The second and third stages of deglutition are entirely reflex actions and once initiated cannot voluntarily be interrupted. The initiation of the second and third stages of swallowing is brought about by contact of swallowed materials with the pharyngeal and peripharyngeal structures. The swallowing act, once initiated, is dominant over other functions occurring in this area. Thus, respiration and speech are interrupted by the second stage of swallowing. The complexity of the act and the high degree of integration necessary are indicated by the fact that the entire second stage of deglutition is completed in less than one second.

With the initiation of the swallowing act the bolus of food on the base of the tongue is rapidly propelled into the pharynx by the downward and backward movement of the tongue. At the same time the larynx moves upward and forward under the base of the tongue. Contraction of

Tongue  
move-  
ments

tion of  
saliva

Functions  
of saliva

Pharyngeal  
transport

the superior pharyngeal constrictor muscles occurs, initiating a rapid pharyngeal peristaltic, or squeezing, contraction that moves down the pharynx propelling the bolus in front of it. The walls and structures of the lower pharynx are elevated to engulf the oncoming bolus. The epiglottis protecting the entrance of the larynx tends to divert the bolus to either side of the pharynx. The cricopharyngeus muscle, or upper esophageal sphincter, which has kept the esophagus closed until now, relaxes as the bolus approaches and allows it to enter the upper esophagus. The pharyngeal peristaltic contraction continues into the esophagus to become the primary esophageal peristaltic contraction. The swallowed bolus moves through the pharynx at a speed of 20 to 25 feet per second, and on entering the esophagus it often is projected deep into this organ.

Since the pharynx serves both the digestive tract and the respiratory tract, there are four possible outlets for swallowed material from the oral pharynx. These are: back into the mouth, up into the nasal pharynx, forward into the larynx, and downward into the esophagus. The swallowing reflex is so well coordinated that food normally takes only one of these possible paths, namely, that into the esophagus. Return into the mouth is prevented by the position of the tongue against the hard palate. Entrance into the nasal pharynx is prevented by elevation of the soft palate against the posterior pharyngeal wall. Entry into the larynx is prevented by this structure being drawn under the base of the tongue and also by the epiglottis diverting material away from the laryngeal opening.

The esophagus lies within the thoracic cavity and the pressure within its lumen is slightly below atmospheric pressure. At its upper and lower end the esophagus is sealed off by two sphincter muscles. These remain closed, opening only in response to the deglutition reflex.

Above, the cricopharyngeus muscle serves as the upper esophageal sphincter, separating the pharynx from the upper esophagus; below, the esophagus and stomach are separated by the lower esophageal sphincter.

Transport through the esophagus is accomplished by the primary esophageal peristaltic contractions. This is a continuation of the peristaltic contraction that originated in the pharynx. The primary esophageal peristaltic contraction is produced by a ring of advancing contracting muscles. Transport of material through the esophagus requires approximately ten seconds. This peristaltic wave serves to create a pressure gradient and sweep the bolus ahead of it. Pressures of 50 to 100 centimetres of water are created during the swallowing of liquids and solids. When the bolus arrives at the lower esophageal sphincter, which lies within the hiatus of the diaphragm, the sphincter relaxes and the swallowed bolus enters the stomach.

When a solid bolus is swallowed, it moves through the esophagus just in front of the advancing peristaltic contraction. If the bolus is too large or if the peristaltic contraction is too weak, the bolus may become arrested in the middle or lower esophagus. If this occurs, secondary peristaltic contractions originate just proximal to the bolus as a result of the local distension of the esophageal walls by the bolus, and propel it on into the stomach.

When a liquid bolus is swallowed, its transport through the esophagus depends somewhat on the position of the body and the effects of gravity. When swallowed in a horizontal or head-down position liquids are handled in the same manner as solids, with the liquid bolus moving immediately ahead of the advancing peristaltic contraction. (The high pressures and strong contractions of the esophageal peristaltic wave make it possible for animals with very long necks, as the giraffe, to transport liquid material through the esophagus to a height of many feet.) When the body is in the upright position liquids enter the esophagus and fall to the lower end and there await the arrival of the peristaltic contraction and the opening of the lower esophageal sphincter, a matter of some eight to ten seconds, before being emptied into the stomach.

