaking peoples into the region has occurred, however, in many waves, one of the earliest of which was that of the Sabaeans from Arabia as early as the 7th or 8th century BC. Their intrusion created the conditions for the emergence of the early Axumite (Aksumite) civilization.

The remainder of the continent is dominated by peoples of black stock: brown to dark brown in colour, with characteristically woolly hair, broad noses, and everted lips. Four principal, though not clearly distinguished, subgroups may be identified: the Sudanic peoples of the region extending across the continent south of the Sahara desert, the Guinea Coast people of the forests of West Africa, the Nilotic of East Africa, and the Bantu of Central and southern Africa. Many of the Sudanic peoples, such as the Malinke, Hausa, Songhai, and Bornu, are Islāmized, and that religion has also achieved substantial gains among such Guinea coast people as the Yoruba

Population density of Africa.

of Nigeria and the Temne of Sierra Leone. Much conversion to Christianity also has occurred, most notably in the coastal regions of sub-Saharan Africa.

The Bantu-speaking peoples

The Bantu-speaking peoples extend over most of the continent south of the Equator. They include such well-known societies as the Lozi in the middle of the Zambezi River region, the Herero of South West Africa/Namibia, and the Zulu of South Africa. Although originally probably stemming from the same stock as the Guinea coast peoples of the Cameroon and east central Nigeria region, the early Bantu homeland was in the woodland region to the south of the Congo rain forests. From there, over the course of several millennia, Bantu speakers spread in all directions, possibly being the first carriers of an Iron Age culture into many areas. Throughout the vast region occupied by Bantu-speaking peoples, remnants of earlier pre-Bantu populations survive. The best known of these are the Pygmies of the rain forests and the San (Bushmen) of the Kalahari—both hunter-gatherers—and the pastoral Khoikhoi (Hottentots) of South West Africa/Namibia and South Africa. Everywhere the Bantu cultivators ex-

panded at the expense of these earlier societies, either absorbing and assimilating them into Bantu culture or else relegating them to the driest or most humid areas.

Finally, in the southernmost parts of the continent, are found white settler populations, largely of Dutch and English origin; smaller communities originating from the Indian subcontinent; and mixed communities of Khoikhoi, European, and Asian extraction known as the Cape Coloured.

The Dutch migrations into South Africa began in the mid-17th century. Originally settling on the coast, the Dutch—or Boers—later moved inland to the Highveld region, where a series of military conflicts occurred between them and the Bantu speakers in the 19th century. Other European settlement took place mainly in the 19th century: the British particularly in Natal, but also inland in what are now Zambia and Zimbabwe and in the East African highlands; the Portuguese in Angola and Mozambique; and the Germans in South West Africa/Namibia.

The presence of large settler populations delayed the achievement of self-government by the African people of South Africa, South West Africa/Namibia, Zimbabwe, Angola, and Mozambique, and has resulted in much bitterness between the races. In North Africa, by contrast, where the extensive settlement of Europeans from France, Italy, and Spain occurred, the growth of Arab nationalism and the emergence of independent states such as Morocco, Algeria, and Tunisia led to the return of many of the colonists to their homelands and political dominance of the indigenous peoples.

Migrations. There have been many movements of population within the African continent, from outside into the continent and from the continent outward. The major movement within the continent in historic times has been that of the Bantu-speaking peoples, who, as a result of a population explosion that is not fully understood, expanded over most of the continent south of the Equator.

The major movements into the continent—of the European settlers in North Africa and of European and Asian settlers in southern Africa—have been described. The great outward movement of people was that of Africans, particularly from West Africa, to the Americas and the Caribbean, which took place during the period of the slave trade from the 16th to the 19th century. Earlier estimates that between 15,000,000 and 20,000,000 Africans were transported across the Atlantic have now been revised to a figure of 10,000,000, which appears more realistic. While their contribution to the development of the New World was of crucial importance, the effect of the loss of manpower to the African continent was considerable and has yet to be satisfactorily analyzed. The slave trade was also active on the east coast of Africa.

Few major movements of population have occurred in the 20th century, although an extensive settlement of Hausa from northern Nigeria took place in what is now The Sudan. Some significant displacements of population also have resulted from situations of conflict, usually involving minority groups different in religion, ethnicity, or culture from the dominant majority. In 1966 the Ibo people of northern Nigeria, for example, returned en masse to their homeland in the Eastern Region, the number of refugees being estimated at more than 500,000.

Another displacement of people occurred when the government of Ghana expelled perhaps 500,000 aliens from the country in 1969. The 17-year civil war in the southern Sudan created an estimated 800,000 refugees, of whom about 300,000 had fled to surrounding countries. Most of the refugees returned to their homes after the settlement of March 1972. Other population movements have been those associated with such phenomena as pastoralism and urbanization.

Population distribution. Africa has about 10 percent of the total population of the world, distributed over a land area representing about one-fifth of the world's total land surface. Such desert areas as the Sahara and Kalahari, however, reduce the amount of habitable land.

The main regions of high population density are along the West African coast around the lower reaches of the Niger River and the coast between the Gambia and Congo rivers; along the east coast from Kenya to South Africa; on the north coast along the shores of Tunisia, parts of western Morocco, and the Lower Nile area; and in the regions of the East African Plateau around the great lakes and the Ethiopian Plateau.

The largest cities

The largest cities (*i.e.*, those with more than 1,000,000 population) include Cairo, Alexandria, and al-Jīzah, Egypt; Kinshasa, Zaire; Lagos, Nigeria; Casablanca; Johannesburg; Addis Ababa, Ethiopia; and Algiers. Many other larger cities are seaports along the coasts or central marketing towns, linked by rail or river with a coast. Examples of seaports are Accra, Ghana; Lagos, Nigeria; and Cape Town. Ibadan and Onitsha, Nigeria; Nairobi, Kenya; and Addis Ababa, Ethiopia are examples of great inland cities.

FORMS OF GOVERNMENT

The main task for many African countries has been to devise forms of government that promote internal unity, as almost every African country is composed of different communities and ethnic groups that are sometimes hostile to one another. Because many of these countries still have a high degree of illiteracy, it is difficult for residents of rural areas and sometimes of towns to give loyalty and allegiance to the central government instead of to the village or tribe, as has been the custom for centuries. Nevertheless, in some areas a sense of supratribal identity was already growing in precolonial times, and kingdoms such as Ashanti and Dahomey (now southern Benin) were developing centuries ago as multinational states.

Morocco has a hereditary head of state with an elected house of representatives (it was suspended from 1972 until the national elections of 1977), but most of the power is vested in the ruler. In most of Africa, however, hereditary rulers have been deposed and their power seized by either military or civilian governments. Examples are Egypt, Libya, Burundi, Rwanda, and Ethiopia.

When independence was granted to the former colonial territories, the constitutions adopted usually provided for democratic elections and a multiparty system of government of western European types. The democratic, multiparty system, however, did not survive long in most countries.

The prevalence of the one-party state

In the majority of African countries the form of government is that of the one-party state, in which the ruling party is absolute and power is concentrated in the hands of the party and especially of its leader, who is usually president and head of government. The justification for the one-party system, it is argued, is that for the economic development of the country only one party is necessary and that an opposition party works against the interests of the people. An opposition party is also said to encourage tribalism and secessionist tendencies, because sooner or later political parties tend to become identified with certain regional interests. Disagreements or differences of opinion, it is believed, should be within the party itself; in effect, in some countries elections are held in which rival candidates both represent the single ruling party.

The danger inherent in a one-party system is that, when there is unemployment or dissatisfaction, the citizens of the country see no way of changing their government except by revolution or coup d'etat. This is one of the most important reasons for the numerous military coups d'etat that have taken place in Africa and that have left the world with an impression that political instability continues to prevail in the continent. During the 1960s, for example, there were military interventions in no fewer than 15 African countries. The existence of a one-party system is not the only reason that coups d'etat take place, but in many instances it provides fertile ground for military intervention. Military governments frequently rule with the aid of civil servants. The civil service thus constitutes a stabilizing force in African countries that are subjected to frequent changes in their forms of government.

In some countries, traditional rulers, especially when they are cooperative with the central government, are the mainstay of local government, continuing the role given them during colonial government as native administration authorities.

In southern Africa, by 1980 only two countries were still ruled by white minorities that have refused to give way to majority rule: South Africa and South West Africa/Namibia, where conflict continues over poltical control of the country. Angola and Mozambique were governed by the Portuguese as states of metropolitan Portugal until 1975.

(D.S.H.W.N.)

VI. Political geography

EXPLORATION AND SETTLEMENT

Although Africa was the first continent whose entire coastline was known, much of its interior remained unknown to the rest of the world until the 19th century. In 1497–98 Vasco da Gama sailed round the Cape of Good Hope to India, but a century later the extreme northeast coast of Europe was not known to western Europeans, and the coasts of Asia, North America, and Australia were not fully known until the 19th century. It is also noteworthy that Africa is the only continent shown in full on the reconstruction of Herodotus' world map, drawn in about 450 BC.

The explorers of antiquity

Phoenicia and Carthage. The Phoenicians were probably the first maritime explorers of Africa. From their coastal citadels of Tyre and Sidon they sailed to many parts of the Mediterranean and founded colonies—the most famous of which was Carthage, which was established on the North African coast, traditionally in 814 BC, and which later surpassed its mother cities in size, power, and influence. The Phoenicians (Carthaginians) did more than any other people of the ancient world to make known the shape and size of the continent of Africa.

About 480 BC a Carthaginian naval expedition set out under the command of Hanno to explore the Atlantic coast of Africa as far as Río de Oro, where a trading post was established at a place named Cerne. From Cerne they sailed on perhaps as far as the Sénégal and Gambia river basins and beyond to what is now Sierra Leone.

Greeks and Romans. The Greeks had founded Cyrene on the North African coast in about 631 BC. Diogenes, a Greek sailor who had been blown onto the East African coast, wrote an account of a journey inland to two great mountains where, he thought, the Nile had its source. In the 2nd century AD Ptolemy, the Greek geographer and mathematician, showed the "Mountains of the Moon" on his maps. Greek and Roman knowledge of Africa, however, was essentially confined to the Mediterranean coastal strip.

The Greeks, mainly seafarers, were not very interested in terrestrial exploration; the Romans rarely ventured farther than was required by the exigencies of military conquest, though at least two minor expeditions across the Sahara took place—those of Septimius Flaccus and of Julius Maternus in the 1st century AD.

The Arabs. The invasions of North Africa from Arabia, which began in AD 640, extirpated almost all vestiges of Greek and Roman influence and eventually unified the diverse peoples of the region. These invasions also carried the Arabs across the Sahara to the south, and close links were developed between North Africa and Africa south of the Sahara. These links, however, did not go beyond the northern fringes of the tropical rain forests, where impenetrable jungle and unknown dangers halted the advance of the Arabs. From the 10th century on, Arab travellers took to Europe the first definite knowledge of trans-Saharan Africa and also of the east coast, where the Arabs established themselves from Zanzibar to Sofala (now Nova Sofala, Mozambique).

The Portuguese. The Portuguese sent out by Prince Henry the Navigator in the 15th century were the first to undertake systematic voyages of discovery southward along the African coast. These and later Portuguese voyages were made in the hope of establishing contact with the rich gold-producing centres that were known to exist in West Africa and also of discovering a sea route to India around the tip of Africa, which would enable the Portuguese to participate in the rich trade of the Indies.

By 1434 Cape Bojador had been rounded, and Senegal and Cape Verde were reached in 1446. In 1482 the Portuguese built the fort São Jorge da Mina (Elmina) on the Gold Coast (now Ghana). The exploration of the African coast was carried past the mouth of the Ogooué River by Diogo Cão, who, in 1482, discovered the mouth of the Congo. In the final years of the 15th century another Portuguese, Pêro da Covilhã, visited most of the Arab settlements on the East African coast as far south as Sofala and travelled to Ethiopia.

By the 16th century, however, the Portuguese were losing ground to the English; by about 1553 English ships were venturing into the Gambia region and had sailed as far as the Gold Coast. By 1595 the Dutch had also appeared on the West African coast and were establishing themselves there.

The exploration of the Niger

Ventures into the interior. The exploration of the interior of Africa is largely the story of the search for the sources of some of the world's greatest rivers. Systematic exploration may be said to have begun with the establishment of the African Association, a group of English scientists and scholars who resolved in 1788 to explore the course of the Niger River to the sea. Under the association's auspices and later under commission by the Colonial Office, Mungo Park, a young Scottish ship's doctor, made two attempts, in 1795 and 1805, to sail down the Niger to the sea. Although he was unsuccessful in reaching the coast to the southeast of his starting point near Timbuktu, he managed on the second attempt to sail as far as Bussa, 1,200 miles downstream, where he lost his life. Several more expeditions finally culminated in the successful attempt by two Englishmen, Richard Lander and his brother, John, who in 1830 paddled down the river from Bussa to the sea.

The source of the Nile. For more than 20 centuries the source of the Nile had excited the imagination of man, yet its discovery proved extremely baffling. In 1856 the Royal Geographical Society sent two explorers, Sir Richard Burton and John Hanning Speke, to find the great lakes that were rumoured to exist in the African hinterland.

They found Lake Tanganyika, and in 1858 Speke discovered Lake Ukerewe, which he named Victoria Nyanza. He also heard of a great river that flowed from the lake at Jinja and assumed that this could only be the Nile. In 1860 he returned to Africa with another English explorer, J.A. Grant, and confirmed that Lake Victoria was indeed the principal source of the Nile.

The Zambezi and the Congo. Another 19th-century explorer, David Livingstone, went to South Africa as a medical missionary; his contact with the slave trade, however, changed his interest from missionary work to exploration. He was convinced that the only way to destroy the slave trade was to open up the interior of Africa to normal trade, and he vowed to break Africa's isolation from the rest of the world or perish in the attempt. In 1853 he set out to trace the course of the Zambezi to its source; after great hardship he succeeded in reaching the Portuguese territory of Angola on the Atlantic coast in 1854. On his return downstream to the east coast, he discovered Victoria Falls. He returned to England after 16 years in Africa, having established that much of the interior of the continent was not a sandy desert but a well-watered country, with large tracts of fertile soil covered with forests and valleys. In 1858 Livingstone returned to Africa and discovered Lake Shirwa, the southern end of Lake Tanganyika and Lake Mweru.

Subsequently, Henry Morton Stanley, a Welsh explorer, continued the explorations that Livingstone had begun. On a major expedition into the interior, which lasted from 1874 to 1877, he sailed around Lake Victoria and Lake Tanganyika and then moved on to the Lualaba River, following it downstream until he had traced the course of the Congo River to its mouth at Boma, on the west coast of Africa.

Colonization and settlement. Although European countries had established trading stations at many points on the African coast, there had been no thought initially of settlement or colonization. But when the industrial revolution, with its demand for raw materials and markets, gained momentum in western Europe, interest began to develop in African colonization and settlement.

By 1884 there had begun a veritable scramble for African territory, which ended in the parcelling up of the continent into a bewildering mosaic of European colonial possessions. The scramble resulted in frequent disputes between the European powers, as their governments manoeuvred to obtain special rights and territories in various parts of Africa. This situation led to the Berlin West Africa Conference (1884–85) to agree upon the orderly partitioning of Africa in general and to decide the future of the territory of the Congo in particular. The "balkanization" of Africa that resulted had long-lasting effects harmful to its unity and an even more inhibiting effect on African economic development. The Berlin West Africa Conference, however, and subsequent colonial conferences, confirmed the claims of the various powers to their respective spheres of influence.

The Berlin West Africa Conference

In the 17th century the Dutch had begun to challenge Portuguese supremacy in the East Indies trade and in 1652 sent Jan van Riebeeck to establish a base at the Cape of Good Hope as a supply depot for the provisioning of ships on the long voyage from Europe to India. Although the Dutch had no intention of establishing a permanent colony, the Dutch East India Company began farming to provide fruits and vegetables for their ships. In time, the settlers pushed inland and formed permanent settlements; and in the 1790s these were established as independent South African republics. After the British had established themselves at the Cape, tension developed between the British and the Dutch (Boers) in South Africa; after a series of conflicts, these elements were combined in the Union of South Africa in 1910.

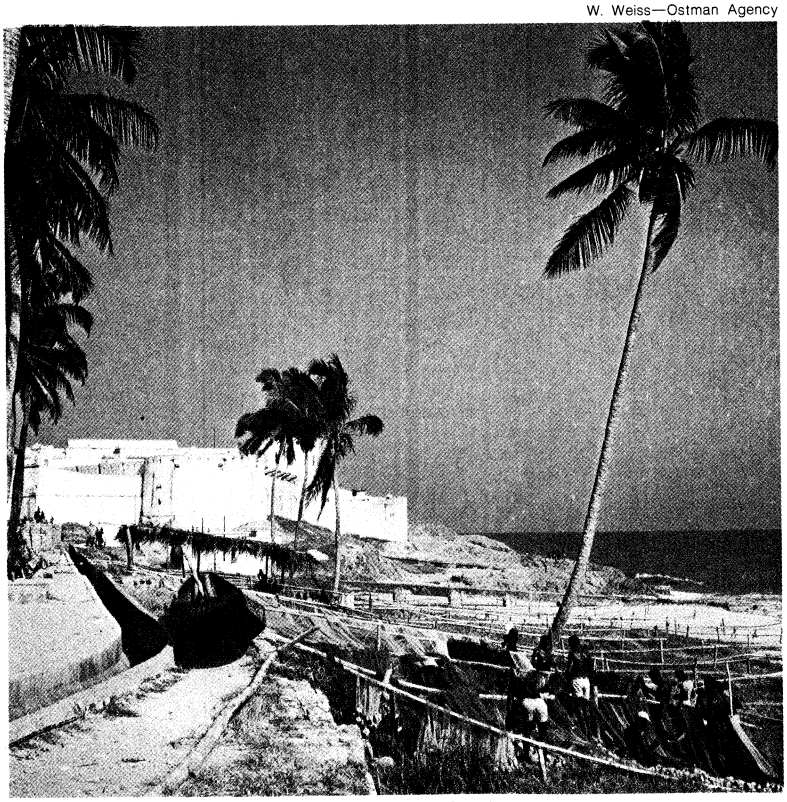
Although the French had a strip of coast in Gabon and settlements in Senegambia, their main possessions were in North Africa, where in the early 19th century they had acquired considerable territory in Algeria, primarily for strategic and geopolitical reasons.

French strategy during the period of colonization was to drive east from their coastal base in Senegal, blocking British expansion north from Freetown, Accra, and Lagos. Simultaneously, the French sent expeditions to the north from the Congo River, and the two pincers met on the shores of Lake Chad, effectively containing the British. Further attempts to extend French territory east across Africa were, however, prevented by the British in 1898 at Fashoda, in the southern Sudan.

The British expanded inland from coastal settlements. In the mid-1880s Cecil Rhodes, a British financier and empire builder, pushed British power north from Cape Colony and succeeded in interposing British territory between Portuguese Angola and Mozambique, thus thwarting the Portuguese ambition of linking these two territories. Britain also established a protectorate over the vast territory of what is now Kenya and Uganda and moved into the Sudan to link up with Egyptian soldiers under British command. In West Africa British possessions expanded considerably as a result of the activities of the colonial adventurer Lord Lugard, who established British control over what is now Nigeria.

Although the Germans did not establish any colonies until the latter part of the 19th century, they quickly acquired the territories of South West Africa, German East Africa (Tanganyika, Rwanda, and Burundi), Togoland, and Cameroun between 1883 and 1885. They lost all these territories as a result of World War I.

At the beginning of the 19th century most colonial possessions were coastal enclaves, but by the beginning of the 20th century the whole of Africa, except Ethiopia, Liberia, South Africa, and nominally Egypt, was under colonial rule; it was to remain so until after World War II, when the era of African independence began.



CURRENT POLITICAL GEOGRAPHY

In 1920 every square mile of the African continent—except the independent states of Ethiopia, Liberia, and the Union of South Africa—was under colonial rule or protection or was claimed by one or the other of the European colonial powers. By the early 1950s, however, African nationalism and the rise of independence movements were widespread, a development that marked the beginning of the rapid decline of imperial power in Africa.

Three major factors were important in the recession of colonialism in Africa. First was the whole political and intellectual climate of the 20th century, which found expression in the concept of self-determination and the right of all peoples to govern themselves. The intellectual climate also was exemplified by the increasing concern for the

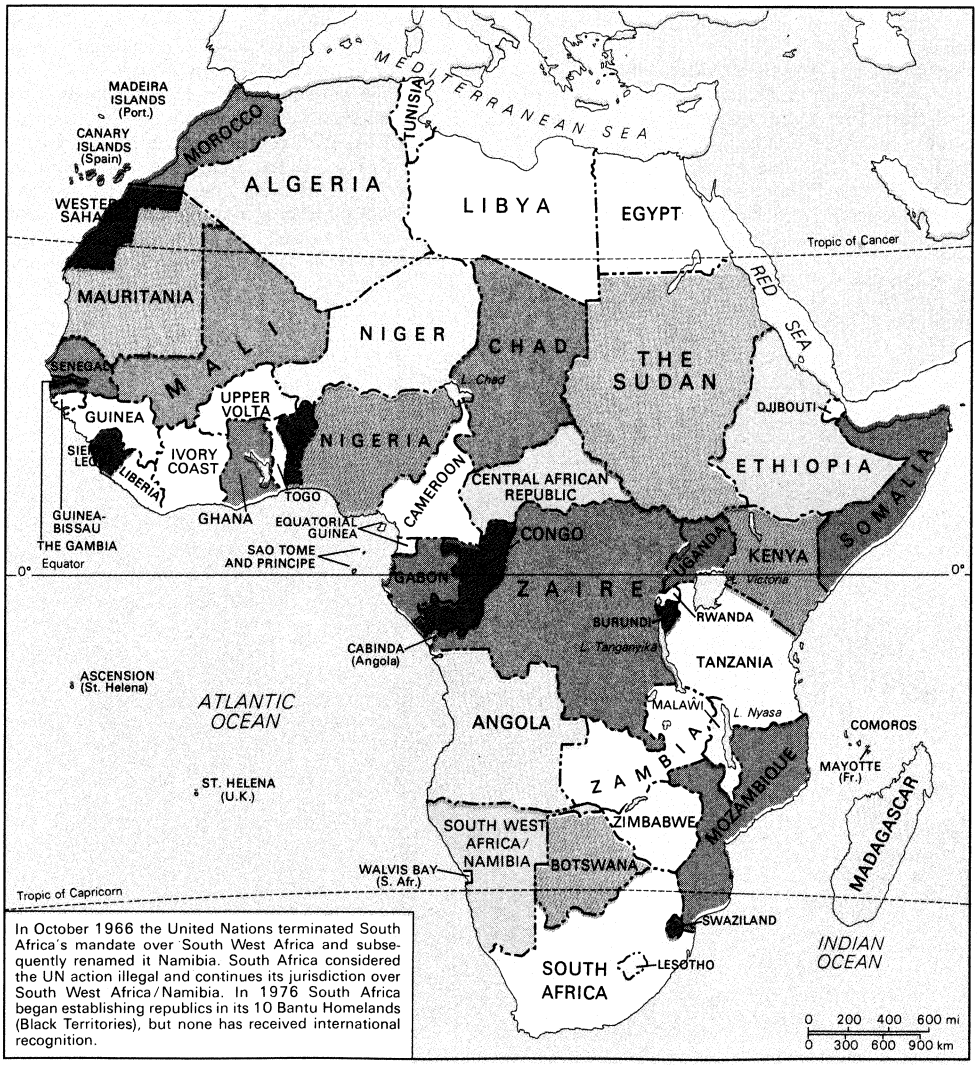
Recession of colonialism

W. Weiss—Ostman Agency

Cape Coast Castle, Cape Coast, Ghana, built by the Swedes in the 17th century.

dignity of the human personality and the entitlement to equality of opportunity. This more enlightened international atmosphere made possible the full operation of a second factor: the increasing awareness by Africans of their own potential power and the translation of this awareness into effective emancipatory action. The third factor was the shift in the world balance of power, resulting from the decline of the strength and influence of the European colonial powers—following two disastrous world wars—and their supersession by new international power structures. Western Europe no longer had the military or economic capability to perpetuate unilaterally its imperialism. Reinforcing this situation was the rise of the Soviet Union and the United States—both professedly anticolonial nations—as the preeminent powers of the latter 20th century.

The history of colonial emancipation has naturally differed from country to country. Generally speaking, however, where machinery existed—even in a vestigial form—to enable political and constitutional change to occur and where the colonial power was sufficiently sensitive and flexible to the requirements of circumstance, the transition from colonial rule to full sovereignty was relatively peaceful. On the other hand, where the colonial power had frozen its policies within the context of the 19th-century approach, it was obliged to resort to repressive colonial wars to maintain the status quo; the inevitable transition thus became bloody and rough. An index of the extent of the change that took place may be seen in the fact that 51 African states had acquired their sovereignty and all but the Central African Republic had acceded to membership in the United Nations by 1980; the independence of Transkei, Bophuthatswana, Venda, and Ciskei, however, were not recognized internationally.



Colonial wars

In 1980 Zimbabwe, the last major colonial territory (where a minority white regime had seized government from Britain in 1965), gained its independence, and the white minority was forced to share power with the black majority. South West Africa/Namibia was the site of continued conflict between South African authorities and black nationalist groups, despite a ruling by the International Court of Justice in 1971 that the South African presence was illegal. Control of Western Sahara is also disputed; fighting continues between Moroccan troops and the nationalist guerrillas who are supported by the Algerians.

The colonial heritage has posed many problems for the African states and has made efforts at cooperation among them difficult. There is the problem of arbitrary and illogical boundaries, most of which mark the extent of imperial advance and usually have no relation to geography or ethnicity. Colonialism has resulted also in a degree of political and economic identification with, and dependence upon, the metropolitan country (particularly strong in the former French colonies) that persists even after independence. Consequently, many African states still find it difficult to pursue international policies without inhibition from extra-African considerations.

The heritage of colonialism

The relatively brief period of European dominance in Africa also resulted in a pattern of institutions and habits inherited from the various colonial powers. This superimposition of mainly Anglo-Saxon and French cultures on the indigenous African cultures created a difference of outlook between English-speaking and French-speaking Afri-

Political divisions of Africa.

African Independent States

	year of independence	population (1980 estimate)
Algeria	1962	18,594,000
Angola	1975	7,078,000
Benin	1960	3,567,000
Botswana	1966	819,000
Burundi	1962	4,512,000
Cameroon	1960	8,503,000
Cape Verde	1975	324,000

can countries that has tended to complicate their relations.

Many African leaders, conscious of this dichotomy, have at various times worked for the development of a pan-African approach to the continent's problems. A product of these efforts was the establishment of the Organization of African Unity (OAU) in 1963, to create a sense of unity and to identify areas in which practical cooperation among African states might be pursued.

MAJOR LANGUAGE PATTERNS

Indigenous African languages fall into such broad categories as the Hamito-Semitic grouping in northern Africa and what some scholars consider the Niger-Kordofanian, Nilo-Saharan, and Khoisan families south of the Sahara. The sub-Saharan language classification is subject to considerable scholarly dispute. The cultural influence of the European colonial powers is reflected in the continuing official use of languages of the former administering powers in large areas of Africa.

In general, Arabic is both the official and unofficial language in states north of the Sahara, as well as in The Sudan. In many other countries, Arabic is also the language of religion. Between the Sahara and the Zambezi River, either English or French is widely understood. French is the official language in the states that formerly made up French West Africa and French Equatorial Africa, as well as in Madagascar (Mulagasy is also an official language) and Zaire. Similarly, English is the official language, or is widely spoken, in the states of West, Central, and East Africa formerly under British administration and is also the official language in Liberia. Portuguese is the language, officially and otherwise, in the countries formerly under Portugal. In South Africa, Afrikaans (which developed out of a colloquial version of 17th-century Dutch) and English are both official. Amharic is the official language in Ethiopia.

Among blacks on the northern fringe of West Africa south of the Sahara, Hausa, a Hamito-Semitic language, is spoken by at least 30,000,000 people. Indeed, Hausa has become—like Swahili in parts of East and Central Africa, spoken or understood by millions of people—a lingua franca that is in use over a wide area, traversing ethnic and political boundaries. Farther west, Dyula, a dialect of Malinke, has also acquired the status of a lingua franca.

Hindi, Gujarati, Urdu, and other languages of the Indian subcontinent are spoken among the Asian communities.

(F.S.A.)

VII. Resource development

The countries of North Africa, unlike those of the rest of the continent, have wide-ranging and ancient traditions of manufacture. At the end of the 19th century, however, Africa as a whole was regarded solely as a potential source of raw materials or as a natural market for Europe. In the course of time, limited industrialization tended to converge around the relatively large expatriate settlements, where technical considerations operated in favour of the industrialization of some areas and transport costs constituted the dominant development factor in others. Though World War II led to acceleration in the process of industrial development, by 1950 the total factory output of manufacturing industries (excluding South Africa) had an estimated value of only about $2,800,000,000, or 7 percent of a gross domestic product (GDP).

Industrial development

After 1950 output rapidly increased—to about 30 percent of a total GDP of $63,000,000,000. The substantial increase and its range were attributable to such factors as increased demand, the substitution of home-produced for imported goods, the encouragement of manufacturing by individual African administrations, and an influx of development capital and petrodollars. Major weaknesses nevertheless were evident, among them high capital costs; the political division of Africa into more than 50 countries, which inhibited mass production and mass marketing; and a scarcity of skilled personnel.

Despite its expansion since about 1950, the relative significance of manufacturing remains considerably smaller than in the advanced countries and smaller also than in Asia (excluding Japan) and Latin America. Furthermore, the share of manufacturing in the GDP varied widely in different African countries in the late 1970s. At the lower end of the spectrum were countries such as Uganda, Togo, and Niger, where the contribution of manufacturing was less than 1 percent of the GDP; at the upper end of the spectrum were countries such as Egypt and Zimbabwe, where the share of manufacturing was about 20 to 22 percent. The total output of manufacturing in South Africa alone was about 50 percent of the output of the rest of Africa.

Of Africa's output (excluding South Africa), Algeria, Egypt, Morocco, and Nigeria each accounted for more than 4.5 percent of the regional manufacturing value added. The remaining proportion of the output was distributed among more than 30 countries.

INDUSTRIES

Manufacturing in Africa tends to concentrate on comparatively simple items and on those where some special advantage is available to the African producer, although the range of products has been widening. In the 1970s industrial production included electric motors, transport equipment, and tractors, while airplanes were also being assembled. The leading heavy industries were chemical and petroleum, coal, and rubber manufacture. Most industrial plants, however, were of the relatively simple kind, being engaged in food processing or in manufacturing textiles,

leather products, and cement or other building materials.

Mining. The mining industry is an increasingly significant source of national income, foreign exchange, and raw materials for the development of local processing industries. In 1960 it accounted for 5 percent of the total GDP of developing Africa; by 1968 it had risen to about 10 percent. In South Africa it declined from 14 percent in 1960 to a low of 9 percent in 1971, but it has been increasing gradually since, reaching 15 percent in 1978. The industry is very unevenly distributed: in the mid-1970s, for example, about half of mineral earnings came from North Africa alone and about 30 percent from southern Africa, while Central and West Africa each accounted for about 8 percent.

Use of iron and steel

Heavy industry and engineering. Except in South Africa, iron and steel are used almost entirely for construction rather than for engineering. There are integrated iron and steel plants in Algeria, Tunisia, Egypt, Zimbabwe, and South Africa, while smaller production facilities—often based on the transformation of scrap—exist in several other countries. In 1978 production in developing Africa was about 1,000,000 tons, while in South Africa it was about 8,000,000 tons. The main producing countries supply between 20 and 80 percent of their own iron and steel requirements; the rest depend mainly on imports.

Petroleum-refining and petrochemical industries. Petroleum-refining capacity (excluding South Africa) was 65,000,000 tons per year during the late 1970s. Based on domestic crude-oil output in a few cases and on imported crude oil in others, 23 countries had at least one petroleum refinery. The development of the petrochemical industry followed the establishment of refineries in some countries. In 1965 there were only three major petrochemical complexes in Africa—in Zimbabwe, Egypt, and South Africa; but by the late 1970s nine additional countries had refinery capacities exceeding 1,000,000 tons—Algeria, Ghana, Kenya, Libya, Morocco, Nigeria, Senegal, The Sudan, and Tunisia.

Manufacturing. In 1978 about 3,154,000,000 square yards of textiles were produced. Most of the output is processed in bleaching, dyeing, and printing establishments that form an integral part of composite spinning and weaving units. With the exception of Egypt, producers have concentrated on the home market and on the manufacture of cotton textiles. Although African countries export textiles, their imports are usually larger. Rayon-synthetic and woollen materials are, for the most part, imported. Ready-made clothing, both domestic and imported, has emerged as a major market factor.

By 1970 most African countries were producing their own beer. South Africa was the leading producer in the late 1970s, followed by Zaire and Nigeria. Production facilities for soft drinks are widespread, and there are more than a dozen plants for manufacturing various types of distilled liquor.

Cement production

By the late 1970s, 29 countries were known to have cement plants. South Africa was the leading producer (7,000,000 tons a year), followed by Algeria (about 4,000,000 tons). The transport costs of cement make its price variable. Prices are lowest on the North African coast, somewhat higher on the west and east coasts, and highest in the inland countries.

Timber, fisheries, animal husbandry. In 1979 there was an estimated 1,700,000,000 acres (688,000,000 hectares) of forests and woodlands: almost 90 percent of the output of wood is used for fuel, 5 percent is converted into sawed wood and veneer logs, and the remainder is directed into other categories. In 1979 sawmills, spread throughout the continent, produced about 205,000,000 cubic feet of sawed wood, of which about one-sixth was exported. Plants for the manufacture of plywood, particle board, and fibreboard had considerable excess capacity.

The pulp and paper industry is concentrated in North Africa and in southern Africa, although a number of small paper mills are established in West, Central, and East Africa. The African output of wood pulp amounted to about 1,300,000 tons in 1979, 60 percent of which was exported—mainly to Europe. The main products of the paper industry proper comprised newsprint (about 270,000 tons), printing and writing papers (350,000 tons), paper and paperboard (about 1,700,000 tons) and industrial paper. The bulk of the output of all paper products was directed to national markets.

In 1979 the world fish catch, including both saltwater and freshwater fish, was estimated to amount to 78,000,000 tons, of which Africa's contribution amounted to 4,800,000 tons. The countries in Africa that contributed the most to this total were South Africa, Nigeria, Tanzania, South West Africa/Namibia, Senegal, Morocco, Ghana, Uganda, Egypt, Zaire, Chad, Angola, Mali, Ivory Coast, Cameroon, and Malawi.

Herring, sardines, and anchovies contribute most to the total catch, followed by jacks, mullets sauries, redfish, bass, and conger in tropical waters and cod, hake, haddock, tuna, bonitas, and bullfish in northern and southern waters. Tilapias and other cichlids constitute the largest catch in inland waters. A series of commissions has been set up around the African continent to control fishery development; these agencies collect statistics, conduct research, and attempt to regulate the operation of the fishing industry. The production (largely by traditional methods) of freshwater fish in 1979 was 1,800,000 tons, of which 737,000 tons were produced in West Africa, 643,000 tons in East Africa, 265,000 tons in North Africa, and 196,000 tons in Central Africa. There is very little freshwater fish production in southern Africa (*i.e.*, south of the Limpopo River).

Africa's wool production in 1980 amounted to 209,000 tons (before being cleaned of grease), or to about 117,000 tons of clean (washed) wool. The chief producing countries are Algeria, Morocco, Libya, Egypt, The Sudan, and South Africa. South Africa alone produces one-half of the entire continental production, the majority of the clip from merino or crossbred merino sheep.

Statistics for the output of cattle hides and of sheepskins, goatskins, and pigskins are notoriously unreliable; it is, however, sometimes assumed that the annual output of hides is in the region of 10 percent of the total population of cattle and that of sheepskins and goatskins in the region of 25 percent. The number of game hides and skins processed and sold annually is not accurately known.

POWER

A spectacular development in the use of electric energy took place in the 1960s, partly because of the growth of the petroleum industry and partly because of the establishment of large hydroelectric plants. From 1937 to 1979 electric-energy production increased 25 times—from 6,500,000,000 kilowatt-hours to 168,000,000,000. The average annual growth rate from 1957 to 1967—a period of great effort and activity—was more than 8 percent, and from 1970 to 1977 it was 7 percent. The proportion of thermal (as distinct from hydroelectric) production, most of which was in South Africa, decreased during the 1960s but remained fairly constant during the 1970s. The general development trend indicates that the public sector will probably absorb the output formerly used by the private sector, which, especially in its industrial aspects, has shown a marked decline. The increased quantity and quality of electric energy have given rise to problems of transmission and distribution. Unlike thermoelectric plants, which may be sited where the consumer demand is greatest, sites of hydroelectric installations are not flexible, the type of transmission lines in use has therefore changed. Although in the 1950s for example it was common practice to use tensions below 220 kilovolt lines, the 1960s marked a change to the use of high-tension lines. In Nigeria 330-kilovolt lines were laid, and similar lines were used in Zimbabwe's system, which feeds the Copperbelt, in Zambia, and Salisbury and Bulawayo, in Zimbabwe. This same system is interconnected in the north with the large Shaba hydroelectric power stations in Zaire. The construction of high-tension lines to supply power to the Shaba Copperbelt was completed in 1982. Two 500-kilovolt lines supply the consumer centres of Egypt from the hydroelectric power stations of Aswān and Saad El Aali. Construction of 533-kilovolt lines to transmit power from the Cabora Bassa hydroelectric station in Mozam-

Electricity distribution systems

bique to South Africa was completed in 1974. The possibility of supplying landlocked states with energy from the large hydroelectric plants in the coastal states is more likely to be considered in the future.

Electric-energy consumption in large urban centres, especially when they are near coastal towns and mining areas where industrial activity has taken shape, has increased considerably. In 1929 per capita consumption of electricity was only 20 kilowatt-hours. In 1949 this rose to about 60 kilowatt-hours and by 1979 had risen to almost 370 kilowatt-hours, although outside the urban centres and industrial zones consumption was on average less than 15 kilowatt-hours per annum. Although some countries have extended networks to the rural areas or have increased the numbers of isolated, low-powered stations and independent networks, progress in rural electrification has not been especially noteworthy.

Hydroelectric power. The technically exploitable hydroelectric resources of Africa represent 3,140,000,000,000 kilowatt-hours per annum, or approximately one-sixth of the world's hydroelectric potential. Hydroelectric resources are unevenly distributed: North Africa has only 5 percent, West Africa 10 percent, East Africa 22 percent, southern Africa 17 percent, and Central Africa 46 percent. Hydroelectric production, which represented about a quarter of overall electric production in 1969, increased to about a third by 1979. Whereas only 18 countries produced hydroelectric energy in 1957, it was produced by 31 in 1979, of which 10 thereby met more than 80 percent of their own electrical needs.

Countries producing more than 50 percent of their needs in 1979 were: Mozambique, Uganda, and Ghana (hydroelectric production exceeded consumption); Zambia (98 percent); Zaire (97 percent); Cameroon (95 percent); Central African Republic (93 percent); Malawi (90 percent); Rwanda (87 percent); Zimbabwe (85 percent); and Tanzania, Gabon, Angola, Kenya, Swaziland, Egypt, Nigeria, The Sudan, Congo, Ethiopia, and Madagascar (more than 50 percent). Large hydroelectric installations are the Aswān High Dam in Egypt, the Inga in Zaire, the Kariba between Zambia and Zimbabwe, and the Cabora Bassa in Mozambique.

Other sources of power. A number of steam power stations are located in ports and cities near the coasts. The largest installations of this kind operate in Tunis; Casablanca and Oujda, Morocco; Dakar, Senegal; Abidjan, Ivory Coast; and in Lagos, Nigeria. Steam power stations using coal are by far the largest, especially in South Africa, which had an installed capacity of 18,400,000 kilowatts in 1979.

Although geothermal energy is potentially a major source of electric production, especially in East Africa where many active volcanoes and hot springs are associated with the Great Rift Valley, there is as yet only one small (220 kilowatts) geothermal power station, in Shaba, Zaire. The most favourable zones for such installations are Kenya, Ethiopia, and Cameroon.

The geothermal power potential

The first nuclear power station in Africa was under construction in South Africa during the early 1980s.

AGRICULTURE, IRRIGATION, AND LAND USE

About one-third of the total land area of Africa is devoted to agriculture: arable land and land under permanent crops represents about 6 percent, permanent meadows and pastures about 26 percent.

Cereals and grains. The distribution of crops is influenced by a series of factors in which rainfall and its distribution play a significant part.

In 1980 Africa had about 54,900,000 acres planted in corn (maize), yielding approximately 29,900,000 tons of grain. Highest yields per acre were recorded in Réunion, Egypt, and Mauritius. Irrigation is practiced in all three countries. The total area devoted to the production of millet and sorghum in 1980 was about 78,300,000 acres. The countries that have developed production of these cereals to the greatest extent are Cameroon, Chad, Egypt, Ethiopia, Kenya, Mali, Niger, Nigeria, Senegal, Somalia, South Africa, The Sudan, Tanzania, Uganda, Upper Volta, and Zimbabwe.

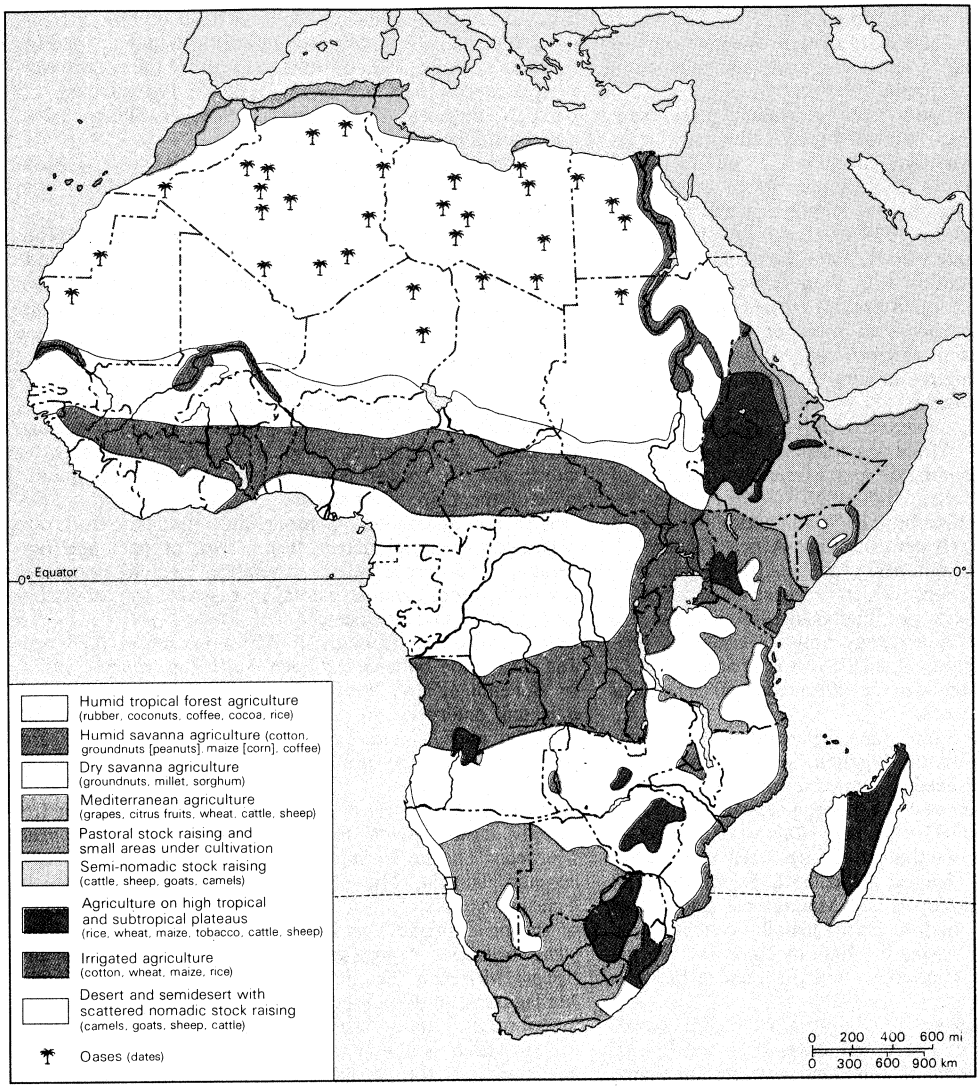
Rice production and consumption have become increasingly important. By 1980 production of unhulled "paddy" rice was about 9,300,000 tons. The most important rice-producing countries are Egypt, Guinea, Ivory Coast, Liberia, Madagascar, Mali, Nigeria, Senegal, Sierra Leone, and Tanzania.