#### DIGESTION IN THE STOMACH

The stomach serves as a temporary reservoir for ingested food and liquids. The size, shape, and capacity of the hu-

man stomach are extremely variable, not only from one individual to another, but also within the same person. The stomach can accommodate itself to the ingestion of small or very large meals. The stomach is capable of dilating to accommodate a meal or liquids whose volume is in excess of a litre without increasing intraluminal pressure within the stomach.

The purpose of the stomach in digestion is to mix the food with the gastric juices and partly to solubilize the ingested meal, preparing it for further digestion in the small bowel. Factors that regulate and control digestion in the stomach include its motor activity, the secretion of hydrochloric acid and enzymes, the rate of emptying the gastric contents into the small bowel, and the various types of chemical reactions taking place.

**Gastric motility.** Three types of motor activity of the human stomach have been observed and described. The first is a small contraction wave of the stomach wall that originates in the upper part of the stomach and slowly moves down over the organ toward the pylorus, the opening into the small intestine at the distal end of the stomach. This type of contraction produces a slight indentation of the stomach wall and it is thought to serve the purpose of mixing the gastric contents. The second type of motor activity is also a contracting wave but is peristaltic in nature. These contractions also originate in the upper part of the stomach and are slowly propagated over the organ to the pylorus. This type of gastric contraction produces a deep indentation in the wall of the stomach. When the peristaltic wave approaches the antrum, or the narrowing end, of the stomach, the indentation completely occludes the lumen, thus compartmentalizing it. The contracting wave then moves over the antrum, propelling the material ahead of it through the pylorus into the duodenum. This type of contraction serves as a pumping mechanism for emptying the contents of the gastric antrum. The third type of gastric motor activity that has been observed in man is best described as a tonus contraction. This type of motor activity decreases the size of the lumen of the stomach, as all parts of the gastric wall seem to contract simultaneously. It is this type of activity that accounts for the stomach's ability to accommodate itself to varying volumes of gastric content. The contraction of the gastric wall tends to be independent of the other two types of motor activity, particularly in different parts of the stomach. The mixing contractions and peristaltic contractions are normally superimposed upon gastric tonus.

Gastric motility can be recorded in man by having the subject swallow a small balloon connected to the end of a soft tube or catheter. The balloon is filled with water or air and the tube is connected externally to a recording device. With this method it is possible to determine the rate, duration, and pressures of mixing and peristaltic contractions. Gastric tonus is recorded by using balloons that detect volume changes. More recently investigators have been making these measurements by means of a "radio pill," a micro-miniaturized electronic transmitting device that is swallowed by the subject and transmits signals from the alimentary canal. These are received, decoded, and interpreted by the physician or technician. Both the mixing and peristaltic contractions of the human stomach occur at a constant rate of three per minute when recorded from the gastric antrum. This rate of three per minute is now recognized as the basic rhythm of gastric activity in man. Neither disease nor drugs alter this basic rhythm, although some drugs are capable of abolishing both types of contractions or stimulating the strength of contractions. The small mixing contractions of the stomach produce a pressure of approximately five centimetres of water. The peristaltic contractions may produce pressures as great as 50 to 60 centimetres of water.

**Gastric secretion.** The gastric mucosa that lines the stomach of man secretes approximately 1,200 to 1,500 millilitres (more than a quart) of gastric juice per day. This juice is highly acidic, because of its hydrochloric acid content, and is rich in enzymes. Gastric juice solubilizes food particles, Initiates digestion, particularly of

The three types of stomach movements

Esophageal transport

tion of  
gastric  
juice

protein, and converts the gastric contents to a semiliquid state called chyme, thus preparing it for introduction into the small intestine and further digestive processes.