The principal wheat-producing countries are Algeria, Egypt, Ethiopia, Kenya, Morocco, South Africa, and Tunisia.

Fodder crops are not widely produced. Cereals for fodder production in subtropical and tropical zones include corn, sorghum, and millet; protein-rich legumes, sown together with these crops, include velvet beans, cowpeas, soya beans, and lablab (a type of bean). In temperate Mediterranean zones oats admixed with broad beans and vetches are also sown. In climatically similar parts of south central, southern, and East Africa, pure stands of alfalfa (lucerne) are fairly widely grown. In the northeast, particularly in Egypt but also in The Sudan, berseem (a clover used for forage) is produced in considerable quantity with the help of irrigation.

Fruits and vegetables. Among the important fruits are bananas, pineapples, dates, figs, olives, oranges and tangerines, and grapefruits; vegetables include potatoes (sweet potatoes), yams, plantains, cassava, tomatoes, onions, pulses, and cowpeas.

Well distributed throughout Africa except in the north and south, the banana has been cultivated to some extent in Burundi, Zaire, Ivory Coast, and as an intensive, irrigated enterprise in Somalia, Madagascar, Tanzania, Uganda, and Angola. Ivory Coast, South Africa, Zaire, Kenya, and Congo are the largest pineapple-producing areas.



Date palm and fig cultivation

A typical tree of desert oases, the date palm is most frequently cultivated in Egypt, Algeria, The Sudan, and Morocco. The fig is cultivated largely in Algeria, Morocco, and Tunisia. The olive tree is grown principally in Tunisia, Algeria, Libya, and Morocco. About two-thirds of the olive production is processed into olive oil.

The principal orange-growing countries of Africa are Egypt, Morocco, South Africa, Algeria, Ghana, Zaire, Madagascar, and Tunisia. The largest yields are produced in countries where basin irrigation is widely practiced. South Africa is the largest producer of grapefruit, and The Sudan is the second largest. In 1980 Africa's total grapefruit production was more than 300,000 tons; production of oranges was nearly 3,800,000 tons; production of lemons, limes, and other citrus fruits was about 480,000 tons.

Potatoes are cultivated in elevated regions in such countries as Burundi, Rwanda, Ethiopia, Kenya, and Madagascar. Countries with Mediterranean climates, such as Morocco, Algeria, Egypt, and South Africa, are also important producers. The sweet potato is also widely grown, as are two species of yam. The plantain, or cooking banana, is grown extensively in equatorial or tropical forest zones. Cassava is widely grown, except in the north, the south, and in very dry regions. Except in Central and West Africa, where the crop is regarded as a staple, cassava is generally treated as famine reserve.

Tomatoes are widely grown, with the largest producing areas bordering the Mediterranean; half are grown in Egypt. Onion production is widely dispersed, with the countries bordering the Mediterranean producing for export. Countries producing green beans on the largest scale are Egypt (80 percent of African production), South Africa, Morocco, and Algeria. Production of beans and peas for drying is much more widespread; major producing countries are Burundi, Ethiopia, Rwanda, Tanzania, Uganda, Zaire, and Morocco. Ethiopia, Egypt, and Morocco are the most substantial producers of dry broad beans, while Ethiopia and Morocco are the largest producers of chick-peas. Lentil production is significant in Ethiopia and Morocco. The cowpea is becoming increasingly important as a legume for human consumption. Best suited to warmer tropical environments, it is produced in Botswana, Madagascar, Niger, Nigeria, Senegal, Uganda, and Upper Volta. Heavy vegetables, such as cabbages and cauliflowers, are principally grown in countries along

Agricultural regions of Africa.

the Mediterranean coast, from where it is possible to export small quantities to southern Europe. Other important vegetables in tropical Africa include peppers, okra, eggplant, cucumber, and watermelon.

Vineyards. Grapes are produced in North and southern Africa. Production, however, has been curtailed in Algeria, initially because of the loss of markets in the European Economic Community (EEC) as a result of the Community's common agricultural policy, and later because of Algeria's attempts to decrease its dependence on wine as the principal agricultural export. A distillery for producing brandy from surplus wine has been installed in Algeria by the Soviet Union, and there has been some resumption of the traditional wine trade between Algeria and France as the result of a trade agreement with the EEC reducing the tariff on wine.

Dairy products. Milk and its products are consumed according to national and development circumstances, either as whole fresh milk, skim milk, buttermilk, fermented milk, flavoured milk, yogurt, butter, ghee (clarified butter fat), soft cheese, processed cheese, manufactured creamery cheese, or as ice cream. No reliable figures are available for production and consumption of exclusively African milk and dairy products. Except in South Africa, Zimbabwe, and Kenya, however, production is known to be insufficient to meet domestic needs.

Miscellaneous crops. The cashew tree is grown to a limited extent in East Africa and to a lesser extent in the coastal countries of West Africa. Yields vary widely. The macadamia nut tree, introduced from Australia to East Africa, yields about 60 pounds of nuts a year when it is 12 to 14 years old.

Coconuts and copra

Coconuts are important in the Comoros, Ghana, Ivory Coast, Kenya, Mozambique, Nigeria, and Tanzania. About 185,000 tons of copra (dried coconut kernels) were produced in 1980. Kola nuts are grown principally in the forested regions of Nigeria, Ghana, Ivory Coast, Sierra Leone, and Liberia. Yield varies, but it averages from 300 to 500 pods per mature tree; each pod contains from six to 12 nuts. The oil palm is grown in areas of heavy rainfall. In 1980 production of palm kernels was about 800,000 tons and of palm oil (which includes pericarp oil from the ovary of the palm, as well as kernel oil) 1,500,000 tons. The largest producers in Africa are Nigeria and Zaire.

Peanuts are widely grown, with production being of particular importance in Cameroon, the Central African Republic, The Gambia, Senegal, Malawi, Mali, Niger, Nigeria, South Africa, The Sudan, Uganda, and Zaire. In 1980 the estimated total yield was 5,300,000 tons of peanuts in shell.

The most important cotton-producing countries in Africa are Egypt, The Sudan, Zimbabwe, Ivory Coast, South Africa, and Tanzania. Production of cotton lint in 1980 was 1,300,000 tons and of cottonseed 2,300,000 tons. Sesame is mainly produced in Ethiopia, Nigeria, Somalia, The Sudan, and Uganda. About 525,000 tons of sunflower seed were produced in 1980, the main producing countries being South Africa, Tanzania, and Mozambique. Castor beans are grown in Ethiopia, South Africa, The Sudan, and Tanzania.

Production of cocoa in 1980 was about 1,000,000 tons, the bulk of which was produced by Cameroon, Ghana, Ivory Coast, and Nigeria. Average yield per acre under

average conditions of management is about 500 to 600 pounds of dry cocoa beans. The most important coffee-growing countries in Africa are Angola, Cameroon, Ethiopia, Guinea, Ivory Coast, Kenya, Madagascar, Tanzania, Uganda, and Zaire. Arabica, robusta, and liberica are the three main types. The principal tea producers are Kenya, Malawi, Mozambique, Tanzania, and Zaire, while the principal producers of rubber are Cameroon, Liberia, Nigeria, and Zaire.

The production of tobacco is widely distributed, the most substantial producers being Malawi, Nigeria, Zimbabwe, South Africa, and Tanzania.

The largest cane sugar producers are Madagascar, Mauritius, Mozambique, Réunion, Zimbabwe, South Africa, Swaziland, and Egypt. Total production in 1980 was about 63,000,000 tons; about 2,600,000 tons of sugar beet were also produced.

VIII. Commerce

TRANSPORTATION

Although there were highly developed transport networks in many parts of Africa in precolonial times, during the colonial era that followed, these networks were restructured to penetrate into the interior from the seaports and, in the main, to serve the commercial and administrative needs of the colonial powers. Their fragmentation, which led to interregional links being but thinly developed, resulted from the juxtaposition of varied and difficult terrains, the economic artificiality of certain national frontiers, the lack of a developed intra-African trade, and the strong orientation of commodity trade with the administering countries. All of this was further complicated by the existence of vast unpopulated areas lying between the main centres.

The fragmentation of African transport systems

The emergence in the 1960s of independent African governments who recognized the need to lift economies from their generally very low levels and, above all, to develop agriculture and embark on industrialization heralded improvements in economic planning, the development of transport networks, and the introduction of cheaper freight rates. But there remained a serious shortage of qualified African labour to plan and manage transport systems at the national or multinational level and, simultaneously, to keep up with the rapid development of transport technology outside Africa.

Animal transport. There is some evidence that before the arrival of the camel, which was introduced into Africa via Egypt at the time of the Arab conquest, bullocks were used either as pack animals or to draw carts from the northern countries across the Sahara to the gold-producing areas of the ancient Sudan. From the 16th century onward, the Portuguese developed transport inland from the coast at Mozambique, and, from the 17th century, first the Dutch and then British settlers from the Cape trekked northward and northeastward with their wagons. Except in such highland areas as Ethiopia where pack animals were and still are used, the tsetse fly often prevented the use of animal transport. With the steady progress in the development of transport infrastructure in many African countries, the use of bullocks in southern Africa, donkeys in North and West Africa, horses in North Nigeria, and camels in West and North Africa and the Horn of Africa has been reduced, but the extent of this reduction cannot be accurately gauged.

Motor transport. The arrival and rapid development of the internal-combustion engine in the 1920s transformed the collection and distribution of goods and personal travel. Roads were built, particularly in North and southern Africa, but also in parts of the west and east. World Bank loans since the 1950s, supplementing contributions to road and highway development from national budgets, financed the building and improvement of road networks in many African countries. A number of highway projects were under construction by the early 1980s. They included the Trans-African Highway linking Mombasa, Kenya, with Lagos, Nigeria; the Trans-Sahelian Highway connecting Dakar, Senegal, with Ndjamena, Chad; the Trans-West African Highway connecting Lagos with Nouakchott, Mauritania; the Trans-East African Highway joining Cairo with Gaborone, Botswana; and the Trans-Sahara Highway linking Algiers with Lagos.

Rail transport. The early railways were constructed partly to facilitate the administration of interior regions and to bring supplies from ports to central consumption or distribution points and partly—especially in the south—to enable valuable minerals or commodities to reach the coast for export. In Africa, as in Europe, the period of railway development extended from the end of the 19th century to the end of World War I, during which time, unfortunately, by constructing railways with different gauges of track and by operating them with rolling stock of different braking and coupling systems, the colonizing powers left a difficult and costly legacy for independent African countries who wished to link themselves together.

As with roads, rail networks have been improved considerably since the 1960s and, as a result, there has been a lowering of transport costs. During the 1960s investment in transport accounted for one-fourth of all development expenditure. Between 1958 and 1966, for example, the World Bank and its affiliates financed the construction of 400 miles of new railway in Nigeria, more than 400 miles of railway extension in The Sudan, and advanced loans for railway extensions in Kenya. In addition, the United States granted loans to Tanzania for railway construction and financed the rehabilitation of the Senegal–Niger Railway running from Senegal to Mali. Railways for carrying iron ore were built in Liberia, Swaziland, and Mauritania. China also extended financial assistance and labour to Tanzania and Zambia for the construction of a railway from the Zambian Copperbelt to the Tanzanian port of Dar es Salaam.

Investment in transport

Air transport. Air transport is the primary means of international and sometimes of national travel in Africa. During the late 1940s and the 1950s great advances were made in the extension and improvement of rail and road services and a transport factor emerged in the introduction of internal and international scheduled air services. The rapid development of air transport increased the movement of goods and people and began to open up the hitherto largely closed interior of the continent. Transport became much quicker and usually cheaper. Since then, internal air services have steadily increased, and intercontinental air transport, especially of passengers, has developed greatly. The largest international airports are at Casablanca; Cairo; Abidjan, Ivory Coast; Addis Ababa, Ethiopia; Nairobi, Kenya; Douala, Cameroon; and Johannesburg.

Navigation. Historically, over the vast interior between the Sahara and the Zambezi River, people or goods were transported by canoe or boat on the great river systems of the Nile, Sénégal, Niger, Congo, and Zambezi rivers and on the few but very large lakes. Where conditions allowed, engine-powered craft later supplemented or displaced canoes, but further development has been slight. Also notable were the construction of lake ports and the installation of rail ferries across Lake Victoria.

Meanwhile, on the coasts, artificial harbours have been developed. New berths have been added to established ports, and several ports have been constructed. In planning new ports, the choice of site, probable costs, and the possibilities of using containers or other unitized loads are taken into consideration.

TRADE

Internal trade. Intra-African trade records frequently understate the amount of trade—partly because of the lack of adequate statistics and partly because of the high rate of smuggling, which allows a substantial amount of traditional border trade to continue unrecorded. Apart from this trade between African states has been handicapped by a tendency for trade to remain concentrated within the common currency areas and trade zones that developed among African countries during the colonial era, by the often inadequate means of transport and communication, by the lack of complementary agricultural or other products, and by the absence of manufacturing industries.

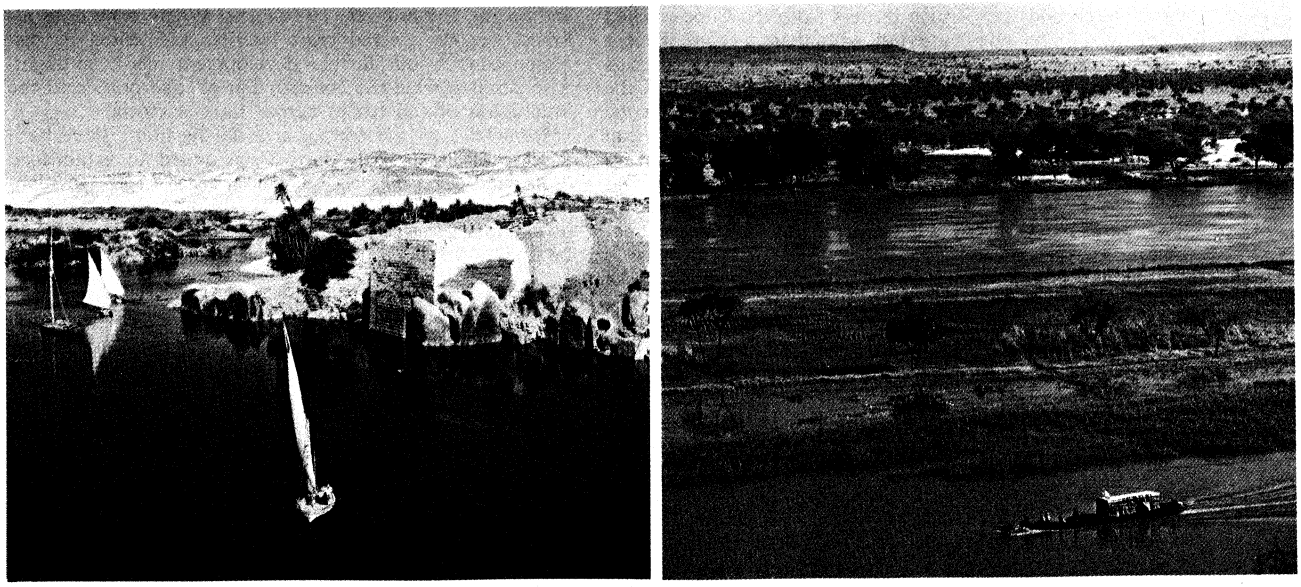
On the average, the proportion of intra-African export trade to total export trade was about 4 percent in 1979, as compared to 14 percent between the Latin-American countries and to 24 percent between developing Asian countries. Much of the intra-African trade consists of food, drinks, tobacco, sugar, cattle, and meat. There is also a good deal of re-export trade between the coastal and inland states, especially in machinery, transport equipment, and spare parts.

Common currency and trade zones that have evolved through the granting of preferences or the operation of common currencies inherited from former metropolitan powers include: the Customs and Economic Union of Central Africa (UDEAC), comprising Cameroon, Gabon, the Central African Republic, and the Congo; The Economic Community of West Africa, comprising Ivory Coast, Mali, Mauritania, Niger, Senegal, and Upper Volta, with Benin and Togo participating as observers; and the Maghrib Permanent Consultative Committee (CPCM), grouping Algeria, Mauritania, Morocco, and Tunisia. The East African Community, founded in 1967 by Kenya, Uganda, and Tanzania, was disbanded in 1978 because of political tensions among the countries.

External trade. Since the outbreak of World War II there has been a considerable expansion in Africa's overall external trade. Between 1938 and 1978, total exports increased in value 53 times (from about U.S. $1,000,000,000 to U.S. $53,000,000,000), while imports increased 43 times from about U.S. $1,500,000,000 to about U.S. $64,000,000,000. This growth compares favourably with that of the other developing regions, such as Latin America; imports, however, now outweigh exports. The large expansion in African exports is generally attributed to the increase in the demand for primary commodities during World War II and in the immediate postwar reconstruction period. Subsequently, the attainment of independence by a large number of African countries, especially in the early 1960s, followed by a bid for economic development, strengthened the export expansion drive. Another reason for the rapid growth in African exports was the temporary increase in the price of primary commodities, although subsequently the general trend, except for petroleum, has been toward depressed commodity prices.

Exports. An important factor that has influenced the growth of African exports was the discovery of petroleum in several countries, notably Libya, Algeria, Nigeria, and Gabon, and the dramatic price increases brought about by the Organization of Petroleum Exporting Countries (OPEC). Other factors include the discoveries and the increased exploitation of much-demanded minerals, such as diamonds, especially in Sierra Leone, the Congo, the Central African Republic, and Zaire; and the exploitation of other minerals, such as uranium ore.

Since independence, attempts have been made to diversify external trade relations, but the record of achievement has not been impressive, because Africa's trade patterns largely reflect the influence of traditional links with the countries of western Europe. A significant export trade has developed with the United States and Japan.



Trade with the EEC and EFTA

The biggest market for African exports is the EEC, in which West Germany, as the largest buyer, received 28 percent of all African exports to the EEC in 1979, France 22 percent, Italy 19 percent, the United Kingdom 12 percent, The Netherlands about 10 percent, Belgium-Luxembourg 7 percent, and Ireland and Denmark the remainder. The United States ranked second in importance in terms of exports, and the European Free Trade Association (EFTA) ranked third. Sweden, Switzerland, and Austria were the largest purchasers in 1979, accounting for 26, 24, and 22 percent, respectively, of the total African exports to the EFTA. Japan and the developing Asian and American countries were also important importers.

In most African states one or two primary commodities dominate the export trade. Of the total export trade in the late 1970s, petroleum and petroleum products accounted for 98 percent in Libya, 93 percent in Nigeria, 91 percent in Algeria, 85 percent in Gabon, and more than 50 percent in the Congo and Angola. Iron ore represented 85 percent of Mauritanian exports and 56 percent of those from Liberia; copper accounted for 95 percent of Zambia's exports and 56 percent of those from Zaire. Statistics for primary agricultural commodities were: cotton from Chad (65 percent) and from Egypt (22 percent). Coffee represented the predominant export item of Burundi (96 percent), Uganda (85 percent), and Rwanda (76 percent) and was a significant fraction for Ethiopia, Madagascar, Kenya, and Ivory Coast. Sugar accounted for more than three-fourths of the exports from Mauritius.

Imports. The tremendous increase of Africa's import trade has resulted in the import bill of most African states exceeding their export earnings; in consequence, many governments have established import restrictions or subsidized many of the required imports. The bulk of imports comes from western Europe, especially the EEC countries, which accounted for more than half of Africa's total imports in 1979. France, West Germany, the United Kingdom, Italy, and Belgium are the principal suppliers—mainly to their former colonies. There has, however, been a substantial increase in imports from the United States, Japan, and South Africa. In 1979 the United States supplied 9 percent of Africa's total imports, Japan about 7 percent, eastern Europe about 3 percent, and Asia (exclusive of Japan) 9 percent. Imports are primarily

required to develop manufacturing industries and are, therefore, confined for the most part to mineral fuels, industrial goods, machinery, transport equipment, and durable consumer goods. Mineral fuels and related materials represented 8 percent of Africa's total import trade in 1978; this proportion varied greatly, however, with some countries exporting mineral fuels and other countries dependent on imported sources. Africa continues to allocate considerable foreign exchange to food imports, which in 1978, for example, accounted for 12 percent of the overall import total. The overall situation has improved only slightly, with per capita food production in Africa for 1977 to 1979 only slightly higher than that for 1961 to 1965; again there is a wide variation, and per capita food production has actually declined in a number of African countries.

Problems and prospects. The most difficult problem facing Africa in its export-promotion drive to the developed countries is the diminishing demand for agricultural primary commodities. The demand for these commodities in the developed countries has reached a saturation point, and this implies that further expansion of African exports can only be achieved through substantial population increases in those countries. Given, however, the generally very low rate of population growth in the developed countries, the demand for primary commodities is not likely to increase substantially. In addition, the slow economic growth of the industrialized countries further reduces demand for both primary and manufactured African exports. Second, African exports continue to meet stiffer tariffs and other trade restrictions in the developed countries, and this makes it more difficult for primary commodities to penetrate those markets. Third, there is growing competition from synthetics and substitutes for many of the African agricultural primary commodities, a fact that further reduces the demand. Again, trade in primary commodities among the developed countries themselves is increasing. In other words, the developed countries are becoming increasingly self-sufficient in such commodities.

Conditions affecting commodity trade

African countries also face competition from other developing countries in Asia and Latin America, particularly in the export of such commodities as rubber, natural fibres, coffee, tin, and copper. Fluctuations in world market prices also create severe problems of with foreign-exchange earnings for most developing countries, particularly those that depend on one or two primary products for much of their export earnings.

There are, therefore, growing fears among the African countries that their export earnings will, in consequence, continue to be adversely affected. This is recognized as a common problem facing developing countries. It is also a point of major concern to international organizations, especially the United Nations Conference on Trade and Development (UNCTAD), which has become an important forum for the discussion of the general problems affecting exports from developing to developed countries. These problems concern the access of primary commodities, semi-manufactured, and manufactured goods to the markets of the developed countries; quotas for certain primary commodities, such as coffee, cocoa, sugar, and copper; and the general attitude of developing countries on these issues in negotiations with the developed countries.

IX. Demographic patterns

CURRENT PATTERNS

With the advent of the colonial era the African continent was divided into small geographically and politically based units that took little or no account of ethnic distribution. These political boundaries persisted—despite the fact that in 1980 none of the mainland African countries remained under colonial rule—and the continent continued to be characterized by a large number of countries with predominantly small populations. Africa's total population, estimated at 482,000,000 by 1980, was divided among 58 countries (including the offshore islands). Of these, almost half had fewer than 5,000,000 residents, seven had more than 10,000,000, and only six had populations of more than 20,000,000.

Density. Covering about a fifth of the world's land surface, Africa had in 1980 a population density of about 40 persons per square mile (105 persons per square kilometre)—this is of the same order as the Soviet Union and the Americas but considerably lower than Europe and Asia—both around 250 per square mile in 1980—and less than half the world average of 84. Wide variations in density occur from country to country in Africa and within countries.

In general, the most densely populated areas are found bordering the lakes, in the river basins, along the coastal belts of North and West Africa, and in certain highland areas, while settlment is the most sparse in the desert and savanna areas. Thus, Rwanda and Burundi, situated in the East African highlands, are the most densely populated countries in Africa; while Western Sahara, Mauritania, and Libya, in the Sahara; and Botswana in the Kalahari, are those where settlement is most sparse. Because much of Africa's total area is desert, semidesert, or swamp and is unable to support human—and in particular agricultural—settlement, a more realistic measurement of population pressure is the density per square mile of arable land. On average, one square mile of arable land in Africa has to support or at least to provide food for 740 people (as compared with 988 people in Europe, 1,550 in Asia, and 620 in South America). In some countries the number is appreciably higher—over 4,200 in Egypt, 2,500 in Mauritius, and 640 in Angola.

Areas of dense population

Internal migration. Mostly rural for centuries, Africa has rapidly become more urbanized. The population in towns of 20,000 or more has increased from about 21,500,000 (10 percent of the total population) in 1950 to about 36,500,000 (13 percent) in 1960 and to more than 60,000,000 (17 percent) in 1970. Indigenous urban centres had long existed in parts of West Africa. In the 19th century the population of Kumasi, capital of Ashanti, was about 30,000 while many Yoruba towns were considerably larger. Before World War II growth was very slow in these and other tropical African urban centres. Since then, an expansion of towns and cities has taken place in sub-Saharan Africa and in those countries along the Mediterranean coast where centres of trade and population have long existed in various stages of growth and decline.

These northern countries are the most urbanized in Africa, with between 20 and 40 percent of their population in towns of 20,000 or more. The biggest city in Africa is Cairo, with a population of more than 5,400,000 in 1979. Other large cities are Alexandria (more than 2,000,000 in 1976); Casablanca, Giza, Kinshasa, Lagos, Johannesburg, Addis Ababa, Cape Town (each with more than 1,000,000 by the mid-1970s); and Accra, Algiers, Ibadan and Nairobi (each between 500,000 and 1,000,000 by the mid-1970s).

In many countries a single large city, usually the capital, often attracts the majority of rural-urban migrants, as well as people from smaller towns. In some countries this has resulted in a situation similar to that of Malaŵi, where in 1966 there were no medium-sized towns (100,000 to 200,000 residents), and the whole urban population (those living in localities of 20,000 or more residents)—save for a few small towns with populations below 20,000—was concentrated in Blantyre. By 1976, however, the urban area of Lilongwe had a population of 75,000, while Blantyre's population had grown to 214,000.

International migration. Most movement occurs across uncontrolled borders and between people of the same tribal groups. Much is seasonal, in any case, and is restricted to labourers and nomadic herdsmen. Controlled immigration and emigration are generally negligible; the only contemporary examples were the forced emigration of Asians from East Africa and the emigration of people from neighbouring West African states caused by the enforcement of the Alien Compliance Order of 1969 in Ghana. Movement of refugees is quite substantial in many parts of Africa, and estimates of the number of refugees have grown fourfold since the late 1960s. By the early 1980s almost every country had small groups of refugees.

In all African countries the majority of the population is of indigenous origin. In South Africa there are large

Substantial minority groups

numbers of Europeans (about 20 percent of the population). Other countries with significant European populations are: Zimbabwe (estimated at 223,000 in 1980), Zambia (12,000), South West Africa/Namibia (113,000), Mozambique (20,000), Kenya (40,000 in 1969), and Senegal (about 47,000 in the later 1960s). Other substantial minority groups are Asian peoples (chiefly in southern and East Africa), Arabs (in West and East Africa), and people of mixed origin.

Population growth and its effects. Birth rates have mostly remained high—about 46 per 1,000 population—with the average number of children per woman being between five and six. A sharp decline in death rates, particularly among infants and small children, is due to the spread of medical services. Population growth rates are in consequence often high. In a number of countries the population has already increased at rates of more than 3 percent per annum, and almost nowhere is the annual increase less than 2 percent. (Rates in Europe are at 1 percent and sometimes lower.)

High fertility and falling mortality considerably influence the age distribution of the population. In most African countries about 45 percent of the population is less than 15 years of age, compared to about a quarter of the population in European countries. People 65 and older constitute a further 3 percent of the population, so that the ratio of the nonworking population to those of working age (generally from 15 to 65 years old) is almost 1:1, as compared to 1:0.5 in developed countries. Thus, theoretically, each member of the working population has to produce enough to support almost one nonworking member.

The labour force. It is estimated that as much as 60 percent of the working population is still engaged in subsistence agriculture and a further 20 percent mainly in production of cash crops. In the sub-Saharan countries the total percentage dependent on agriculture is likely to be nearer 90.

Women in the labour force

The remainder of the working population is divided mainly between government service (including the police and armed forces), personal services (*i.e.*, domestic services, laundry, and hairdressing), and an increasing number of mining and industrial projects. Underemployment, particularly in the agricultural sector, is widespread, and unemployment has risen, especially in urban areas. Participation in labour by women varies considerably from country to country. Women in paid employment are generally fewer than men, though a large proportion of women in sub-Saharan countries are engaged in subsistence agriculture—if only part of the time. Women are also employed in the civil service, in trading (especially in West Africa), in domestic service, and to an increasing extent in light industry.

FUTURE TRENDS

The demographic patterns in Africa have, in general, evolved over a long period of time, although some patterns have occurred since the 1960s. Further changes are expected to be much more rapid.

Predicted growth rates. With better health facilities and with wider education in such fields as hygiene, nutrition, and child care, the mortality rates are likely to decrease steadily for some time. Fertility, however, is expected to remain constant or even to increase slightly, with further improvements in the health situation of the general population and with the settlement of nomadic peoples. In consequence, the annual rates of population growth for most countries of the region might by the end of the 20th century even rise above 3 percent. Africa's growth rate became the highest in the world during the mid-1970s, when it surpassed those of Latin America.

This high rate of growth will inevitably place a very heavy burden on the resources of the developing African countries, particularly in terms of housing, health services, education, and employment and, in some countries, on arable land and food supplies. Some 3 percent or more of the gross national product (GNP) will be absorbed by the population growth; this will mean that the GNP of these countries must grow by more than 3 percent per year in real terms in order to maintain its present standard of living.

Population policies. In several countries the realization of the effects of rapid population growth has led to official policies aimed at reducing birth rates and at slowing down (though not eliminating) population growth. The implementation of these policies has taken the form of full-scale family-planning programs (including the weakening of child-bearing incentives, such as family allowances and paid maternity leave), the establishment of maternal- and child-health services (including contraceptive advice and supplies), and, in certain cases, the legalization of abortion.

The countries that have adopted such official policies are Botswana, Ghana, Kenya, Lesotho, Mauritius, Morocco, Seychelles, South Africa, Tunisia, Uganda, and Egypt. Of these, only Egypt did not show a decline in the birth rate by the mid-1970s. In addition, many other countries have voluntary agencies that provide family-planning advice and services with active government support; there are others that allow such agencies to function unofficially. A few countries, such as Gabon and Cameroon, still have policies encouraging an increase in the birth rate.

Prognostications of population

If birth rates in the African countries remain high and if mortality continues to fall, the population will increase by about 30 percent by 1990, and by 2005 it will be more than double its 1980 size. The continuation of these vital rates will also further increase the proportion of the population in the younger age groups and thus their dependency on the working population.

The rate of growth of urban populations is expected to continue to accelerate, and by 1980 more than 100,000,000 persons (22 percent of the population) were living in towns of 20,000 and more. In large towns in particular, growth rates are expected to vary from 6 to 10 percent. By the end of the 20th century it is likely that between 30 and 40 percent of the population will be settled in towns of 20,000 or more, and—including the smaller towns—at least half the population will be living in an urban environment. (R.K.A.G.)

General works: PAUL BOHANNAN and PHILIP CURTIN, *Africa and the Africans*, rev. ed. (1971), the best introductory work on modern Africa; REGINE VAN CHI-BONNARDEL, *The Atlas of Africa* (1973); *Africa South of the Sahara* (annual), a reference work; GEORGE H.T. KIMBLE, *Tropical Africa*, 2 vol. (1960); R. MANSELL PROTHERO (ed.), *A Geography of Africa*, rev. ed. (1973); ALFRED T. GROVE, *Africa South of the Sahara*, 2nd ed. (1970); WILLIAM A. HANCE, *The Geography of Modern Africa*, 2nd ed. (1975); M.F. THOMAS and G.W. WHITTINGTON (eds.), *Environment and Land Use in Africa* (1969); L. DUDLEY STAMP and W.T.W. MORGAN, *Africa: A Study in Tropical Development*, 3rd ed. (1972); REUBEN K. UDO, *A Comprehensive Geography of West Africa* (1978); R.J. HARRISON CHURCH, *West Africa: A Study of the Environment and of Man's Use of It*, 8th ed. 1980.

Geology: RAYMOND FURON, *Géologie de l'Afrique*, 3rd ed. (1968; Eng. trans., (1963); LUCIEN CAHEN and N.J. SNELLING, *The Geochronology of Equatorial Africa* (1966); S.H. HAUGHTON, *Geological History of Southern Africa* (1969); EBERHARD MACHENS, "Das Präkambrium von Afrika," in FRANZ LOTZE (ed.), *Handbuch der stratigraphischen Geologie*, vol. 13, part 2, pp. 414–551 (1968); *Lexique stratigraphique international*, vol. 4, *Afrique* (1969). (*Spècial studies*): *Bulletin de la Société géologique de France*, vol. 11, no. 2 (1969), issue devoted to the geology of Mauritania; *Annales de la Faculté des Sciences de Clermont-Ferrand*, no. 41 (1969), report of the fifth symposium on African geology; MAURICE LELUBRE, "Chronologie du précambrien au Sahara central (Chronology of the Precambrian in the Central Sahara)," in *Age Relations in High-Grade Metamorphic Terrains*, pp. 27–32 (1969). (*Comprehensive geological maps*): *Structural Outline of Africa*, 1:10,000,000, 1 sheet (1958); *International Geological Map of Africa*, 1:5,000,000, 9 sheets (ASGA–UNESCO, 1963); *International Tectonic Map of Africa*, 1:5,000,000, 9 sheets (UNESCO, 1968).

Physical geography: (*Climate*): B.W. THOMPSON, *The Climate of Africa* (1965); and *Africa: The Climatic Background* (1975), provide background information. Also useful, although somewhat dated, is BERNHARD HAURWITZ and J.M. AUSTIN, *Climatology*, pp. 325–354 (1944). GLENN T. TREWARTHA, *The Earth's Problem Climates*, 2nd ed. (1981), gives a more advanced account of the major climatic anomalies in Africa. (*Relief*):

There are several descriptive works on the relief or physiography; one of the most comprehensive of these is LESTER C. KING, *The Morphology of the Earth*, 2nd ed., pp. 241–309 (1967). (*Drainage*): There are numerous works on drainage patterns. A coherent account of drainage, mainly in West Africa, is given in M.F. THOMAS and G.W. WHITTINGTON (eds.), *Environment and Land Use in Africa*, pp. 83–102 (1969). H.E. HURST, *The Nile* (1952), is a classic and is still the best account of the regime of the Nile and its tributaries. MARTIN A.J. WILLIAMS and HUGUES FAURE (eds.), *The Sahara and the Nile: Quaternary Environments and Prehistoric Occupation in Northern Africa* (1980), details the evolution of land forms and human settlement in the region. For southern Africa, the most detailed textbook account is found in J.H. WELLINGTON, *Southern Africa*, vol. 1, pp. 339–508 (1955). The basins of the continent's remaining major rivers and lakes are adequately described in the handbooks, published by the NAVAL INTELLIGENCE DIVISION OF THE BRITISH ADMIRALTY, on *The Belgian Congo*, pp. 11–35 (1944), *French Equatorial Africa*, and *Cameroons*, pp. 39–44 (1942). (*Soils*): H.L. SHANTZ and C.F. MARBUT, *The Vegetation and Soils of Africa* (1923; reprinted 1971), was the first systematic account of major soil groups. Far more modern and useful is S.J. SCHOKALSKAJA, *Die Böden Africas* (1953; orig. pub. in Russian, 1948), which is a basic text. For tropical Africa, particularly, R.P. MOSS (ed.), *The Soil Resources of Tropical Africa* (1968), presents a discussion of the framework within which tropical soils may be described. Among other books and reports for certain regions, PETER M. AHN, *West African Soils* (1970), may be mentioned.

Vegetation and animal life: Most works on African vegetation and animal life are regional and do not embrace the whole continent. The best broad summary of vegetation south of the Sahara is R.W.J. KEAY'S annotated *Vegetation Map of Africa South of the Tropic of Cancer* (1959), which gives a highly condensed account. There is no good modern handbook of African mammals as a whole, but GLOVER M. ALLEN, *A Checklist of African Mammals* (1939), is valuable, even if out of date and inaccurate. RICHARD LYDEKKER, *The Game Animals of Africa*, 2nd ed. rev. (1926); P.L. DEKEYSER, *Les Mammifères de l'Afrique noire française*, 2nd ed. (1955); and JEAN DORST and PIERRE DANDELOT, *A Field Guide to the Larger Mammals of Africa*, 2nd ed. (1972), give good accounts of the larger mammal species and are useful as references to historical and contemporary abundance. Bird faunas are discussed in a number of regional textbooks; the most useful are R.D. ETCHECOPAR and FRANCOIS HUE, *Les Oiseaux du Nord de l'Afrique, de la Mer Rouge aux Canaries* (1964; Eng. trans., *The Birds of North Africa, from the Canary Islands to the Red Sea*, 1967); C.W. MACKWORTH-PRAED and C.H.B. GRANT, *African Handbook of Birds*, 6 vol. (1952–73), covering respectively East and northeastern Africa, the southern third of Africa, and west Central and West Africa; and AUSTIN ROBERTS, *The Birds of South Africa*, rev. by G.R. MCLACHLAN and R. LIVERSIDGE, 3rd ed. (1970). R.E. MOREAU, *The Bird Faunas of Africa and Its Islands* (1966); and B.P. HALL and R.E. MOREAU, *An Atlas of Speciation in African Passerine Birds* (1970), are essential for students of distribution. Butterfly distribution has been discussed along the same lines by R.H. CARCASSON, "A Preliminary Survey of the Zoogeography of African Butterflies," *E. Afr. Wildl. J.*, 2:122–157 (1964). S.H. SKAIFE, *African Insect Life*, new ed. rev. by JOHN LEDGER (1979), is a classic. V.F.M. FITZSIMONS, *Snakes of Southern Africa* (1962), is useful to herpetologists. Two general nature histories, approaching fauna from somewhat different standpoints although complementary to one another, are LESLIE BROWN, *Africa: A Natural History* (1965); and ARCHIE CARR and THE EDITORS OF LIFE, *The Land and Wildlife of Africa*.

Natural resources: (*Hydrology*): JEAN ARCHAMBAULT, *Les Eaux souterraines de l'Afrique Occidentale* (1960), a manual for engineers and technicians dealing with the hydrogeological characteristics of West African states of French expression; F. MONIOD, B. POUYARD, and P. SECHET, *Le Bassin du fleuve Volta* (1977), a statistical analysis of the region's hydrology; ROBERT P. AMBROGGI, "Water Under the Sahara," *Scient. Am.*, 214:21–29 (1966); F.M. COSTER, *Underground Water in Tanganyika* (1960). (*Mineral resources*): UNITED STATES BUREAU OF MINES, *Mineral Facts and Problems* (published every five years), is a standard reference work on mineral commodities in the world, and *Mineral Industries of Africa* (1976) provides a concise summary of the mineral industries of each country. Modern mineral maps of Africa include the *Mineral Map of Africa*, 1:10,000,000 (ASGA–UNESCO, 1968) and explanatory note (1969); and S.A. MUSYLEV, *Map of Mineral Resources of Africa*, 1:10,000,000 (Ministry of Geology of the U.S.S.R., 1966) and explanatory note (1970). The ECONOMIC COMMISSION FOR AFRICA (ECA), *Survey of Economic Conditions in Africa, 1960–1964* (1967), and the *Yearly Statistics of Industrial Production;* the INSTITUTE OF GEOLOGICAL SCIENCES, *World Mineral Statistics* (HMSO, annual); MINING JOURNAL, *Mining Annual Review* (annual); UNITED NATIONS, *Statistical Yearbook* (annual); and the UNITED STATES BUREAU OF MINES, *Minerals Yearbook* (annual), are all periodical works describing new developments in exploration, mining, processing, marketing, and technology, together with statistical data about the mining industry throughout the world. General reviews of the mineral resources of the continent may be found in RAYMOND FURON, *Les Resources minérales de l'Afrique*, 2nd ed. (1961); NICOLAS DE KUN, *The Mineral Resources of Africa* (1965); and UNESCO, *A Review of the Natural Resources of the African Continent* (1963). Reports on individual commodities are published and brought up-to-date by many organizations, of which the four following works are good examples: ECA, *East Africa and the Aluminum Industry* (1965); OECD–ENEA, *World Uranium and Thorium Resources* (1965); UNITED NATIONS, *The World Market for Iron Ore* (1968); UNITED STATES BUREAU OF MINES, *Copper: Materials Survey* (1965). In addition, maps for specific commodities are published, such as the ECA–ASGA, *Coal Map of Africa*, 1:10,000,000, 2 sheets and explanatory note (1966); and the ASSOCIATION OF AFRICAN GEOLOGICAL SURVEYS, *Iron Ore Deposits in Africa*, 1:10,000,000 (1970).

Human resources: A.L. ADU, *The Civil Service in Commonwealth Africa: Development and Transition* (1969); K.M. BARBOUR and R.M. PROTHERO (eds.), *Essays on African Population* (1961, reprinted 1975); LEONARD BARNES, *Africa in Eclipse* (1971); E.A. BOATENG, *A Political Geography of Africa* (1978); K.A. BUSIA, *Africa in Search of Democracy* (1967); ROBERT CHAMBERS, *Settlement Schemes in Tropical Africa: A Study of Organizations and Development* (1969); BASIL DAVIDSON, *The Africans: An Entry to Cultural History* (1969), and *The African Genius: An Introduction to African Cultural and Social History* (1969); RUTH FIRST, *The Barrel of a Gun: Political Power in Africa and the Coup d'Etat* (U.S. title, *Power in Africa;* 1970); WALTER FITZGERALD, *Africa: A Social, Economic, and Political Geography of Its Major Regions*, 10th ed. rev. by W.C. BRICE (1967); B.W. HODDER and D.R. HARRIS (eds.), *Africa in Transition: Geographical Essays* (1967); WILFRED KNAPP, *North West Africa: A Political and Economic Survey*, 3rd ed. (1977); ELLIS AYITEY KOMEY and EZEKIEL MPHAHLELE (eds.), *Modern African Stories* (1964); P.C. LLOYD (ed.), *The New Elites of Tropical Africa: Studies Presented and Discussed at the Sixth International African Seminar at the University of Ibadan, Nigeria, July 1964* (1966); P.J.M. MCEWAN (ed.), *Twentieth Century Africa* (1968), and with ROBERT B. SUTCLIFFE (eds.), *The Study of Africa* (1965); W.B. MORGAN and J.C. PUGH, *West Africa* (1969); DAVIDSON NICOL, *Africa: A Subjective View* (1964); W.T.W. MORGAN (ed.), *East Africa: Its Peoples and Resources*, 2nd ed. (1972); JOCELYN MURRAY (ed.), *Cultural Atlas of Africa* (1981); A.M. O'CONNOR, *The Geography of Tropical African Development* (1971); R.S. WASSING, *The Arts of Africa* (1970; U.S. title, *African Art*, 1968). The *African Historical Demography* (1977), published by the CENTRE OF AFRICAN STUDIES, UNIVERSITY OF EDINBURGH, is a collection of essays addressing historical and contemporary demographic issues. The GROUPE DE TRAVAIL DE DEMOGRAPHIE AFRICAINE has issued *Recensements africains* (1980–), with demographic profiles of individual African countries.

Exploration and settlement: SAMUEL WHITE BAKER, *The Albert Nyanza* (1866); HEINRICH BARTH, *Travels and Discoveries in North and Central Africa*, 3 vol. (1857–58, reissued 1965); VERNEY LOVETT CAMERON, *Across Africa* (1877); HUGH CLAPPERTON, *Journal of a Second Expedition into the Interior of Africa* (1829, reprinted 1966); DIXON DENHAM and HUGH CLAPPERTON, *Narrative of Travels and Discoveries in Northern and Central Africa in the Years 1822, 1823, 1824* (1826); ROBERT JAMESON, *Narrative of Discovery and Adventure* (1830); MARY KINGSLEY, *Travels in West Africa* (1897); RICHARD and JOHN LANDER, *Journal of an Expedition to Explore the Course and Termination of the Niger* (1832); DAVID LIVINGSTONE, *The Last Journals of David Livingstone*, 2 vol. (1874, reprinted 1970); MUNGO PARK, *Travels in the Interior Districts of Africa* (1800); JOHN HANNING SPEKE, *Journal of the Discovery of the Source of the Nile* (1863, reissued 1971); HENRY MORTON STANLEY, *How I Found Livingstone* (1872, reissued 1972), and his *Exploration Diaries* (1961)—all narrative accounts of African exploration and travel by the explorers. ANDREW BOYD and PATRICK VAN RENSBURG, *An Atlas of African Affairs* (1962), concise notes on African historical, economic, and political developments; *Africa Contemporary Record* (annual), a survey of political, economic, and social developments; JAMES L. GIBBS (ed.), *Peoples of Africa* (1965; abridged ed. 1978), a good, comprehensive study on sub-Saharan Africa; LEONARD FRANK HOBLEY, *Opening Africa* (1955), a good, concise history of African exploration from early times; HENRY HERSCH HART, *Sea Road to the Indies* (1950), an account of Portuguese voyages to the East Indies; SIR HARRY HAMILTON JOHNSTON, *History of the Colonization of Africa by Alien Races* (1899), a

comprehensive earlier study of the history of colonization in Africa; ALAN MOOREHEAD, *The White Nile*, rev. ed. (1971), and *The Blue Nile*, rev. ed. (1972), together a most absorbing study of the Nile's exploration in the 19th century; HEINRICH SCHIFFERS, *Wilder Erdteil Afrika* (1954; Eng. trans., *The Quest for Africa*, 1957), accounts of 2,000 years of exploration of Africa.

Commerce: UNITED NATIONS, *Yearbook of International Trade Statistics* (annual), a basic document for statistical data on international trade; ECA, *Africa's Trade: Trends, Problems and Policy Issues* (1968), a brief but concise outline of problems of Africa's external trade. The INTERNATIONAL MONETARY FUND publishes *Surveys of African Economies*, with chapters on the economic resources and performance of individual African countries.

Transport: E.W. BOVILL, *The Golden Trade of the Moors*, 2nd ed. rev., with additional material by R. HALLETT (1968), describes the influence of the trans-Saharan trade routes on the peoples north and south of the desert. The IMPERIAL ETHIOPIAN GOVERNMENT HIGHWAY AUTHORITY, *Ethiopia: Progress in Highway Transport* (1967), is a description of the road building and road transport industry in Ethiopia. The AFRICAN DEVELOPMENT BANK, *Survey of African Regional Transport Studies* (1969), is an inventory, covering the period 1960–68, of transport studies that affect more than one African country.

Resource development: UNITED NATIONS, *World Energy Supplies*, Series J, no. 11, 12, and 13 (1968–70); NEVILLE RUBIN and WILLIAM WARREN (eds.), *Dams in Africa* (1968); ECA, *Energy Development in the Countries of the East African Sub-Region* (1965), *Energy Development in the Countries of the West African Sub-Region* (1966), and *Energy Development in the Countries of the Central African Sub-Region* (1967).

Demographic patterns: ECA, *Demographic Handbook for Africa* (1975), is a comprehensive volume containing data and analysis of demographic levels and trends. See also the UNITED NATIONS, *Demographic Yearbook* (annual), and *World Population Prospects As Assessed in 1980* (1981), which contains population projections and projections of mortality and fertility trends; ECA, *Size and Growth of Urban Population in Africa* (1968), which assesses levels and trends of urbanization in the different African countries and subregions; *Europa Yearbook*, containing the latest population estimates of African cities and towns; and the publications of the French Institut National de la Statistique et des Etudes Economiques, a major source for data on French-speaking African countries. Other works include JOHN C. CALDWELL and C. OKONJO (eds.), *The Population of Tropical Africa* (1968), a compilation of papers presented at a conference in Ibadan, Nigeria in 1966; WILLIAM A. HANCE, *Population, Migration, and Urbanization in Africa* (1970); and WILLIAM BRASS *et al.*, *The Demography of Tropical Africa* (1968), a comprehensive volume analyzing demographic data.

African Languages

Although no definitive count exists, the number of separate and distinct African languages, as estimated by various authorities, ranges from 800 to more than 1,000. Thus, Africa is unquestionably the world's most polyglot continent. The linguistically most homogeneous area of Africa is the northern part, in which Arabic predominates from Egypt to Mauretania, albeit in a number of sharply distinguished dialects. The most important dialect cleavage is between the Egyptian–Sudanese varieties and those of the Maghrib (from Libya westward). Intermingled with the Maghrib dialects are the Berber languages, concentrated principally in Algeria and Morocco. They range as far east as the Siwa Oasis in western Egypt, as far west as the Senegalese–Mauretanian border area, and as far south as the southern rim of the Sahara. The nomadic Tuaregs speak a Berber language. Nubian, a totally different language, is spoken as far north as southern Egypt along the Nile, but its links are clearly with the languages of sub-Saharan Africa.

Sub-Saharan languages

In sub-Saharan Africa the linguistic picture is far more complex. Except for the Khoisan (Bushman and Hottentot) languages of the extreme south, approximately the entire southern third of Africa is occupied by the relatively closely interrelated Bantu languages. They extend eastward from roughly the Nigerian–Cameroon border to the Indian Ocean. Bantu and non-Bantu languages are considerably interspersed around the northern Bantu border, running through Cameroon, slightly south of the northern boundary of Zaire, and through Uganda and Kenya. There are Bantu enclaves as far north as Somalia and non-Bantu enclaves in northern Tanzania. It is the area north of the Bantu and south of the Sahara that is linguistically the most diverse; there the languages are most numerous and their interrelationships most remote and difficult to establish with certainty.

This article is divided into the following sections:

I. General considerations
  Language classification
  Similarities and correlations
    Common features of the African languages
    Linguistic, racial, and cultural interrelations
II. Niger-Congo languages
  Classification
    West Atlantic subgroup
    Mande subgroup
    Voltaic (Gur) subgroup
    Kwa subgroup
    Adamawa-Eastern subgroup
    Benue-Congo subgroup
  Adoption of foreign words and sounds
III. Chari-Nile and Nilo-Saharan languages
  Classification
    The larger Nilo-Saharan group
    Languages of the Chari-Nile group
    Controversies concerning classification
  Linguistic characteristics
    Phonology
    Grammar
    Writing
IV. Khoisan languages
  Classification
  Linguistic characteristics
    Phonology
    Grammar
    Vocabulary
    Writing and texts

I. General considerations

Because probably not more than 30 African languages have more than 1,000,000 native speakers, a number of lingua francas have developed in various areas as a means of coping with this enormous linguistic diversity. Arabic, in addition to having the largest number of native speakers of any language of the continent, is sometimes used as a lingua franca, in its literary form by educated non-Arab Muslims, and in a number of colloquial varieties by much of the non-Arab population of The Sudan and Chad. Swahili, a Bantu language heavily influenced by Arabic, is official in Tanzania and Kenya and is used as a lingua franca throughout most of East Africa including eastern Congo. Other important lingua francas include Lingala, also a Bantu language, in western Congo; Fanagalo (vulgarly known as "kitchen Kaffir" or "mine Kaffir"), a pidginized form of Zulu with many English and Afrikaans loanwords, in South Africa, particularly in the mines; and Sango, a pidginized form of Ngbandi (included in the Adamwa-Eastern subdivision of Niger-Congo by some scholars) with many French loanwords, spoken in the Central African Republic.

African lingua francas

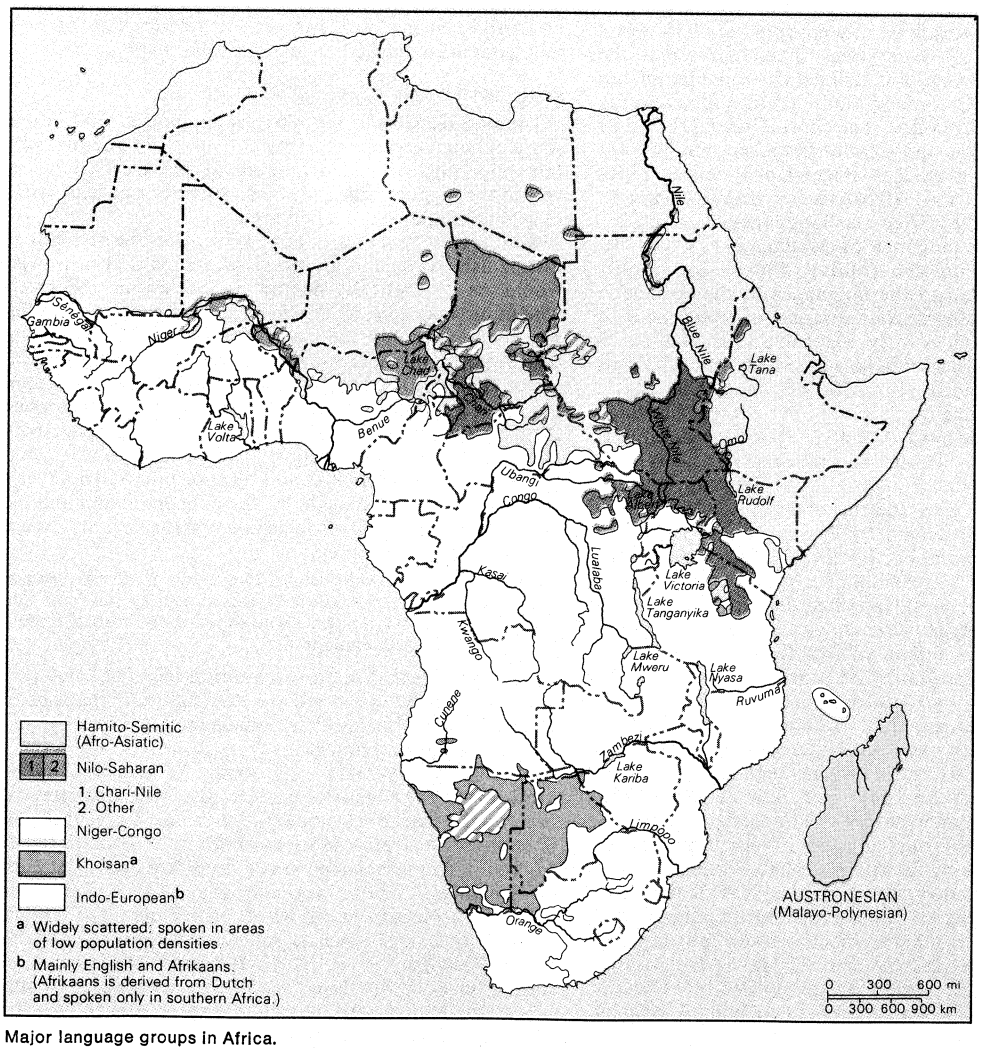
In addition, there are Bambara-Maninka, a Mande language used in Mali, Guinea, and Ivory Coast; Hausa, spoken in northern Nigeria and neighbouring areas; Amharic, used throughout Ethiopia, where it is the official language; Wolof, the language of Dakar, widely spoken throughout Senegal and The Gambia; and Kongo (Kikongo), a Bantu language that is used in the area of the mouth of the Congo River and is also spoken in a pidginized variety known as Kituba.

Standard European languages, particularly English and French and, to a lesser extent, Portuguese and Italian, also serve as lingua francas, generally among the better educated, in areas in which they are or were the colonial languages and where they enjoy or have enjoyed official status. Localized varieties of European languages are also spoken in numerous parts of Africa, such as Pidgin English, a widely used lingua franca of Cameroon and West Africa; Krio, a creolized form of English, which differs slightly from Pidgin English and is used by the local population of Freetown, Sierra Leone; a variety of forms of Creole Portuguese, which are spoken in Cape Verde,

the islands of São Tomé and Príncipe, and Portuguese Guinea; and Afrikaans, an outgrowth of Dutch, which serves along with English as an official language of South Africa.

LANGUAGE CLASSIFICATION

Early attempts at classification



Although word lists of a number of sub-Saharan languages were recorded by Europeans as early as the 15th and 16th centuries, and the first grammar of a sub-Saharan language (Kongo) was published in 1659, extensive study of African languages and systematic attempts at grouping and classifying them did not begin until the 19th century. In 1854 Sigismund Koelle, a missionary living in Freetown, Sierra Leone, was able to collect substantial word lists of roughly 150 languages, principally of West Africa but also including some belonging to the Bantu family. He established 11 groups, leaving approximately 40 languages unclassified. His groups are generally small, rarely exceeding 15 members, and he made no systematic attempt to explore wider relationships. He laid the groundwork for establishing the Mande family, which has been universally accepted ever since. (The term "family" is used loosely in this article, sometimes referring to large groupings of languages and sometimes referring to subgroups or branches of these groupings. Niger-Congo, for example, is usually called a language family, but its subgroups [*e.g.*, Mande] and its sub-subgroups [*e.g.*, Bantu] are often referred to as families as well.)

The unity of the Bantu family, although suggested by a number of earlier writers, was first established in 1862 by the German scholar Wilhelm Bleek, who gave it its name, the word for "people" in most languages of the family. During approximately the same period, the work of several scholars suggested that Ancient Egyptian, the Berber languages, certain languages of northeastern Africa called Cushitic (*e.g.*, Galla, Somali, Beja, and Afar [Danakil]), and perhaps others (*e.g.*, Hausa) were remotely related to one another and to the Semitic family. These languages were called Hamitic at the suggestion of a French Semitist, Ernest Renan, who was also the first to propose the name Cushitic, because the peoples speaking these languages coincided roughly with the descendants of Ham (one of whom was Cush), according to the biblical account in Genesis, just as the people speaking the Semitic languages coincided with the descendants of Shem (Sem).

The first attempts at an overall classification of African languages were those made by the Austrian linguist Friedrich Müller in 1876–88 and by the German Egyptologist Karl Richard Lepsius in 1880. Müller, who classified all the world's languages on the basis of a correlation of linguistic and racial groupings (the latter determined largely by hair type), set up the following divisions within Africa: (1) Bushman-Hottentot, as a subdivision of the languages of the tufted-haired peoples (the Papuan languages of New Guinea formed the other subdivision); (2) Bantu and (3) Negro, both subdivisions of the languages of the fleece-haired (*vliesshaarig*) peoples; (4) Hamitic, (5) Semitic, and (6) Nuba-Fulah, all three subdivisions of the languages of the wavy-haired (*lockenhaarig*) peoples. Linguistically, Nuba-Fulah was completely heterogeneous and was abandoned by later scholars.

Lepsius' classification

Lepsius proposed an alternative classification of the languages and peoples of Africa, of which the three major divisions were (1) Semitic; (2) Hamitic, including Hausa, which he grouped with the Berber or Libyan branch, and Hottentot, neither of which had been classed as Hamitic

Major language groups in Africa.

by Müller; and (3) the Negro languages, consisting of two subdivisions, Bantu and Mixed Negro, composed of many subgroups, and containing all the indigenous languages of Africa not included in the other divisions.

During the early part of the 20th century, a revision of this classification emerged from the work of the two leading German Africanists, Carl Meinhof and Dietrich Westermann. Meinhof added a number of languages to Lepsius' Hamitic grouping, namely Fulani, a major West African language, and a group of East African languages, including Masai and Bari. Westermann attempted to show the unity of virtually all the non-Bantu, non-Hamitic, and non-Semitic languages of Africa; he designated them Sudanic. Thus, a threefold division was established: Bantu, Hamitic, and Sudanic. The Bushman languages of southern Africa were sometimes treated as a separate group and sometimes linked with Sudanic, and Semitic was generally linked to Hamitic, though not included within it. Not everyone accepted this classification. French scholars, in particular Maurice Delafosse and Lilias Homburger, restricted Hamitic to Ancient Egyptian, the Berber languages of North Africa, and the more heterogeneous Cushitic group of languages of northeastern Africa. They connected Hottentot with the Bushman languages while grouping the other languages classed by Meinhof as Hamitic in the very general Negro-African or Sudano-Guinean family, to which they also believed the Bantu languages to be affiliated.

Westermann himself revised his views of the earlier classification scheme and came to regard the great majority of the languages of West Africa (*i.e.*, the Western Sudanic languages) as more closely related to Bantu than to the languages farther east, previously regarded as Sudanic. Sir Harry Johnston, a British Africanist, likewise pointed out similarities between Bantu and many West African languages that he termed Semi-Bantu.

Joseph Greenberg's classifications

No single scheme was generally accepted in 1955, when Joseph Greenberg, a United States linguist, presented the earlier version of his major classification of the languages of Africa. In 1963, Greenberg made public a substantially revised version of his work that consolidated previously unclassified languages and smaller language families into four large linguistic stocks—Niger-Kordofanian, Nilo-Saharan, Khoisan, and Afro-Asiatic (Hamito-Semitic). They included all the indigenous languages of Africa except Malagasy, the language of Madagascar, which belongs to the Austronesian (Malayo-Polynesian) family and is thus unrelated to the languages of the continent. The Niger-Kordofanian group consists of two branches, Niger-Congo, which is very extensive, and the much smaller Kordofanian group, so named because all of its members are located in Kurdufān province, The Sudan. Kordofanian contains a number of subgroups, of which Kadugli-Korongo is most distantly related to the others. In fact, its inclusion within the group is open to serious question. Niger-Congo consists of Westermann's Western Sudanic group plus Bantu, whose interrelationship had earlier been advocated by Westermann. Greenberg differed from Westermann, however, in that he treated Bantu as a subgroup of one of the branches of Western Sudanic rather than an independent unit related to Western Sudanic as a whole. Greenberg also argued strongly for the inclusion of Fulani in this family. (Fulani had been regarded as Hamitic by Meinhof, but some French scholars had already advocated its relationship to other West African languages, such as Serer of Senegal.) Furthermore, Greenberg extended Niger-Congo eastward to include languages of Central Africa, such as Ngbandi of the Central African Republic and Azande (Zande) of Zaire, with which Westermann had not dealt.

The Nilo-Saharan group consists of six branches, of which Chari-Nile is by far the most heterogeneous. This family is the least adequately substantiated of the four. The Khoisan languages comprise the Bushman and Hottentot languages of southern Africa and two languages of Tanzania, Sandawe and Hadza (Hatsa). Afro-Asiatic, which is Greenberg's name for Hamito-Semitic, consists of five branches: (1) Semitic, represented in Africa by Arabic and the Ethiopic languages, of which the most important are Amharic, the official language of Ethiopia; Tigrinya, the predominant language of Eritrea; and Ge'ez, the liturgical language of the Ethiopian Church, which is no longer spoken; (2) Ancient Egyptian and its daughter language, Coptic, now extinct; (3) the Berber languages of northern Africa, including Kabyle of Algeria, Riffian and Shluh (Shilha) of Morocco, and Tuareg, or Tamashek, of the Sahara; (4) the extensive and diversified Cushitic group of northeastern Africa, whose most important members are Somali and Galla; (5) Chadic, spoken in Chad, Cameroon, and northern Nigeria, although Hausa, its best known and most widely spoken member, is used throughout much of West Africa.

Branches of Afro-Asiatic (Hamito-Semitic)

Hamito-Semitic languages also are spoken in the Middle East. For this reason, they will be treated in a separate article (see HAMITO-SEMITIC LANGUAGES).

Because of the inexact nature of the procedures for establishing genetic classification and also because of incomplete data on the majority of African tongues, differences of opinion exist on various aspects of Greenberg's classification. Some scholars, such as the Hungarian linguist István Fodor and the English Bantuist Malcolm Guthrie, insist that genetic interrelationship of a group of languages can be established only by demonstrating regular phonological correspondences among them, as have been shown among the Bantu languages, for example. Greenberg and his supporters, however, maintain that similarities in both sound and meaning between two or more languages, which are too numerous to be dismissed as mere coincidence and are found in that part of language least susceptible to borrowing (*e.g.*, grammatical elements, body parts and functions, common natural objects and phenomena, and lower numerals), must be attributed to genetic relationship. Nevertheless, there are no rigorous procedures for determining how similar two items must be in sound and meaning to be considered evidence for genetic relationship or how many items are needed to rule out other explanations.

SIMILARITIES AND CORRELATIONS

Common features of the African languages. Although African languages are extremely diverse in structure, certain phonological and grammatical features are widespread throughout much of the continent or at least within extensive and well-defined areas.

Tones and clicks

Phonological features. Tone—*i.e.*, the use of pitch to distinguish words and grammatical forms that otherwise would be phonetically identical—occurs in the overwhelming majority of sub-Saharan languages. The famous click sounds are largely restricted to two language groups of southern Africa: the Bushman and Hottentot (Khoisan) languages and the southern Bantu languages (*e.g.*, Zulu, Xhosa, and Sotho), which borrowed them from the Bushman- and Hottentot-speaking peoples. Clicks are also common to three East African languages, Sandawe, Hadza, and Sanye, but nowhere else on the continent or outside it. The consonants *kp* and *gb*, called coarticulated labiovelar consonants, are, in Greenberg's words,

> distributed over a wide belt of languages of diverse genetic affiliations from the Atlantic Ocean almost to the Nile Valley. Outside of Africa these sounds are only known from a restricted area of Melanesia. . . .

Other phonological features common in Africa but rare in the rest of the world are word-initial combinations of a nasal sound plus another consonant (*e.g.*, *mb* or *nd*), and implosive consonants.

Grammatical features. In some African languages, words generally consist of a root only, with grammatical affixes rare and even nonexistent in a few languages. These are often referred to as isolating languages. Other African languages have words that are composed of many elements. Those languages are subdivided into the agglutinative languages (in which each element of a word has a distinct and separate meaning and form) and inflectional languages (in which the various elements of meaning may be fused into such forms as prefixes or suffixes or the entire word may change internally to indicate grammatical relationships).

In some of these languages, a single word might be equivalent to a whole sentence in English or other European languages. Thus, in Swahili, a Bantu language, "we will not hit him" is expressed in a single word, *hatutampiga*, in which *ha* is the negative marker, *tu* the verb subject "we," *ta* the future-tense marker, *m* the verb object "him," and *piga* the verb "hit." The verb likewise may undergo modifications in meaning through the addition of suffixes; thus *pigwa* means "(to) be hit," and *pigana* "(to) hit one another."

Noun classes and gender

A widespread feature among African languages employing words composed of more than one element is a system of noun classes (see below *Benue-Congo subgroup*), particularly marked in the Bantu family but also occurring in a wide variety of West African languages, as well as in certain languages of Kurdufān province, The Sudan. All of these languages have been grouped by Greenberg in his Niger-Kordofanian family, although others in this family lack this feature altogether.

Grammatical sex gender is not nearly as widespread as noun classes. It is characteristic of the Semitic and Hamitic languages (although lacking in some members of the Chadic branch) and of other languages such as Hottentot and the closely related Naron Bushman language of South Africa and of the much more distantly related Sandawe and Hadza languages of Tanzania. Gender is likewise found in East Nilotic but not South Nilotic (these two comprise what was earlier known as "Nilo-Hamitic") or West Nilotic (previously known simply as Nilotic). Gender plays an even more restricted role in other African languages, such as Bongo, a language of the southwestern Sudan in which different pronouns are used for masculine and feminine 3rd person singular. The great majority of African languages, however, do not make this distinction, but many of them do distinguish between animate and inanimate personal pronouns.

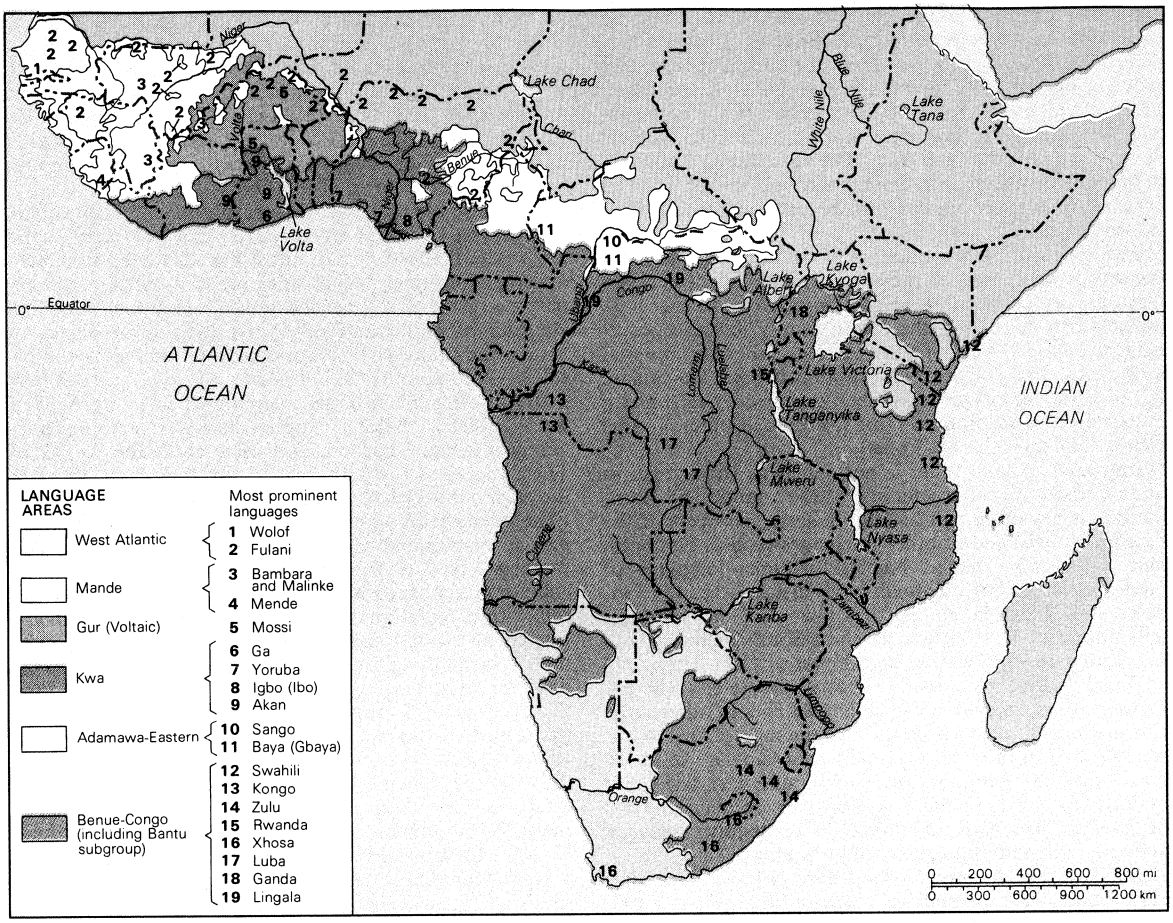
Linguistic, racial, and cultural interrelations. It is difficult to find strict correlations between linguistic, cultural, and racial groupings, either in Africa or elsewhere in the world. Groups speaking identical or closely related languages may be strikingly different racially, culturally, or both; while groups that are very similar racially and culturally may speak different and even unrelated languages. Thus the Damara (or Bergdama) of South West Africa, who speak the language of the Nama Hottentot, are sharply distinguished from the latter both racially and culturally. The Damara have much darker pigmentation and other more Negroid physical features and are predominantly nonpastoralists. Likewise, the Arusha of northern Tanzania, who speak the language of the pastoralist Masai, are horticultural (*i.e.*, agricultural without use of the plow). On the other hand, the forest-dwelling Pygmies, who are spread over much of central Africa, form a distinct racial and cultural group and are exclusively hunters and food-gatherers, yet they have no distinctive language. Instead, they speak the languages of their various neighbours, such as Bantu, Moru-Mangbetu (grouped by Greenberg in the Central Sudanic branch of Chari-Nile), and reportedly Sere-Mundu (grouped by Greenberg in the Adamawa-Eastern branch of Niger-Congo).

Broad correlations between race, language, culture

Some broad correlations can nevertheless be made between language groupings and the variables of race and culture, as long as these are not interpreted too rigidly. The Bushmen of southern Africa form a distinct racial, cultural, and linguistic group, and, though the Hottentot are akin to them linguistically and racially, they show important cultural differences, most notably that the Hottentot are pastoralists, not hunters and gatherers. The Berber-speaking peoples of North Africa likewise form a relatively homogeneous racial, cultural, and linguistic group; they are Caucasoid and pursue a mixed agricultural and pastoral way of life. Only the Sahara-dwelling Tuareg are exclusively pastoral nomads and caravaners. The Cushitic peoples of northeastern Africa, who like the Berbers speak languages of the Hamito-Semitic family, represent varying degrees of Caucasoid and Negroid elements. Some of the more prominent among them, such as the Beja or Bedawiye of The Sudan and the Saho-Afar and Somali of the Horn, are nomadic pastoralists. The Galla of southern Ethiopia, the most numerous of all Cushitic peoples, include some pure pastoralists, but the great majority practice agriculture and husbandry. Their neighbours to the north, the Agau of central Ethiopia, do likewise, though they have largely assimilated culturally to their other Semitic-speaking neighbours, while retaining their Cushitic form of speech.

The unusually tall and slender Nilotes of The Sudan, such as the Dinka and Nuer, are sometimes considered a subrace of the Negroid; but it has also been suggested that their physical peculiarities are at least to some extent the result of differences in diet rather than heredity. Herding of cattle and other livestock is predominant among the majority of Nilotic peoples (including the so-called "Nilo-Hamites"), but nearly all practice some horticulture, with the striking exception of certain groups of Masai. Certain Nilotic peoples, however, are predominantly sedentary horticulturalists, such as the Anuak of The Sudan and the Luo, principally in Kenya, who are the most numerous of the Nilotic peoples.

The overwhelming majority of the Bantu and the peoples of western and central Africa are sedentary horticulturalists. Likewise, most of these peoples belong linguistically to Greenberg's Niger-Congo family, although some fall within Nilo-Saharan, and others within the Chadic branch of Hamito-Semitic; furthermore, they comprise the overwhelming majority of the Negro race, which, however, is no more homogeneous a physical group than the peoples of Europe. The most important group of pastoralists in West Africa are the cattle-herding Fulani, who are widely distributed over the savanna belt just south of the Sahara. They are physically as well as culturally distinct from their neighbours, but linguistically their closest affinities are with the sedentary horticultural Negroes of Senegal. Cattle raising likewise plays an important role among certain Bantu peoples of eastern and southern Africa, such as the Ganda, Nkole (Ankole), Sotho, and Nguni peoples. Among some of the East African Bantu (*e.g.*, the Nkole, Rwanda, and Rundi) cattle ownership has been the prerogative of a privileged group probably of Nilotic origin and known by various names, such as Hima (Panda) and Tutsi; these people are physically and culturally distinct from their agricultural neighbours, although totally assimilated to them linguistically.



(M.F.Go.)

II. Niger-Congo languages

The Niger-Congo family is the largest family of languages in sub-Saharan Africa, with 890 known member languages. All are considered to be distinct languages and not dialects. The named dialects of these languages number in the many thousands; if the variant names for the same language or for the same dialect are to be counted, the figure must be further expanded. For example, for Swahili, there are 17 named separate dialects, 15 additional variant names for some of the dialects, and at least four "nicknames" for popularized or debased forms of the language.

The classification of such a large and diverse family was first accomplished in 1949 by Joseph Greenberg, who demonstrated the genetic unity of this group on the basis of an examination of documentation of all the languages of Africa. The primary sources for such a massive comparison consist of published descriptions or vocabularies of tribal languages made by missionaries or colonial officers; these were written in European languages because practically none of the African languages had any written tradition of their own. Usable documents stretch back for only about 125 years, and there are still indigenous languages that either have not been reported at all or lack sufficient detail or accessibility to be included in any final count of Niger-Congo languages. Thus the figure given here may have to be revised upward, especially as there is no evidence that the indigenous languages of sub-Saharan Africa are dying out. On the contrary, of a list of such languages collected in the mid-19th century, only one is known to have become extinct.

The area in which the Niger-Congo languages are

Distribution of the Niger-Congo languages.

Location of the Niger-Congo languages

spoken is fairly easily demarcated (see map) and includes the entire sweep of sub-Saharan Africa with the exception of the Horn of Ethiopia. All indigenous peoples of sub-Saharan Africa west of the Nile are speakers of Niger-Congo languages with the exception of a few to the extreme south (Bushman–Hottentot peoples) and a more substantial number along the northern rim of the area (speakers of Chadic or Nilo-Saharan languages).

A conservative estimate of the total number of speakers of Niger-Congo languages is 181,000,000. Such a figure is obtained by adding the populations (as of the middle 1960s) of the 32 countries of tropical and southern Africa and then subtracting the number of European and Asian speakers reported for South Africa. (It is assumed that the number of speakers of Niger-Congo languages in the countries to the north of the tropical belt omitted by this method—especially in Mali and Upper Volta—would be balanced out by the number of indigenous non-Niger-Congo speakers enumerated in the included populations—especially in Nigeria and Uganda.)

Table 1: Niger–Congo Languages with More Than Three Million Speakers

	subgroup	estimated number of speakers*
Fulani (Fulbe)	West Atlantic	7,360,000
Malinke (Mandingo), *et al.*	Mande	3,010,000
Mossi	Voltaic (Gur)	3,800,000
Yoruba	Kwa	6,580,000
Igbo (Ibo)	Kwa	6,430,000
Akan group	Kwa	3,300,000
Rwanda (Banyaruanda)	Benue–Congo	4,880,000
Kossi (Kosa)	Benue–Congo	3,470,000
Makua	Benue–Congo	3,460,000
Zulu	Benue–Congo	3,110,000

*Figures rounded off to the nearest 10,000.

CLASSIFICATION

The Niger-Congo family is divided into six genetic subgroups. Viewed on a geographical continuum from northwest to southeast, these are:

1. West Atlantic, 43 languages
2. Mande, 26 languages
3. Voltaic (Gur), 79 languages
4. Kwa, 73 languages
5. Adamawa-Eastern, 112 languages
6. Benue-Congo, 557 languages

This subclassification results from very fundamental and very old divisions in the language family, and each subgroup represents the results of separate developments that can be estimated to be about 5,000 to 10,000 years old at the least. Obviously, such a deep division has yielded widely separated languages—separate not only in geographic distribution but in elements of the sound systems, grammars, and vocabularies as well. It is surely safe to say that there is no one feature common to the entire group and that the recognition of their relationship depends upon a truly global view of the evolution of a few separate ancestral languages into the thousands of descendant languages spoken throughout the world today. Because this linguistic evolution is neither random nor chaotic, it is possible by means of a very careful plotting of common clusters of features to establish the approximate degrees of relationship even when neither the intermediate nor earliest stages of the protolanguages concerned have been reconstructed. Greenberg used this method to include the nearest relatives of the Niger-Congo languages with them in a superfamily that he designates as "Niger-Kordofanian." This grouping contains two branches: all the languages here considered, namely the Niger-Congo family, and a coordinate branch of the Kordofanian family of languages, spoken in the Nuba Hills (Jibāl an-Nūbah) of Kurdufān province, The Sudan.

Niger-Kordofanian

West Atlantic subgroup. The centre of gravity of the 43 West Atlantic languages would seem to lie in the Senegal–Guinea area, in which are found the two most important languages—Wolof and Fulani (the latter also

known as Fulbe, Fula, and Peul). The area is also the locus of the great majority of the other languages. Fulani, the language of a highly mobile pastoralist people numbering as many as 6,000,000, is also found in a scattered distribution as far east as Chad. The immense extension of this language and its association with cattle and Islām led earlier researchers to give it a special place outside the other West Atlantic languages—in fact, outside what is now recognized as Niger-Congo. It was first isolated in 1883 by an Englishman, Robert Needham Cust, who based his work on that of Friedrich Müller, an Austrian linguist. The German Karl Richard Lepsius classified it as one of the "mixed Negro" languages not fully sub-Saharan or Bantu (1880). Subsequently, it was included as a "Hamitic" language in the German Africanist Carl Meinhof's influential classification (1912), which was adopted by many scholars writing in English.

A feature of Fulani that is shared systematically with some of the other West Atlantic languages is an "alternation" whereby both the beginnings and the endings of words go through parallel changes according to grammatical considerations. This feature is found in its greatest elaboration only in Fulani; it is represented in either vestigial or undeveloped form in most of the other West Atlantic languages. This fact made Fulani appear more different from the others than it actually is and contributed to its misclassification. It is of interest to speculate why this most "vigorous" of the West Atlantic languages should be the most difficult or complex in its grammatical system. ("Vigorous" is used here in the sense that it has several millions of speakers, and also in the sense that it is associated with a dynamic expansionism). By comparison, Latin indicated grammatical case, gender, and number only by the endings of words, and English has virtually eliminated case and gender and has largely simplified number to a single suffix.

Bambara and Mende languages

Mande subgroup. The Mande subgroup includes 26 languages, of which the most prominent are Bambara of the Mali–Guinea area and Mende of Sierra Leone. In contrast to the classification of the West Atlantic subgroup, there has been little doubt as to the identification of the languages in the Mande subgroup. This certainty results from the subgrouping conforming closely to the "classic" expectation of language differentiation, in which a small number of contemporary languages are clearly seen to share a number of striking features not found elsewhere. Such features presumably provide evidence of early segregation of the ancestor language of the subgroup and of a continued effective isolation. Examples of such key features in the Mande languages are the systematic distinction between free and dependent nouns (see below) and the form and use of numerals.

As would be expected, however, the results of a longer period of independent development have also deflected the attention of many researchers to the differences of Mande from the Niger-Congo group—*i.e.*, to the common negative evidence of relationship with the rest of the Niger-Congo family. This negative evidence led Maurice Delafosse, in 1924, to propose two criteria for the identification of this subgroup: (1) a complete absence of the noun-class system that characterizes other West African languages and (2) a complete absence of tonal contrasts. Investigators who view Mande languages in terms appropriate to the group itself have shown that this is a prejudiced view and that a more positive formulation of these criteria is possible. Such a restatement would run somewhat as follows: (1) Instead of the particular distinctions among nouns reflected in the grammatical classes of the other subgroups of Niger-Congo, the Mande subgroup has elaborated a grammatical distinction between free and dependent nouns—nouns referring to "alienable" or "transferable" possessions, as opposed to "inalienable" possessions such as kinsmen or parts of the body. (2) The role of tone is tied to features other than those of semantic reference (*i.e.*, the meaning of the word taken in isolation).

Whereas Chinese and other tone languages use changes of pitch to distinguish meaning in words with the same configuration of consonants and vowels (when pronounced by themselves), the Mande languages reveal a different use of tone, one that also differs from practically all the other Niger-Congo languages. In the Mande languages, a difference in meaning based on tone seems to demand a contrast of complete utterances, which are usually made up of more than one word. This contrast of entire utterances places Mande at one end of a continuum of distinctions based on tone, because linguists are still finding many variations in the situation of "meaningful semantic tone" or "contrastive tone patterns in isolation" that seem to demand some sort of context in order to be operative. In this respect, it is of interest that most of the differences in meaning between complete utterances that are identical except for tone in the Mande languages are more of a grammatical nature than of a semantic one. It must be stressed, however, that the Mande languages *are* tone languages and that the contrasts so produced are discrete and absolute and thus not of the "sliding" nature of speech melody. In form, they are closer to the question intonation of English, but in function they perform grammatical work internal to the sentence rather than coextensive with it.

Role of tone in the Mande languages

It is striking that several independent writing systems based on the syllable (which is the unit that bears the tone) have been reported for Mande languages. The best known of these is the one devised for the Vai language, although Mende, Toma (Loma), and Kpelle also have indigenous syllabic writing systems. This type of writing is somewhat reminiscent of the writing system of Chinese (in which the syllable is often both the tone-bearing unit and the meaning-bearing unit) and of Cherokee, an American Indian language.

Voltaic (Gur) subgroup. The Voltaic (Gur) subgroup includes 79 languages spoken in Upper Volta and the upper halves of Ghana and Ivory Coast. Mossi is the most prominent of them. The term Gur was used as early as 1886 to designate the languages centred around Ouagadougou in what is now Upper Volta and northern Ghana. Languages with such names as Gurma or Grunshi (Gurunsi) were later related, and the first syllable of the names was taken as a name for the group. In 1911 Delafosse used the designation "Voltaic" for the same group, probably because many of the Gur languages are spoken in the Volta River Basin.

The study of the Voltaic languages as a group is important because they do not partake strongly of any entrenched typological or grammatical "manifestations" (such as the "manifestations" of sex gender distinctions in Indo-European, triconsonantal roots in Semitic, and so on). A wide range of possibilities is present, and, if any "manifestation" is at all apparent, it is a tendency toward simplification and serial constructions. This means that there are a very small number of closed grammatical classes and a greater reliance on constructional markers. Nevertheless, it is important, when considering any of the 1,000 or more languages surveyed in this article, to emphasize that each language within the subgroup is also important for its own sake. Each language reveals a particular way of communicating about the world, a way that is fully developed and elaborated in its own terms. These spoken languages are certainly not "underdeveloped" or primitive. In fact, the very complexity of analyzing the Voltaic languages (or any other group of natural languages) in terms and categories sufficiently "universal" to be operational both for those who already speak the languages and those who want to learn something about them reflects their developed nature.

Typological significance of the Voltaic languages

The most widely known characteristic of the Voltaic (Gur) languages is the realization of the Niger-Congo noun classes in the shape of parallel prefixes and suffixes, in which the suffixes appear to be dominant. In languages like Mõõre and Dagbane, for instance, nouns for a "person" end with the suffix *-a* (*-u* in Kasem), which is replaced by *-ba* in the plural. This feature is somewhat reminiscent of Fulani of the West Atlantic subgroup but differs in that it typically appears in the form of separable syllables in the Voltaic languages, rather than as an alternation or mutation of the beginning and ending consonants of the root itself, as in Fulani. The partial classifi-

cation of human beings, animals, and liquids into separate grammatical classes provides evidence for the original nature of such classes in the ancestral Niger-Congo language. So does the fact that this classification governs the participation of variant forms of the detachable suffixes (or suffix–prefix frames) in sentence constructions calling for pronoun-like behaviour—referential, possessive, demonstrative, relative, and so on. Thus, Bargu has the suffix *-a* for the "person" class, a suffix that always "governs" the occurrence of *yé* as independent pronoun, *yù* as object marker, and *yè* as one demonstrative.

Ga, Yoruba, Igbo: prominent Kwa tongues

Kwa subgroup. The Kwa subgroup includes 73 languages, many of which are prominent (*e.g.*, Ga, Yoruba, Igbo). This grouping includes some of the most well known of the Niger-Congo languages and some with the greatest number of speakers. The Kwa languages are spoken in the belt of tropical forest through the southern section of the West African bulge. They are the languages of the former great kingdoms of tropical West Africa, such as Ashanti (Akan or Twi language), Dahomey (Ewe), Oyo (Yoruba), and Benin (Bini language). In addition, the large decentralized group of Ibo (Igbo) also speak a Kwa language. Each of these languages has millions of speakers and a growing written literature, and one of them, Yoruba, boasts the earliest published dictionary and grammar written by a native speaker. It is symptomatic of the position of these languages in modern life, however, that these Yoruba works were written in English by an African Anglican churchman, Bishop Samuel Crowther. English or French remains the national language of the countries in which Kwa languages are spoken, and interest in employing the local languages is largely restricted to religious or academic institutions based on European models.

Like the Voltaic subgroup, the Kwa languages are diverse in their structure and characteristic features, and examples of this diversity are found in the roles of tone and vowel harmony. The continuum from clear tones in isolated dictionary citations to modification in sentence context referred to in connection with the Mande languages is particularly striking in the Kwa languages. Thus, some investigators heard consistent pitch levels that could be noted on a musical staff for any one speaker (in at least one Kwa language, Grebo of Liberia, there are four such levels). Others, such as those investigating Akan, heard just as clearly that there is a complicated system of pitches that are varied according to transitions between syllables or interrelations among syllables. It is as yet unclear just which, if either, of these systems is historically earlier: whether the clear tone levels are a crystallization of the distinctions imposed by contextual reactions with other tones or whether the languages that have almost lost all independent lexical tone are a newer reinterpretation of a previous system of fixed pitches.

Vowel harmony in the Kwa tongues

Vowel harmony involves a system of mutual selection or restriction among the vowels that can go into the makeup of a word. The vowels in a word are said to be in "harmony," with high vowels usually occurring with high vowels, front vowels with other front vowels, and so forth, in such a way that a constant feature seems to be realized throughout the word. Vowel harmony of a type peculiar to sub-Saharan languages is called "cross-height" vowel harmony by the British scholar John M. Stewart. In this situation, the higher of two varieties of a vowel selects the matching higher variety of another vowel and vice versa. Thus, *u* (as in "rule") would occur with *o* (as in "bone"), and the lower sound ʊ (as in "pull") with the correspondingly lower ɔ (as in "law"). Stewart also summarized evidence for contrast in the formation of the sounds in terms of the advancement of the root of the tongue. Under conditions of change of a vowel system, this leads to reinterpretations that cloud the nature of earlier contrasts and add to the variety found in the Kwa languages.