Although man secretes gastric juice constantly, the composition of the juice is quite variable, depending upon the stimulus that evoked the gastric mucosa to secrete. It is useful to consider gastric juice as a mixture of secretions from the parietal cells, located in the gastric glands, and from the nonparietal structures in the gastric mucosa. The gastric juice is made up mainly of water, hydrochloric acid, and other inorganic constituents, including sodium, potassium, calcium, phosphate, bicarbonate, and sulfate. The organic constituents of gastric juice include mucus, the gastric enzymes, and the intrinsic factor of Castle. Each is described below.

**Parietal-cell juice.** Parietal-cell juice is essentially a solution of hydrochloric acid whose concentration is about 0.1 Normal (*i.e.*, 0.1 gram-molecular weight of hydrochloric acid per litre of solution). Hydrochloric acid is formed within the parietal cells, collected in small canaliculi within the cell, and emptied into the lumen of the gastric gland. The secretion is then carried to the surface of the mucosa and emptied out into the lumen of the stomach. Basal gastric secretion is measured in man, after an overnight fast, by placing a tube within the stomach to aspirate all secretions for an hour after awakening. A normal adult will usually secrete from two to four milliequivalents of hydrochloric acid per hour under these conditions. Patients with duodenal ulcer may secrete two to three times this amount.

**Nonparietal-cell juice.** In addition to the parietal cells, there are many other cells in the gastric mucosa that contribute to the composition of gastric juice. The zymogenic or chief cells of the gastric glands are the source of the enzyme pepsin. These cells contain zymogenic granules packed with the pro-enzyme pepsinogen. Pepsinogen is released into the lumen of the gastric gland and is transported to the lumen of the stomach. There it is converted into active pepsin and initiates the digestion of proteins. The gastric juice also contains small amounts of other enzymes. These include a gastric lipase, lysozyme, urease, and carbonic anhydrase. These latter enzymes are less important than pepsin in digestive function. Their exact cellular origin is unknown. Recent studies on human pepsin have demonstrated that at least four pepsin enzymes are contained in gastric juice. Pepsinogen is activated to pepsin by the presence of hydrochloric acid.

**Gastric mucus.** An important constituent of gastric juice is mucus. Mucus is secreted by the cells that line the neck of the gastric glands and by the surface epithelium cells. Two types of mucus have been recognized in gastric juice. One is called visible mucus, as it has a whitish colour and is thick, viscous, and even jelly-like. The other type of mucus is transparent or soluble mucus. This type of mucus forms a protective layer, approximately one millimetre thick, over the gastric mucosa. It is thought that it is this type of mucus that protects the gastric mucosa from the highly acid gastric juice that contains active pepsins and prevents the juice from digesting the stomach itself. Soluble mucus is alkaline in reaction and thus inactivates any pepsin molecules that diffuse into it.

**Intrinsic factor of Castle.** The gastric mucosa also secretes a mucoprotein known as the intrinsic factor of Castle, which combines with vitamin B<sub>12</sub> in the diet. The binding of vitamin B<sub>12</sub> by the intrinsic factor is necessary for the absorption of B<sub>12</sub> from the small intestine. Vitamin B<sub>12</sub> is essential for the normal maturation of red cells in the bone marrow (see VITAMIN; NUTRITION AND DIET, HUMAN). When the gastric mucosa is unable to secrete intrinsic factor in the gastric juice, there is no binding of B<sub>12</sub>, and pernicious anemia results.

Phases of gastric secretion. The process of gastric secretion can be conveniently divided into phases, depending upon the primary mechanisms that evoke the gastric mucosa to secrete gastric juice. A brief description to each phase follows.

**Cephalic phase.** The cephalic phase of gastric secretion occurs in response to stimuli received by the senses; that is, taste, smell, sight, and sound. This phase of gastric

secretion, is entirely reflex in origin and is mediated by the vagus (10th cranial) nerve. Thus, at the sight or smell of an appetizing meal, the gastric mucosa is stimulated to secrete gastric juice in anticipation of the meal that will soon arrive in the stomach. Ivan Petrovich Pavlov, the famous Russian physiologist, originally demonstrated this mechanism of gastric secretion in dogs years ago. He prepared a small gastric pouch, with intact vagal innervation, that could be drained to the outside through a cannula for the collection of gastric juice. Each day when the dogs were fed, a bell would ring at the beginning of the meal. Gastric juice secreted by the small gastric pouch was collected for a period of time at the start of the meal. After a few days or weeks merely ringing the bell would cause the small gastric pouch to respond by pouring out copious amounts of gastric juice. When the vagus nerve is cut in experimental animals or man, the cephalic phase of gastric secretion is abolished.