It is very difficult to provide a generalized "profile" of the Kwa languages that would give an idea of what is typical of a language of this subgroup. A stereotype would be that the words are mostly short and the nouns begin with vowels. Proper names often appear to be quite long, however, because they are compounds or phrases made up of several words. Many words of Kwa origin are found in the Americas, as is the pantheon of Yoruba gods in South America and the Caribbean.

Adamawa-Eastern subgroup. The Adamawa-Eastern subgroup comprises 112 languages spoken in the Central African Republic and northern parts of Cameroon and Zaire. These geographically remote languages are the least known of the Niger-Congo family. The subgroup's most prominent members are Sango and Baya (Gbaya). The name Adamawa-Eastern implies a combination of two recognized sub-subgroups: Anamawa and Eastern. None of the language names of this subgroup is well-known to outsiders, with the possible exceptions of the ethnographically noted Azande (Zande) and the trade language Sango.

Sango is clearly simplified from a dialect of one of the Adamawa-Eastern languages. It shows the result of contact with French as well as the usage of many river tribes in trade along the Ubangi River. It is the lingua franca of the Central African Republic and is extremely widespread as a second language in Central Africa. Many other pidginized trade languages based on an African vernacular are also spoken in this central area of the great rivers; *e.g.*, a pidgin dialect of Swahili, Kituba (a pidgin form of Kongo [Kikongo]), and Lingala.

Benue-Congo subgroup. The Benue-Congo subgroup comprises 557 languages, spoken from Nigeria to South Africa. Its most prominent members include Swahili, Kongo (Kikongo), and Zulu. In terms of numbers of speakers and geographical extension, Benue-Congo and Bantu are practically the same entity. That is, compared with the many millions of speakers of Bantu, the speakers of non-Bantu languages are only a tiny minority of Benue-Congo speakers. Furthermore, the Bantu speakers are spread out over most of middle and southern Africa, whereas the remainder of Benue-Congo speakers occupy only a corner of the northwest extension, mostly in Nigeria. The only two major non-Bantu Benue-Congo languages are Efik and Tiv, found in eastern Nigeria.

Bantu, largest Benue-Congo subgroup

The following description sacrifices a consideration of the numerous but less important non-Bantu languages of the subgroup for a still superficial view of the Bantu languages. The most notable feature of the Bantu languages is their system of noun classes (concord). This has also been called "alliterative" concord because it often entails a repetition of the same syllable as prefixes at the head of successive words in the sentence. An example, drawn from Swahili, provides an illustration: *wa-tu wa-le wa-mefika* (noun–demonstrative–verb) "those people have arrived." Such prefixes as *wa* represent an intersection of two systems: one syntactic (function in the sentence) and the other paradigmatic (mutually exclusive replacements in the same position in the sentence). Syntactically, the shape of the prefix can vary according to the part of speech to which it is attached—a prefixed syllable may be different in the noun, adjective, possessive, locative, or verb. That there is agreement (*i.e.*, a concord element is present) with virtually all parts of speech creates an aesthetically pleasing system by means of an exhaustive display of marked relationships in the sentence.

Paradigmatically, the system of concord is most simply viewed as being based upon the governing noun in its singular or plural form. That is, the noun belongs to one of a number of noun classes that determine the proper set of concording elements to be used throughout the part of the sentence dominated by that noun. These sets (which can be thought of as replacement sets) come in pairs according to whether the governing noun is singular or plural; *e.g.*, in Swahili, the singular form *m-tu yu-le a-mefika* "that person has arrived" contrasts throughout with the plural form *wa-tu wa-le wa-mefika* "those people have arrived." This alternation of singularity and plurality is, of course, more closely related to the semantics of the noun than to its purely grammatical function. The paradigmatic system goes even further in this direction by making a rather loose use of other possible semantic contrasts (especially: person–nonperson and countable–noncountable) in assigning nouns to noun

Noun concord in Swahili

classes. In no language, however, is there a strict relation between meaning and noun class. Nevertheless, the tendency in this direction again stimulates a sense of completeness of aesthetic form and has added to the fame of Bantu languages as abstract figures.

Correlates of these noun classes (in both form and function) are found in all branches of Niger-Congo except Mande and only slightly in Kwa. This led some early researchers to combine all of them as one subgroup and later led to a typological distinction between noun-class and non-noun-class languages. This distinction is not very useful, however, because there are a number of languages with rudimentary or partial noun-class systems, and it even seems possible for a language of entirely different ancestors to adopt noun prefix alternation.

Swahili remains the best known Bantu language. It is the national language of Tanzania and is used as a lingua franca throughout East Africa. The use of Swahili for this purpose is facilitated because it no longer makes use of tone—it is an isolated non-tone language in the Bantu area. There is another phenomenon related to tone in the Bantu languages besides its disappearance in Swahili that should be mentioned: there exists an area of "tonal reversal," a geographic area centred in the western Congo in which the tonal realizations in words and sentences are the mirror images of what they are elsewhere in Bantu languages; *i.e.*, high tones become low tones, and vice versa.

Area of tonal reversal

Another distributional characteristic is the presence of a prefix form made up of two syllables as opposed to the form with only one. Following out the implications of the geographic distribution as well as the function of this feature is of help in mapping the prehistory of the Bantu languages. As in all other areas of the world, however, it is the distribution of certain items of vocabulary, or of vocabulary replacements, combined with the application of laws of sound change, that produce the most valuable historical conjectures. An impressive amount of work has been done on the reconstruction of ancestral Bantu word roots and the sound system used to realize them. As early as the 1890s, Carl Meinhof postulated an original sound system and started working out the shifts that it had been subjected to in order to produce the various Bantu languages as they are spoken today. Meinhof called his systematic reconstruction Ur-Bantu, and most subsequent historical research (and much actual description of contemporary languages) has been based on his surprisingly trustworthy descriptions. *Comparative Bantu* (4 vol., 1967–70), by Macolm Guthrie of the University of London, is a much fuller and more painstakingly detailed compendium of the entire geographical distribution of the Bantu languages.

Although textbooks and grammatical lessons have been published for many Niger-Congo languages, those of the Bantu area are by far the most numerous. In part, this availability reflects the influence of the South African linguist Clement Doke and the department of Bantu studies at the University of the Witwatersrand in South Africa, which was in direct touch with a huge area of Bantu-speaking peoples.

ADOPTION OF FOREIGN WORDS AND SOUNDS

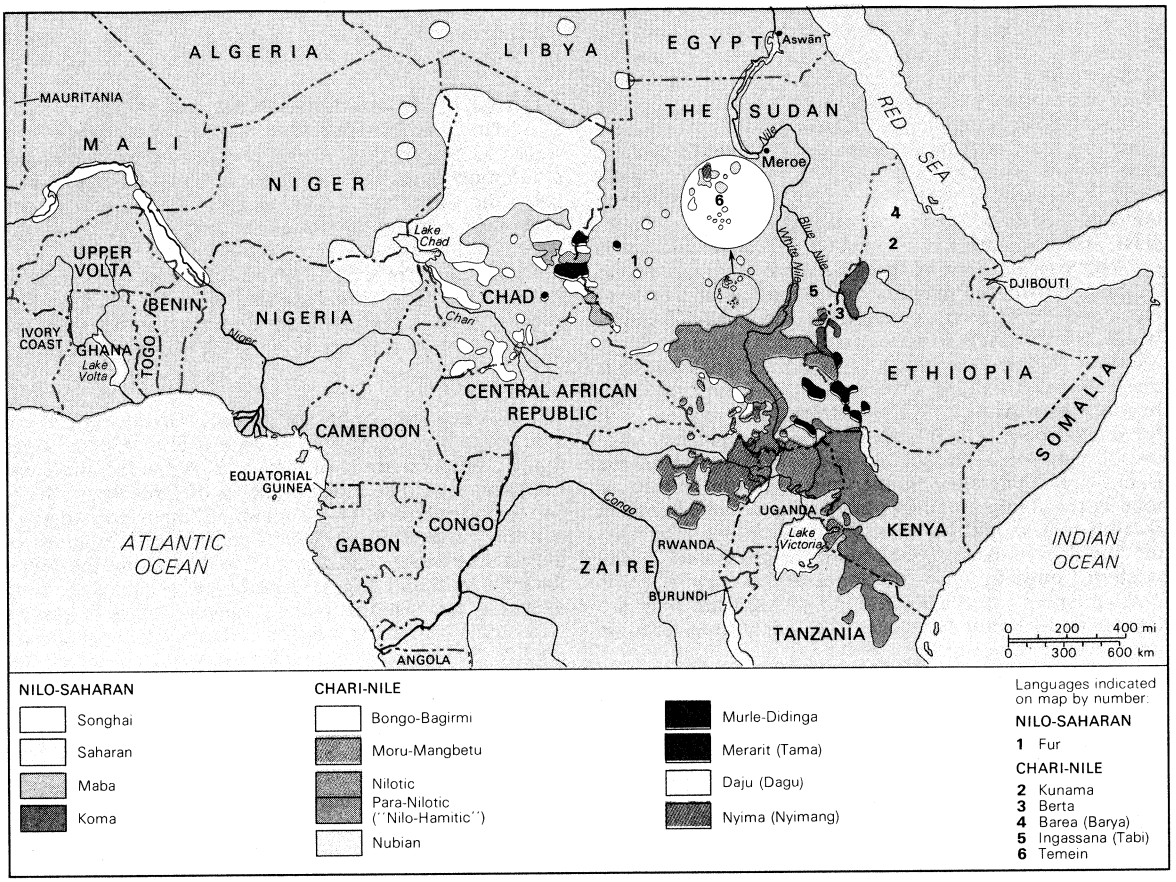
All the subgroups of Niger-Congo contain languages that show evidence of intensive contact with each other or with languages outside the group to such an extent that special mechanisms are in operation for the inclusion of borrowed words (such as the assignment of nouns to a particular noun class). This does not make them especially unusual from the standpoint of the world's languages, but the borrowing of the very difficult click consonants from the neighbouring Bushman–Hottentot languages into the Bantu languages of South Africa is definitely remarkable. Clicks are especially widespread in Zulu and Xhosa—the first consonant of even the name Xhosa itself stands for a click. This dramatic exception to the theory of language change that states that languages alter in order to simplify or economize the effort of sound production seems to require a special explanation. Possibly in-marrying Bushman or Hottentot wives used their native click sounds as disguised forms of words that would be taboo in Zulu or Xhosa. (D.W.C.)

Borrowing of click sounds

III. Chari-Nile and Nilo-Saharan languages

The term Chari-Nile refers to a group of languages presumed to be genetically interrelated, or descended from a common ancestral language. Joseph Greenberg proposed the Chari-Nile family as part of his overall classification of African languages. At first, he designated the group by the name Macro-Sudanic (1955), but in 1963 adopted the term Chari-Nile. The name Chari-Nile is geographically descriptive in that virtually all of the languages in the family are located in the watersheds of the Nile and the Chari rivers or in the areas in between them.

CLASSIFICATION



The larger Nilo-Saharan group. Greenberg, as of 1963, regarded Chari-Nile as only a branch of a larger family, Nilo-Saharan, of which it is by far the most heterogeneous. The other branches of Greenberg's Nilo-Saharan family are: (1) Songhai, an important language with no close relatives, which consists of a number of dialectal varieties (*e.g.*, Zerma) spoken along the Niger River in Mali and Niger; (2) Saharan, a language group including Kanuri, the major language of northeastern Nigeria, as well as its relative Teda and its more distant relative Zaghawa, both of which are spoken to the east of Kanuri, principally in Chad, but also in The Sudan; (3) Maba, a group of interrelated languages of Chad; (4) Koma (also written Coman), a group of interrelated languages of the Ethiopia–Sudan border area; and (5) Fur, a language of Darfur province, The Sudan.

Languages of the Chari-Nile group. Greenberg considered Chari-Nile to be composed of four branches. The first, Kunama, is a language of northern Ethiopia (Eritrea), contiguous to Barea (Barya), an Eastern Sudanic language (see below); Berta, the second branch, is spoken in the Ethiopia–Sudan border area. Central Sudanic, a large and heterogeneous group of languages, extends over northwestern Uganda, the southern Sudan, northeastern Zaire, Chad, and the Central African Republic, although it is interspersed with languages of other groups. The British Africanists Archibald N. Tucker and Margaret A. Bryan (1956) regarded Central Sudanic as two distinct unities, which they hesitated to group together; one group is Bongo-Bagirmi, of which Bagirmi, Sara, and a number of other languages are found in Chad and the Central African Republic, while Bongo and its closest relatives are concentrated in the extreme south of The Sudan near the Zaire and Uganda boundaries. The other division is Moru-Mangbetu (like Bongo and Bagirmi, these are the names of individual languages), which is concentrated in northeastern Zaire but overlaps into Uganda. In addition, it includes Efe, Lendu, and Madi, which is linked to Moru. The fourth and most heterogeneous branch of Chari-Nile is Eastern Sudanic.

The 10 subgroups of Eastern Sudanic

Eastern Sudanic consists of 10 subgroups: (1) Nilotic extends from southern Sudan through Uganda, Kenya, and northern Tanzania, although it is interspersed with languages of other groups, and includes the so-called "Nilo-Hamitic" languages. (This name is controversial; see below *Nilotic and "Nilo-Hamitic."*) The Nilotic subgroup includes Shilluk, Dinka, and Nuer in the southern Sudan, Acholi in northern Uganda, and Luo, in western Kenya along Lake Victoria but overlapping into Tanzania. The Nilo-Hamitic languages include Bari and Lotuko (Lotuho) in the extreme south of The Sudan; Karamojong in northern Uganda (just to the west of Acholi) and its neighbour and close relative Turkana across the border in Kenya; Nandi and Suk, just to the south of Karamojong; and Masai, extending from southern Kenya into northern Tanzania.

(2) Nubian is spoken along the Nile from Aswān, Egypt to Meroe, The Sudan (*i.e.*, Nile Nubian), and a number of dialect enclaves in the Nuba Hills of Kurdufān, The Sudan (*i.e.*, Hill Nubian), as well as in two separate enclaves, Midobi and Birked, in Darfur, The Sudan. The

Distribution of the Nilo-Saharan and Chari-Nile languages.
Adapted from A.N. Tucker and M.A. Bryan, *Linguistic Analyses: The Non-Bantu Languages of North-Eastern Africa* (1966); Oxford University Press (for International African Institute), London

relationship of Midobi and Birked to one another and to the other varieties is not close. Currently, Birked is giving way to Arabic. Nile Nubian consists of three languages, of which the northernmost, Kenuzi (Kenzi), and the southernmost, Dongolese, are closely related, almost to the point of mutual intelligibility; Mahas, located between the two, is a more distant relative and includes a subdialect, Fadidja, spoken to the north.

(3) Murle-Didinga designates a group of closely interrelated languages spoken on both sides of the Sudan–Ethiopia boundary; Murle and Didinga are individual languages within the group. (4) Barea (or Barya), a language of northern Ethiopia, is spoken just to the north of Kunama. (5) Merarit (also written Mararit), spoken on both sides of the Chad–Sudan border, comprises a group of closely interrelated languages; actually, Merarit is only one language of the division, which also includes Tama, for which the group is sometimes named. (6) Ingassana, also known as Tabi, is found in the eastern Sudan just north of Berta. (7) Daju, or Dagu, is the name of a group of closely related languages spoken in widely separated enclaves in Chad and The Sudan; most of them are called Daju or some variant of the name.

Recent additions to the Eastern Sudanic branch

Three subgroups of Eastern Sudanic were added by Greenberg in 1963; the first two had previously (1955) been treated as entirely independent language families, while the third had not been mentioned. These are: (8) Nyangiya, also known as Teuso, a group of dialects or closely related languages of northern Uganda, whose inclusion in Eastern Sudanic Greenberg regards as only tentative (this is omitted on the map); (9) Temein, a language of Kurdufān, The Sudan; and (10) Nyima, or Nyimang, also found in Kurdufān. Another language, Afitti, spoken about 100 miles (160 kilometres) to the north, evidently should be grouped with Nyima.

Controversies concerning classification. There has been much disagreement about the classification of various groups of African languages and considerable confusion in terminology.

Nilotic and "Nilo-Hamitic." Some scholars have objected to grouping the so-called "Nilo-Hamitic" languages together with Nilotic. This question has been at issue since the earliest attempts at African linguistic classification. One of the first proposed systematic classifications (1877–78) established the very heterogeneous Nuba-Fula group, named for two of its members, Nubian (an Eastern Sudanic language, according to Greenberg) and Fula, or Fulani (a West African language). The group also included Masai, subsequently classified as "Nilo-Hamitic," but not the other Nilotic or "Nilo-Hamitic" languages. This classification, made in the 19th century by Friedrich Müller, was based mainly on a simplistic correlation with racial categories determined largely by hair type. Müller recognized a close affiliation between Bari (subsequently classed as "Nilo-Hamitic") and Dinka, a Nilotic language. Dinka, Shilluk, Nuer, and Bari were grouped under the heading Nile languages (*Nil-Sprachen*) within the Negro group, as distinct from the Nuba-Fula group. (Later Müller admitted the close affinities between Masai and Bari, previously pointed out by Karl Richard Lepsius, but attributed them to a mixture of two distinct elements in Bari.)

Objections to grouping Nilotic with "Nilo-Hamitic"

In 1880 Lepsius proposed another of the early classifications of African tongues. As a result of his views that Masai and Bari were related, the genetic affiliation of Masai, Bari, Nuer, Dinka, and Shilluk was generally accepted, and languages showing clear affinities to them were included as they became known (*e.g.*, Lotuko, Nandi-Suk, Luo).

In 1902 Sir Harry Johnston divided these languages into two groups, one of which he called Nilotic, including Dinka, Shilluk, Acholi, Alur, Lango, and Luo. He proposed no specific name for the second group, which later came to be known as "Nilo-Hamitic," but included in it Masai, Turkana, Lataka (*i.e.*, Lotuko), Nandi, Suk, and Karamojong. He posited a distant relationship between the two groups but also noted some striking lexical similarities between Somali (a Hamitic language) and the sec-

ond, or "Nilo-Hamitic," group that led him to conclude that the latter resulted from a mixture of one group of people related racially and linguistically to the Somali and another related to the Nilotes.

Most investigators of this period grouped these languages in much the same way as Johnston; for example, the English diplomat and scholar Sir Charles Eliot stated:

> East Equatorial Africa is the home of a group of tribes which cannot be called Bantu or Hamitic, and have received no satisfactory designation. The group contains at least two subgroups. One of these, including the Shilluk, Dinka, Bari, Acholi, and Jaluo [*i.e.*, Luo], inhabits the banks of the Nile and the shores of Lake Victoria; the other has its headquarters in the highlands of . . . East Africa. . . . Its chief members are the Masai, Nandi, Turkana, and Suk. . . . To these should probably be added Latuka [*i.e.*, Lotoho] but our information about it is slight. . . . Karamojo is not well known but is apparently closely allied to Turkana.

Correspondence of Sir Charles Eliot's classification with Nilotic and "Nilo-Hamitic"

Except for Bari, which was put in the first group for reasons more geographic than linguistic, but which is actually closely related to Masai, Eliot's two divisions correspond exactly to Johnson's—namely, Nilotic and what later became known as "Nilo-Hamitic."

A sharply different view was introduced in 1912 by Carl Meinhof, who denied the linguistic unity of the two groups suggested by Johnston and Eliot. Meinhof regarded the term Nile (or Nilotic) merely as a geographic concept. He clearly considered Bari and Masai to be Hamitic languages (*i.e.*, related to Somali and Galla, among others) and also, presumably, Lotuko, Turkana, Nandi, and Suk. (He was not, however, explicit about these.) Dinka and its close relatives—Shilluk, Nuer, Luo, and others—were classified as Sudanic; the resemblances between the two groups (in particular those between Dinka and Bari, which had been pointed out by Müller) he attributed to borrowing. Meinhof's most important reason for allying Masai and its close relatives to the Hamitic languages was that in both groups nouns have grammatical gender and other inflectional complexities, which are absent in Nilotic languages such as Shilluk, Luo, and their close relatives.

Much earlier, Lepsius also had noted the presence of grammatical gender in Masai, a trait to which he attributed great importance for genetic classification, but he specifically ruled out any Hamitic affiliation because gender is expressed very differently in the Hamitic languages. Because of Meinhof's great prestige and preeminence among Africanist linguists, his views were widely accepted. The scholar Dietrich Westermann (in 1912), however, regarded all of the above as Nilotic languages, dividing them into the Niloto-Hamitic (Nilo-Hamitic) and Niloto-Sudanic subdivisions, which correspond to the groups delineated by Johnston. On the other hand, contrary to general practice, he also included among the Niloto-Sudanic languages another group, Moru-Madi, of western Uganda and eastern Congo. Greenberg subsequently included Moru-Madi within the Central Sudanic family, which he considered a branch of Chari-Nile and, thus, ultimately but distantly related to Nilotic.

In 1935, Westermann claimed that the relation between Niloto-Sudanic and the Sudanic languages of West Africa was not as close as the relation of the latter to Bantu, whose interrelationship he had sought to demonstrate in 1927. Greenberg was to designate this family, Bantu included, as Niger-Congo. Westermann likewise expressed doubt as to the affiliation of "Nilo-Hamitic" to the Hamitic languages and reaffirmed the unity of Nilotic and "Nilo-Hamitic." Greenberg also adopted this position and argued persuasively against the relationship of "Nilo-Hamitic" to the Hamitic languages and, consequently, against the misleading nature of its name, which he changed to Great Lakes and which, together with Nilotic, formed the southern branch of his Eastern Sudanic family.

Doubtful affiliation between "Nilo-Hamitic" and Hamitic

The German Africanist Oswin Köhler proposed, in 1955, the name Nilotic for the entire southern branch and divided it into three subdivisions: West Nilotic (including Nuer, Dinka, Shilluk, Luo), East Nilotic (including Bari, Masai, Lotuko, Karamojong), and South Nilotic (including Nandi, Suk, Tatoga). (The last two had usually been grouped together as Nilo-Hamitic, while the first had simply been designated Nilotic.) In 1963 Greenberg subsequently accepted Köhler's grouping and nomenclature. Tucker and Bryan, while still maintaining the unity of "Nilo-Hamitic " and hesitating to group it unequivocally with Nilotic (in the older restricted sense, equivalent to Köhler's West Nilotic), proposed a new name for the group, Para-Nilotic, thus avoiding any implication of Hamitic affiliation.

The wider relationships of the Nilotic family. The question of the relationship of Nilotic (in Köhler's extended use of the term) to other African languages and language families has been raised at various times. In 1920 the English anthropologist G.W. Murray noted similarities between Bari and Nubian and, in fact, between Nubian and the Nilotic and "Nilo-Hamitic" languages as a whole. He also linked these languages to Kunama, Barea, and the recently discovered Tabi (also known as Ingassana). Westermann suggested in 1935 that Didinga might be a distant branch of Nilotic and had earlier (1912) made a similar claim for the Moru-Madi group. All these languages were subsequently classed by Greenberg either as Eastern Sudanic or within the wider grouping of Chari-Nile.

Apart from Eastern Sudanic, the most heterogeneous subgroup of Chari-Nile is Central Sudanic. Its unity was first suggested in 1940 by Tucker, who included it in a group of languages that he called Eastern Sudanic, a term that he admitted was essentially geographic because it included another group of different and distinct languages, among them Ndogo-Sere and Azande. (Greenberg subsequently incorporated these into Niger-Congo.) Greenberg introduced a terminological confusion here by calling part of Tucker's Eastern Sudanic group Central Sudanic and using the name Eastern Sudanic for an entirely different group of languages. Although Tucker hesitated to unite the Moru-Madi and Bongo-Bagirmi languages—which together comprise Greenberg's Central Sudanic—into a single family, the evidence that he himself presented appeared to support such a grouping.

Opposition to Greenberg's groupings

Some scholars doubt that adequate evidence has been presented for regarding the whole of Eastern Sudanic as a valid subdivision of Chari-Nile or even for regarding the whole of Chari-Nile as a valid subdivision of Nilo-Saharan. Although Nilo-Saharan and the more heterogeneous subdivisions within it are far from conclusively established, no convincing alternatives have been suggested.

LINGUISTIC CHARACTERISTICS

The Chari-Nile languages are a very heterogeneous group whose structural features, both phonological and grammatical, are in no way uniform or easily characterized. Furthermore, the great majority are not adequately described, and their comparative study is still in its infancy.

Phonology. Nearly all Chari-Nile languages seem to be tonal (*i.e.*, words and grammatical forms are differentiated by pitch), as are the overwhelming majority of sub-Saharan languages. Some varieties of Nubian may be exceptions, but the question has yet to be fully investigated. Central Sudanic languages generally have only syllables that are open (*i.e.*, end in vowels); some final vowels in the Bongo-Bagirmi languages of this division, however, are semi-mute or whispered. Other Chari-Nile languages have syllables that are open as well as closed (*i.e.*, end in consonants). Central Sudanic languages likewise differ from other Chari-Nile languages in that they are the only ones with the labiovelar consonants *kp* and *gb* (articulated with both the lips and the soft palate), which are common in much of West and Central, but not East, Africa. As in other African language families, a large number of Chari-Nile languages distinguish dental from alveolar or retroflex stops, among them most Central Sudanic languages, Nyima, Temein, Murle-Didinga, Hill Nubian, and West Nilotic. (The dental stops, *t* and *d*, are pronounced with the tongue tip against the back of the upper teeth; the alveolar and retroflex stops are pro-

nounced with the tongue tip farther back along the roof of the mouth.) Some Chari-Nile languages—most Central Sudanic languages, Daju, the Murle-Didinga group, and Bari (East Nilotic)—distinguish implosive and explosive voiced stops; the former are pronounced by drawing the air into the mouth, the latter by expelling it. The vowel systems of most Chari-Nile languages are fairly rich, the great majority seeming to distinguish seven or more vowel qualities. Apparent exceptions are Daju, Nile Nubian, and possibly Kunama, which have only five vowels. Many languages make distinctions in the length of vowels (*e.g.*, Nile Nubian, Nilotic, Daju, Kunama), but not all (*e.g.*, Central Sudanic, Nyima). In Nilotic languages a contrast exists between so-called breathy versus hard vowels, sometimes analyzed as close versus open. Nasal vowels occur in Sara-Mbai of the Bongo-Bagirmi group within Central Sudanic but in no other Chari-Nile language.

Vowel systems of the Chari-Nile language

Grammar. No Chari-Nile language has concordial noun classes like those of Bantu (see above *Benue-Congo subgroup*) and many of its more distant relatives in West Africa, but grammatical gender is distinguished in three very different Chari-Nile groups. It is prominent in East Nilotic (*i.e.*, "Nilo-Hamitic" minus the Nandi-Suk-Tatoga group) but absent in the other Nilotic languages. There are two genders of nouns, normally indicated by a determiner (in Masai, these are *l* for masculine, *n* for feminine) with various grammatical functions. On the other hand, gender is not distinguished in the personal pronouns, but in Daju (grouped by Greenberg in Eastern Sudanic) there are three genders (masculine, feminine, neuter) distinguished in the 3rd person singular pronoun ("he," "she," "it") but not in the noun. The same usage occurs in Bongo but in no other Central Sudanic language.

A few Chari-Nile languages distinguish exclusive forms from inclusive forms of the 1st person plural pronoun. The exclusive pronoun excludes the hearer (*e.g.*, "he and I"="we"); the inclusive includes him (*e.g.*, "You and I"="we"). Among such languages are Lendu (alone among Central Sudanic languages), Daju, most West Nilotic languages, and Teso (alone among East Nilotic languages). Virtually all Chari-Nile languages except Berta and Nyima formally distinguish plural from singular nouns, some by means of prefixes (*e.g.*, the Moru-Mangbetu languages within Central Sudanic, and Temein) but most with suffixes (*e.g.*, the Bongo-Bagirmi languages within Central Sudanic, Kunama, Barya, Daju, Ingassana, Murle-Didinga, Nyangiya, and East and South Nilotic, which together comprise "Nilo-Hamitic"). West Nilotic utilizes suffixes sometimes, as well as change of tone, vowel length, or vowel quality. These processes can also be found to some extent in other branches of Nilotic. Affixes are sounds or groups of sounds that are added to the beginning (prefixes) or end (suffixes) of a word or inserted in the middle (infixes). In Chari-Nile, it has been noted that two pairs of singular–plural affixes are widespread, though not universal; these are also used to some extent outside this family. The affixes are *t* and *k*, confined principally to nouns, and *n* and *k*, principally used with pronominal elements. The *t* and *k* forms occur in fewer languages than the *n* and *k* ones, and only in languages in which the *n* and *k* are also found. The significance of these grammatical features for the historical and comparative study of the Chari-Nile languages remains to be investigated.

Widespread use of specific affixes in Chari-Nile

Writing. Only one Chari-Nile language, Nubian, has a written tradition of any antiquity. Dating from the 8th to the 11th centuries, the script was employed by Christianized Nubians in much the same area as that occupied by modern Nile Nubian speakers. Generally called Old Nubian, this written language most closely resembles Mahas among the modern dialects. It was abandoned after the Nubians adopted Islām and survives only in ancient manuscripts and inscriptions that were not deciphered until 1906. (Since the adoption of Islām, Nubian has occasionally been written in Arabic script.) Old Nubian utilized a script derived from that of Coptic, which in turn was adapted from the Greek alphabet. Coptic added seven non-Greek letters of Egyptian demotic origin to represent non-Greek sounds. Nubian retained three of these letters, in addition to adding three new ones from cursive forms of Meroitic letters.

Meroitic, the extinct language of an even more ancient Sudanese civilization (*c.* 300 BC to AD 100), may be related to the Chari-Nile languages, but too little is known to establish any conclusive tie. It is not closely allied to any existing language. Surviving only in inscriptions, Meroitic was written in a consonantal alphabet derived from Egyptian hieroglyphic writing and in a cursive form partly of Egyptian demotic and partly of indigenous origin. In the first decade of the 20th century the script was deciphered by the English Egyptologist Francis Griffith.

Since the colonial period a number of Chari-Nile languages, particularly in Kenya, Uganda, and The Sudan, have been written in derivatives of the Latin alphabet and are used for religious and educational purposes. Nearly all of the languages are Nilotic. Of these, Luo, a West Nilotic language and one of the major indigenous languages of Kenya, has the largest vernacular literature. It also has the largest number of speakers of any Nilotic tongue (and, in fact, of any Chari-Nile language). Other West Nilotic languages, however, such as Dinka and Nuer of The Sudan and Acholi of Uganda, have some vernacular literature, as does Kalenjin (Nandi-Kipsigi), a South Nilotic language of Kenya.

Languages using Latin-based alphabets

(M.F.Go.)

IV. Khoisan languages

The Khoisan languages are click languages spoken in southern Africa. The term Khoisan was created to subsume the related Bushmen and Hottentots (*i.e.*, the Khoisanid peoples) under a common name and has become increasingly accepted since its creation in 1928. The word is derived from Khoikhoi and San, the names of the peoples called, respectively, Hottentots and Bushmen by the Afrikaners (Boers) of South Africa.

The languages of the group are now usually divided into three groups—North, Central, and South Khoisan. They are spoken by remnants of a yellow pre-Bantu population, the so-called Bushmen, who are hunters and collectors living in and around the Kalahari and who number between 35,000 and 40,000. A Khoisan language is also used by the so-called Hottentots, pastoralists surviving with about 40,000 Nama speakers in South West Africa, where the Nama language has also been adopted by the Bergdama, a non-Khoisanid people (about 53,000), and by the Hai-//'om Bushmen (about 3,000 speakers). The Khoisan family comprises about a dozen languages and dialect clusters such as Nama, !Kora, Naro, /Kham, !Khung, Kxoe, and others. (The unusual symbols in the names of the languages stand for clicks; they are listed in Table 2 and are explained below in the section on phonology.)

Table 2: Notation of Clicks

	characters used in text	International Phonetic Alphabet	Zulu conversion
Dental	/	ǀ	c
Alveolar	≠	ǂ	
Alveopalatal (or retroflex)	!	ǃ	q
Lateral	//	ǁ	x
Bilabial	⊙	ʘ	

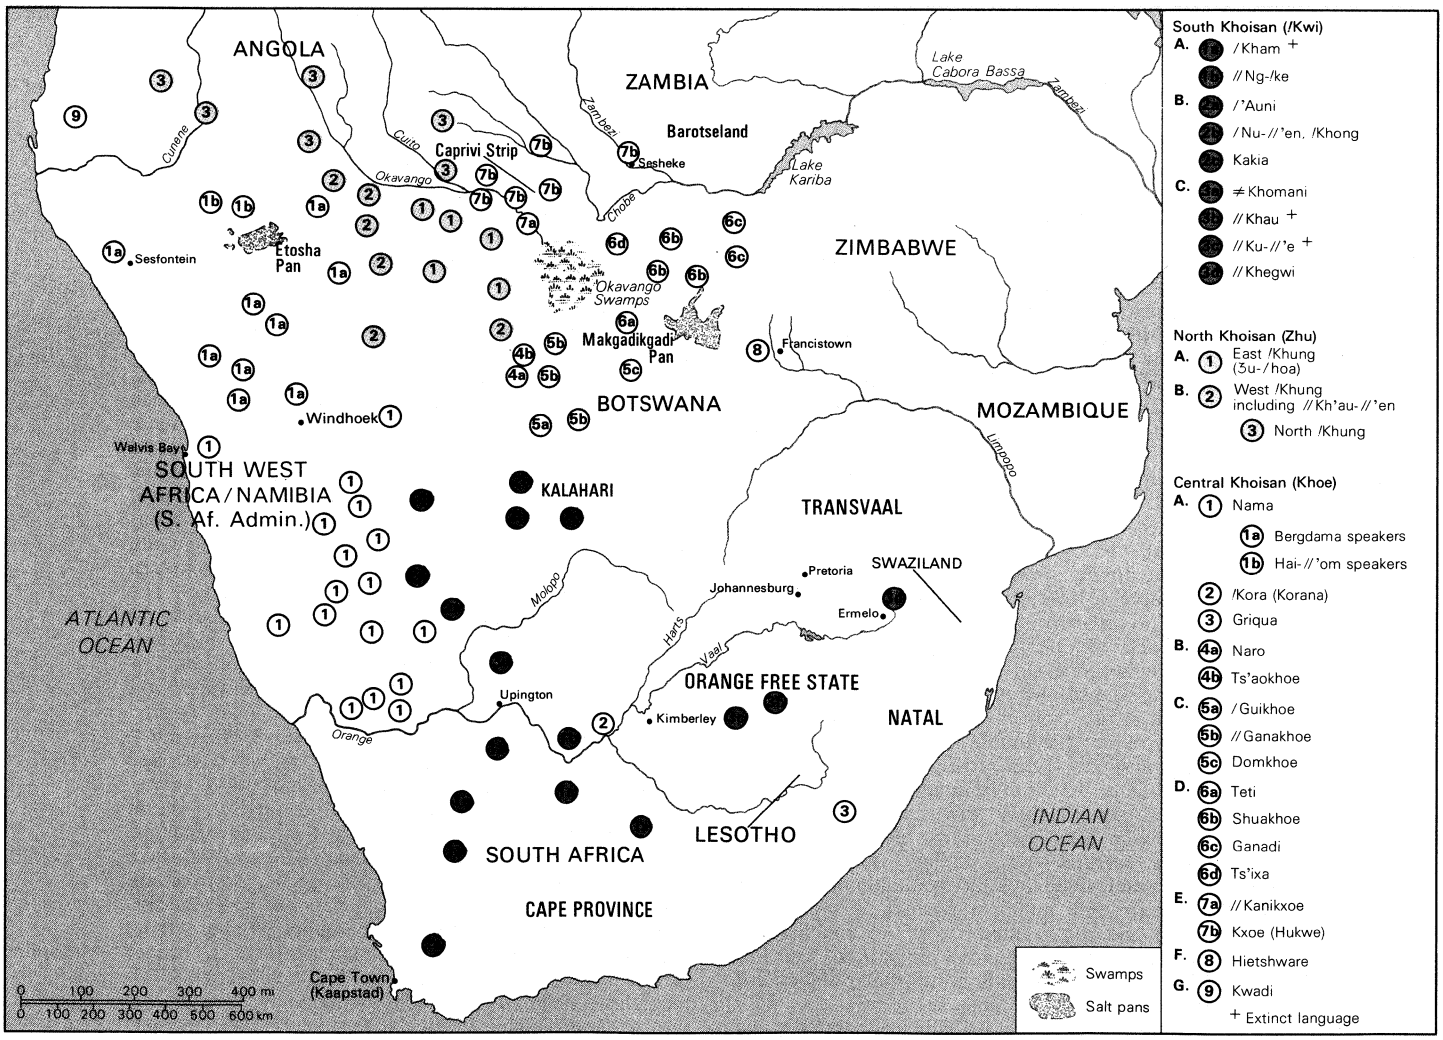
The assumption of a genetic relationship between all the languages of the Khoisanids and the application of the term Khoisan to this language "family" are problematic. Criteria brought forth against the point of view of a genetic relationship are the cleavage in morphology and vocabulary between sex-gender languages (Central Khoisan) and nongender languages (North Khoisan and South Khoisan), on the one hand, and a similar cleavage in morphology and vocabulary between North Khoisan and South Khoisan, on the other. These arguments are countered by the fact that there are a number of common words and a few particles, traceable by comparison of sound and meaning, in two or more of the three groups of

Problems of Khoisan genetic relationship

Khoisan. These permit the establishment of a strong hypothesis for a genetic, though remote, relationship. Regular sound correspondence, however, has not been found in all common items; this is the most difficult part of the Khoisan problem.

The Khoisan hypothesis is built on: (1) common special features of the phonological system—*e.g.*, clicks are regarded as inherent to the languages; (2) widespread and common patterns of root formation, combined with special patterns of consonant distribution; (3) the occurrence of some probably related particles in more than one group; and (4) the occurrence of related words (sound-meaning units) in two of the groups, but more rarely in all three groups—*e.g.*, the terms for "chin," "lungs," "throat," and "wound."

In addition to Khoisan proper, there are two click languages, Sandawe and Hadza (Hatsa), spoken by peoples in Tanzania; these languages possess a few words, affixes, and particles that justify the assumption of a distant relationship with Khoisan. The link between Central Khoisan and Sandawe is supported by the racial affinities of the Sandawe and Hottentots. The relations between Khoisan and Hadza are more remote. All studies on this subject are still in the initial stages. The U.S. linguist William E. Welmers proposed the tentative extension of the Khoisan family into Macro-Khoisan, including Sandawe and Hadza. In 1962 Joseph Greenberg subsumed Khoisan proper and Sandawe and Hadza under the title Khoisan.



Some Central Khoisan gender affixes were at one time considered as possibly related to the Hamitic languages. Today, the basis for the Hottentot-Hamitic hypothesis is generally regarded as too narrow for conclusiveness and the hypothesis has been given up for lack of evidence.

CLASSIFICATION

All classifications of Khoisan are based on a general comparison of morphology and vocabulary. Lack of sufficient language material limits systematic comparative studies. While the division into groups is fairly consistent, the classification within the groups must be regarded as preliminary. The first classification of these languages, made by the German linguist Wilhelm Bleek in 1858, distinguished between the Hottentot and Bushman languages according to the gender–nongender dichotomy. This remained the traditional model until 1927, when Bushman was subdivided into Northern, Central, and Southern groups. These groups were maintained in D.F. Bleek's *A Bushman Dictionary* (1956), in which the Hadza language was included in the Central Group.

Modern theories of classification

Since 1950, several attempts at a reclassification of the languages of the Khoisanids have been proposed. The contribution of Greenberg to the Khoisan hypothesis was to include Hottentot in the Central group and, as mentioned above, to extend Khoisan to include the more closely related Sandawe and the more distantly related Hadza. Greenberg's main aim was to trace far-spread common elements in Khoisan as evidence for the genetic relationship of the groups. The method is based on sound-meaning comparison. The South African scholar E.O.J. Westphal separated the languages of the Bushmen from the gender languages that he interpreted as of Hottentot origin. Later, he divided the languages of the Khoisanids into five genetic groups, and in 1963 he further revised his classification of the non-Hottentot tongues by establishing four genetically unrelated groups, to which he gave the status of language families (1965); in 1971 he reduced these to three families. A new classification of

Tentative distribution of the Khoisan languages.

Central Khoisan was put forth by Oswin Köhler in 1962, which showed the special position of the Nama and !Kora dialects of the Hottentots within the Central Khoisan group (see below).

There is no general agreement on the division of the South Khoisan languages. Some special phonological and morphological features characterize South Khoisan as a coherent and genetically related group of languages whose divergences must go back to a much older separation than that in Central and North Khoisan. South Khoisan speakers were probably the first Khoisanid migrants to reach South Africa.

The following is a classification, proposed by Köhler, of the languages subsumed in the three major Khoisan groups (a comma between languages indicates a close relationship; a semicolon designates a more distant relationship):

South Khoisan: /Kham, //Ng-!ke; /'Auni, Xatia, /Nu-//'en, !Khong, /Namani, Kakia; ≠Khomani, /Nhuki, //Khau, //Ku-//'e, Seroa, //Khegwi (Batwa), !Gãne.

North Khoisan (dialects): East !Khung (ʒu- /hoa), West !Khung (called //Kh'au-//'en or Auen in its southern area), North !Khung (!'O-!Khung in Angola), closely related to West !Khung.

Central Khoisan: Nama, spoken by the Bergdama and by the Hai-//'om; !Kora (Korana); Griqua; Naro, Ts'aokhoe; /Guikhoe, //Ganakhoe, ≠Heβa-khoe, Domkhoe; Teti, Danisa, Hura, Shuakhoe, Ts'ixa; //Kanikxoe, Kxoe (Hukwe, Kwengo, Bumakxoe, including Bugakxoe); Hietshware, /Haitshuari, Mohisa; Kwadi (tentatively classified as Central Khoisan by Köhler in 1968 and Westphal in 1971).

Sandawe has similarities to Central Khoisan and may be regarded as distantly related. Hadza shows some relationships to Khoisan and relatively few connections to Sandawe. Its inclusion in Khoisan is problematic and assumes a very high, abstract level of classification, presupposing that the languages separated a long time ago and that a great number of cognates and common features that normally attest to a common origin were lost over an extended period. This high level of classification is also characteristic of all three Khoisan groups.

LINGUISTIC CHARACTERISTICS

Phonology. Most characteristic of the Khoisan languages are the click sounds, which form a subsystem of the consonants. Clicks are produced by simultaneous closure of the tongue with two areas in the mouth, one at the soft palate (the velum), and the other at such prevelar locations as the teeth, alveolar ridge, or palate. After the closures are made, the body of the tongue is moved down and back, so that the enclosed part of the mouth cavity becomes larger. This causes a lowering of the air pressure in the cavity. The click noise occurs when the tip of the tongue is lowered, breaking the partial vacuum and allowing air to rush into the cavity.

Click sounds as a subsystem of the consonants

There are two types of release of clicks. In one the bilabial, dental, and lateral closures are released by an imploding affricate (a sound beginning as a stop and ending with more or less distinctly audible friction); the alveolar and alveopalatal (or retroflex) closures are released by a hard implosive sound. Both releases are called ingressive, or influx, releases, meaning that the air rushes into the mouth. The second type is called egressive, or efflux, release; it results from the velar closure. In this case the air rushes out of the mouth. A click plus efflux are considered as a single sound rather than as a consonant cluster. In the South Khoisan languages there is also a bilabial click with labial closure; this is like the sound of a kiss. The Khoisan click mechanisms also combine with other phonetic features—*e.g.*, voicing (vibration of the vocal cords), nasalization—to produce additional sounds. The clicks occur only in initial position in word roots (also in compound roots), rarely in affixes and particles. Some of the Khoisan click sounds were adopted into Bantu languages, notably the Nguni group that includes Zulu and Xhosa (see Table 2 for click notations).

Unless followed by a vowel, the effluxive part of a click is represented by a separate symbol. In this text, the symbols are as follows: /a = dental click plus vowel; /h = dental click plus aspiration; /x = dental click plus velarization; /x' = dental click plus velar ejected efflux; /' = dental click plus glottalization; and /n = dental click plus nasalization. According to this system, as well as in the general orthography of personal and place names, *k* or *g* is used to indicate the velar closure of the click to make the words readable for the general reader who omits the initial click sound. In this case *k* is used to indicate an unvoiced click and *g* a voiced click. The examples given above thus read as follows: /a = / ka or /ga; /h = /kh or /gh; /x = /kh or /gh; /x' = /kh' or /gh'; and /' = /k' or /g'. In the case of nasalization (/n), *k* and *g* are not usually written.