Gastric juice secreted in response to vagal stimulation either directly, by electrical impulses, or by stimuli received through the special senses is rich in enzymes and highly acid.

**Gastric phase.** The gastric phase of gastric secretion begins when food enters the stomach. This can occur in a normal way after eating a meal or experimentally by introducing food into the stomach of an animal through a cannula connected to the outside. Pavlov observed that when food was placed through a gastric cannula into the stomach without the dog's knowledge, gastric secretion would begin after about 15 minutes. The gastric phase of gastric secretion is brought about by certain mechanical, chemical, and hormonal events. Distension of the stomach causes the mucosa to secrete. As the food becomes solubilized in gastric juice, the products of protein digestion elicit further gastric secretion. Distension of the gastric antrum by food, or the contact of the antral mucosa with the products of protein digestion, causes the antrum to release gastrin, a hormone that stimulates the gastric mucosa to secrete hydrochloric acid and pepsin. The gastric phase of gastric secretion lasts throughout the period of time that food is in contact with the gastric mucosa, and this particular phase is terminated when gastric emptying is complete.

**Intestinal phase.** When gastric chyme enters the small intestine it initiates the intestinal phase of gastric secretion. When food is placed experimentally directly into the small intestine by means of a tube, gastric secretion is elicited. The intestinal phase of gastric secretion may last for as long as 8 to 10 hours. Products of protein digestion are most potent in eliciting this phase of gastric secretion, but carbohydrates, fats, ethyl alcohol, and even water, when placed directly into the intestine, will elicit gastric secretion. The intestinal phase of gastric secretion, although lasting much longer than the cephalic or gastric phases, is the weakest of the three. Of the three phases of gastric secretion described above, it is the gastric phase during which the greatest amount of hydrochloric acid is secreted.

**Interdigestive phase.** Even after a prolonged fast the gastric mucosa continues to secrete small amounts of gastric juice containing hydrochloric acid and pepsin. This has been termed the interdigestive phase, or basal secretion, of the gastric mucosa.

Regulation of gastric secretion. As mentioned previously, gastric secretion in man is stimulated and regulated primarily by neural (vagus) and humoral mechanisms. Stimulation of the gastric mucosa by way of the vagus nerves has already been mentioned; intact vagal innervation is essential for the cephalic phase of gastric secretion. Vagal innervation is also important in the gastric phase of gastric secretion because the vagus potentiates both the release of gastrin from the gastric antrum and also the response of the parietal cells to secrete hydrochloric acid.

The primary humoral mechanism regulating gastric secretion is the release of the gastric hormone gastrin from the gastric antrum. Small amounts of gastrin are apparently released continuously from the gastric antrum when the vagus is intact. As digestion proceeds in the stomach,

Cause of  
pernicious  
anemia

Neural  
and  
humoral  
stimulation

the products of protein digestion stimulate the **antrum** to release additional quantities of gastrin. Gastrin then stimulates parietal cells to secrete large amounts of hydrochloric acid. As the contents of the stomach become more and more acid, the acid chyme comes in contact with the antral mucosa. This then inhibits the release of gastrin from the antrum. Thus, there is a "feedback" mechanism related to the degree of acidity of the gastric contents. When the contents of the gastric antrum are less acid the mucosa releases gastrin. When the contents of the gastric antrum are more acid the release of gastrin is inhibited.

Another **humoral** substance that regulates gastric secretion is enterogastrone, a gastrointestinal hormone released from the duodenum in response to stimulation by various types of food coming in contact with the duodenal mucosa. Fat is the most potent stimulus for the release of the hormone. Enterogastrone inhibits both gastric secretion and gastric motility. Thus, as food enters the duodenum from the stomach, enterogastrone acts as a brake on both gastric emptying and gastric secretion. Two additional hormones, glucagon from the pancreas and secretin from the duodenal mucosa, exert some inhibitory effects on gastric secretion.