In the Khoisan languages, there are intricate systems of tones. The main vowels are *a*, *e*, *i*, *o*, and *u*; ɛ as in "bed" and ɔ as in "all" do occur, but not in all languages, and the ə sound, as the *a* in sofa, is relatively rare. Nasalized *ã*, *ĩ*, and *ũ* are most common. Pharyngealized (or pressed) vowels and vowels with intermittent glottalization occur in North Khoisan and, to a much lesser degree, in South Khoisan but seldom in Central Khoisan. (A pharyngealized vowel is one produced with constriction of the pharynx, the area at the back of the mouth before the esophagus.) A characteristic feature of the consonants is their use in clusters with final velarization (articulation of the back of the tongue with the velum, or soft palate), aspiration (an accompanying puff of breath), or glottalization (accompanying closure of the glottis). This occurs in all three Khoisan groups.

Grammar. Because the grammatical features of the various Khoisan languages are so divergent and lack overall uniformity, they will be discussed in three groups—South Khoisan, North Khoisan, and Central Khoisan.

South Khoisan. The languages of the South Khoisan group are characterized by a great number of different grammatical elements and processes. For example, the plurals are formed not only by the addition of suffixes but also by reduplication (*i.e.*, the repetition of an element to indicate plural, as "bird-bird" for "birds"), by partial change of the stems, and by completely different stems, called suppletive forms. In the formation of tenses and moods, a variety of particles occurs before the verb. Significantly, there is no class or gender distinction in the South Khoisan languages, except for a few traces in the /Kham language. The normal sentence order is subject–predicate–object.

Types of plural formation

North Khoisan. The North Khoisan dialects are characterized by an almost complete absence of affixes (endings, prefixes, and so on). The relations of the words to one another and their function in particular utterances are designated by particles (similar to English prepositions such as "to," "for," or "with") and by word order. The tense of roots functioning as verbs is shown by an optional preceding particle for present and future time, by nothing for the past tense, or by an expression describing time ("now," "tomorrow," etc.) if used in a sentence without context. As in the South Khoisan languages, there are suppletive (different) stems for some plurals; *e.g.*, *!hũ* means "to kill one," but *!'oa* means "to kill many." The North Khoisan dialects, also in common with the South Khoisan tongues, lack a passive construction and have the basic sentence order of subject-predicate-object.

Central Khoisan. In the treatment of the Central Khoisan languages, the Kxoe language of the west Caprivi Strip (South West Africa/Namibia) will serve as representative. The Central languages have a highly developed morphology. Kxoe adds suffixes that indicate gender—masculine, feminine, and common in the dual and plural and masculine, feminine, and neuter (*i.e.*, undetermined, with affix *a* or no affix) in the singular—to roots that take noun (nominal) endings. The same gender suffixes are added to the 3rd person pronouns (originally demonstratives). In grammatical gender, masculine implies "long, narrow, strong," and feminine suggests "short, round, broad, weak." For example, */u* or */u⊙ma* "canoe" is masculine, while */u⊙hɛ* "ferry" is feminine. Gender distinction is also found in the 1st persons (except singular) and 2nd persons.

Masculine and feminine gender

There are six tenses for the verb, with the present tense also expressing whether the subject is standing, sitting, or lying. Unlike the other Khoisan groups, the Central Khoisan languages have a passive form, which is frequently used. In sentence order, subject–object–predicate is the most usual, but subject–predicate–object is also common, and object–subject–predicate occurs if the subject is a pronoun or a nominal.

Vocabulary. Khoisan vocabulary is highly adapted to the needs of life in a poor natural environment, especially to the hunt, to the gathering of food, and to all skills serving the preservation of life. As a result of contact with other cultures, loanwords have been adopted—*e.g.*, from European languages into Nama, from Bantu into Kxoe. Native Khoisan creations that reflect non-native innovations also occur; *e.g.*, Kxoe */am-mũ-'o-xo* "clock, watch" is literally "sun-see-on-thing." The use of words in a figurative sense to label new objects is another process for word-formation. Examples include Kxoe *yɛ-≠'am* "bridge," which is literally "hole upper side," and *kuru* "to drive [a car]," which derives from "to press the bellows." Gender symbolism also plays a role in the formation of words for objects in the contact cultures; *e.g.*, the Nama masculine term */nũ-b* means "leg," while the feminine counterpart */nũ-s* means "wheel."

Basic numbers exist for 1 and 2 and, in some languages, for 3; higher numbers, however, are circumscribed. For example, the number 4 in Kxoe is literally "lick hand bone quantity"—that is, "the finger with which one licks out a pot." The numbers in the languages of the Bushmen seldom go beyond 10; this contrasts greatly with the practice in Nama, and in Hottentot in general, in which there is a decimal system with noncompound numerals from 1 to 10.

In general, the unit of the vocabulary equivalent to the word in European languages is a root whose category as a noun or verb is determined by the context and by the use of noun and verb affixes or particles. Compound words are often used to extend meaning, as English derived words do (*e.g.*, in Kxoe, *kx'â-xò*, literally "drink [verb]-thing" means "beverage").

Writing and texts. About 10 Khoisan languages have been recorded with various degrees of intensity by missionaries and linguists. The best known are Nama, Kxoe, !Khung, and /Kham, followed, to a lesser degree, by !Kora, ≠Khomani, //Khegwi, Naro(n), and /'Auni. The old individual methods for recording clicks were superseded by the Lepsius system (1854), which is, with some modifications, still in use. Studies in Kxoe, !Khung, !Khong, /Guikhoe, and Sandawe have been carried out in recent times, with current research concentrating on !Khung. In view of the difficulties of research among vanishing bands of peoples, the prospects of gathering sufficient material in the remnant Khoisan languages are not good.

Folklore collections

The largest collection of folkloristic texts was taken down in the now extinct /Kham language of the Cape of Good Hope. Next to /Kham, the most comprehensive collection of texts on history, folklore, and traditional and modern life was recorded in the Kxoe tongue. Texts on folklore and history also exist in Nama and Korana and to some extent in !Khung. Literacy is found only in the Nama language, among the Nama and Bergdama. In !Khung, the first two primers were printed in 1969.

(1876–88), contains one of the earliest attempts at an overall classification of African languages; GEORGE PETER MURDOCK, *Africa: Its Peoples and Their Culture History* (1959); THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics*, vol. 7, *Linguistics in Sub-Saharan Africa* (1971); ARCHIBALD N. TUCKER and MARGARET A. BRYAN, *The Non-Bantu Languages of North-Eastern Africa* (1956), the most detailed survey of all the Chari-Nile languages and language groups, plus many others; *Linguistic Analyses: The Non-Bantu Languages of North-Eastern Africa* (1966), linguistic sketches of the languages included in Tucker and Bryan (1956); DIEDRICH WESTERMANN, *Die Sudansprachen, eine sprachvergleichende Studie* (1911), an attempt to demonstrate the interrelationship of five West African languages (Twi, Ga, Ewe, Yoruba, and Efik) and three from East Africa (Kunama, Nubian, and Dinka), thereby seeking to show the unity of all the Sudanic languages; *Die westlichen Sudansprachen und ihre Beziehungen zum Bantu* (1927), weakens the case for the interrelationship of all the Sudanic languages by showing a closer interrelationship between the Western Sudanic and Bantu languages; "Charakter und Einteilung der Sudansprachen," *Africa*, 8:129–148 (1935), revises the author's earlier views on the Sudanic languages; and with MARGARET A. BRYAN, *The Languages of West Africa* (1952), the most detailed survey of the languages of West Africa.

Niger-Congo languages: Current Trends in Linguistics, vol. 7, *Linguistics in Sub-Saharan Africa* (*op. cit.*), is the most authoritative source on the Niger-Congo languages. This volume includes, among others, articles on West Atlantic, Mande, Voltaic, Kwa, Adamawa-Eastern, Benue-Congo (exclusive of Bantu), and Bantu. Significant light is thrown on the history and current research in these languages, and the "Check-List of African Language and Dialect Names" by WILLIAM E. WELMERS is an indispensable guide to the problem of variant names for languages. A summary of selected facts about the languages may be found in the series called *Handbook of African Languages*, sponsored by the International African Institute, especially the two volumes on Bantu by C.M. DOKE (1945 and 1954), the two on the same subject by MALCOLM GUTHRIE (1948 and 1953), and the one by DIEDRICH WESTERMANN and MARGARET A. BRYAN on the *Languages of West Africa* (*op. cit.*). The most important comparative study of the Bantu languages is presented in MALCOLM GUTHRIE, *Comparative Bantu: An Introduction to the Comparative Linguistics and Prehistory of the Bantu Languages*, 4 vol. (1967–70). The following periodicals are devoted entirely to articles on African languages, of which the overwhelming majority are concerned with Niger-Congo: *Bantu Studies*, *Journal of African Languages*, *Journal of West African Languages*, *Afrika und Übersee*, *Studies in African Linguistics*, *African Language Studies*, and the *African Language Review*.

Chari-Nile languages: MERVYN W.H. BEECH, *The Suk: Their Language and Folklore*, with introduction by SIR CHARLES ELIOT (1911); MARGARET A. BRYAN, "The T/K Languages: A New Substratum," *Africa*, 29:1–21 (1959); "The *N/*K Languages of Africa," *J. Afr. Lang.*, 7:169–217 (1968); MORRIS GOODMAN, "Some Questions on the Classification of African Languages," *Int. J. Am. Linguistics*, 36:117–122 (1970); OSWIN KOEHLER, "Geschichte der Erforschung der Nilotischen Sprachen," *Afrika und Übersee*, vol. 28 (1955), a history of the investigation of the Nilotic languages, including "Nilo-Hamitic," and suggesting a new subgrouping; G.W. MURRAY, "The Nilotic Languages: A Comparative Survey," *Jl. R. Anthrop. Inst.*, 50:327–368 (1920), an attempt to prove the common ancestry of Nubian, Bari, Masai, and Shilluk; P.L. SHINNIE, *Meroe: A Civilization of the Sudan* (1967), includes a discussion of the Meroitic language; BRUCE G. TRIGGER, "Meroitic and Eastern Sudanic: A Linguistic Relationship?" *Kush*, 12:188–194 (1964); ARCHIBALD N. TUCKER, *The Eastern Sudanic Languages* (1940), compares, among others, the languages renamed Central Sudanic by Greenberg, and concentrates on the Moru-Madi group and Lendu; DIEDRICH WESTERMANN, *The Shilluk People: Their Language and Folklore* (1912), discusses the classification of the Nilotic languages.

Khoisan languages: (Classification): E.O.J. WESTPHAL, "A Re-classification of Southern African Non-Bantu Languages,"

J. Afr. Lang., 1:1–8 (1962): "The Click Languages of Southern and Eastern Africa," *Current Trends in Linguistics*, 7:367–420 (1971); and "The Linguistic Prehistory of Southern Africa: Bush, Kwadi, Hottentot, and Bantu Linguistic Relationships," *Africa*, 33:237–265 (1963), with maps; L.W. LANHAM and D.P. HALLOWES, "Linguistic Relationships and Contacts Expressed in the Vocabulary of Eastern Bushman," *Afr. Stud.*, 15:45–48 (1956); for a comprehensive list of classified languages, see D.F. BLEEK, *A Bushman Dictionary* (1956). (*Distribution*): OSWIN KOEHLER "Die Khoe-sprachigen Buschmänner der Kalahari: Ihre Verbreitung und Gliederung," *Kölner Geogr. Arbeiten. Festschrift Kurt Kayser*, pp. 373–411 (1971), with map. (*Phonology*): C.M. DOKE, "An Outline of the Phonetics of the Language of the Chũ: Bushmen of North-West Kalahari," *Bantu Stud.*, 2:129–166 (1925); D.M. BEACH, *The Phonetics of the Hottentot Language* (1938). SNYMAN, *An Introduction to the !Xu (!Kung) Language* (1970); D.F. BLEEK, "Bushman Grammar: A Grammatical Sketch of the Language of the /xam-ka-/k'e'," *Zeitschrift für Eingeborenen-Sprachen*, vol. 19–20 (1928–30); L.F. MAINGARD, "The ≠Khomani Dialect of Bushman," in J.D.R. JONES and C.M. DOKE (eds.), *Bushmen of the Southern Kalahari* (1937); F. RUST, *Praktische Namagrammatik* (1965), based on material of H. Vedder and J. Olpp. (*Comparative studies*): OSWIN KOEHLER, "Studien zum Genussystem und Verbalbau der zentralen Khoisan-Sprachen," *Anthropos*, 57:529–546 (1962), deals with gender and verb system of Central Khoisan; D.F. BLEEK, "A Short Survey of Bushman Languages," *Zeitschrift für Eingeborenen-Sprachen*, vol. 30 (1939–40). (*Vocabulary*): D.F. BLEEK, *A Bushman Dictionary* (1956), a compilation of all language material available, except Hottentot; J.G. KROENLEIN, *Wortschatz der Khoi-Khoin-Namaqua-Hottentoten* (1889), on Nama. (*Oral literature*): W.H.I. BLEEK and L.C. LLOYD, *Specimens of Bushman Folklore* (1911), texts in /Xam with translation and annotations. (*General information*): I. SCHAPERA, *The Khoisan Peoples of South Africa* (1930), deals also with distribution and classification. (*Eyasian languages*): O. DEMPWOLFF, *Die Sandawe* (1916), with a chapter on language and vocabulary; D.F. BLEEK, "Traces of Former Bushman Occupation in Tanganyika Territory," *S. Afr. J. Sci.*, 28:423–429 (1931).

(M.F.Go./D.W.C./O.R.A.K.)

African Peoples, Arts of

This article is concerned primarily with the arts of sub-Saharan Africa, which is often called black Africa, from the predominant skin colour of its peoples, some of whom, the Bushmen and Pygmies, are more properly described as yellow; but the prehistoric art of the Sahara is also included as an extension of The Sudan (the belt of open country stretching across Africa from east to west, just south of the Sahara). The arts of settlers (from Europe and Asia) of the colonial period are not included except insofar as they have influenced the arts of black Africa.

Subdivisions of black Africa

The continent can be subdivided in a variety of ways. In this article it is divided, for the sake of convenience and consistency from section to section, into five areas, corresponding primarily to geographical regions: the open grasslands of The Sudan, the woodlands and forests of West Africa, the basin of the Congo River, the East African savannas, and those of South Africa. These divisions do not necessarily correspond to other possible divisions, such as linguistic or religious ones. Nor do they reflect homogeneous artistic production. The western part of The Sudan, for example, is an area rich in sculptural styles and production; in the eastern part, however, sculpture has been little developed, partly because of the less settled way of life; and artistic expression manifests itself mainly in music and oral literature. Again, colonial experiences in French-speaking and English-speaking Africa have given to contemporary literature a unity of theme and language that corresponds not to geographical regions but to the way the European colonial powers divided the continent.

Influences from outside have also subdivided the continent on a basis of religious tradition. Christians in black Africa form subgroups of traditional cultural units, their artistic expression being often totally alien, though sometimes expressing the imported values through traditional modes, as in the music and dance of the Aladura churches of Nigeria or the Oye-Ekiti sculptures, with Christian subjects. The primary concern in this article, however, is with peoples who have their own religious system—often called pagan animist—which their arts reflect. Islām, however, for about a millennium, has been converting black Africans, with the result that in many areas it has become so closely integrated into the culture of the people that it must be regarded as their traditional way of life; the arts of these peoples, too, will therefore be considered.

This article is divided into the following sections:

I. Theoretical considerations
  The African conception of art and the artist
  Backgrounds of African arts
  General characteristics of African arts
  African arts in the contemporary world
II. Literature
  Oral traditions
  Modern literatures
III. African music
  Music and society
  The structures of African music
  African musical instruments
IV. Performing arts
  General characteristics
  African dance
  African drama
V. Visual arts
  Types of African visual art
  Sudanic cultures
  West African cultures
  East African cultures
  Southern African cultures
  Central African cultures

I. Theoretical considerations

THE AFRICAN CONCEPTION OF ART AND THE ARTIST

In attempting to understand the arts of Africa, non-Africans must free themselves from a conceptual framework that separates factors in a way not always relevant for Africa. The West sets both artists and the arts apart from the rest of life: there are special buildings for the performing arts, and artists expect to be able to support themselves entirely from the practice of art. In Africa the artist may be professional in the sense of having served a long apprenticeship to acquire a specialized skill for which he is paid, but it is only those sculptors who work mainly for sale to Europeans or those musicians performing in large cities who can support themselves exclusively from their art. Although artists are sometimes thought by their countrymen to possess a special temperament, as among the Gola, or a special prestige gained by their skill, as among the Baule, which sets them apart, they nevertheless remain integrated members of the community and must still cultivate their farms.

The African artist as a "professional"

Skill in one or more of the performing arts is often a prerequisite to high rank in an African society: a chief or a priest may have to be a skilled dancer, for example, among the Yoruba and Ashanti; and in order to understand messages sent to him by his drummer he must also have mastered that art. A good deal of the respect such chiefs enjoy accrues from their artistic skills.

The Western distinction between artists and craftsmen is not usually relevant in Africa; the sculptor does not consider it demeaning to produce domestic utensils of wood, and in consequence everyday objects tend to be well made and well designed. The West, with its emphasis on specialization, has had to relearn the value of functionalism; yet this is a value that modern man's peasant ancestors, like Africans in traditional society, took for granted.

Field investigations have revealed that in African societies there are generally accepted standards by which an artist's performance or product is evaluated. A sculpture, for example, that does not reach the minimum standard will be rejected at once. Basically, this means that its form must comply to the norm established by the tradition for the class of object to which it belongs; for

instance, a mask required for a cult must possess features that distinguish it from the masks of other cults. The application of critical standards may vary to some extent from one art form to another within the society: a fine old sculpture, because of termite damage, may be replaced by a new one of inferior quality, but a poor dancer can never replace a good one. The reason for this is that the effectiveness of the ritual depends directly on the skill of the dancer, whose creation exists only at that moment in time, whereas the carving used in the ritual is generally seen as no more than a vehicle in which a spiritual force is brought into action during the performance of the ritual. Exceptionally, the Rega (Lega) judge sculptures on the basis of their effectiveness in use.

Integration of African arts

An important factor, which is only beginning to be appreciated by non-Africans, is that Western academic disciplines have separated out (as has been done in this article) artistic phenomena that in Africa are conceived as a unit. Because an African mask can be enjoyed as a work of sculpture when torn from its context and isolated, immobile, in a museum case, Westerners tend to equate "African art" with sculpture. Africans, however, do not consider the mask a discrete entity; it is part of a costume, and it is of no importance until it is danced in, to appropriate music and lyrics. When an Ibo sculptor was asked to carve a mask that could be taken to America as an example of his work, he produced a carving of a human figure wearing the mask, explaining that the full beauty of the masquerade would not be seen in the mask alone.

For an African, in fact, the sculpture is likely to be the least important element; costumes for the masquerade, for example, are considered more important than the mask, which is sometimes dispensed with completely. The *egungun* (ancestor) cult of the Yoruba may employ masks or elaborate sculptured headpieces or, with equal effect, merely a costume that hides the body entirely. In some societies the dancing is also considered more important than the mask: the Igbira, when watching a masquerade, criticize the dancing rather than the sculpture. Consequently, the dancer or costume maker enjoys greater prestige than the carver in these societies. Often the musician is the highest ranking artist, while the respected *griots* of the western Sudan are musician, singer, poet, and historian all at the same time.

The arts in Africa for too long have been observed through Western eyes; the data have been recorded and interpreted ethnocentrically, with unfortunate results. For a long time it was thought, for example, that the African artist was anonymous and that he worked in a style which, in some mysterious way, expressed the collective volition of his community. (Such ideas are still being expressed.) In fact, African artists were anonymous only because investigators had not bothered to ask for their names; the anonymity was only a reflection of Western ignorance. The situation is comparable to that in medieval Europe, in which the alleged anonymity of the artist simply reflects the incompleteness of written records; for with more careful examination of those that do survive, the names of many artists have been revealed. Thanks to field studies, the names of hundreds of African sculptors are now known throughout the rest of the world. The greater the sculptor's skill, the greater his fame among his countrymen, and, in consequence, the more widely spread are his sculptures. A performing musician similarly achieves individual fame, which is closely associated with his repertory. Even the composer of a piece that others perform is often remembered by name, though perhaps as often only the clan to which he belongs or his village is remembered as having originated it.

Freedom of the artist

Any art product in a traditional African society is required to conform to the norms for the class of object; but provided these minimal requirements are met, the artist has considerable freedom to express his own ideas. For example, among the Mende the *bundu* mask of the Sande (women's initiation society) has a closely prescribed shape (Figure 1), but the artist is free to represent the hair as elaborately as he wishes. Similarly, the masks of the Gelede society of the Yoruba have a prescribed

Figure 1: Mende *bundu* mask of the Sande (women's initiation society), wood, Sierra Leone. In the Manchester Museum. Height 38.1 cm.
Frank Willett

form for the cap mask itself, but the carver is encouraged to be inventive in the superstructure; for the purpose of the dance is to please the witches—that is, potentially all women in the community—so the more unusual his idea, the more effective the ceremony will be. Thus, the set of masks carved for a 1969 series of ceremonies at Meko represented a kerosene pressure lamp; a couple riding a motorcycle; two hunters with a boar; and a carpenter sawing wood in his workshop.

BACKGROUNDS OF AFRICAN ARTS

For an understanding of the African arts, a knowledge of their context in the society in which they originate is required. The carver's use of masses and of open space may produce an aesthetically successful sense of weight or of lightness, but the degree of the artist's technical success can be fully appreciated only if one knows the function the piece was intended to have in the society. Similarly, the rhythm for which African music is praised in the West often has subtleties that escape the untutored ear; and the combination of rhythm and tune played by so-called "talking drums" is subtly related to the tones and rhythms of the drummer's spoken language, which has to be understood before the drumming itself can be appreciated or analyzed.

The arts and the structure of society. All African arts reflect the structure of the society in some degree. This is especially clear in societies that have a hierarchical organization. For example, in Ashanti and among the Yoruba, there are special dances reserved for the king, others specifically for chiefs, and others for priests. Again, sculptured objects—for example, ceremonial staffs and swords—are the prerogative of specific ranks in the society. Among the Yoruba, bead-embroidered objects have a very restricted distribution, confined mainly to the king and his family; though beadwork emblems may be allowed to his chiefs, as is the practice at Ife. In Benin, castings in brass and carving in ivory (Figure 2) were restricted to the king and the palace altars, though permission could be given for small (and, very exceptionally, large) castings to be made for lower ranking members of the community. No such concession ever appears to have been made in the use of ivory. The king's palace is usually decorated with motifs that echo his position in society; the palace of the kings of Dahomey, for example, is

decorated with painted low-relief sculptures of royal emblems and events of their reigns. Even in societies whose social stratification is simply one of age groups, there are dances belonging to each individual group. In some societies, the playing of one-note parts in musical consort may express the greater importance attached to the group than to the individual. Occupations, too, are reflected in the arts. In some societies each occupational group has its own dances, as well as its own festival; and some have special ceremonial emblems. The head of the smiths in a Yoruba town has a curved iron rake with a decorative brass handle that is both an emblem of his position and a piece of ritual equipment.

The arts and religion. One of the most widespread religious ideas regularly finds expression in the arts; namely, the cult of the ancestors. The community is commonly seen as composed of the unborn, the living, and the dead. Life is conceived of as cyclical: each individual goes through these three stages, and it is the ancestors who send children. The Fang express this continuity in the figures that guard the bones of their ancestors (Figure 3; right), for these figures combine the proportions of the newly born—large head, long body, and short limbs—with the marks of maturity, adult sexual organs. Because the ancestors are concerned in the affairs of their descendants, they are made manifest, often by means of masks, in the *rites de passage*, during which an individual member of the community changes his position in the cycle of existence. Thus, the Dogon of the Niger Bend employ masks when the young men are initiated into full membership in the community, at funerals, and, later, to send the spirits of the deceased to join the other shades. Among the Dogon, too, everyday objects such as stools and doors (Figure 3; left) are decorated with the figures of ancestors to invoke their protection. The entire Dogon people reassert their unity every 60 years by making a Great Mask for each separate community in turn.

The role of masks

Art, environment, and way of life. The arts also reflect both the environment and the way of life. Wood sculpture is naturally most highly developed where suitable wood can be easily obtained, but a settled agricultural existence is also necessary. Because nomadic hunters such as the Pygmies cannot carry sculptures around with them, they express themselves instead in the arts of music, dance, and oral literature. In open country lacking timber, both hunters and pastoralists may express themselves visually, through painting (for example, Bushman paintings and those in the Tassili), as well as in the non-

visual arts. Architecture, too, shows adaptations to the environment—for example, in providing insulation in hot climates; to social structure, in providing separate huts within the family compound for each wife and her children; and to the type of existence, as in settled communities, where special places are often reserved for musicians and dancers. Dances often enact ritually the means of food production, as in dances of planting and harvest; and the music that accompanies planting among the Dogon accelerates at the end, as if to symbolize growth.

The environment is important to the historian of the arts, for in most parts of black Africa it is exceptional for wooden objects—sculpture and musical instruments—to be preserved. The history of sculpture has to be written largely in terms of stone, metal, and pottery; the history of musical instruments through their representation in these media.

Intertribal and intercultural relations. In attempting to break away from the idea that the African arts are "primitive," when in fact they are highly sophisticated, the term tribal arts has been suggested. Unfortunately, this term attempts to define the form of the society in which the arts are produced rather than the characteristics of the arts themselves. Furthermore, a "tribe" is by no means a fixed and defined social unit. At different times and in different circumstances an individual would identify himself with a social grouping of greater or lesser size, usually seen in opposition to another group of comparable size. Thus, in the Cameroon grasslands, groups based on a single large settlement have been regarded as separate tribes, though they share the same culture; and the 10,000,000 or so Yoruba-speakers have often been regarded as a single tribe despite the fact that they live in large, separate settlements, which are veritable city-states. The assumption of the reality and permanence of tribal boundaries has led to serious misunderstandings about African art. One critic, for example, has suggested that "every tribe is, from the point of view of art, a universe to itself. . . . The tribe is an exclusive 'in-group,' which uses art among many other means to express its internal solidarity and self-sufficiency, and conversely, its difference from all others." There are cases where this is in some sense true. The Dogon, for example, use the *sigui* ceremony and the Great Masks carved for it to express their unity; yet the basic form of the mask, with a very simplified human face surmounted by a tall, flat panel, is shared with the neighbouring Bobo (Figure 4) and Mossi. On the one hand, cult groups, together with their sculptures, overlap "tribal" boundaries—for example, the Poro society is found among peoples in the modern countries of Guinea, Sierra Leone, and Liberia; on the other hand, individual sculptors carve masks for the society's rites in a variety of "tribal" styles as different in character as the Dan and the Ngere modes. The attempt to refine the precision with which one can locate the place where sculptures were carved is further complicated by the fact that sculpture has been traded to and used by totally unrelated groups; for example, Ibibio sculptures are found among the Edo, who live 150 miles away, on the other side of the Niger River. Some similarities of form, however, may be due not so much to diffusion among peoples as to sharing a common heritage. It has been suggested, for example, that the wide distribution of the so-called heart-shaped face, found across the Congo Basin from the Lega to the area of the Ogowe River, is an indication of great antiquity and that the form was spread by the dispersing Bantu-speaking peoples. That it has also been found, however, among the Ibo, who do not speak a Bantu language, may perhaps imply diffusion of the form rather than migration of its users. Reconstructing history from present-day distributions is thus a dangerous pursuit, justified only in the total absence of archaeological and historical data.

Difficulty of defining "tribe"

Implicit in the study of African cultures is the assumption that they were without change before the first contacts with Europeans. This assumption seems to arise not from positive but from negative evidence; that is, the fact that documentation of past changes is lacking, whereas recent changes can easily be documented: Western musical instruments, for example, are commonly employed; and an army gas mask is used in a traditional Ibo masquerade. Yet change seems to be an integral part of the human experience: no society is or ever has been totally unchanging, though the pace of change in Africa might be faster now than it used to be. Thus, scholars may hope one day to write a history of African visual arts. Sufficient evidence has already been found to demonstrate change with time in the visual arts of the Tassili, of the Bushmen, and of Ife and Benin. Because of their impermanent nature, it may never be possible to write the history of African music or dance. Yet scholars will not too easily abandon the hope of doing so; evidence of dance in Meso-America between 500 BC and AD 1500, for example, has been deduced from sculptures and painted pottery.

The role of change in African art

Probably the greater the freedom an artistic tradition allows to the artist, the greater the receptivity to outside influences, particularly when the arts have a secular as well as a religious function. Indeed masquerades in modern Ghana and the so-called fairy masquerades in Sierra Leone, both essentially secular, seem to have been taken over from European papier-mâché masks used for Mardi Gras and Christmas celebrations. The changes under European influence, however, were exchanges: as a result of African influence via the Americas, Western popular dance now emphasizes rhythm, whereas, formerly, as in traditional country dances, or the minuet, space was much more important. Similarly, Western sculptors learned not only to simplify natural forms in their creations but also to enclose space within their masses.

GENERAL CHARACTERISTICS OF AFRICAN ARTS

Westerners still have a long way to go in understanding the arts of Africa and the cultures that produced them. While the importance of studying African arts as an integrated whole is now recognized, for example, relatively little has been done in the field to discover values that apply across Western disciplinary boundaries. One critic who has made the attempt points out that soft materials

such as clothing are represented in Yoruba sculpture as hard and polished; and he compares this to the penetrating sound of rattles and hand clapping and the high pitch of bells and gongs that characterize Yoruba music. Similarly, in singing, a woman soloist's voice often stands out by reason of a high-pitched, penetrating metallic timbre. Perhaps these reflect the same value placed on clarity of line in sculpture. The same critic has also drawn attention to the importance of a "coolness" of expression in the faces of Yoruba sculptured human figures, a quality that avoids emotional expression and that is also expected of dancers in certain cults from which violent dance gestures, too, are excluded. This composure is also an ideal in general human behaviour, not only among the Yoruba but also, as another critic has shown, among the Gola of Liberia, where "the ability to be nonchalant at the right moment . . . to reveal no emotion in situations where excitement and sentimentality are acceptable" is much admired. Among the Gola, too, the dancer should not look emotionally involved.

Avoidance of emotional expression

The arts in Africa are rich in overtones of meaning, echoing the world view of the community; but their investigation is fraught with difficulty. The investigator, for example, may inadvertently lead his informant to produce, simply to please him, the answer he seeks. Moreover, the investigator seeks out the person he judges to be the most knowledgeable member of the community and writes a description of the cosmogony or of the symbolism of the society from that person's evidence. Probably very few other members of the community would share in the subtlety of his interpretation; and in many cases the structure of the society, with successive grades of initiation, reflects this uneven distribution of insight. Thus, what might be presented as the cosmogony or symbolism of an African people may not represent knowledge shared by the entire population. Some of the apparent contradictions in information available to scholars may well arise from the fact that different individuals in a society may have different depths of understanding. Moreover, variation is to be expected from place to place. Even a people like the Yoruba, many of whose cults are widespread, have other cults of very localized distribution; generalizations about the symbolism or cosmogony of the Yoruba people, therefore, must be made circumspectly.

A further complication is the common belief that artists are the best sources of critical information about the arts of their society. In fact, African artists usually refuse to judge their own work and are unwilling to assess that of others, whereas critical judgments of the most important art in a society (for example, the dance) may be obtained quite freely from any of the onlookers.

AFRICAN ARTS IN THE CONTEMPORARY WORLD

In the second half of the 20th century, the arts in Africa are changing more rapidly than ever before. As society changes, the occasions when traditional art forms are required become less frequent; but they are replaced by demands of a new kind, to which African artists are responding. Since colonial times, many potential artists have received advanced Western training, first at European institutions and, more recently, at African universities. Attendance at these institutions has removed the artist from his own society, which would have provided a traditional training; but it has exposed him to Western techniques, values, and traditions, thus broadening his horizons so that he has been able to draw on any tradition that interests him. Thus, Ayo Bankole has composed a Christmas oratorio in Yoruba for soloists, chorus, organ, and drum ensemble; comparable eclectic experiments are conducted in the other arts. Some visual artists as well as musicians have rejected the religion of their ancestors and have found inspiration in Christianity instead.

Traditional literature in Africa was oral, and written literature is an entirely new African art form; it has already produced some writings worthy of a place in world literature. Much of the writing reflects the problems of a changing society (*e.g.*, Chinua Achebe's trilogy), both in looking back to the value system of the past and in seeking new values for the future—an involvement in society that reflects the traditional position of the African artist.

The multiple roles of artists in traditional society are continued also into Western forms: the best known African film producer, Sembene Ousmane, is also a novelist; Demas Nwoko not only sculpts and paints but also designs stage settings; and Wole Soyinka, who built his reputation as a playwright and poet, has written one of the best African novels.

Skills in Western forms, however, seem to have encouraged an interest in the corresponding traditional arts, and modern artists often consciously employ traditional forms. For example, Vincent Kofi's bronze sculpture "Awakening Africa" (Figure 5) is a reclining nude figure, a subject and an attitude more familiar in Western art,

Ulli Beier

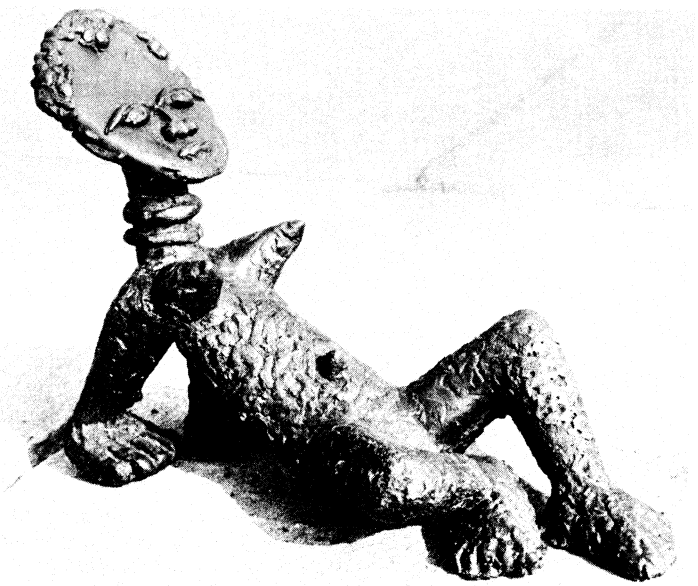

Figure 5: "Awakening Africa," bronze sculpture by the Ghanaian sculptor Vincent Kofi.

with the head and neck drawn from a traditional form of Ashanti sculpture in wood and terra-cotta.

The intermingling of African and Western traditions is currently producing a striking richness in the arts. One aspect of this is the development of what might be regarded as folk art: artists without formal training, either traditional or Western, have been offered the opportunity through workshops in Salisbury (Rhodesia) and Oshogbo (Nigeria) to express themselves in both traditional and Western media. Oshogbo artists, such as the sculptor in cement Adebisi Akanji and the graphic artist Jimoh Buraimoh, have stayed rooted in their community and have found patrons there in a way that Western-trained artists have yet to do. Many visual artists of Oshogbo have drawn inspiration from the writings of Amos Tutuola, who himself can be regarded as a folk artist; for his novels recombine traditional folktales into new stories that are recounted in a form of English closer to that of the Nigerian streets than to the Standard English of the other Nigerian writers. *The Palm-wine Drinkard* has been translated into Yoruba, adapted for the stage by Kola Ogunmola, and is one of the most successful items in the repertory of popular theatre in western Nigeria. Similarly, there has grown up since 1962 the Yoruba Folk Opera, associated particularly with the name of Duro Ladipo, employing traditional music to tell traditional stories in an overall form of presentation that is essentially Western. It was the need to find scene painters for Ladipo's productions, in fact, that led to the establishment of the Oshogbo artists' workshop (known as Mbari Mbayo).

Folk art

There is at present a richness of self-confident creativity in all Nigerian arts that is reminiscent of Elizabethan England. Here clues may be sought to the future of the arts

on the whole continent. Artists with a predominantly Western training have drawn their patronage from outside their own people. Their horizons, wider than those of their ancestors, permit them a wider range of expression, usually entirely personal. The work of painters and sculptors is often African in subject matter but not especially African in style. If they continue to be eclectic, their contribution may well be the valuable one of reducing the emphasis on national and continental characteristics; but they may turn increasingly to their own artistic traditions and eventually develop new African forms of art. For the present, however, it is the folk artists, serving primarily their own communities, who are developing new and specifically African art forms. What is certain is that the present richness of production in all African arts augurs well for the future. (F.Wi.)

II. Literature

The term African literatures is intended to cover both the oral traditions and the mainly 20th-century writings of the Negro, Bantu, and Nilotic peoples living in the part of the African continent south of the Sahara. Though it is not possible to claim a genuine cultural unity for the several thousand peoples living in this area, certain cultural features can be traced throughout black Africa. Especially after World War II, a political consciousness of belonging together, expressed in a Pan-African movement, gained in strength. It is, moreover, convenient to treat the cultures of these peoples separately from that of the Arabs of North Africa, whose traditions, being Islāmic, are basically different, and from that of the European culture of white South Africa. (See ISLĀMIC PEOPLES, ARTS OF; see LITERATURE, WESTERN.)

With the slave trade, oral traditions spread from Africa into the New World, and many African myths, songs, and sayings have survived in the Caribbean and the Americas, where they have helped to give birth to a rich syncretic culture. (Literature by black writers in the Western Hemisphere is discussed in LITERATURE, WESTERN.)

The first modern African writers to be heard significantly in the West, the French-speaking poets of the Negritude movement (see below) of the late 1940s and 1950s, have generally been the most insistent on identifying themselves as African, or black, writers. The majority of English-speaking writers, at a conference in Kampala in 1962, made it clear that they wished to be judged on their merits as writers, not just as "African writers." By the mid-1960s, however, with the development of a larger body of writings by English-speaking Africans and with the growing distance of French-speaking writers from their colonial situation, the apparent differences between French-speaking and English-speaking African writers had begun to seem more verbal than real.

Despite the fact that modern literary activity in Africa exists in relation to vast illiterate populations with their own rich vernacular cultures and is conducted in three major European languages—French, English, and Portuguese—as well as in dozens of printed African languages, certain habits of expression, themes, and approaches to imaginative creation do appear to merit the discussion of this literature as a continental phenomenon. By the 1970s, however, the time was approaching when discussion of "African" literature would need to be accompanied by more precise examination of certain emerging national literatures, such as those of Nigeria, Senegal, and Cameroon. The body of published literature existing in the three European languages is certainly sufficient to be studied in its own right and not merely as a series of exotic extensions of French, Portuguese, or English literature. Furthermore, it is only by the study of African literature comparatively and in its continental context that the true features it has been displaying to the world since its emergence in the mid-20th century can be discovered and understood.

Emergence of national literatures

ORAL TRADITIONS

The poetic and narrative forms of oral tradition among the tribes living south of the Sahara are immensely rich and varied. Most tribes have creation myths and cosmologies; some have pantheons of gods and a body of myths to explain their relationships. The worship of these gods involves praise songs, oracular verse, and incantation. The courts of chiefs usually employ professional bards who are both praise singers to the chief and court historians of the tribe.

During initiation and puberty rites the young men of the tribe, in a period of seclusion in the forest, are made acquainted with tribal history and lore, though this practice is dying out under pressure from modern education and employment. Not all oral traditions are bound up with religion or tribal institutions. There are forms whose only purpose is entertainment, such as proverbs, riddles, animal and trickster tales, and dilemma tales. Even these, however, have a certain didactic function, since they help to establish social norms and to teach sophisticated use of the language.

An important feature of African oral traditions is their close link with music: poetry exists almost exclusively in chanted form or as song, and, among West African peoples with tonal languages (*e.g.*, the Akan and the Yoruba), much poetry is recited on the "talking drum" rather than spoken or sung.

Relation of poetry to music

Myths. African creation stories are perhaps the most varied and imaginative in the world. The Kono of Guinea believe that the original force in the world was Death, who existed before God; the Lozi of Zambia see God as retreating helplessly from the cruelty of man; the creator goddess of the Ijaw peoples of the Niger Delta allows man to choose his own fate before he is born. The Pangwa of Tanzania have a fantastic vision of the world as having been created from the excrement of ants. The Yoruba of Nigeria tell of a creator who got drunk on palm wine and so created cripples and albinos. The most detailed cosmology known, requiring seven days for its recitation, is that of the Dogon, a people living in what is now the West African republic of Mali. An unusually attractive creation myth is that of the Fulani of Mali, who, being herdsmen, have centred their mythology on the sacred substance milk:

> At the beginning there was a huge drop of milk.
> Then Doondari came and created the stone.
> Then the stone created iron;
> And iron created fire;
> And fire created water;
> And water created air.
> Then Doondari descended the second time. And he took the five elements
> And he shaped them into man.
> But man was proud.
> Then Doondari created blindness and blindness defeated man.
> But when blindness became too proud,
> Doondari created sleep, and sleep defeated blindness;
> But when sleep became too proud,
> Doondari created worry, and worry defeated sleep;
> But when worry became too proud,
> Doondari created death, and death defeated worry.
> But when death became too proud,
> Doondari descended for the third time,
> And he came as Gueno, the eternal one,
> And Gueno defeated death.
>
> (Eng. trans. by Ulli Beier in *The Origin of Life and Death*, 1966.)

According to nearly all African mythologies, God first agreed to give man eternal life, but his message was perverted through the stupidity or malice of the messenger. Several hundred variants of the myth of the perverted message are known, distributed over almost the whole of Africa south of the Sahara.

The most elaborate pantheons of gods are probably those found among the Yoruba of Nigeria and the Fon of Dahomey. These deities (*orisha* or *vodun*) are often seen as being, at one and the same time, legendary kings and founders of cities and supernatural spirits and controllers of the elements.

The story of a god must often be gleaned from cryptic references embedded in his praise names (*oriki*, or *mlenmlen*). These are curious mixtures of praise, description, joking abuse, and prayer; and, although the phrases have been handed down for centuries, the singer is free to add

new ones. Thus, Shango (the Yoruba god of thunder and lightning) is compared to the power and rumbling noise of the railway.

The most widely used poetic form

Poetry. The praise name is probably the most widely used poetic form in Africa. It is applied not only to gods but to men, animals, plants, and towns. Most important in many African communities are the praise names of chiefs and war leaders, as, for example, those of the great Zulu chieftain Shaka:

> He is Shaka the unshakeable,
> Thunderer-while-sitting, son of Menzi.
> He is the bird that preys on other birds,
> The battle-axe that excels over other battle-axes.
> He is the long-strided pursuer, son of Ndaba,
> Who pursued the sun and the moon.
> He is the great hubbub like the rocks of Nkandla
> Where elephants take shelter
> When the heavens frown . . .
>
> (Eng. trans. by Ezekiel Mphahlele)

But there are numerous other poetic forms: the Yoruba distinguish between praise names (*oriki*); the poetry of lineages and towns (*orile*); oracle verse (*odu*); hunters' songs (*ijala*); the poetry of masqueraders (*iwi*); incantations (*ofo*); songs (*orin*); and improvisations (*rara*). Incantations play an important part in all African traditions. The Ibo diviner, for example, invokes truth before consulting his bones:

> What will it be today?
> Success or failure? Death or life?
> Ha! The flood cannot run uphill.
> What is the evil spirit that throws his shade
> between me and truth?
> I hold my sacred staff against it.
> Here is the East, there is the West;
> Here the sun rises—
> See the truth come riding on the rays of the sun.
>
> (Eng. trans. by Romanus Egudu, in *Black Orpheus*)

A common poetic form is the magic formula, in which the meaning of the words is often obscure. These formulas are sacred combinations of words the correct repetition of which, accompanied by the proper ritual, is believed to be effective both in curing and cursing.

Probably the most elaborate body of poetry is that of the Ifa oracle among the Yoruba. Even the most learned priest is not expected to know it all, and the recital of the most important *odu* takes a whole night. The poems are accompanied by stories that constitute the mythological or historical precedents by which the diviner judges his client's case.

Every situation in African life is accompanied by poetry and song. The herdsman praises his bull ("My bull is dark like the raincloud in a storm" [Dinka]); the young warrior sings of his bride ("Neither her heel nor her palm are rough, but sweet to the touch like liver" [Fulani]); children invent a song to comment on an important event ("Europeans are little children, at the riverbank they shot an elephant, its blood became a canoe and it sank" [Nyasa]); the widower mourns the death of his wife ("What are your wares that they sold out so quickly?" [Akan]).

Animal-trickster stories

Folktales. The best known type of African folktale is the animal-trickster story. In Bantu Africa (East, Central, and South Africa) and the western Sudan, the trickster is the hare; in West Africa, the spider (Ghana, Liberia, Sierra Leone) or the tortoise (Ibo, Benin, Yoruba). The dominant characteristic of the trickster is his ingenuity, which he often uses to gratify his greed and satisfy his malevolence. But, despite his faults, he enjoys the audience's sympathy because by his trickery he usually defeats bigger and stronger animals. The Yoruba consciously poke fun at their own faults when they tell stories of the tortoise-trickster. Sometimes the tortoise's cunning defeats itself, as, for example, in the delightful tale in which the tortoise steals from the gods a calabash that contains all the wisdom in the world. He hangs it around his neck and is so eager to get home with it that, when he comes to a tree trunk lying across the road, he is unable to cross it because the calabash gets in his way; and in his anxiety he fails to think of putting it on his back. Frustrated, the tortoise smashes the calabash, and so, ever since that day, wisdom has been scattered all over the world in tiny pieces. Anansi (the spider-trickster, of whom stories are told among the Akan of Ghana and, as Anancy, in Jamaica) often appears as a mythological figure, the fiendish opponent of the sky god who steals the sky god's stories or tricks him into allowing disease to enter the world. In this function he shows some similarity with the Yoruba trickster god, Eshu, who consistently opposes the other gods and thwarts their intentions. There are a number of African tribes that also have story cycles about human tricksters—for example, the stories of Yo in Dahomey, the Lay cycle of the Iraqw in Tanzania, and the Zulu Uhlakanyana stories.

A variant of the trickster story is the escape story, in which the hero extricates himself from an impossible task by imposing an impossible condition. One such story tells how a cruel king of Benin ordered his subjects on pain of death to build a new palace but to start at the top and build downward. All were in despair until one wise old man went to the King and said that they were now ready to begin and would he, according to tradition, come and lay the foundation stone?

Dilemma tales

Stories of another kind, told for entertainment, usually on moonlit nights, are dilemma tales, in which the audience is invited to supply the ending or solution. An example of a dilemma tale told among the Wolof (Senegal, The Gambia) is as follows. Three brothers journey to a strange land and are all married to the same girl, with whom they sleep in turn. One night she is murdered by a robber, and the eldest brother, with whom she is sleeping, is condemned to death on suspicion. He begs leave to visit his father before he dies. When he is late in returning, the second brother offers to die in place of him. As he is about to be executed, the third brother steps forward and "confesses" that he is the murderer. But, at that moment, the eldest brother rides in, just in time to embrace his fate. Which of the brothers (the listeners are asked) is the most noble?

In another group of tales, prominent features of animals are explained (*e.g.*, ". . . so that is why the tortoise has a broken back").

Proverbs and riddles. "Proverbs are the palm oil with which words are eaten," say the Ibo. The art of conversation and argument depends, in fact, on their use. By them the speaker shows his learning, and often only the first half of a proverb is spoken. Thus, when a man says, "We know whom we love . . .," the audience knows that what is implied is ". . . but we don't know who loves us." Use of proverbs also enables the speaker to attack an opponent obliquely, without mentioning his name or the subject of the dispute. Proverbs express not only a people's inherited wisdom and code of behaviour ("If a child washes his hands, he will eat with kings" [Ibo]) but also their imagination and sense of humour ("If the earthworm does not dance in front of the cock, he will still be eaten, but at least the cock cannot say that he was provoked" [Yoruba]). The largest collection of African proverbs, made by a Swiss Lutheran missionary, J.G. Christaller, and published at Basel in 1879, contains 3,600 in the Twi language of Ghana.

Riddles used as metaphors

Riddles usually take the form of a statement, not a question. So, in the riddle "People run away from her when she is pregnant, but they rejoice when she has delivered" (the answer is a gun), the question "What is it?" is understood. Often the riddle is an exercise in metaphorical speech, intended to display the questioner's imagination rather than to test the cleverness of the audience (*e.g.*, the Yoruba "We tie a horse in the house, but its mane flies above the roof, to which is answered "fire" and "smoke").

Survival of oral tradition. By the mid-20th century many oral traditions, particularly those associated with traditional ritual, were disappearing, and poetic forms were gaining new content and application (*e.g.*, praise names, applied to politicians; songs of abuse during elections, often taking the form of incantations). Nationalism and higher education tended to make Africans more conscious of their cultural heritage, and the collection and

conservation of oral traditions was no longer left to foreign anthropologists. Some of the best, most authentic collections are those by African writers and scholars that began to be published in the 1930s and that increased in number after World War II.

African folklore has come most powerfully alive in modern writing in the works of Amos Tutuola. *The Palm-wine Drinkard* (1952) and *My Life in the Bush of Ghosts* (1954) are inspired re-creations of the world of Yoruba folklore. Tutuola, whose long rambling tales are improvisations on traditional themes, is a born storyteller. Better than any exact translation, his books convey the rich inventiveness of traditional Yoruba folktales, the rather grim humour of which is often mingled with fear, pain, and other extremes of sense or impression.

MODERN LITERATURES

Though the written literatures in Swahili, in the main Bantu languages—Zulu, Xosa, and Sotho—and in Yoruba antedate in origin those in European languages, they are discussed after the more considerable modern literatures in French, Portuguese, and English—the so-called metropolitan languages of Africa. Ironically, African nationalism and anticolonialism had to find expression in the languages of Africa's colonial rulers.

French. The first contemporary written and printed literature to emerge was born as a protest against French rule and the policy of assimilation. Its leading figure was Léopold Sédar Senghor, who in 1960 was elected first president of the Republic of Senegal. In Paris during the 1930s he met Negro writers from the French Caribbean such as the poets Aimé Césaire from Martinique and Léon Damas from French Guiana. Together, they began a critical examination of Western values and a reassessment of African culture, and they founded *Présence Africaine* (1947–), Africa's leading literary journal. Senghor's anthology *Anthologie de la nouvelle poésie nègre et malgache* (1948; "Anthology of the New Negro and Madagascan Poetry") was an important influence in the formation of the idea of a Negritude (a term first used by Césaire) that should include poets outside Africa—in the French Caribbean territories and in Madagascar, for example. Senghor's poems are sometimes regarded as examples of 20th-century French poetry in the manner of Paul Claudel or St. John Perse, but they are, in fact, essentially African: his love poetry, in particular, is intensely so in structure and tempo. His themes are those of Negritude: he attacks the soullessness of Western civilization ("no mother's breast, but only nylon legs") and proclaims that African culture alone has preserved the mystic warmth of a life that could still revive "the world that has died of machines and cannons." This culture, says Senghor, gains strength from its closeness to nature and constant contact with "the ancestors"; Western culture is out of step with the world's natural and ancient rhythm. Therefore, he proclaims, "[We are] the leaven that the white flour needs." In his long rhapsodic lines he has tried to make the French language swing and dance in the rhythms of his native Serer language.

Poetry of Senghor

Another Senegalese, Birago Diop, has similarly explored the mystique of African life in a volume of poems, *Leurres et lueurs* (1960). His fellow countryman David Diop wrote the most violent and full-blooded protest poetry to be produced by the Negritude movement: "When civilization kicked us in the face, when holy water slapped our cringing brows. . . ."

Negritude novelists

The most important Negritude novelists are the Cameroonians Mongo Beti (pseudonym of Alexandre Biyidi), who wrote *Le Pauvre Christ de Bomba* (1956; *The Poor Christ of Bomba*, 1971), and Ferdinand Oyono, author of *Une Vie de boy* (1956; *Houseboy*, 1966) and *Le Vieux Nègre et la médaille* (1956; *The Old Man and the Medal*, 1967). All three novels aim to explode the French colonial myth of France Outre-Mer: that the French West African possessions were not really colonies and that educated Africans are thus simply "black Frenchmen." Both Oyono's main characters—in the first novel, the houseboy; in the second, the old man—live under the illusion that they are the white man's friends and protégés; both learn through bitter experience that the white man is merely exploiting them. Beti's novel is similarly a novel of disillusionment, but here it is the white man, Father Dumont, whose ideals are shattered. After many years as a missionary in Africa, he is finally forced to realize that under a colonial system the missionary becomes the involuntary servant of the administration and so, whatever his personal convictions, is inevitably part of the colonial setup.

The second generation of French African writers was less concerned with the public rhetoric of Negritude. Thus, though the Congolese poet Tchicaya U Tam'si sometimes speaks of his people's sufferings ("My race remembers the taste of bronze drunk hot"), he does not claim to be the spokesman of his race. In *Le Mauvais Sang* (1955; "Bad Blood"), *Feu de brousse* (1957; *Brush-Fire*, 1964), *À triche-coeur* (1960; "A Game of Cheatheart"), *Épitomé* (1962), and *Le Ventre* (1965; "The Belly"), he explores his personal agonies in Surrealist poems in the dense texture of which mythological, Christian, and sexual imagery is juxtaposed.

Camara Laye became famous with his romantic autobiography *L'Enfant noir* (1953; *The Dark Child*, 1954), which draws a poetic, idyllic picture of life in a traditional African town. His most important work, however, is the novel *Le Regard du roi* (1954; *The Radiance of the King*, 1956), which describes a white man's quest for personal salvation in the mysterious atmosphere of the West African jungle. It is regarded as among the most imaginative novels to have come from Africa; in its haunting atmosphere and nightmarish intensity, it reminded some critics of the Czech writer Franz Kafka, though the debt to Kafka is limited, and the book is in many respects profoundly African and Islāmic. In a third novel, *Dramouss* (1966), Camara Laye, who in 1965 became a political refugee in Dakar, attacks the harsh methods of Guinea's ruling party.

Importance of *Le Regard du roi*

In the 1960s there was an important development of the philosophical novel in French-speaking Africa, notably by Sheikh Hamidou Kane in *L'Aventure ambiguë* (1961) and by Yambo Ouologuem in *Le Devoir de violence* (1968; "Bound to Violence"). Both writers belong to the Islāmic western Sudan and present their novels partly in the form of "dialogues," either between Islām and Western materialism or between traditional autocracy and Christian compassion.

Portuguese. The 20th-century poetry of Portuguese Africa, know chiefly through Mário de Andrade's *Antologia da Poesia Negra de Expressão Portuguesa* (1958), is mainly extremely militant. Aldo do Espirito Santo sings passionate songs of freedom: "And the blood of lives fallen/in the forests of death,/innocent blood/drenching the earth/in a silence of terrors/shall make the earth fruitful,/crying for justice." Both Mário de Andrade and the more important Agustinho Neto became actively engaged in the Angolan liberation movement.

José Craveirinha, an *assimilado* (*i.e.*, assimilated to Portuguese culture and Roman Catholicism), like all the African writers who have published work in Portuguese Africa, is yet deeply concerned with the problems of race and discrimination: "All feel/uneasiness/at the undoubted whiteness of my bones/white as the breasts of Ingrids or Marias/in Scandinavian lands. . . ." Lourenço Marques, the centre of a considerable literary and artistic activity, has also produced Luís Bernardo Honwana, one of Africa's outstanding short-story writers.

English. Although a genuine African literature in English did not emerge until the 1950s, writing in English by Africans goes back to the 18th century. Perhaps the most remarkable of the works published in England by West Africans sold into or born in slavery and later freed is *The Interesting Narrative of the Life and Adventures of Olaudah Equiano or Gustavus Vassa, the African* (1789; 3rd ed., enlarged, 1790), the first account by an African of his native country. In the 19th century, with the spread of missionary schools, several Africans published prose works in English, among them Samuel Adjai Crowther (see below *Yoruba*), Africanus Horton, and Edward Blyden; in the early 20th, the Ghanaian

18th- and 19th-century English writings

minister of religion Rev. Carl Christian Reindorf wrote one of the first works by an African to make use of oral traditions, *The History of the Gold Coast and Asante* (*c.* 1911); and Casely-Hayford, also a Ghanaian, wrote *Ethiopia Unbound* (1911), a strange mixture of novel, autobiography, and pamphlet.

In the 1940s great advances were made. Popular novelettes, known as Onitsha novels, from the name of the famous market where they were sold, began to be written, and a number of pioneer writers—among them Michael Dei-Anang and Raphael Armattoe of Ghana, Dennis Osadebay of Nigeria, and Edwin Barclay of Liberia—began to publish poems that, technically often crude and somewhat didactic in theme and style, prepared the way for later poets.

The institution in 1948 of university colleges at Accra and Ibadan caused a sudden increase in the number of West Africans receiving a literary education, and the upsurge of the 1950s and 1960s in poetry, the novel, and drama can be related to the emergence of this new generation. The most intense literary activity was in Nigeria, the Ibo proving particularly prolific. Cyprian Ekwensi, who began as an Onitsha pamphleteer, had had six novels published in London by 1969, the most successful being *Jagua Nana* (1961), the story of a Lagos prostitute. Onuora Nzekwu explored the relationship of the educated Ibo to his traditional culture in *Wand of Noble Wood* (1961), *Blade Among the Boys* (1962), and *Highlife for Lizards* (1965). Nkem Nwankwo created the comic figure of *Danda* (1964), the irreverent anti-hero of a novel perhaps inspired by traditional trickster tales. But the outstanding Ibo novelist was Chinua Achebe. All his novels present the conflict of emergent Africa: in *Things Fall Apart* (1958) he showed the impact of British rule on Ibo village life; in *No Longer at Ease* (1960) he analyzed the conflict in the mind of an African civil servant in Lagos whose life is torn between the social pressures of upper class urban life and the demands of his village union; in *Arrow of God* (1964) he again explored the breakup of traditional values and the struggle for political power in an Ibo village. His most committed novel, *A Man of the People* (1966), is a bitter, disillusioned story of political corruption and intimidation in independent Nigeria, ending—prophetically—with a military coup.

Literary activity in Nigeria

The development of Nigerian literature owed much to two related centres in Ibadan. The journal *Black Orpheus* (1957–), with Ulli Beier and Janheinz Jahn as its first co-editors, took its name from Jean-Paul Sartre's famous "Orphée noir" (1948), the introduction to Senghor's anthology (see above), and from Jahn's anthology, *Schwarzer Orpheus* (1954). Inspired by *Présence Africaine* and the First Congress of African Writers (Paris, 1956), *Black Orpheus* published the earliest efforts of African writers in English to find a literary mode of expression. A second influence on the establishment of an independent Nigerian culture was the foundation (1961) of the Mbari Club, a meeting place for new writers and artists that also published the work of many poets and playwrights; a third was the University of Ibadan, where many writers studied (and some later taught), thus, to some extent, avoiding the dichotomy set up in French African writers between their French education, with higher education abroad, and their African cultural heritage.

Role of the Mbari Club

Among poets published by Mbari was Christopher Okigbo, who, until his tragically early death in 1967 while fighting for Biafran independence, was the most polished and prolific Nigerian poet. In *Heavensgate* (1962) and *Limits* (1964), he developed a sensuous, esoteric style. His poetry reads like incantation: mysterious, often obscure, but always musical and intensely evocative.

Suddenly becoming talkative
like weaverbird
Summoned at offside of
dream remembered
Between sleeping and waking,
I hang up my egg-shells
To you of palm grove,
Upon whose bamboo towers hang
Dripping with yesterup wine
A tiger mask and nude spear . . .

(From G. Moore and U. Beier's *Modern Poetry from Africa*, 1963.)

Works of John Pepper Clark

Like Okigbo, John Pepper Clark graduated from Ibadan. His passionate *Poems* (1962) and *Song of a Goat* (1961) were first published by Mbari. Clark is the most urgent and immediate of the Nigerian poets. Less reflective than Soyinka, less meticulous that Okigbo, he works out each poem on the impetus of a single lyrical impulse. He has also written successful plays: *Song of a Goat*, which was performed in London at the 1965 Commonwealth Festival, is the tragedy of a woman, childless because her husband is impotent, who is advised by the priest to have a child by his younger brother. *The Ozidi of Atazi* (performed in the early 1960s; published, 1966) is a stage version of a traditional Ijo ritual play, which in his native village would take seven days to perform.

One of Nigeria's most sensitive poets is Gabriel Okara, whose novel *The Voice* (1964) is a fascinating linguistic experiment—he forces English into the straightjacket of Ijo syntax, so producing an extraordinary and archaic effect, often as beautiful as it is bizarre.

Plays of Wole Soyinka

Africa's most famous playwright is a Nigerian, Wole Soyinka. By the early 1970s he had published nine plays. All are set firmly in contemporary West Africa. In his lighter mood he makes fun of pompous village teachers, as in *The Lion and the Jewel* (first performed Ibadan, 1959; published 1963), or of the cunning "prophets" of the upstart dissident African churches as in *The Trials of Brother Jero* (1962). More important, however, are his serious plays, revealing skepticism and disillusionment. In *A Dance of the Forests* (published 1963), written for and performed to celebrate Nigerian independence in October 1960, he criticized the myth of the glorious African past, rejecting the Negritude concept that the revival of African culture must be inspired by the African cultural heritage alone. *Kongi's Harvest*, which opened the World Festival of Negro Arts (Dakar, Senegal; April 1966), is a brilliant satire on African dictatorship. Though many of its "hero's" traits seemed to be borrowed from the Ghanaian political leader Kwame Nkrumah, Soyinka has made it clear that he had no one person in mind but was attacking the new trend in African nationalist politics.

Soyinka's tragic view of life is most fully expressed in his play *The Road* (published 1965), first performed at the 1965 Commonwealth Arts Festival, and in his novel *The Interpreters* (1965). Publication in 1967 of *Idanre*, his first collection of poems, established him as a poet of distinction. Here, too, he explored his tragic sense of the difficulties and cost of human progress. He has always played an active part in public life, forming two theatre companies, 1960 Masks and the Orisun Players, and lecturing successively at Ife, Lagos, and Ibadan, where he headed the Drama School.

While Nigeria has dominated the literary scene in West Africa, other African nations have also contributed to the new literature. Among the most important poets in the late 1960s were a Gambian, Lenrie Peters, and a Ghanaian, George Awoonor-Williams (now known as Kofi Awoonor). The early work of both was published by Mbari: Peters' *Poems* and Awoonor-Williams' *Rediscovery and Other Poems* (both 1964). Peters brings an unusual scientific intelligence to bear in his poetry, while Awoonor-Williams is deeply concerned with his native Ewe poetic tradition and the means of extending this in English.

In Ghana Efua Sutherland sparked off a theatre movement inspired by folk drama, founding the Drama Studio in Accra. Her own principal plays are *Foriwa* and *Edufa* (both 1967). The most gifted Ghanaian playwright is the young Ama Ata Aidoo who, in *The Dilemma of a Ghost* (1965), explored the complex cultural conflict arising in a village in Ghana when a young man returns from his studies abroad with an Afro-American wife. Her second play, *Anowa* (1969), greatly extended her dramatic range with its study of a tragic misfit in traditional Ghanaian society.

In East Africa in the 1960s, literature was only just coming to birth; and the literary review *Transition* (Kampala,

Uganda; 1961–) played an important part in encouraging young writers. Already, however, James Ngugi had emerged as East Africa's leading novelist, with two novels—*Weep Not Child* (1964) and *The River Between* (1965)— in which he tried to do for his native people, the Kikuyu, what Achebe had done for the Ibo. In a third novel, *A Grain of Wheat* (1967), he reflected profoundly on the meaning of heroism and of national independence. But in the late 1960s the most original talent in East Africa was that of Okot p'Bitek, whose long poem *Song of Lawino* (1966) treats the conflict of cultures with freshness and imagination. The simple device of making it a lament spoken by an illiterate woman, who complains about the strange ways of her university-trained husband, provided p'Bitek with a new approach to a familiar theme and also helped him to find a new and vigorous language, closely based on his native Lwo.

Short stories of protest by South Africans

The emergent work of African and Coloured writers born in, though often living in exile from, the Republic of South Africa has been dominated by the political fact of apartheid. Most find the short story the best medium of protest, among the most successful being Bloke Modisane; Todd Matshikiza; Ezekiel Mphahlele; Richard Rive; a Cape Coloured writer, Alex La Guma; a journalist, Can Themba; and Arthur Maimane. In the late 1950s, *Drum* magazine provided an important forum for these writers.

Autobiographies are among the most moving and significant works by black South Africans. Mphahlele's *Down Second Avenue* (1959) has become a South African classic; and Alfred Hutchinson's *Road to Ghana* (1960) and Bloke Modisane's *Blame Me on History* (1963) are passionate documents in which the authors try to overcome by expressing it the humiliation of their experience as Negroes living in white South Africa.

The outstanding non-white novelist in South Africa in the 1960s was Alex La Guma. His superb eye for detail makes it possible for him to let the horror of a situation speak for itself, so that he never becomes sentimental or overemotional in describing it. His three short novels, *A Walk in the Night* (1962), *And a Threefold Cord* (1964), and *The Stone-Country* (1965), are tense works of protest. The subtlest treatment of the recurrent theme of race relations, however, was perhaps that by Lewis Nkosi in his play *The Rhythm of Violence* (1964).

The outstanding poets of the 1960s were all relatively young—Mazisi Kunene, William Kgositsile, K.A. Noortje, and Dennis Brutus. Brutus is a restrained and mature poet whose chief concern is to preserve human sensitivity in a world of brutality. Though personal suffering and the sufferings of his people loom large in his poetry, it never becomes self-pitying:

> Somehow we survive
> and tenderness, frustrated, does not wither.
> Investigating searchlights rake
> our naked unprotected contours;
> over our heads the monolithic decalogue
> of fascist prohibition glowers
> and teeters for a catastrophic fall;
> Boots club on the peeling door.
> But somehow we survive
> severance, deprivation, loss.
> Patrols uncoil along the asphalt dark
> hissing their menace to our lives.
> most cruel, all our land is scarred with terror,
> rendered unlovely and unlovable;
> sundered are we and all our passionate surrender
> but somehow tenderness survives.
>
> (From his first collection, *Sirens, Knuckles, Boots*, Mbari Publications, Ibadan, 1963.)

Bantu. Literacy came to most of Bantu-speaking Africa in the 19th century with the advent of missionaries and the establishment of mission schools. By the second half of the century, Africans were editing newspapers and participating in translating the Bible and John Bunyan's *Pilgrim's Progress* into the Bantu languages; and the first African minister of religion to be trained abroad, the Xhosa Tiyo Soga, completed his studies at Glasgow University in 1856. Generally, therefore, the period from the mid-19th century, when Western education was becoming established, to the early 20th, when Bantu-language books began to roll off the presses, was one of culture shock, affecting the majority of Africans through Christianity and a significant minority through education.

Influence of Christian missionaries on Bantu writing

Since missionary education had made them question the validity of their own culture, African writers at first turned their backs on their own rich heritage of story, song, poetry, myth, legend, and chronicle and adopted Western forms—the novel, drama, and rhyming and metrically structured poetry. In narrative, reform on Christian lines became an obsession: the "Pilgrim's Progress" theme, the "prodigal-son" theme, the "unquestioning-obedience" theme, the "reward-of-sin" theme, etc. abound. In third-person narrative the author often interrupts the story to sermonize, warn his characters of impending danger, or muse parenthetically over an incident. All this could also, of course, be partly due to the African heritage of didactic tales and of audience participation in their telling.

Christian influence is most prominent in characterization: in general, a character is either Christian and good or non-Christian and bad. Virtue is typified by an overemphatic version of the "turning-the-other-cheek" dictum, which degenerates into an inertia that tolerates provocation by simply not reacting, or by a robot-like reaction in which complete obedience is the ideal. As the "good" characters become less true to life, so the rogues are, in contrast, human, alive, fun loving. Because characters are either saints or satans, they lack that most intriguingly human trait—unpredictability. Change from satan to saint or saint to satan is often sudden and mercurial. Much concern is expressed at the threat to social cohesion arising from periodic absences from their tribal villages of the young men, who go away to find work in the mines or in industry. The "country" is associated with innocence, the city with corruption.

Problem parents are not spared, and, stylistically, this results in a transgenerational plot pattern. First, the background is given—the parents' mistakes in bringing up their children; then, the story proper shows its effects. The flashback technique seems unknown.

Drama has three main technical faults: "mobile scenes" allow an actor to move over a distance much wider than the stage can legitimately represent; characters offstage continue to be seen and heard, while those onstage are forgotten; and parts of the story are narrated, not shown in action.

In poetry, many have attempted to use rhyme and syllabic metrical structures unsuited to the Bantu languages, while many are apparently to a great extent ignorant of the phonology of their own languages and sometimes, therefore, "rhyme" letters, not sounds. When they use the techniques of heroic poetry—a genre forming part of their own cultural heritage—their poetry immediately improves.

Outstanding Bantu writers

These criticisms apply to many, but by no means all, writers in Bantu languages. Despite the need to adjust to new forms, many writers have achieved distinction. Foremost among them is Thomas Mofolo of Basutoland, who, for his three novels written in his native Sotho, is generally regarded as the first important African novelist of the 20th century. The third, *Chaka* (1925; *Chaka, a Historical Romance*, 1931), is a Sotho classic. Later writers include Xhosa A.C. Jordan (*Ingqumbo Yeminyanya*, 1940, "The Wrath of the Ancestors"), the Zulu poet B.W. Vilakazi, of Natal (*Inkondlo ka Zulu*, 1935 [revised 1965], and *Amal'Ezulu*, 1945; Eng. trans. together *Zulu Horizons*, 1962), the Xhosa poet S.E.K. Mqhayi (*Inzuzo* ["Gain"]), Kopano Mushashu, H. Citepo, and the Zulu J.L. Dube, whose *Insila kaShaka* (1930; *Jeqe, the Body-servant of King Shaka*, 1951), about the chief who brought the Zulus to power, was the first novel to be published by a Zulu in his native language. (D.P.K.)

Yoruba. The Yoruba (who live mainly in Nigeria and partly in Dahomey) have an unusually rich oral tradition of myths, legends, folktales, and songs. Their written literature probably began in 1844 with the translation of

the opening chapters of St. Luke's Gospel by Samuel Adjai Crowther, a former slave who, freed by British traders, trained as a missionary and finally became a bishop. As in the Bantu languages, early literature consists mainly of translations from the Bible, the hymnbook, and Bunyan's *Pilgrim's Progress.*

Novels of Fagunwa

Original literature began with *Igbo Olodumare* (1947; "The Forest of God"), the first of a series of fantastic novels by Chief D.O. Fagunwa that gained immense popularity among the Yoruba. By 1970 the total edition of Fagunwa's five novels ran into hundreds of thousands.

Fagunwa's novels are loosely constructed adventure tales containing many folklore elements: spirits, monsters, transformation flights, gods, magic, and witchcraft. But, though the plots are conventional, the style is lively, and Fagunwa's sense of humour is typically Yoruba. His language is visual: a sad man "hangs his face like a banana leaf"; a quarrel "sticks in the throat like a fishbone"; a liar "has blood in his belly but spits white saliva."

Fagunwa created a vogue for fantastic novels among the Yoruba and probably had some influence on Tutuola, whose works in English belong to the same genre. Other writers tried to break away from this tradition, and I.O. Delano's *Aiye d'aiye Òyinbo* (1955; "It's a White Man's World") was the first of a series of realistic novels.

Modern Yoruba literature finds its most vigorous expression in the theatre, with its origins in the morality and biblical plays performed in the breakaway African churches. The first professional Yoruba theatrical company, Ogunde's Theatre Party, was founded by a playwright, Hubert Ogunde, in the 1940s. Ogunde's plays blend elements of music hall and slapstick with astute political satire. The most famous, *Yoruba Ronu* (performed 1964; "Yorubas, Think"), was such a biting attack on the prime minister of Western Nigeria that Theatre Party was banned from the region—the first instance of literary censorship in Nigeria. Ogunde laid the foundations of Yoruba theatre's commercial success and prepared audiences all over Nigeria for his followers.

His colleague E.K. Ogunmola (more successful as actor, mime, and director than as playwright) refined Ogunde's techniques, replacing saxophones with Yoruba drums and writing much more tightly constructed plays, gentle social satires, in which he laughs at, without passing judgment on, folly and weakness. His most typical play is *Love of Money* (performed *c.* 1950 and widely played under its English title), but his greatest success was with an adaptation of Tutuola's *Palm-wine Drinkard* (performed 1963).

Historical plays of Duro Lapido

As literature, the most rewarding dramas are Duro Lapido's historical plays. Making full use of the richness of traditional Yoruba poetry, Lapido created a trilogy about the history of the kingdom of Oyo—*Ọba Kò So* ("The King Did Not Hang"), *Ọba moro* ("The King of Ghosts"), and *Ọba waja* ("The King is Dead"), which were published together in 1964 as *Three Yoruba Plays.* In its entirety this work has the power and ultimate serenity of ancient Greek tragedy. The most outstanding Yoruba playwright, Wole Soyinka, though he writes in English, is not uninfluenced by trends in Yoruba theatre.

Yoruba is perhaps the only African language to produce a magazine devoted to contemporary writing. *Olokun* (1967– ; published twice yearly at Ibadan University) features the work of such modern poets as S.A. Babalola and A. Faleti. (U.Be.)

Swahili. Swahili is the only Bantu language with a tradition of written literature, in Arabic script. The oldest manuscript dates from the 17th century. Apart from some diplomatic correspondence and chronicles, until the 19th century, when missionaries began to collect stories from oral tradition, all Swahili literature was poetry. It drew its inspiration from the Islāmic literatures in Arabic, Persian, and Urdu taken to the east coast of Africa by Oriental traders and scribes. Though some early narrative poems in Swahili are translations or paraphrases of the long odes (*qaṣīdahs*) of the classical period of Arabic literature, none has been traced to an Arabic epic.

Swahili epic poetry is written in four-line stanzas, each line having eight syllables. The most important epics preserved are the *Muhamadi* (6,280 stanzas), a versified life of Muḥammad, the longest written epic in any African language; the *Rasi 'l-Ghuli* (4,384 stanzas), describing the punitive expedition of ʿAlī, Muḥammad's son-in-law, against the evil king whose name gives the poem its title and the conquest for Islām of his country, the Yemen; the *Herekali,* or *Tambuka* (1,145 stanzas), the oldest Swahili epic (the earliest manuscript is dated 1141 [AD 1728]), which describes Muḥammad's legendary campaign in AD 630 against the Byzantine emperor Heraclius; and the *Huseni* (1,209 stanzas), about the life and death of Ḥusayn ibn ʿAlī. Its representation in Swahili literature is of particular interest for the study of Shīʿism (a branch of the religion of Islām) in East Africa.

Epic poetry in Swahili

Other epics (by 1972 more than 70 titles were known) treat Muḥammad's wars against the unbelievers or tell stories of the women in his life (Khadījah, ʿĀ'isha, Fāṭimah) and of the biblical prophets such as Adam, Ayubu (Job), and Yusufu (Joseph). In the early 19th century, secular poetry began to be written, and an epic cycle of *c.* 1900 describes the Swahili wars against Germany. The tradition of the national hero King Liongo, *Liongo Fumo,* a complex of songs that plays an important part in Swahili culture, is of great interest for the study of myth and ritual.

The first secular poet known by name is Muyaka ibn Haji al-Ghassaniy (1776–1840), whose style remains popular. His poems were edited as *Diwani ya Muyaka . . .* (1940). Two important 20th-century poets were Sheikh Amri Abedi and Mathias E. Mnyampala.

Most prose writings are based on traditional legends in a vivid Oriental style, first collected and recorded by Europeans. Modern writers of this type of Oriental saga are David Diva and Omar Shariff. The first writers to introduce the novella form into Swahili literature were James Mbotela in *Uhuru wa Watumwa* (1934; "Freedom for the Slaves") and Muhammad Saleh Abdullah Farsi in *Kurwa na Doto* (1960), a story set in his native Zanzibar. The first detective writer is Muhammed Said Abdulla, whose *Mzimu wa Watu wa Kale* appeared in 1960.

Swahili is the only Bantu language in which history was recorded before the arrival of the Europeans. The town chronicles of Lamu, Mombasa, and Pate have been published, but the Swahili version of that of Kilwa is lost. An important publication is Liajjemi's chronicle of the Wakilindi (1962).

The greatest 20th-century writer in Swahili, Shaaban Robert, stood between two civilizations (his father was a Christian; he returned to Islām) and two literary periods. He wrote didactic stories, Oriental in tradition and style, and also introduced the essay. His fluency and command of language reveal him as a true master of letters. (Ja.Kn.)

III. African music

Music composed and performed in traditional forms by indigenous Africans south of the Sahara is considered to be "African music." North of this area there prevails a distinct musical style heavily influenced by Islāmic music. This definition of African music excludes the performance by Africans of music whose origin is clearly foreign to their communities, such as the musical styles of America, Europe, and the Middle East, prevalent in certain regions of Africa. African music is the "classical" music of the continent. In that it is transmitted from ear to ear with uninterrupted continuity from past generations of Africans, it is also folk music. It is constantly evolving as performers add or subtract elements of the music at will while remaining within the accepted framework of local practice. This process gradually transforms the original or previous conception of a given piece of music into something different but always contemporary.

Although there are many tribes that have little tradition of carving or other plastic art, there is no community in the whole continent without its own music, which in most cases is considerably complex. African music is characteristically polyrhythmic (consisting of simultaneous, distinct rhythmic patterns) and polyphonic (consisting of simultaneous sounds or melodic lines). Like folk musi-

cians elsewhere, African musicians do not actively conceptualize the abstract principles of their music. Yet the unhesitating participation by all members of an African community in a musical performance implies the existence of common, though unverbalized, principles underlying their music making.

This discussion of African music will survey briefly the relation of music and society in Africa, the process of musical composition, and the characteristics of musical scales, songs, and melodies. There will follow more detailed discussions of rhythm, of part singing and harmony, of interlocking techniques and inherent note patterns. Finally, there will be an examination of the different instruments used in African music.

MUSIC AND SOCIETY

Social functions of music. As with largely preliterate communities elsewhere, most African music is socially controlled; *i.e.*, organized in relation to the activities and needs of everyday life. Use of music in a social or private event may be either traditional or spontaneous. Traditional musical activities are mostly combined with such fixed occasions as festivals, rites, and religious celebrations. Spontaneous music making occurs in the private and recreational spheres. In traditional combinations, there are rigid prescriptions regarding roles, responsibilities, general framework, and performance. In spontaneous music, the instruments, songs, and texts—with certain exceptions—enjoy great freedom of expression. Traditional musical activities include marriages, funerals, rites of cult groups such as warrior associations, communal labour, celebrations in connection with chiefship, and worship of the gods. In many cases, the musical activity takes much of the actual time of the event. Such places of performance as the village square, the street, the shrine, the courtyard, or the chief's palace are the musical centres of African communities.

Songs associated with life cycles

Throughout Africa, songs of several kinds are associated with the various ages of life—from infancy, through childhood, adolescence, and maturity, to old age. The repertoire of a single village community may include several hundred songs in traditional styles, all of which are appropriate to one or another of the many seasonal, religious, and social occasions. In addition, secular dance songs and songs of entertainment follow the familiar cycle of novelty, popularity, and decline within a relatively short period. The currency of a dance or popular song is usually longer in rural areas than in towns.

Work songs are the constant companion of much manual labour such as hoeing, threshing, and pounding grain in a mortar. These songs provide the rhythmic compulsion that keeps the work going at a steady pace and thus makes it a form of dance. In Malawi (in southeast Africa along Lake Nyasa), for example, three women will pound together in one mortar, alternating their blows either in rhythm with their song or in cross-rhythm with it (*i.e.*, with rhythms at variance with those of the song). In many situations of communal labour in Africa, there occurs the same responsorial (soloist/group) principle used in the sea chantey in Europe and America: the leader singing different phrases and the body of workers answering with the refrain. Hauling, lifting loads, digging, and hammering are typical rhythmic activities in which responsorial singing is commonly employed.

Cross-cultural influences. During its long history, African music has been subject to many changes. Most influential in recent times is its encounter with Western music, religious as well as academic and popular. Such influences include Afro-American music by way of jazz and Afro-Brazilian music. Dating further back was the Arabization of the African Middle Ages. Arabization in West African music, for example, led to the reduced use and sometimes complete disappearance of harmony. Melodies were also influenced: in Arab-influenced areas there is a preponderance in vocal and instrumental music of the portamento (sliding from one note to the next) and ornamental melodic style characteristic of Arabic music. The Sudanic area (stretching from the Atlantic coast eastward to Ethiopia, south of the Sahara and north of the Equator/), particularly the ancient Fulbe and Hausa states, reveals the greatest increment in Arabic and Oriental instruments. Among them are the *algaita* oboe; the long-tubed *kakaki* trumpet of the Hausa and Nupe peoples; and a number of bowed string instruments.

Impact of Western music

The complex structure of African music has unwittingly created social and psychological repercussions as the continent has developed in the 20th century. Western educators at first dismissed African music as "primitive," and substituted for it in the schools the simpler forms of Western music. Missionaries, fearing the possible association of African music with heathendom, discouraged it. Both professions, together with the phonograph industry, represented the weight and authority of successful material culture. They have persuaded a proportion of Africans—especially those in towns and institutions—to accept their foreign musical prejudices. The result has been the adoption of a popular facade of exotic (to Africa) and semi-exotic music. Such music lacks the normal structure and continuity of African traditional music and is constantly spurred into activity through the usual channels of commercial publicity. Thus in modern Africa, there are the many forms of Western-influenced urban social music that, originating in the streets, conquered the ballrooms, the radio stations, and the commercial disc market. In Ghana and Nigeria, it is named highlife. Its main features are intertribal appeal and the use of Western band instruments and of chords typical of the Western system of harmony. In addition, some African musicians and scholars have begun composing works aimed at the concert hall, church, and school, but which seek to recreate traditional musical styles.

The influence of Western music is important in that it has stimulated misgivings about the integrity of indigenous African culture. Thus many African leaders stress the need for imitation of foreign arts rather than originality. No such doubts appear among the active practitioners of African music who have not broken the thread of artistic continuity. It is to these musicians that future Africans will look for inspiration if they wish to achieve further maturation of their unique musical art.

THE STRUCTURES OF AFRICAN MUSIC

Diverse historical backgrounds, intense attachment to regional spoken languages, widely contrasting environments, and great distances between peoples have created a rich repertoire of many differing styles of African music. They have, however, many characteristics in common and there is evidence pointing to certain degrees of uniformity in the abstract principles underlying African music.

Speech tone and music

In structure, African melodies are closely associated with each of the many languages of the continent. In addition to deriving distinctive characteristics from the stress and rhythm of the spoken language, they are influenced by tone. In most African languages, the meaning of a given sound depends on the tone at which it is spoken. For sung words to be understood, melodies must rise and fall in agreement with the tones of the spoken words. Dependence of melody on speech tone is a common characteristic of musical styles throughout the continent. Other common traits include spontaneous creation; improvisation by performers within traditional frameworks of melody and rhythm; frequent use of polyphony and harmony; and complex rhythmic organization.

Composition. Many composers of African songs maintain that their melodic inspiration is founded upon the tone profile of spoken phrases in their own language. Good craftsmanship demands that sung melody should follow as closely as possible, with certain exceptions, the rise and fall of normal tone sequences. In a song of more than one verse, the initial melody must be modified to accommodate the tone sequences of the new words. In instrumental music, when the composer discovers a satisfactory sequence of notes, he plays it immediately upon his instrument to crystallize its form, "to get it into his hands." In this way, both the tone contour of sung words and the physical action of the hands upon the instrument

act as memory aids to the composer, equivalent to the function of musical notation in other cultures.

The composer of new songs or the person who adds new words or variations to an established style of music is recognized as an important member of society, for he helps to crystallize the general opinions and taste of the community. In preliterate African society, only those songs that are popularly considered to be valid remain in common use and can therefore be taken as genuine expressions of local sentiment. Songs of approval or disapproval voiced by all the village may have profound social and moral effect upon behaviour. Songs of praise or derision may be directed toward individuals or groups, and, if supported by public opinion, may have considerable political significance.

Status of composers and performers

Musicians are not usually considered as a class apart. Everyone normally takes part in the singing and dancing to the best of his ability or, if sufficiently skilled, in the playing of instruments. Gifted musicians may become semiprofessional through popular demand. In several communities, professional minstrels and small troupes of actors tour the towns and villages. They give shows with mime to the accompaniment of drums and other instruments and recite legends or tell stories. In many cases, songs are a characteristic part of the performance—a rudimentary form of light opera.

Musical scales. A musical scale is a particular series of notes within an octave (as, from c to c′ on a piano keyboard, encompassing eight white keys). To most African musicians, the series of notes in a scale is usually thought of in descending order from treble to bass, as with the early Greeks. Many Africans also have a "magnitude" concept of pitch according to which treble notes are "small" and bass notes "large." This contrasts with the Western "altitude" concept, with treble notes "high" and bass notes "low."

The choice and use of distinctive scales appear to be an identifiable characteristic of the music of different tribal or linguistic groups. Within a single community, the exact pitch of the tonic, or basic note of the scale, may vary; but the scale's pattern of intervals (distances between notes) remains relatively consistent whatever its starting point. The awareness of the "correct" ideal pitch of the intervals of the scale is notable among instrumentalists who play in ensembles, such as the xylophonists of the Chopi of southern Mozambique, the lute and lyre players of the Ganda of Uganda, and the *mbira* (thumb-piano) players of the Shona of Rhodesia and central Mozambique.

Basic scale types

Examination of the tuning of instruments of fixed pitch, such as the xylophone and *mbira*, shows that about 40 percent of African communities use pentatonic scales—*i.e.*, scales with five different notes in each octave, as, 1–2–3–4–5–(1′). About 40 percent use heptatonic, or seven-note scales, and the remaining 20 percent use hexatonic, or six-note scales. The interval of the perfect octave is common to most African scales. Other intervals usually considered important are the perfect fourth and the perfect fifth. These are sometimes modified, either up or down, by the application of some local tuning system, such as the equidistant system, which is found in many parts of Africa.

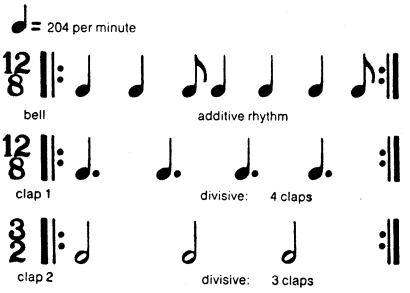
In the equidistant system, all of the intervals of a scale (whether pentatonic, hexatonic, or heptatonic) are the same size. The Western major scale, by contrast, uses intervals of two sizes, five whole tones and two half tones. Intervals as small as the Western half tone are rarely encountered in African scales. Nevertheless, there are ethnic groups like the Guro and Gere nations of the Ivory Coast whose harmonic singing gives the impression of being highly chromatic, due to the use of "augmented" and "diminished" melodic intervals (intervals wider or narrower than "normal").

More than one scale may be used in a single community for different purposes. Various classes of instruments are recognized as demanding their own distinctive scales, so that, for example, the unequal tuning of *mbiras* and xylophones within the same locality may prevent their being played together.

Song forms. Song types are often determined by their function: dirges for funerals, hunters' songs, heraldic songs for chiefs, praise songs, songs of insult, criticism, commentary, narration, proverbial songs, religious songs. They may be sung privately by individuals, with or without instrumental support, or they may be sung publicly by single performers, groups, choirs, with bands and orchestras, according to function and occasion. Group singing is particularly common and usually utilizes the basic formula of cantor and choir: soloist's lead and group's response.

Songs are usually built on short melodic units. A period, or unit, of two phrases (A,B), for example, may be repeated over and over. Such a form, called litanic from its repetition of a short melodic formula, can develop a number of extensions, for example A B A′ B′ or A B A C. The counterparts to such litanic forms are sequential forms, in which, for example, choir and cantor alternate sequences of unrepeated phrases, as A B C D. Litanic and sequential forms may also be employed in combination. The treatment of the text is in most African music strictly syllabic (*i.e.*, one syllable of text per one note of music). For song types with "open-end" forms (litanic, sequential) that can be added on to indefinitely, short melodic or rhythmic formulas are often used to signal the end of a piece.

Melody shape. The general pitch pattern of a melodic unit is falling; *i.e.*, it starts on a high tone and falls, either direct or in a series of steps, to a lower tone. The movement from note to note is often stepwise (without skipping any notes of the scale) in seconds (as, d–c) or in thirds (as, e–c). Intervals larger than a fourth rarely appear in sequence. Similarly a sequence of more than three ascending tones is unusual in most parts of Africa. Rising, falling, and level melodic direction is strongly guided by speech tone. Departures from this guiding relationship between words and melody are considered "artistic" and call for great ingenuity. (H.Ty./A.M.D.)



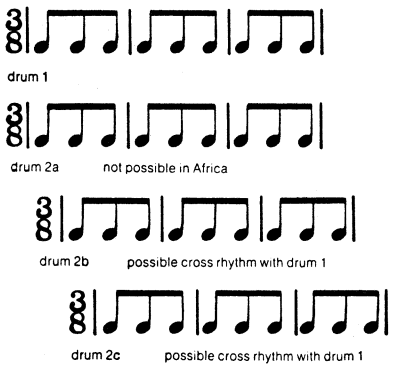
Rhythm in African music. African music is based on two very different forms of rhythm. Divisive rhythm divides time into equal pieces and results in a regular pulse (as in most Western music). Additive rhythm adds together little pieces of time of unequal length with a stress at the beginning of each piece, resulting in irregular beats. Further, African rhythmic technique falls into two distinct classes: the technique used in drumming on the one hand, and that used for songs, hand clapping, bells, rattles, and other instruments on the other. The latter may be called the "background rhythm," as it is against this that the drums usually play.

Background rhythm. The principle of background rhythm is well illustrated by songs accompanied by hand clapping. The essential principle is that the stresses of the song and the stresses of the claps must not keep in step. A rhythmic clash or tension is normally set up between the pulses of the claps and the stresses in the song melody. The simplest and most usual way of achieving this is to use a divisive rhythm for the claps and an additive rhythm for the song. Each clap will have either two basic time units per clap, or three. The irregular song stresses are bound to clash with either. The situation is more complicated if the claps use an additive rhythm, such as that often called by scholars the standard pattern, consisting of two-beat units (♩) and three-beat units (♩.).

The additive song stresses now cut across an additive clap pattern.

Still more complex is the frequent use by Africans of a multiple background rhythm. This may consist of several different clap patterns played simultaneously, together with a bell or two and a rattle, each with its own rhythm-pattern. These patterns will be either divisive or additive. Usually the claps will be divisive and may include clapping two against one, three against two, or four against three: the bell and rattle often have additive patterns.

Against all these, the song uses an additive pattern. The essential feature of such background rhythms is that they start their patterns on the same beat together, then cross over each other during the pattern, then start together again each time the patterns repeat.



Influences on choice of rhythm

The additive rhythm of the song is not a fixed pattern in any one song. It arises from two factors: the shape of the tune and the natural emphases arising from it; and the normal speech accents of the song text. (Such accentuation is similar to the stresses in ecclesiastical plainsong.) There are also some songs, especially for children, in which the rhythmic stress is divisive. In such songs the melodic accent overrides the influence of speech accent.

All songs that take a clap must be organized so that in each section there are two divisive claps or a multiple of two (as in the above example, four claps by the first clapper). Or each section must contain three divisive claps or a multiple of three. Or there may be a combination of these, such as two plus three. The whole song, including all integral repeats, nearly always contains a total number of claps that is a multiple of two or three (such as 16, 24, or 36). When additive clap patterns are used in the background rhythm, they also normally add up to a total that is a multiple of two or three.

The songs dealt with so far are all songs that the African finds it natural to clap to. There is, however, another class of songs which, he says, cannot take a hand clap. Such songs are in completely free rhythm. They are necessarily additive in structure, for the rhythmic stresses arise once again both from the nature of the tune and the spoken accents of the text.

Drumming rhythm. The rhythmic technique of African drumming is fundamentally different from that of the background rhythms. The basis of the system is to set up a permanent cross-rhythm between each drum. Thus if two drums are playing in triple time (three-beat patterns), there are three possible ways of combining them. Only two combinations are normal in Africa (options *b* and *c* below):

Note that the main beat of the second drum must not coincide with the main beat of the first: in options *b* and *c* they are permanently crossed, a continuous rhythmic tension being thus established.

But drumming is not merely beating out rhythms. Each drum is capable of producing beats of different pitch and of different quality according to the manner of hitting the drumskin. Every drum pattern is therefore a rhythmic tune, and, furthermore, the tune of each individual drum is distinguished from all of the others by the basic pitch of the drumskin. In a drum set, each drum lies at a different pitch.

The example given above is only schematic: in practice, the first beats of each drum pattern will be crossed, but each drum will also be playing a different pattern. But it also shows yet another basic feature of drumming which is that whatever their patterns, and however crossed, the several drum patterns must be built out of the same basic time units. Thus if the basic time unit of the first drum is an eighth note played at the rate of 420 notes per minute, then the other drums must make their patterns out of this same unit of time. The only exception known is the rare case where one drum plays at four against three to the other.

Dance and instrumental rhythms

African dances exhibit the full flowering of African rhythmic procedures. Customs vary from tribe to tribe. An example is a case where a bell, a rattle, hand clap, song, and three drums—small, medium, and master drum—are used, as with the Ewe people in Ghana. The song, which has an additive rhythm, is first sung rubato by the leader (rhythm consciously diverging from strict beat). It is then continuously sung a tempo (in strict rhythm) by leader and chorus. The bell now enters, closely followed by the rattle, both usually playing additive rhythms. The people start clapping one or more divisive rhythms. The small drum starts playing a divisive rhythm whose main beat is permanently staggered with that of the bell. The master drum comes in with a long irregular pattern rhythmically crossed with everything else. Lastly, the middle drum enters with a short standard reply to the master's pattern (each of the master's patterns has its own reply on the middle drum). This pattern will be crossed with the other drums, and may be either additive or divisive. There is now a whole galaxy of crossed rhythms, and it is against this astonishing ensemble that the people start dancing, each dancer selecting one instrument to dance to, and thus dancing in cross-rhythm to all the others. Such a rhythmic thrill is entirely unknown in Western music.

Rhythmic variations

The master having established his first pattern by several repetitions now embarks on his main task. This is to play freely created improvisations using some fragment of the rhythmic pattern as a basic motif. His object is to work up the dancers to high enthusiasm and at the same time to accompany the song in suitable rhythmic terms. The variations are highly additive in rhythm. Having exhausted all possibilities of the pattern, he now starts on another one—to each dance there are a number of master-drum patterns. The middle drummer changes to the reply proper to the new pattern, the small drum keeps on with its original pattern, and the master starts variations based on his new pattern. African dance music is thus a combination of fixed patterns and free, spontaneous creation. One can never hear the same dance played exactly in the same way. The whole system is vitally creative and of ever-changing interest.

How can such a cross-rhythm ensemble end? There are two ways. In some areas, all that happens is that one drummer gets tired and stops playing: the cross-rhythm is broken and collapses, and the dance just peters out. In other areas (*e.g.*, among the Ewe in Ghana), the master drummer gives a signal on his drum, at which all the drums change to the "ending pattern," which, at its last few notes, brings all the drums into phase, with a final simultaneous beat by them all.

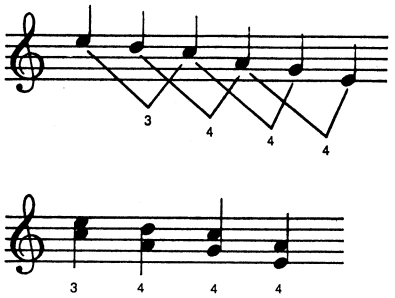
The full complexity of African rhythm is found preeminently in the forest areas—around the Gulf of Guinea and in the Congo basin. By and large, the further one moves from these areas the weaker becomes the cross-rhythmic setup, so that the music changes into something approaching the Western system, in which divisive rhythms tend to preponderate. Nevertheless, the above principles of background music and of drumming never disappear entirely. Dance music is the flower of African rhythmic virtuosity. All forms of rhythm in music, whether vocal or instrumental, are based on the essential rhythmic principles exhibited in the dance, although the degree of complexity varies considerably in different parts of the continent. (A.M.J.)

Multipart singing and harmony. Multipart singing and harmony in several regions of Africa have been observed by travellers from the earliest periods of Western contact with Africa. From the 18th century on, written transcriptions of such music have also been available. As early as 1719, for example, the missionary Peter Kolbe transcribed the music of the Hottentots (a Khoisan people) at the Cape of Good Hope. His account described a type of polyphony characteristic of the music of some Khoisan peoples even today. Numerous sources describing harmonic multipart music, sometimes with transcriptions, are found in the 19th and early 20th centuries.

With the beginning of the 20th century, phonograph recordings became available. Wax cylinder recordings made before World War I illustrate the harmonic techniques of several African peoples.

Basic principles of harmony

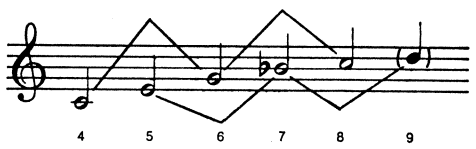
Two principles of harmonic organization can be distinguished in African multipart music: homophonic and polyphonic. In homophonic multipart singing, all melodic lines, though different in pitch, are rhythmically the same. They begin and end together. In polyphonic singing, the combining individual lines differ rhythmically. They have noncoinciding starting points and may be of different length. In the context of African music, both homophony and polyphony are usually considered linear, each combining voice having equal right. (In contrast, in Western part music, one part, usually the topmost, may be given more importance.)



Geographical distribution of homophony

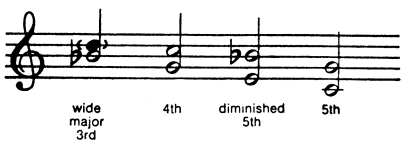
Homophony is the most important principle of traditional harmony in vocal music of Africa south of the Sahara. Found in several large geographical patches spread from West to Central, East and Southeast, and South Africa, it comprises many different stylistic types. Polyphony, on the other hand, is restricted in its geographical distribution. The vocal music of Khoisan communities (in the western part of southern Africa) is predominantly polyphonic, as are the vocal styles of the Pygmy tribes of both the Ituri (Zaire) and the Upper Sangha (Congo-Brazzaville, Central African Republic). In other parts of Africa, isolated islands of polyphony often occur among or between largely homophonic communities. Thus the otherwise homophonic Gogo, a people of central Tanzania, employ polyphony in certain songs, and Nyakyusa children of southwestern Tanzania use yodel and polyphony in some of their songs. A distinct style of polyphony is found in much of the music of the peoples of the lower Zambezi valley and parts of Mozambique, Rhodesia, and the Transvaal. Vocal polyphony also occurs in South Africa.

Homophonic part singing. One of the basic techniques in multipart vocal music in several African communities is that melodic lines thought by the singers to be identical are sung at different pitch levels. In many instances this leads to the rigid parallel singing of a melody at distinct pitch levels; for example, parallel fourths, one part beginning, say, on c, the other on f, or parallel thirds, the parts beginning, say, on c and e. Such parallel singing is homophonic, for all voice parts move together. There are two main streams of African harmony, some tribes using thirds, others using mainly fourths and fifths or octaves and unison singing. In many areas harmonic movement must be parallel because of the importance of speech tone.



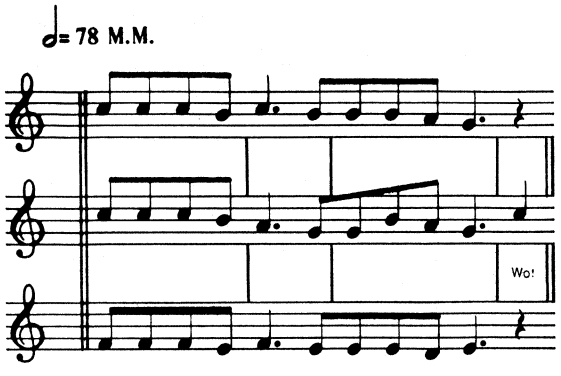
The actual harmonies that ultimately emerge from this parallel singing technique depend on the type of scale used by the singers. Thus parallel singing based on pentatonic scales necessarily differs from that based on heptatonic scales, because these scales have different intervals. Many communities in the harmony areas of Central and East Africa and some in West Africa form harmonies by a principle common to much harmonic part singing south of the Sahara: the harmonizing note for a given note is regularly found in the next note but one of the scale. In the case of two singers, the second one skips one step in the scale and duplicates the melodic line of the first singer at the new level. The precise harmonies that result from this "skipping process" vary from one African community to another according to the type of scale the musicians use; harmony and scale type are interrelated.

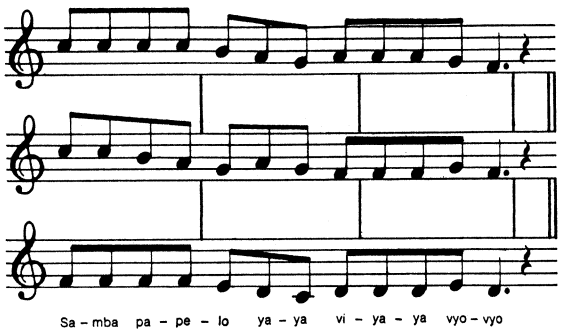
In many cases, the particular scale used allows the homophonic part singing to go beyond rigid parallel singing. An example occurs in some music of the Pangwa, Ndendeule, and other peoples in southern Tanzania and Malawi, specifically in one type of pentatonic scale. When the skipping process is used for harmonizing melodies, the result is a sequence of parallel fourths interrupted at one point by a third. Thus the example shows how notes in a pentatonic scale (e′–d′–c′–a–g–e) can be harmonized using the skipping process.



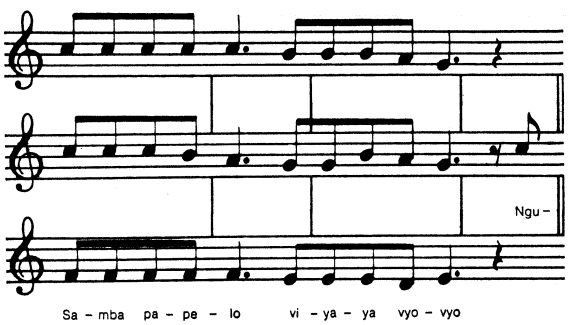
In another mode of the same pentatonic scale, d′–c′–a–g–e–d (from top to bottom), plain parallel fourths would be obtained.

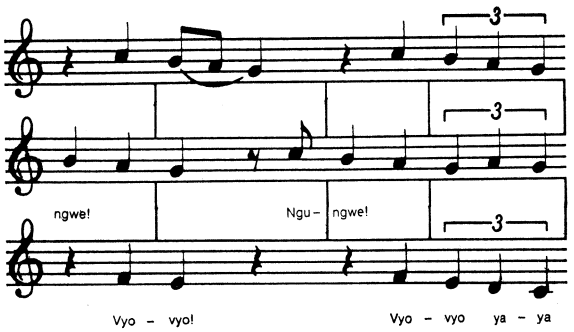
A fascinating harmonic system results from application of the skipping process to the scale of the Gogo of Tanzania. Their scale is an extract of the natural harmonic series—the notes ("partials") produced, say, by a natural trumpet or by a string vibrating simultaneously in halves, thirds, fourths, etc. In this case, the sequence of notes is chosen from the higher partials, usually the fourth through the eighth, or more rarely, through the ninth. This scale gives rise to a typical chord progression that is the hallmark of most Gogo vocal music. The following shows the notes of the scale and their number in the series of partials.



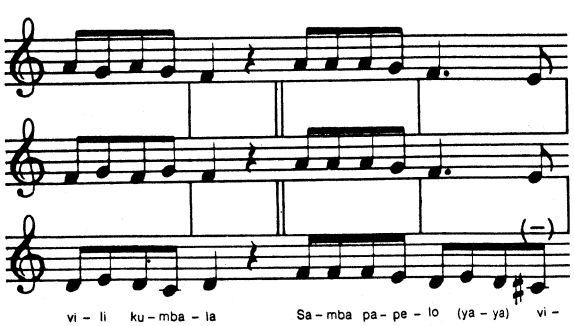


(The seventh partial is flatter in pitch than Western notation indicates.) The optional ninth partial is shown in black and in parentheses. Braces indicate notes forming chords when the skipping process is used. A typical chord progression resulting from this scale is

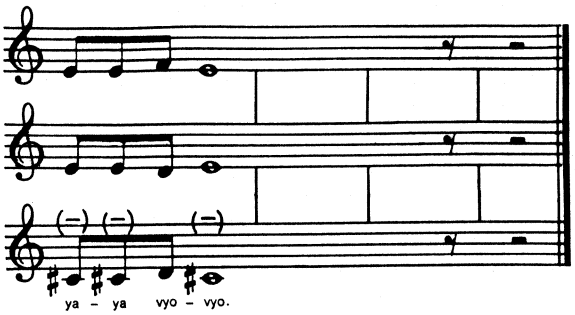


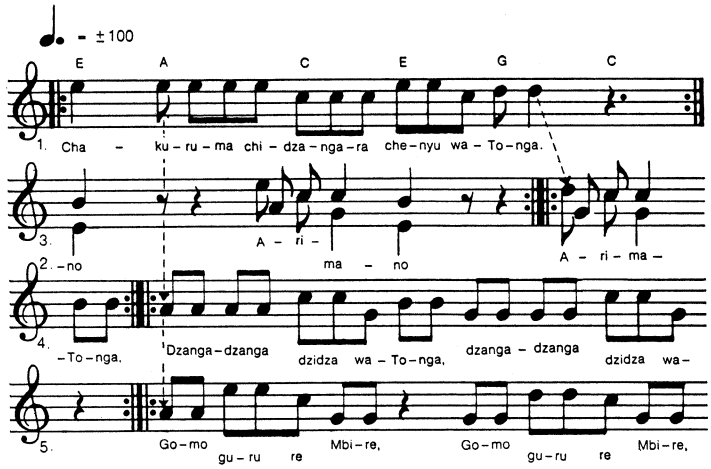


Chains of thirds



In heptatonic scales the application of the skipping process yields chains of thirds. According to the type of scale used these can be alternating major and minor, parallel major, or "tempered" neutral thirds. (Unlike the fourth, fifth, or octave, the third can vary somewhat in size without losing its identity. Western music uses major thirds, as, c–e, and minor thirds, as, c–e♭; a neutral third is anywhere in between in size.) One of the largest African heptatonic-scale areas using homophonic harmony encompasses most of Angola and northwestern Zambia and southern Zaire. Here the skipping process is simultaneously employed in two directions, both up and down the scale. The result is three-part harmony in triads (thirds plus fifths, as, c–e–g). Theoretically, all three lines move in parallel. Nevertheless, each singer can leave his own level at any time and move into that of his neighbour. The result of this liberty is that the harmonizing voices very frequently move in oblique and contrary direction relative to one another (rather than in parallel direction). The following extract of a song from Sakateke, Angola, provides an example of this type of homophonic harmony.





Polyphonic singing. In contrast to the type of homophonic part singing just discussed, in polyphonic part singing the individual voice parts are rhythmically independent. An analysis of a threshing song of the Karanga, one of the Shona peoples of Rhodesia and Mozambique, will illustrate what may happen in a polyphonic part singing area. This particular song, recorded in Rhodesia, is in five voice parts. Parallel movement is not allowed, so the skipping process cannot operate. Instead, the harmonic principle is that the parts must all follow a fixed chord sequence, here E A C / E G C. The letters refer to the basic notes of the chords. The chords themselves usually consist of two notes, a basic note, say c, and the fifth, as, c–g, or c–g′.

Using this chord sequence, vocal parts are constructed which contrast as much as possible melodically and rhythmically. The rhythmic cycle is 18 pulses long. As in drumming, cross-rhythms are set up: parts two and three answer part one at the end of its cycle; parts four and five begin shortly after the beginning of part one's cycle. The individual rhythm patterns of each part are also distinct. Part one uses divisive rhythm, dividing the 18 beats into six groups of three beats. The remaining voice parts use additive patterns built up of two-beat and three-beat units.

Instrumental music, such as for the *mbira* (thumb piano, see below *African musical instruments*), panpipes, and xylophones also tends in this part of Africa to be based on standard chord sequences. An example for the *mbira* is C E G / C E A / C F A / D F A. (A.Ty./G.K.)

Interlocking techniques. An important technique of combination in many kinds of African instrumental music is described as interlocking. This is one of the techniques of cross-rhythm and results in composite patterns made up by two or three instruments or parts alternating in playing notes. It is found in parts of East, West, and Central Africa.

A basic characteristic of interlocking is the absence of a common guide-pulse to be taken as reference point by all players. In a Western music ensemble, or a jazz band, all the players share a "beat," one common metric point of departure. They may even beat their feet to mark it. While there are many traditional African musics in which such a common reference pulse does exist (even where there is polymeter), in several others the musicians

in a group relate their parts to individual reference pulses, which can stand in various relations to each other.

One type of relation is for the pulse of one performer, or group of performers, to fall exactly in the middle of the other's. This type of interlocking occurs, for example, in the music of the *amadinda* and *embaire* xylophones of southern Uganda. A special type of notation is now used for these xylophones, consisting of numbers and periods. A number indicates that a player strikes a note; the value of the number refers to the note in the scale, as 5, the fifth note of the scale. An underlined number should be read an octave down; *i.e.*, 5 is an octave below 5. A period indicates that no note is struck. Numbers and periods occupy an equal space of time known as an elementary pulse, the smallest segment of time used in this type of music.

The following is an example of interlocking as played on the *amadinda*. The melodies are actually played in parallel octaves; that is, each melody is played at the notated pitch and also at the pitch an octave below:

Musician A plays: 4.3.4.1.3.3.4.2.3.4.2.1.4.3., etc.
(in parallel octaves) ↑
Musician B plays: . . .5.3.3.5.5.3.5.2.3.5.1.1., etc.
(in parallel octaves)
↑ = place of entrance for musician B

In interlocking music of this type, one musician's positive action of striking a note always coincides with a negative action or "non-strike" of his fellow musician, who at that moment lifts his beater. The effect is such that both series of equal-spaced notes seem to interlock like the teeth of a cog wheel. Each of the two musicians, however, feels his own series of notes as "on beat."

Variations of the interlocking technique

In the very fast *mangwilo* xylophone music of the Shirima of northern Mozambique, the interlocking technique is exploited further. In some compositions by two virtuoso players, each musician interlocks with the right hand only. The left hands play different rhythm patterns superimposed over the interlocking pattern.

Triple interlocking is another type, used, for instance, in drum music in Zambia and also in southern Uganda in the music of the *akadinda* xylophone. Here a group of three musicians plays a short pattern of equally spaced notes in parallel octaves. Three musicians sitting opposite them interlock with another pattern that fits two equally spaced notes between each note of the first group's pattern. In numerical notation it looks like this:

Three musicians play: 2..4..2..2..1..1..2..5..
(in three octaves) ↑
Three opposite musicians play: .14.35.14.35.14.35.14.35
(in three octaves)

Interlocking techniques allow African instrumentalists to produce resultant patterns—overall patterns formed by all the players—that are unbelievably rapid. The resultant pattern of the above *akadinda* musical example is: 21443521423511413521453 5. This series of 24 notes, when played by expert musicians, is at a speed of approximately 600 notes per minute. But each musician, for himself, in terms of his own beat, plays one third that fast.

Inherent note patterns. Closely associated with interlocking techniques, but not necessarily depending on them, is the composition of inherent note patterns. These are rhythmic and melodic patterns that emerge when series of notes in distinct intervals are played at high speed.

The human ear does not perceive isolated particles of sound, but a "gestalt." When sequences of many notes are played rapidly, the ear cannot follow each note. As a result, the hearing tends to pick out and re-group the material forming several melodic–rhythmic patterns, seemingly independent from each other. Thus the total heard image of the music differs from the pattern of notes actually played. In a series of notes that are large intervals apart, for example, the ear picks out the notes of about the same pitch level and perceives them as a group. This psychological perception of a "gestalt"—an inherent note pattern—is an important element in listening to and composing some kinds of African instrumental music, particularly in Central and East Africa.

Function of inherent note patterns

Inherent note patterns are not accidental or coincidental; they are recognized and consciously employed by African musicians. In southern Uganda, there are even specific terms referring to them. The main function of inherent note patterns is to suggest words—text passages of the song that is outlined by instrumental accompaniment. Thus in the music of the *ennanga* harp of Uganda, the inherent note patterns suggest certain phrases of the vocal part. In a performance of the traditional harp song "Olutalo olw'e Nsinsi" ("The Battle of the Nsinsi") by the former court musician Evaristo Muyinda, one inherent pattern seemed to speak the words "Batulwanako ab'edda!" ("How They Forget Those Ancients!") long before they were actually sung. Muyinda often introduces a new phrase of text by first accentuating the corresponding inherent rhythm on the *ennanga*. Once the melody is firmly established as a "gestalt," it is sung. By slight accentuation or melodic variation during performance, the harpist may bring one or another of the already existing inherent patterns into prominence. This results in a musical development of the song's text.

(G.K.)

AFRICAN MUSICAL INSTRUMENTS

The existence of musical instruments in West, Central, and southern Africa has been noted since the 14th century. From the description of early travellers up to the 17th century, it is clear that African coastal communities had a rich and varied musical repertoire. The same can be said of most African peoples to this day and particularly of those who live in the interior in well-wooded regions where effective materials for the construction of instruments is close at hand. Present-day African musicians make and play several varieties of sophisticated instruments. But they also make good use of natural objects, spurning nothing that would suit their purpose. For this reason, the range of objects put to musical use in Africa may be far wider than in many other societies that rely exclusively upon conventional instruments of mass production.

Like all musical instruments, African instruments fall into four major categories, based on the way in which the instrument produces sound. In chordophones, or string instruments, a vibrating string produces sound. In aerophones, or wind instruments, a column or body of air is made to vibrate. In idiophones, the instrument's body itself vibrates, or parts of it; an example is a bell or xylophone. In membranophones, a stretched membrane vibrates; the prime examples are drums.

Chordophones: string instruments. Chordophones are musical instruments in which a string is set in motion by striking, plucking, or bowing and sometimes by a current of air. There are four main types: zithers, lutes, lyres, and harps. All are found in profusion throughout Africa.

The zither family. The strings of a zither are stretched between the two ends of the body. According to the shape of the body, zithers are classified as bow, stick, board, trough, or raft zithers. Most African zithers need an external resonator (besides the body itself) to increase the sound. Such resonators may be a small sheet of metal, a gourd or box, or often the open mouth of the player. The string or strings of a zither may be open (*i.e.*, one note to a string), or they may be stopped by the fingers to produce higher notes. Sometimes a string may be divided into two segments, each producing a different note. This is done either by pulling the string back toward the body at some point by a small cord, or by wedging a length of stick between the body and the string. Most stick and bow zithers have only one string. Trough, board, and raft zithers may have from five to eight (or more) strings on which chords can be played.

Variations of the zither

Several African communities use a friction bow, a bow zither in which a string or a thin band of palm leaf is made to vibrate by rubbing a stick along a series of notches cut into the instrument's body. In this case, the mouth is the usual resonator; the vibrating string is held across the open mouth. Harmonics are produced as on a Jew's harp, by altering the shape of the cavities of the throat and mouth as if by "silent" singing.

In the *lesiba*, a stick zither of the Sotho of Lesotho, the player sets the string in vibration by alternately blowing and drawing in his breath across a short length of quill attached to the end of the string. As long as the string vibrates there is an uninterrupted sequence of notes. The pitch is varied by stopping the string with the fingers at the far end. Harmony may be added by simultaneous humming or singing.

The lute family. Lutes comprise the family of string instruments that have a body and a neck along which the string or strings are extended beyond the body itself. A lute may also have a bridge, a piece of wood that the strings pass over and which transmits their vibrations to the instrument's body, which consequently serves as a resonator. Lutes may be plucked or bowed; the word "fiddle" is a general term for bowed lutes. Bows in East Africa are frequently made of sisal fibre, which is rubbed with rosin to increase the friction of the bow on the string. In Malawi, a simple sliver of bamboo, lubricated by spittle, is used. The necks of African lutes do not have fingerboards, as do guitars and violins. The strings are usually stopped by pressure from the backs of the fingers, and not, as on a violin, by pressing the string against the fingerboard. Occasionally the string is pinched between thumb and finger. Most African members of the lute family have only one string.

Several African stringed instruments are not easily classified, being considered lutes by some, zithers or harps by others. One African instrument consists of a body and several necks in the form of thin bows, one for each string. The strings are attached directly to the edge of the body and the tip of each bow. This instrument is called a *pluriarc*, but it can also be classified as a multiple bow harp. Another is the West African *kora*, usually known as a harp lute. Twenty or more strings are stretched in two banks from a neck, over notches in the two sides of a bridge, which stands on the calabash resonator body, and attached to the edge of the body.

The *pluriarc*

The harp family. In harps, the strings are attached to and run vertically away from the soundboard or the membrane that serves as a resonator (in a lute, in contrast, the strings are parallel to the soundboard). All African harps are plucked. The instrument may be held horizontally or vertically. Five to eight strings are usual, tuned by tuning pegs. The African harp is not found with a pillar between the body and the tip of the neck, as on the European harp. For this reason, and because of the curved shape of the neck, it is sometimes called a bow harp. Harps occur mostly in the tropical regions of Central and East Africa; their distribution is limited. In the *ennanga*, a bow harp of the Ganda people of Uganda, a small ring of lizard skin encircles the bow near each tuning peg. This is adjusted to touch the vibrating string lightly so that it emits a buzzing rather than a clear tone. Such a buzzing tone is cultivated in many other African instruments.

The lyre family. The lyre has a body with two extended arms connected at their upper ends by a yoke or crossbar to which the strings are attached. Most African lyres are tuned by friction pads on the yoke. Like tuning pegs, they regulate the string's tension, hence its pitch. Some lyres, such as the *litungu* of the Wanga of Kenya, use a bridge; others such as the *endongo* of the Ganda use none. Like the African harps, lyres are plucked by the fingers of both hands.

Aerophones: wind instruments. In wind instruments, a column or body of air is made to vibrate by a stream of air, such as the player's breath.

Pipes. African pipes are made of reeds, bamboo, or, in some regions, the tip of an antelope horn. The performer blows across the end of the pipe, producing a single note. To produce double notes some players open a hole in the tip of the horn or reed and open and close it with a finger or thumb. Two-tone messages can be sent from one hunter to another without alarming their quarry. Ensembles of end-blown pipes are frequently played together by a number of performers; each is responsible for inserting his one note into the music at the correct moments.

When a number of simple end-blown pipes of different pitch are bound together in a raft they are called panpipes. Panpipes may be played by one performer or in ensembles, as with the single pipes. Among the Nyungwe, of the Zambezi River valley in Mozambique, over 30 panpipe players may take part in the *nyanga* dance, sounding their pipes with alternating sung notes and dancing together in a circle.

Uses of panpipes

Flutes. Flutes with a number of finger holes are found in most regions of Africa. Some flutes are open at each end. These are held vertically and are blown from one end. Such flutes may have a V-shaped notch cut into the upper or mouth end. Transverse flutes (held horizontally like a European orchestral flute) may be closed at both ends or open at the far end only. Flutes are usually played solo because of the great difficulty in making multiple-holed flutes sound in tune with each other; the *ndere* flute ensembles of the Ganda people are an exception.

Reed pipes. Reed pipes use a single or double vibrating reed to set the pipe's air column in motion, as in the clarinet or oboe. They are rare in Africa except in regions where they were introduced by Arabs.

Trumpets and horns. Wherever there are cattle or wild antelope, horns are used as single note noisemakers or, with longer horns, as trumpets. Ensembles of open-ended instruments made of horns, gourds, or a mixture of both materials, are used in royal music in many chief's courts in East Africa. Such horns produce two notes and are employed in the same way as in the pipe ensembles. The *makondere* horn bands of Uganda are well-known examples.

Singing horns, or kazoos. Singing horns are usually made from hollow gourd stems. They have a mouth hole cut in the side and are sometimes fitted with a membrane over the smaller end. As they are sung into, the membrane emits a buzzing sound. Such a buzzing membrane is called a mirliton or kazoo. Singing horns, such as the *malipenga* of the Cewa people of Malawi, are used to give the singing voice a semi-instrumental quality.

Idiophones: hard vibrating instruments. These instruments include objects that are struck, shaken, or otherwise set in motion. They produce either melodic sounds, as with the xylophone, or non-melodic noise, as with rattles, bells, seedpods, clappers, and tubes, or any object that can be made to sound effectively. Three varieties of idiophone are particularly important: the xylophone, the *mbira*, or thumb piano, and the slit drum.

Xylophones. Xylophones are instruments in which several tuned, resonant wooden slats are struck to produce different melodic notes. In Africa, they are found exclusively in the better wooded regions. They vary from simple logs of wood laid across a pair of banana-stalk supports, as among the Ganda, to well-made instruments in which the slats are attached to a frame. Examples of frame xylophones, with a resonator for each note, are those of the Chopi of Mozambique and the Malinke of Guinea. Resonators vary from small tree-fruit shells to broader and longer shapes of cultivated gourds, graduated in size. Xylophones are played with rubber-tipped beaters or with short lengths of stick. They are tuned to the local pentatonic, hexatonic, or heptatonic scale. In some areas, the pentatonic and heptatonic scales used resemble similar scales found in Southeast Asian and Indonesian xylophones, suggesting cultural contact through Indonesian colonists who settled in Madagascar in medieval times. In East Africa and Zaire a single, large, unresonated, free-note (*i.e.*, nonframe) xylophone is played by two, three, or four performers at the same time. Among the Chopi of southern Mozambique, ensembles consist of as many as 40 instruments ranging in size from treble to double bass.

Mbiras. The *mbira* family of instruments is unique to Africa. *Mbiras* consist of an array of metal or fibre reeds attached firmly at one end to a soundboard or resonator. The instrument is usually held between the palms of the hands, and the tips of the reeds are plucked with the thumbs, or thumbs and first fingers. In northeastern Zaire and the Transvaal, the instrument is slung from

the shoulder by a cord and played with the fingertips. The *mbira* is also known as *likembe, marimba, kalimba, chisanji,* thumb piano, and by other regional names. The common term *sansa* is not correct; it is not found in Africa.

Different varieties are set apart by the nature of the array of reeds, their number and tuning, and by the type of resonating body to which the reeds are attached. Rectangular boards or boxes are common, but bell-shaped resonators, rafts of papyrus stalks, small fan-shaped bodies, or even metal bodies are found. Many instruments have, in addition to their soundboard, an external resonator made of a gourd or other material. In a few places larger bass instruments occur; *e.g.,* in Nigeria, Cameroon, and Uganda.

The tuning varies throughout the continent; pentatonic, hexatonic, and heptatonic scales being employed according to local tradition and taste.

Mbira music is highly melodic. The tone preferred by most African musicians is not clear but, rather, edged artificially by devices such as shells, metal rings, or mirlitons placed so that they buzz when the reeds vibrate. *Mbiras* are mostly used to accompany solo singing but are also played in ensembles of three or more.

Slit drums. Hollowed logs, or slit drums, are found in forest regions. They are made by carving a log into shape externally and hollowing it out internally with long chisels through a slit cut in the top of the log. They vary in size from ten or more feet long and four or five feet in diameter, to instruments small enough to be held in the hand and are often carved in the shape of an antelope. By carefully varying the thickness of the two flanks on either side of the drum, two main pitches or tones can be produced. Other tones can be produced by striking other parts of the body. As with membrane drums, wax may be added to the flank of a slit drum to lower its tone. Slit drums are used for signalling by sending two-tone messages and for production of loud, many-tone rhythms. They are among the most versatile of all African percussion instruments, and are often used in combination with membrane drums.

Membranophones: drums. In membranophones, a stretched membrane, usually a cattle, antelope, or water-lizard hide, vibrates to produce sound. These include the whole family of drums. In addition, mirlitons are often considered membranophones, because a vibrating membrane produces their characteristic buzzing sound.

Drums vary in pitch and tone colour according to the weight and shape of the body (as, pot-shaped, hourglass-shaped, cylindrical), the size of the membrane, and the manner of playing. They are played by the hands, sticks, or both. In size they vary from a few inches to six or eight feet. In addition to body size, weight, and shape, drums are classified according to whether they are single or double headed (*i.e.,* with a membrane at one or both ends); whether the body is open or closed; and according to how the membrane is attached. These characteristics affect the quality of the drum's sound. Wax or other material may also be placed in the centre of the membrane to lower its pitch or to produce a falling note rather than a clear-pitched note. A mirliton may be attached to the side of a closed drum; the pulsations of air inside the drum cause the mirliton to vibrate, giving the drum a buzzing tone.

Friction drums are made to vibrate by the friction of the player's wetted or resined hand rubbing on a thin stick, which is pegged to the centre of the drum membrane.

There are three usual ways of attaching the membrane. It may be pegged to the body, usually the case with heavier hides. It may be pinned with multiple small pegs or nails, usually with lighter membranes. Or it may be laced, as with double-headed drums. In West Africa, the lacings on the hourglass-shaped "talking drum" are pressed toward the drum body, tightening the tension of the membranes and thus raising the drum's pitch.

Musical role of drums

Drums are more closely associated by foreigners with African music than any other instrument. This is partly because when drums are played together their volume of sound may draw attention away from the sound of other instruments and voices. Drums in Africa are used mostly for entertainment and to accompany dances. In some instances, specially constructed drums are revered as symbols of authority and national honour and are played only upon ceremonial occasions.

Drums may be played singly, or more usually in small ensembles of two, three, or four. Batteries of drums are played by many communities and notably in several regions of East Africa, Rwanda, Burundi, and Zaire. In Uganda, for example, an ensemble of as many as 15 drums, tuned to a pentatonic scale of more than two octaves, is played by six drummers. Ensembles of up to 20 drums or more are played by the Makonde people of East Africa, and sets of as many as nine or ten wax-tuned drums are played by a single performer in Malawi.

(H.Ty.)

IV. Performing arts

GENERAL CHARACTERISTICS

The dance and drama of Africa are both exciting and original; the dance in particular can be fiercely beautiful or tenderly expressive. But perhaps the most important characteristic of each is its vigour, its life-enhancing quality and purpose. This is entirely appropriate, since each was developed by peoples who, whatever their local differences, were primarily concerned with life, its protection and augmentation, often in a hostile environment. The dance especially can be regarded as an African people's life in action, inextricably linked with its religious and cultural beliefs and illuminating the meaning of both as ties that bind a society together and at the same time give meaning to its structure. Unfortunately, this significance is being lost as the indigenous cultures of Africa give way to foreign influences and as their tightly knit communities break up with the rapid growth of urban mixed communities. African theatre, however, has responded to the stimulus of Western dramatic literature and has added to its richness and variety. In its turn, the West has received African dance forms and styles and readily acknowledges what seems to be a native genius for physical expressiveness and communication.

General observations about the nature of ritual dances performed by primitive peoples apply, by and large, to those that developed early in Africa. The occasions for ritual celebration, at which dancing was an essential part, included the hunt, harvest, birth, puberty, marriage, sickness and recovery, and death (Figure 6). Some dances were "pre-theatrical" and others contained the seeds of drama.

The terms theatrical and dramatic have acquired their fullest significance and technical meanings within the context of Western culture. A theatrical act demands, above all else, a distinction between performer and onlookers, the former displaying some special skill for the delight of the latter; thus an acrobat in the circus engages in a theatrical act. A dramatic act further demands that the performer should imitate an existence other than his own; thus an actor impersonating an acrobat in a play about a circus engages in an act that is both theatrical and dramatic. Many African dances, forming only part of a complete ritual, were pre-theatrical in the sense that they were performed by a section of a community that had developed special skills (of athleticism, grace, endurance), while the rest of the community watched and thereby formed an embryonic audience (Figure 7). The skills, of course, were not primarily acquired for purposes of display nor to give pleasure to the onlookers but to enhance the potency of the ritual; as one scholar points out, however, the nature of dances that require unusual skill in performance encourages an aesthetic desire to perform well, in addition to any other impulse. Some dances were semi-dramatic inasmuch as they employed mimesis, or imitation, the essential element of drama. Another scholar describes, for example, a rainmaking ritual in East Africa, in which this element of imitation is readily apparent: after water had been sprinkled on the ground from a new gourd bowl, the rain dance followed, "imitating with soft pattering feet the first slow thunder-

Pre-theatrical aspect of African dances

drops, then more swiftly, to the swirling of the women's skirts, the rapid falling of steady rain." In the hope of ensuring a successful hunt—for on its outcome could depend a community's food supply—dances were evolved in which the animals to be hunted were impersonated by dancers, often wearing skins and specially constructed masks to heighten the illusion; they were "captured" and "killed" by the hunters. The logic of this stemmed from a hope that, in the words of a modern scholar, "the desired goal, through being dramatized, becomes more readily accessible, almost as if once a pictorial hint is given to nature it might be hard to erase it."

Historians of the drama are strangely silent about the theatre in Africa before the 20th century, and it might easily be supposed that none worthy of the name existed independent of the dance. This was by no means the case. In parts of Africa a theatre developed that was exactly suited to the people's social and emotional needs. The dance, meanwhile, did not depend entirely upon religious inspiration; the natural urge to express joy and emotion was also satisfied.

AFRICAN DANCE

The kinds of dance developed by African peoples for performance on important ceremonial occasions range from the ecstatic, convulsive frenzy of the medicine, or shamanistic, dance to the subdued discipline (at any rate among certain peoples) of the funeral dance. The basic patterns followed in any and all of these dances might be either abstract or mimetic.

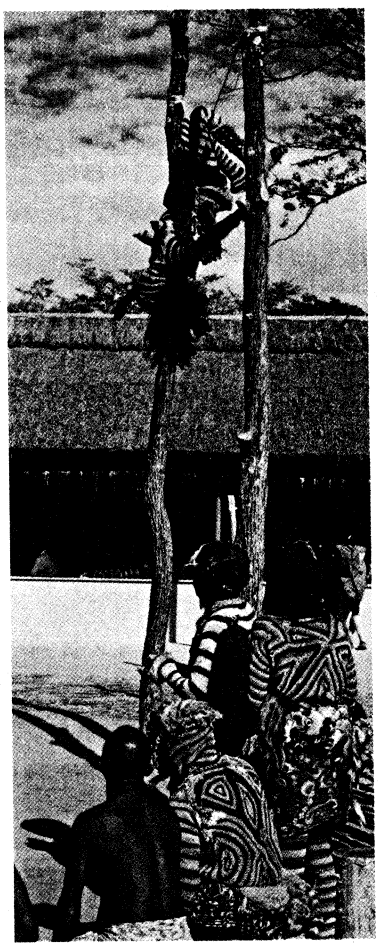

Figure 7: *Theatrical aspects of African dance.*
(Left) Fetish dancers of the Guere Wobe tribe performing during a funeral dance, Petit Duekoue, Ivory Coast. The dancers serve as "intermediaries" between the masked figure and the men of the village. (Right) Tribesmen of the Matable village performing an acrobatic ceremonial dance, Victoria Falls, Rhodesia.
(Left) Marc & Evelyne Bernheim—Woodfin Camp, (right) David Martindale—FPG

Abstract and mimetic patterns of the dance. *Abstract patterns.* The ceremonial mourning dance performed at the funeral of a member of the Akbia tribe (in the southern Sudan) provides an example of a dance of abstract pattern. At dawn, 30 women of the tribe, wearing garments made from natural forest creeper and plastered with mud, move in a single file around a mango tree. Their dance step is a simple, jerking, forward shuffle. The accompanying musicians repeat an unresolved phrase of five descending notes. Misery is expressed not by any concrete symbol or image but by the monotony of rhythm and movement: the women's concentration expresses mourning. In their long dance, which lasts for seven days and nights, they are also thought to be accompanying the deceased along the first, difficult part of his transitional journey into the world of spirits. The dance is thus full of meaning; it is a distillation of tribal belief, and it expresses a definite mood.

Dances performed for sheer joy

At this point, however, it should be stressed that dances were not always motivated by religious belief but were sometimes performed for sheer joy; such dances were abstract. As one dance historian explains it:

> Many . . . dances derive simply from social-expressive urges, the collective desire to move, to exercise rhythmically, to entertain oneself. Thus, after an evening meal, a Mambuti Pygmy of Central Africa may casually strike a drum, simultaneously hopping in place from one foot to the other, and eventually entice the entire camp to join him in an all-night affair. . . . Such dances are not meant to portray or depict anything, whether concrete or other-worldly. They are quite abstract in idea and intent, meant primarily for kinesthetic enjoyment.

Mimetic patterns. Those dances in which there is implicit some kind of "wish"—perhaps for fertility, for success in the hunt, for rain, for a good harvest—commonly contain mimetic patterns that match their generally symbolic theme, as in the rain dance described above. A dance performed during the six-day Incwala festival (Swaziland, southern Africa) may stand as a further example. During the festival, a number of things are celebrated—the new year, the chief's authority, a renewal of tribal energy—and one dance is performed for the purpose of "renewing the chief's strength." His warriors dance first, while they throw a new green gourd high into the air, from one to the other. At a certain point the chief joins in the dance, demonstrating his skill and strength by throwing the gourd ever higher and higher. The gourd is regarded as the repository of energy that will pass into the chief; therefore, the gourd must not be dropped, because, should this happen, the vital energy will be drawn into the ground instead of being transferred into the chief's person.

Variety of dance styles. Cultural temperament determines to some extent the dancing style that a given people develops. The outgoing peoples of Central Africa, for example, according to one scholar

> exhibit the explosive, enlarged bodily movements so markedly missing from the Far Eastern dance world. The flinging up and down, the centrifugal leaping and kicking that bespeak an "outgoing" extrovert cultural temper appears definitely to belong to the dance-forms of Central Africa.

The same characteristic is found in extroverted peoples of other parts of the continent, such as the Zulus of the south. The reverse also holds good: the same scholar describes the Pygmy people of the Central African region, "particularly the branch or branches following nomadic life-patterns in the heart of the forest . . . shy, subdued, retiring . . . song, dance, and drumming during feasts . . . often very soft." (The acrobatic dancing of other Pygmy groups, which are far from "shy, subdued, retiring," impressed observers as long ago as the 7th millennium BC, when some of their number were brought to Egypt for the purpose of dancing in religious processions.)

The range of African dancing styles is very wide indeed (Figure 8); the same kind of dance will be danced very differently from one tribe to another, and even neighbouring communities will evolve an idiosyncratic style. Equally numerous are the kinds of bodily movement that give a dance its overall character; in southern Africa, for example, there are stamping dances (of the Nguni), shaking dances (Xhosa), striding dances (Sotho), step dances (Tswa, Zulu, Sotho), and acrobatic dances (Tswa, Ndau).

Kinds of bodily movement

The instruments used to provide musical accompaniment are everywhere chiefly those that mark rhythm

Figure 8: *Styles of African dance.*
(Left) Women of the Tiongofoloha village performing the slow, rhythmic movements of a funeral dance, Ivory Coast. (Right) The fast, agile movements of the Intore (Watusi) people during the ceremonial lion dance, Lake Kivu, Zaire. The headdress is symbolic of a lion's mane. (Bottom) Wakamba boys performing a type of "leapfrog" dance, Makindu, Kenya.

(above all drums and gourd rattles), though pipes are also used. Rhythm is rather frequently reinforced by clapping, while the human voice often cries out cadences that intensify whatever particular emotion is being expressed in the dance itself.

African dance in the 20th century. As the African peoples lose their cultural identity to superimposed cultures, the web that gives their indigenous dance coherence gradually loosens. Their themes have been handed down from generation to generation, and a break in continuity means that many are forgotten; others continue to be performed, but, as the culture that gave meaning to their original statement is eroded, the dances lose an inner life and significance that nothing can fully restore. Today, although traditional dances are performed, they are as often informed by nostalgia as by dynamic religious belief.

AFRICAN DRAMA

Over and above the dramatic patterns of the dance, exchanges of dialogue in heightened speech eventually began to appear in religious ritual ceremonies. In West Africa, for instance, where the communities of the Limba people supported a moon cult, dialogue appeared in a solemn ceremony held at the time of full moon. Before the moon dance was performed, the sacrificing priest begged the "moon god" (impersonated by the cult's chief priest, masked and robed) to send prosperity in the coming month. The "god" was then given drink. The dance that followed was performed by two groups of 14 dancers, representing the two phases of the moon. Toward the end of the month another ceremony was held, at which the chief priest appeared as the "dying god" who told his followers not to mourn because he would rise again to new life after three days and three nights.

Despite this theatrical instinct for dance dramas, there was little need in Africa for the development of an independent "religious" theatre comparable to Western tragedy. In an interesting study of religious processes among the Ndembu people of Zambia, in Central Africa, a modern scholar analyzes the dramatic structure of the society itself, which is such that it might be said to supply the cathartic effect of formal tragic action. The study suggests that in any crisis involving either an individual belonging to the community or factions within it, when feelings of anxiety, fear, and aggression are aroused, the people have recourse to "ritual remedy" (which involves the recounting of traditional causes of trouble and their associated feelings), thereby restoring amity and cooperativeness and regaining confidence in their capacity to cope with the present problem.

Theatre comparable to Western comedy

Development of popular theatre. There developed nonetheless something very like the Western concept of comedy as a vehicle for social criticism and recreation. Among its early occasions were the purification rites held annually to "cleanse" the people of any and every evil. One ethnologist has likened some of these purification rites to the Roman Saturnalia, festivals characterized by excess. Another has mentioned a freedom of speech at some purification rites that parallels the medieval "Feast of Fools" in the West, at which the established order was overturned and the "king" waited on his "servant." Even kings, chiefs, and gods were mocked:

> O King, you are a fool.
> We are taking the victory out of your hands.
> O King, you are impotent.
> We are taking the victory out of your hands.

The psychology behind this topsy-turvy situation is that, by mockery, the community "soul" would be "cool and quieted."

The instinct for mockery survived. A vigorous community theatre evolved and still survives in many rural parts of Africa. Performances celebrate seasonal festivals; everyone is involved, joining in well-known narrative expositions (which often recount the deeds of past kings and heroes) by forming processions, by chanting, singing, miming, and by responding in chorus. The themes and presentation are handed down orally from generation to generation and are known to all members of the community. There is no impatience for a "plot twist"; every moment is savoured as it arrives.

In the hands of secret associations of artisans—somewhat similar to trade guilds of craftsmen in medieval Europe—an almost professional African theatre developed. The entertainment devised was akin in material and versatile showmanship to that given by a commedia dell'arte troupe of popular players in Renaissance Europe. A modern scholar has described a performance given by the semi-religious Ekong association of Ikot Obong village in the Calabar province of Nigeria, a community of the Anang people. This particular association rehearses weekly for six years, and the entertainment devised during rehearsal is presented publicly in the village clearing during the dry season of the seventh year, afterward touring to surrounding villages and communities.

> During the six years of practice, a complicated seven hour routine was originated and mastered to perfection by the members. This routine included: music played by an eleven man percussion orchestra, featuring characteristic [*Ekong*] rhythms; patterns danced by a chorus of eighteen men; songs of ridicule sung by the orchestra and dance chorus and masked soloists; plays enacted by puppets and an entourage of fourteen men, some wearing masks; dances on stilts by two men; and the mystifying movements of a life-size wooden carving of a female fertility spirit enwrapped by the coils of a python. I was told that other [*Ekong*] groups present additional specialities, such as acrobatics, sleight-of-hand magic, and tight rope walking, by skilled entertainers.

The entertainment is carefully fashioned to be as relevant as possible to the neighbourhood. Detailed information about the private lives of certain individuals from a chosen community is secretly obtained, and these people are singled out for special ridicule. There is also more generalized satire, especially in the skits, and, of the five watched by the scholar, "two ridiculed nativist churches, and the other three corrupt diviners, domineering wives, and adulterous wives who run off with their lovers." Audience participation is expected, and the onlookers will come into the playing area and show their approval of any particularly excellent actor.

Generalized satire

Development of modern theatre. Even this "professionally" sponsored theatre declined with the intrusion of Western cultures. For example, whereas before the coming of the British in 1901, the Afaha subtribe of the Anang people had 28 Ekong organizations, 50 years later they had only two. As one modern scholar puts it:

> the concentration of population in urban areas, with the influence of the cinema and other vehicles of non-African culture, is creating a demand for ready-made leisure entertainment in place of the communally created functional drama. . . . So side by side with traditional drama is being formed an African theatre which exploits the ideas and techniques of the European stage.

African writers have adapted Western plays into African languages and have written original plays, and dramatists such as Wole Soyinka and Athol Fugard have made their mark in Western countries—as did Pearl Primus and her dancers in 1952, the Ballets Africains of Keita Fodeba in 1956 and 1957, the Negro jazz opera *King Kong* in 1961, and a Zulu adaptation of Shakespeare's *Macbeth* in 1971. Those associated with African theatre are aware that they have much to teach their colleagues in the West, who, beginning in the 1960s, became preoccupied with the problem of escaping the restrictions imposed by its "literary" drama and the respectable but often dull theatre it had produced. In the words of the Nigerian playwright Wole Soyinka,

> African drama is sophisticated in idiom. Our forms of theatre are quite different from literary drama. We use spontaneous dialogue, folk music, simple stories, and relevant dances to express what we mean. Our theatre uses stylised forms as its basic accepted disciplines. I am trying to integrate these forms into the drama of the English language.

(Si.M.)

V. Visual arts

The visual arts—sculpture, painting, and architecture—consist of more or less enduring forms in contrast to music, dance, and oral literature, which are ephemeral.

Once made, the products of the enduring arts continue to exist independently of their creators and their cultural context. Sculpture, thus, can be taken away and studied outside Africa. It is for this reason that "African art" has come, in the West, to mean almost exclusively sculpture. But, while it is true that sculpture has been Africa's greatest contribution to man's cultural heritage, the other visual arts—painting, architecture, and the decorative arts—have also contributed to it.

TYPES OF AFRICAN VISUAL ART

Decorative arts. The study of African art might well begin with the human body itself, for the body has served as a support for painting (especially the bodies of dancers in ceremonies accompanying passage rites marking birth, initiation into adult status, marriage, and death) and for sculpture in the forms of hairdressings and scarifications, both of which are often elaborated into designs of great beauty and are represented, in turn, on sculptures of human figures. Indeed in Africa, the scarifier and the hairdresser are regarded as artists, and, among the Guro, the hairdresser enjoys considerable prestige.

Pottery is made in agricultural communities wherever there is suitable clay and sufficient wood for the open fire in which the pots are fired. Decoration by incision is most widely practiced; carved roulettes are also used. Painting is not common south of the Sahara, although entire pots are often washed all over with a pigment.

Basketry is made by either the simple interweaving of elements or by the coiling of multiple strands, around which is wrapped a flat element stitched through the next inner turn. In general, coiled basketry is characteristic of the savanna areas, and woven baskets are common in the forests. Mats and containers are made by both techniques.

The weaving of raffia fibres was practiced in antiquity and reached its artistic peak in the pile cloths of the Kuba of Zaire. This art is widespread in agricultural communities, usually employing cotton, although some of the finest weaving, such as the *kente* cloths of the Ashanti of Ghana, also employs imported silk and similar threads. Women usually weave wide cloths on a vertical loom, but in West Africa men weave on a horizontal loom, producing long strips only two to four inches wide. In West Africa, one or more techniques of resist dyeing are used on imported cloth. The dye is resisted by applying a pattern of starch either with a stamp, as in the *adinkra* cloth of the Ashanti, or through a metal stencil or painted freehand, both of which are used in Yoruba *adire*. In Benin, Dahomey, and Ashanti, appliqué decoration is also found.

Leatherwork is especially important in the savannas, where pastoralism is practiced. It has reached a high standard among the Hausa and the northern Yoruba, both of whom make pouffes for export. In East Africa, many peoples not renowned for sculpture are skillful leatherworkers (*e.g.*, the Masai) and often paint the surfaces of their leather shields.

Jewelry is made in gold and silver by lost-wax casting and by smithing. Imported glass beads have been used for centuries in most of Africa, as necklaces and bangles, as decorations on leather garments, and applied to satchels and calabashes.

Architecture. A variety of materials is used in African architecture. Buildings made entirely of stone are relatively rare, but, in some cases, clay buildings have been carefully maintained and preserved in their original form for several centuries. People of simple technology (*e.g.*, the Bushmen) provide shelters from twigs; Pygmies in the forests build simple beehive huts thatched with leaves. Round houses characterize the dwellers in The Sudan and the grasslands of East Africa (where the Masai, however, construct rectangular buildings), while in the Congo Basin both round and rectangular houses are found. In the forests, houses of a basically rectangular form are usual, elaborated in accord with local custom, the plastic qualities of clay being exploited not only to decorate the surface but sometimes with the effect of turning the building itself into a kind of sculpture. Western materials, such as cement blocks and corrugated metal or asbestos sheeting, are encouraging a swing from round to rectangular forms, which are more easily built from these materials. In the larger cities, skyscrapers, conference halls, and other buildings have been built similar to those pioneered in the West but sometimes affording scope to African artists in requiring carved doors or mural decoration in paint or mosaic.

Painting. The earliest surviving African art consists of painting and engraving found in rock shelters of the Sahara from at least as early as the beginning of the 5th millennium BC and continuing into the 20th century there and sporadically elsewhere in Africa as a minor form of artistic expression wherever suitable smooth rock surfaces are available. Other forms of painting that have received less attention include the above-mentioned body painting and the painting of house walls, utilitarian objects (Figure 9), and sculptures. In the case of masks, the painting may, as among the Yaka, enhance the sculptural forms; but it may well completely ignore them, as among the Kalabari Ijo (Ijaw). Apparently, for the Kalabari Ijo, the act of painting is of greater importance than that of carving because, although the sculpture provides a home for the spirit, it is the act of painting that brings the spirit to reside in the mask.

Rock painting and engraving

Sculpture. *Mediums.* Although wood is the principal medium of African sculpture, many other mediums are employed: copper alloys, iron, ivory, terra-cotta, unfired clay, and, infrequently, stone (Figure 10). Unfired clay is and probably always was the most widely used medium in the whole continent, but, partly because it is so fragile and therefore difficult to collect, it has been largely ignored in the literature. Small figurines of fired clay were excavated in a mound at Daima near Lake Chad in levels dating from the 5th century BC or earlier, while others were found at Zimbabwe in deposits of the later part of the 1st millennium AD. These imply an even earlier stage of unfired clay modelling. About the time of these lower levels at Daima (which represent a Late Stone Age pastoral economy), there was flourishing farther to the west

the fully Iron Age Nok culture, producing large, hollow sculptures in well-fired pottery, some of the stylistic features of which imply yet earlier prototypes in wood.

Copper-alloy castings afford evidence of very great sculptural achievements from as early as the 9th century AD, when the smiths of Igbo Ukwu were casting lead-bronze, which is highly ductile, and smithing copper, which is not. Some three or four centuries later the smiths of Ife, seemingly unaware that unalloyed copper was not suitable for casting (or perhaps wishing to demonstrate their virtuosity), used it to produce masterpieces such as the seated figure in a shrine at Tada (see below *Nupe*) and the so-called Obalufon mask in the Ife Museum. In fact, however, zinc brasses were used more than unalloyed copper. The largest corpus of this work is from Benin, where zinc brasses were used almost exclusively, the zinc content increasing with time. These copper-alloy castings, together with terra-cotta sculptures the traceable history of which goes back even further, are the main evidence for the early history of sculpture in sub-Saharan Africa.

That iron should be used as a medium of sculpture may appear unusual; but in many parts of Africa wood carvings are made by blacksmiths. Among the Bambara, the blacksmiths work in both mediums, in totally different styles; the Yoruba blacksmiths, however, work solely with metal, making skillfully sculptured staffs in wrought iron. It has been suggested that the abstraction found in many sculptural styles, especially in the western Sudan, may be due to their having been made by blacksmiths, the forms of forged iron objects being carried over into wood sculpture; but this theory carries little conviction.

Stone sculpture occurs in several separate centres, employing both hard and soft rock, but there is usually not much evidence of a development through time in a single place. Ivory is a highly prized medium in many parts of Africa. Its fine texture makes it suitable for delicate sculpture, while its rarity leads to its employment in many societies for items of great prestige. Stone sculpture

Tools. African wood sculptures are carved with similar tools throughout the continent. An ax may be used to fell the tree; but an adz, with its cutting edge at right angles to the shaft, is used for the substantive work of carving. The skill achieved with this tool is astonishing to the Western observer. Thin shavings can be removed with speed and accuracy, creating a surface (especially when the form is convex) that shows slight facets that catch the light and add to the visual interest. More intricate work is done with knives. A pointed iron rod heated in the fire may be employed to bore holes in a mask for attachment to the costume and to permit the wearer to see. The surface of the sculpture is sometimes polished with the side of a knife or sanded down with rough leaves. Details are commonly picked out by charring with a red-hot knife (as among the Ibibio), or the carving is immersed in mud to darken its surface before oiling (as among the Dan group).

It has been suggested that native-made iron was of poor

Figure 11: Wood figures in the pole style, southwestern Ethiopia. In the Ethnographical Collection, Zürich. Height (left) 47 cm, (right) 41.9 cm. The woven cloth is also of Ethiopian origin.
Holle Bildarchiv, Baden-Baden, West Germany

quality, barely adequate for the task of carving any but the softest woods and that it was this technical inadequacy that led to cubistic qualities in African sculpture. Native wrought iron, however, is capable of accepting a very fine cutting edge, so it would appear that the qualities of African sculpture do not result from technical inadequacy but rather from the artist's intention.

Style. Attempts have been made to define a "primary" style of sculpture in Africa—a style which, although in contemporary use, is thought to have survived from the earliest period of African wood sculpture. Usually this "primary" style is equated with pole sculpture (Figure 11), in which a minimum amount of wood is removed from a piece of tree trunk to convey an impression of a human figure, with facial features sketched in and arms represented in low relief against the trunk. This rather abstract style is contrasted with "round" sculpture, which, because it is more naturalistic in its representations, is thought to have originated later. But, like other polarities that have been suggested, such as "concave" and "convex," both extremes of any pair of opposites may be shown to occur simultaneously in many groups. Artistic style is perhaps better seen as a continuum between the two extremes of abstraction and naturalism, neither of which has a valid claim to priority in time; for both styles occur even within the corpus of Nok sculpture, the earliest surviving in sub-Saharan Africa.

Sculpture and religion. Certain striking characteristics of African sculpture cannot be explained without knowledge of African religious beliefs. For example, the human navel is often exaggerated, especially in figures of ancestors such as those of the Lulua (Bena Lulua). This appears to be because it marks the link between one generation and the next. All African religions emphasize the continuity of life between the dead (ancestors), the living, and those not yet born. It is probably for this reason, rather than because of a preoccupation with ideas of fertility as such, that ancestors are commonly represented with emphasized sexual organs as well as navels.

Belief in the continuity of life

Another general notion is that the representation of an object shares in the life-force of the object itself, *e.g.*, the representation of an animal brings something of the characteristic qualities of that animal to bear on the situation. This perhaps explains why African sculptures have been referred to as idols, even though they are not strictly objects of worship. The mystical participation of the object in its image—which also lies at the base of some European witchcraft practices—enables the African to control the forces represented. He may harness the life-forces of many animals to produce a concentration of life-force more powerful than the one he fears (as, for example, the Dogon in driving away to their final abode the spirits of the ancestors); or he may, by providing an image of an ancestor (as, for example, in the ancestor "stools" of the Kalabari Ijo), furnish his spirit with a place to live now that it is no longer confined to a human body. For the living must know where the spirit is so that they can avoid offending it and can keep it happy by offering it food.

SUDANIC CULTURES

Types of art. *Painting and engraving.* The earliest known African art consists of more than 30,000 engravings and paintings on rocks in the Sahara. At the time most of these works were executed (from about the beginning of the 5th millennium BC into the 2nd) the area was open savanna, comparable to the Sudanic belt of the present day, supporting animals no longer found in the desert but represented in the art. Representation of the changing fauna makes it possible to divide the art into a succession of periods, the divisions being confirmed by changes in style and in the economy and artifacts possessed by the artists. In later periods the art spread into the western Sudan, across to the Horn of Africa and, possibly, into southern Africa (see below *Southern African cultures; Southern Bantu; Bushmen*).

The earliest engravings (in southern Oran, the Tassili, and Fezzan) reflect a hunting economy and represent such wild animals as the extinct buffalo *Homoioceras antiquus* (formerly called *Bubalus*, hence the name Bubalus period assigned to these earliest engravings), the elephant, rhinoceros, hippopotamus, giraffe, ostrich, and large antelope. The human figures are armed with clubs, throwing-sticks, axes, and bows. Frequently very large (ranging from a few inches to more than 20 feet), the drawings are fairly naturalistic representations (Figure 12).

Radioactive-carbon dating indicates that there was human occupation (if not drawing) in the Tassili from the mid-6th millennium BC. Paintings in the Tassili seem to begin a little later than the engravings, for *Homoioceras* is not represented, though elephant, ostrich, and giraffe are. One scholar has distinguished upward of 30 styles of paintings, the earliest assigned to the Archaic period, which seems to correspond to the later part of the Bubalus period of the engravings. Because these paintings often represent men and women with globular heads or wearing masks reminiscent, in a general way, of those used in black Africa at the present time, it has been inferred that the artists were black.

Cattle period

There follows, both in painting and in engraving, the Cattle period. *Homoioceras* is no longer represented, though other wild animals are, and the appearance of domestic cattle indicates that pastoralism had by then become the basis for human life. The bow is the principal weapon. Bones of domestic cattle and of *Homoioceras* were found together in a deposit dated by radioactive carbon to the mid-4th millennium BC, thus dating this transitional phase of the art. The style of engraving is less naturalistic, the poses are stiffer; in contrast, the paintings are more naturalistic, with compositions and a sense of space, if not strictly of perspective. The Cattle period ended with the introduction of the horse about 1200 BC.

The Horse period is subdivided into three periods. The first is the Chariot sub-period, in which the elephant was the only pachyderm still depicted, cattle continued to be represented, and mouflons, or wild sheep, and domesticated dogs appeared. The earliest chariots were carefully rendered with a single shaft and a horse on each side; later chariots consist only of a shaft with two wheels, and human figures are reduced to two isosceles triangles set apex to apex. Spears and shields are introduced and, later, daggers. The Horseman sub-period reflects a change from horse driving to horse riding, though chari-

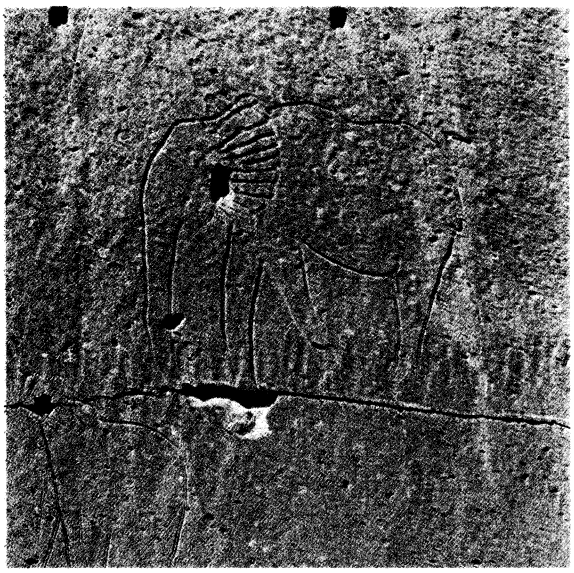

Figure 12: *Rock painting and engraving In the Sahara.* (Top) Painting of herdsmen and cattle, Sefar, Tassili, Algeria, Cattle period. 3.05 m × 1.05 m. (Left) Engraving of an elephant, Bardai, Chad, Babulus or Cattle period. Height 20.3 cm.
(Top) J.D. Lajoux, (bottom) Emil Schulthess—Black Star

ots continue. Next, the camel was introduced, possibly as early as 700 BC and certainly by Roman times, producing the Horse and Camel sub-period. Cattle had become very rare, and the drawings were reduced to between seven and 16 inches (17 to 40 centimetres) in length, whereas in the earlier sub-periods they were between 10 and 20 inches (25 to 50 centimetres) in length, and sometimes as long as three feet.

Because continuing desiccation led to restricted distribution of the horse (represented mainly in Mauritania), the Camel period reflects only present-day fauna: camel, antelope, oryx, gazelle, mouflon, ostrich, humped cattle, and goat. At first the spear was the only weapon depicted, but later the sword and firearms were added, weapons that are still in use. The style is highly schematic, and sizes of the drawings range between six and eight inches (15 to 20 centimetres). This period has continued up to the present time, for their owners still paint and engrave representations of camels in the Sahara.

Sculpture of the Nok culture

Sculpture. The earliest known sculpture of large size in the Sudan is that produced in terra-cotta by the Nok culture, which flourished extensively in northern Nigeria from the 5th century BC into the early centuries AD (Figure 13). These people were the first-known manufacturers of iron in western Africa, furnaces at Taruga having been dated between the 5th and early 3rd centuries BC; they continued, however, to use stone tools. Of well-fired clay, their sculptures represent animals naturalistically; human figures, however, are depicted with heads that are usually tubular, but sometimes conical or spherical, and with simple tubular trunks and limbs. Although generally found in fragments, it would appear that the human figures often must have been four to five feet (120 to 150 centimetres) in height. The sculptural form sometimes presents features that appear to have been carried over from wood carving, probably implying the existence of earlier sculptures in that less durable material. The heads seem to have been large in proportion to the rest of the body, a feature which, like the forms of eye and nose and many other details, has parallels in recent sculpture in many parts of West Africa (see below *West African cultures*). Thus, the art of Nok indicates the antiquity of many basic canons of West African sculpture, but the precise relationship between ancient and modern forms is obscure; for the modern Sudanic forms tend to be somewhat skeletal, in contrast to the fuller, more Nok-like forms of the Guinea Coast.

Not far from the Nok area, at Daima near Lake Chad, small, simple clay animal figures were by the 5th century BC being made by a population of Late Stone Age herdsmen. A little later they began to extend the legs of the animals, and some time after AD 1000 they began to make animals covered with little spikes. The last are similar to examples found on sites of the Sao culture in the Chari Valley, where more elaborate human figure sculptures, thought to represent ancestors and probably spirits, have also been found. Radioactive-carbon dates for these range from the 5th century BC to the 18th century AD.

Many other sculptures in terra-cotta of uncertain age have been found farther west; for example, around Jenne and Mopti. They may have some association with the medieval empires of Ghana and Mali, which, for all their extensive trade contacts across the Sahara, did not significantly change the basic structure of society in the western Sudan. Cults of the earth and of agriculture continued unimpeded, so that many of the sculptures used in these cults today probably represent ancient traditions.

The oldest wood sculptures to survive (three have been dated by radioactive carbon to the 15th to 17th century AD) are from caves in the Bandiagara escarpment, south of the bend of the Niger River in the area now occupied by the Dogon (see below), who attribute them to an earlier population, the Tellem. These figures, usually of simplified and elongated form, often with hands raised, seem to be the prototype of the ancestor figures that the Dogon carve on the doors and locks of their houses and granaries; but investigations have confirmed that the Tellem are ethnically a different people from the Dogon, so the art style appears to have been handed on from one people to another.

The hut as a basic architectural unit

Architecture. The traditional architecture of The Sudan consists of a basic unit, the cylindrical mud hut with a conical thatched roof, which may stand completely alone, as among the Tiv, or be grouped into compounds with separate huts connected by a wall, as among the Dagomba. The walls of the individual huts, commonly decorated by painting or low-relief decoration, are often built upon a ring of stones, which may be all that survives of a deserted settlement. This form has been modified in a variety of ways. The Jaba (Ham) have made the plan oval and built transverse walls inside with large cavities that serve as granaries. The Masa (Musgu) continue the walls upward and inward, forming a single curve of wall and roof.

With Islām, which began to spread among the Negro peoples of The Sudan in the 11th century AD, came the mosque. There were already 12 in the city of Ghana in 1067–68. In the early 14th century Mansa Mūsā, ruler of Mali, brought as-Saheli from Egypt to design mosques at Gao and Timbuktu, probably modifying the established tradition. He is credited with the introduction of the fired brick. Accompanying Islām came a square house unit with a flat mud roof supported on beams, the weight of which usually required a different technique of building —sometimes using pear-shaped, dried-mud bricks, as in Kano, and everywhere requiring buttressing to counter the outward thrust. These houses are usually incorporated into family compounds by means of an encircling wall. Many communities that are not Muslim, such as the LoWiili, also build square houses, and it is a moot point whether or not this shape represents Muslim influence. The Dogon build square, flat-roofed, multi-story houses and tall, circular granaries, as if they had drawn on both traditions (Figure 14). The Nupe, however, though effectively Muslim, live in compounds composed of circular huts, which they sometimes pave with circular pottery tiles broken with a mallet to produce a flat, hard-wearing surface. At Daima, at the end of the 1st millennium AD, circular huts were paved with potsherds set on edge, a technique otherwise mainly found among the Yoruba (where it seems to be as old) and at Benin.

Decorative arts. Leatherwork is highly developed—so-called Morocco leather comes from northern Nigerian sheep and goats. Horse trappings, saddlebags, pouffes, and satchels are made, while leather decorations are applied to basketry hats worn by the pastoralists of the area. Baskets are usually made by the coiling technique and are often lidded. Pottery, made among settled communities, may be decorated by incision and rouletting (*e.g.*, the Hausa). Calabashes are widely used and may be incised or decorated with pokerwork. Silver jewelry is cast and then chased.

Dogon. Dogon sculpture is intimately linked with the cult of the ancestors. Figures are made to house the spirits of the deceased on the family shrine, and masks are used to drive the spirits away at the end of the mourning period. One type of mask, called *sirige*, has a very tall, flat projection above the face (a feature found also in the masks of the Mossi and Bobo), which is said to represent a multi-story house. The Great Mask, never worn and made anew every 60 years, represents the primordial ancestor who met death while he was in the form of a serpent. Paintings on rocks and on stone slabs used for circumcision seem to depict masks. Iron staffs topped with human figures are also made, and some personal ornaments are cast in bronze.

Bozo. Sometimes regarded as the earliest inhabitants of the region, the Bozo fishermen of the Niger Bend sculpt large bull masks, which apparently are carried on poles.

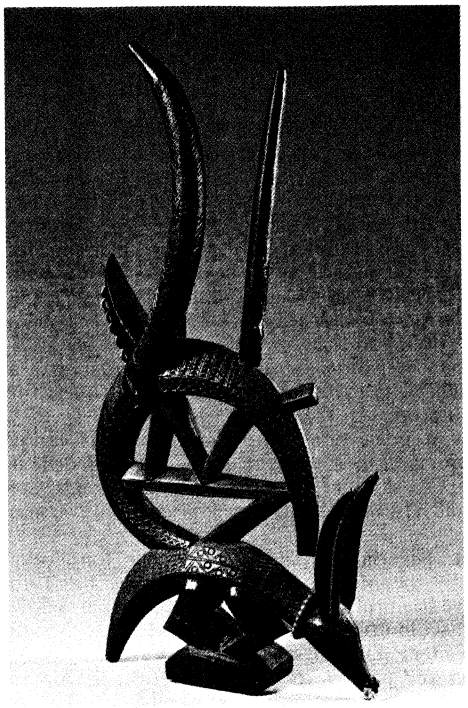

Figure 15: Bambara dance headdress in the form of an antelope, representing the spirit of Tyiwara, who introduced agriculture, wood, Mali. These headdresses, attached to a wickerwork cap, are worn by farmers who, at the time of planting and harvest, dance in imitation of leaping antelope. In the Nationalmuseet, Copenhagen. Bambara masks

Bambara, Malinke, and Marka. The Bambara have six societies to which males can belong, and each has its own type of mask. The Ntomo is for young boys before circumcision. Their masks have a line of vertical projections placed transversely over the human face, representing man as God first created him. The Komo is the custodian of tradition and is concerned with all aspects of community life—agriculture, judicial processes, and passage rites. Its masks are of elongated animal form decorated with actual horns of antelope, quills of porcupine, bird skulls, and other objects. Masks of the Kono, which enforces civic morality, are also elongated and encrusted with sacrificial material. The Tyiwara uses a headdress representing, in the form of an antelope, the mythical being who taught men how to farm (Figure 15). The Kore, concerned with the sky and with the bringing of rain to make the crops grow, employs masks representing the hyena, lion, monkey, antelope, and horse. In addition are created masks of the Nama, which protects against sorcerers. Originally forming successive grades of initiation, the latter five societies now seem to function independently. Originally intended to promote the fertility of the crops by mystical means, the Tyiwara ceremony is now largely concerned with honouring the most energetic farmer and with encouraging others to greater efforts. Ancestor figures of the Bambara clearly draw on the same artistic tradition as do many of those of the Dogon; so also do their sculptures in wrought iron. Rectangular intersection of flat planes is a stylistic feature common to Bambara and Dogon sculpture. The masks and figures of the Malinke are closely similar to those of the Bambara. While the masks of the Marka derive their form from Bambara models, they make more extensive use of brass sheet decoration; they appear in pairs, apparently representing the courtship of man and woman.

Mossi. The Mossi have been largely Islāmized; but members of the Wango society, at funerals of important persons, still employ a mask with an oval face, surmounted by a tall frontal plank with pierced decoration, resembling the *sirige* mask of the Dogon, from which it is probably derived. A simplified form also is made in sheet iron. The masks are said to be made by a group of blacksmiths of Kurumba origin.

Kurumba. The Kurumba are best known for their antelope dance headdresses, attached to a basketwork cap. They may owe something to the antelope headdress of the Bambara but are very different in function and style. Moreover, they are elaborately painted in geometric designs before each appearance at a funeral, at which headpieces in the form of a crocodile and one of more abstract form are also used. Recent examples have been carved so as to cover the wearer's face.

Bobo-Ule and Bobo-Fing. The Bobo-Ule hold ceremonies invoking the deity Do to send rain at the time of planting and again at harvest. For these ceremonies, they use a variety of masks. One has a flat, circular face and projecting mouth and beak, with a tall vertical panel above (resembling Dogon *sirige* and Mossi masks) decorated with geometric designs in black, white, and red paint (see Figure 4). These masks are said to represent owls. A similar mask, with horizontal panels, represents a butterfly (Figure 16). There are also masks in the form of birds, scorpions, antelope, and cattle that do not have these projecting panels. All of these masks are also used for funeral ceremonies. The Bobo-Fing carve masks in hardwood, representing human faces and ram, antelope, and bush-cow heads, with strongly developed sensitivity to sculptural form.

Lobi-speaking peoples. The various Lobi-speaking groups do not seem to use masks at all but produce ancestor figures, commonly made of mud as well as wood, with heads apparently used as puppets. They also make a characteristic three-legged stool, with a head and two legs at one end and a third leg sloping outward at the opposite end. These are used by older men, who pound the ground with them in a septennial *dyoro* festival that honours the Volta River, on the banks of which these people live.

Sculpture of the Lo society

Senufo. The Senufo produce a rich variety of sculptures, mainly associated with the Lo society (known more widely as the Poro), to which all adult men belong and which maintains the continuity of religious and historical traditions, especially through the cult of the ancestors. During initiations, headpieces are worn that have a flat, vertical, round or rectangular board on top, decorated by paint or by pierced work. Many wood carvings of male figures depict these headpieces, sometimes on rhythm pounders used by young initiates, who beat the earth to call upon the ancestors to take part in the ceremony and purify the earth. Several types of mask are used. The *kpelie*, a human face with projections all around, is said to remind initiates of human imperfection. Animal-head masks usually combine characteristics of several creatures—hyena, warthog, and antelope. A type of animal mask called *waniugo* has a cup for a magical substance on top; these masks blow sparks from their muzzles in a nighttime ritual protecting the village from sorcerers. Among the Naffara group of the Senufo, masks of similar form, but with an interior cavity too small for a human head, are carried on the top corner of a rectangular,

tentlike costume called *kagba*. This mask is the symbol of the Lo, which only initiates may see. In the Korhogo region, *deguele* masks appear in pairs at funerals. They are of plain helmet shapes topped with figures whose bodies are carved to resemble a pile of rings. Figures of the hornbill are used in initiation, and groups of birds on a pole are trophies for the best farmer. Figures of women and of horsemen are used in divination. Shrine doors and drums are carved in relief, and small figures and ritual rings are cast in bronze. For many years the Senufo have been producing large quantities of carvings for the European market.

Nafana. The Nafana and their neighbours use flat masks known as *bedu*, which appear in pairs, the male about five and the female about seven feet (150 and 210 centimetres, respectively) tall. They appear every night for a month at the winter solstice, blessing every house in the village against disease and misfortune. They are also used for funerals.

Fulani. The Fulani are basically nomadic pastoralists who range across from Senegal to the Cameroon grasslands. Many of them have settled on the Upper Niger, where they have formed a kind of caste system for their various artists—goldsmiths and leatherworkers, blacksmiths and potters—all of whom have been drawn from the indigenous population. Indeed, the only truly Fulani expression of the visual arts (apart from the decoration of calabashes) consists of body decoration, which reaches its height in the annual *gerewol*, a beauty contest between men, whose faces are painted and who wear metal bracelets, bead necklaces, and head ornaments. The women regularly wear elaborate hairstyles (often featuring golden rings around separate locks of hair), together with a profusion of jewelry. The Fulani express their quest for beauty in all aspects of their lives, even in the way they pack their few possessions onto their transport cattle, carefully arranging their decorated calabashes and their woven covers to show to advantage. Fulani designs are geometric and are thought to antedate their conversion to Islām.

Body decoration

Hausa. In Nigeria the Sudanic belt has long been dominated by the Muslim Hausa who, since the 19th century, have been ruled by Fulani emirs. No representational wood sculpture is produced by the Hausa, though for centuries their buildings have been decorated inside with molded and painted low-relief decorations (Figure 17), which have more recently been applied to the exteriors. Both decorative and of a high technical standard are their crafts: leatherwork for saddles, bags, hilts, and sheaths; gold and silver jewelry; ironwork; pottery; weaving and embroidery (Figure 18). Of special interest are containers made from split green cowhide dried over a mold in what is called the *tandu* technique. These lidded bottles are extremely light and almost indestructible.

Other groups in northern Nigeria. The dominance of the Hausa and Fulani has driven many groups to take refuge in the rocky hills of northern Nigeria. Most of these peoples have been little studied from an artistic point of view and have become known only through a very few examples of their work. Some of the peoples who became Muslim are thought to have lost their traditions of sculpture because Islām discourages the depiction of living creatures.

Nupe. The Nupe have been Muslim for some centuries and are best known for their glass beads and their sheet metalwork decorated in engraved and repoussé (hammered in relief) designs that are part of the Islāmic heritage. Their stools, in a variety of forms, show similar Islāmic decoration. Yet they have also produced many doors carved in low relief in a blend of decorative designs, which are consonant with Islāmic teaching, and

stylized representations of God's creatures, which are not. Masking traditions continue vigorously, however. Carved and painted masks are made for the *elo*, a purely secular performance intended only to entertain (nowadays on the Prophet's birthday), and perhaps introduced, like the *gugu*, which appears with it, from the Yoruba. (The name *gugu* appears to be derived from the Yoruba *egungun;* see below *West African cultures: Yoruba*). The *elo* mask has a human face with a motif (sometimes a human figure) rising above it, flanked with stylized horns. The *gugu* wears a cloth mask decorated with cowrie shells, but sometimes Yoruba *egungun* masks are used. The *ndako gboya* appears to be indigenous and entirely pagan in character; a spirit that affords protection from witches, it is controlled by a small secret society that cleanses communities by invitation. The mask is not sculptured but consists of a tall tube of white cotton supported inside on a bamboo pole about 12 feet (370 centimetres) long.

That Nupe art should have been influenced by the Yoruba is not surprising. Not only do Yoruba live among the Nupe, but there are bronzes in the Nupe villages of Tada and Jebba—one of them apparently an Ife work, and another in a more recent Yoruba style, with its hands clasped in a gesture of their Ogboni society. Others of this group, which include the largest castings ever made in black Africa, share features with Benin sculpture and have other elements that are widely distributed in time and space on the Lower Niger. Nupe tradition says these sculptures were taken from Idah, the Igala capital, in the early 16th century. Many of them were probably already ancient, but unfortunately nothing is known of ancient Igala bronze casting (see below *Igala*).

Tada and Jebba bronzes

Afo. The most important of the groups known from relatively few pieces is the Afo, who live just north of the confluence of the Niger and Benue rivers. Best known for mother-and-child figures, which apparently represent the tutelary spirit of the village, their carvings have been found among many of their neighbours. They also employ enormous bush-cow masks covered with detachable small figures; highly abstracted dance headdresses; and masks with white faces thought to have originated with their neighbours to the south—the Idoma and Ibo (see below *West African cultures: Ibo*).

Mama. The Mama are known mainly for animal headdresses that brilliantly abstract the essential characteristics of the bush cow, the waterbuck, and the reedbuck for the *mangam* ceremonies, which encourage the crops to grow. Carvings of human figures appear unfinished, with facial features sometimes totally omitted.

Ham and Koro. The Ham and Koro around Nok have abstract dance headpieces decorated with red abrus seeds, which are used in agricultural ceremonies, and cups, in the form of human figures, used in an annual sacrifice and in second burial ceremonies subsequent to interment. The Koro apparently carve for both groups. The Ham also have a masquerade *dodo*, which wears a netted costume covering the entire body, without a sculptured mask.

Montol and Goemai. The Montol and Goemai have netted fibre masks, with stylized features, worn with palm-leaf costumes. Carved masks called *gugwom*, representing wooden crocodiles, are used at the millet harvest and at the burial of chiefs. Both groups use carvings of human figures in healing rites. The figures are obviously traded in the area, for their style is found also among the Kanam, Yergum, and Angas; but their source is uncertain. In the southern part of the Goemai area is found another mask, that is the Goemai version of the *aku onu* mask of the Jukun (see below).

Jukun. The Jukun, situated athwart the Benue Valley, which was a route of contact between the northeast and the confluence with the Niger, was a strong kingdom by the late 14th century AD and by the 17th century controlled Bauchi and Gombe, far to the north. Its power was ultimately broken by the Fulani in the early 19th century. Despite its historical importance, little has been published on its arts. It is known, however, that bronzes were cast. Surviving pieces include small animals with wide-open mouths, intended as containers; two large bronze neck rests; and a cylindrical cast box with lid. The best known Jukun sculpture is the *aku onu* mask, perhaps the most abstracted form of the human head known on the whole continent. The mask represents a beneficent spirit who speaks for the ancestors both when good fortune is celebrated and at funerals.

Tiv. The Tiv place paired wooden figures—male and female—to the right of the door of the house of the senior wife as part of a religious rite for warding off catastrophes, famine, and disease. In collections, the Tiv are represented more commonly by their very detailed brass castings—mostly snuff takers—for the modelling of which a rubbery latex is used instead of the more usual wax.

Idoma. Idoma sculptors commonly carve without commissions, so that the customer not only chooses what he wants but also determines the use to which it is put. This may be a recent change, however, for formerly all of the dance societies had characteristic masks. That of the *ogrinya*, for men who had killed an elephant, a lion, or a man, was a headpiece often with a white, heart-shaped face. The Akatakpulakpula, a society of elders, had an elephant mask six feet (180 centimetres) long. Both societies perform at harvests and at funerals of members. White-faced figures usually represent the spirit Anjenu and are used in curing the sick.

Igala. The Igala aristocracy claim descent from the Jukun, but no sculptural evidence for this has been published. Evidence of contact with Benin, with which the Igala were frequently at war, does exist, however: the *ata* of Igala wears a fine 15th–16th-century Benin brass mask as his sign of office. The castings at Tada and Jebba (see above *Nupe*) are supposed to have been brought from Igala. Eastern Igala masks, with flat or concave whitened faces, show influence from the Idoma, Ibo, and perhaps Afo. Western Igala masks are usually black and varied in form. All seem to be primarily concerned with the ancestor cult, but some have judicial functions too. Figures are used to protect the family's well-being. Formerly, doors were carved in relief.

Igbira. The Igbira, on the opposite bank of the Niger, have many dance societies, few of which employ carved masks. The societies that do use masks traditionally employ those that have prominent foreheads, noses, and mouths; their surfaces are left unsmoothed. Currently, they also use indiscriminately masks imported from many other traditions—such as Yoruba, Edo, Ibibio, and Bassa Nge—probably because to them the dance is far more important than the sculpture.