**Gastric digestion.** Digestion is not carried to completion in the stomach. Experimental evidence in man shows that approximately 30 to 50 percent of ingested starches and approximately 10 to 15 percent of ingested protein may be digested in the stomach. Little, if any, of ingested fat is digested there. Thus, the stomach is not primarily a digestive organ and is not essential to life. Its main function is to convert the ingested meal into chyme by mixing it with gastric juice in preparation for delivery into the small intestine, where most of the digestive processes occur.

**Digestion of carbohydrates.** When a meal has been thoroughly chewed and adequately mixed with saliva, the amylase in the saliva will continue its digestive action on starches in the stomach as long as the acidity of the gastric contents is not too high. Each digestive enzyme has an optimum hydrogen ion concentration, or pH, at which it can function most effectively. The optimum pH of amylase is approximately 6.8, slightly on the acid side of neutral (7.0). Thus, as the gastric contents are mixed with gastric juice and hydrochloric acid, the pH of gastric contents decreases (*i.e.*, becomes more acid) and the amylase activity diminishes accordingly.

**Digestion of proteins.** The proteolytic enzyme secreted in the gastric juice is pepsin. Pepsin has an optimum pH of approximately 2.0 and splits proteins mainly into the less complex proteose and **peptone** fragments of the protein molecules. Few amino acids or polypeptides are released from protein by the action of pepsin. Thus, protein digestion in the stomach is only partial—about 10 to 15 percent, as mentioned previously. Gastric secretion in response to a meal will have the highest concentration of pepsin within the first hour. As the volume of gastric juice increases, the concentration of pepsin falls. During the later stages of gastric digestion, when the volume of gastric juice diminishes, the concentration of pepsin increases.

Pepsin is not the only proteolytic enzyme in gastric juice. Others include cathepsin and gastricin. These proteolytic enzymes have an optimum pH of 4.0 and 3.0, respectively. Their activity is of relatively minor importance.

**Digestion of fats.** Little if any digestion of fats normally occurs in the human stomach. There is some evidence, however, for a gastric lipase, a tributerase with an optimum pH between 4.0 and 5.0 and inactive at pH below 2.5. The origin of this lipase is unknown and it acts only on short-chain fats; *i.e.*, those with less than five carbon atoms. Much of the fat in the human diet contains 18 carbons in the fatty acid chains; tributerase has little if any activity on these fats and is of negligible significance.

**Gastric absorption.** Although the stomach absorbs few products of digestion, it is capable of absorbing a great many other substances.

**Foodstuffs.** Components of the diet that can be absorbed through the gastric mucosa include glucose and other simple sugars, amino acids, and some fat-soluble substances.

**Water.** Water moves freely from the gastric contents across the gastric mucosa into the blood. The net absorption of water from the stomach, however, is small, because water moves just as easily from the blood across the gastric mucosa to the lumen of the stomach. To demonstrate absorption of water from the stomach, isotopic, or "heavy," water is introduced into the stomach by a tube, and the presence of the isotope in the blood is then determined. In man about 60 percent of heavy water placed in the stomach is absorbed into the blood in 30 minutes. In normal young adults the mean rate of water absorption from the stomach is about 2 percent of the gastric contents per hour.

**Alcohol and drugs.** A number of alcohols, including ethyl alcohol, are readily absorbed from the stomach. The membranes of the cells that line the stomach are composed of lipids or fat substances, thus items in the diet that are fat soluble penetrate the membranes of the cells lining the stomach. Since ethyl alcohol and a number of other drugs are somewhat soluble in fat, they are absorbed directly from the stomach. The pH of the gastric contents also determines whether or not some substances will be absorbed. At a very low pH, for example, aspirin is absorbed almost as rapidly as water from the stomach, but as the pH of the stomach rises it is absorbed much more slowly.

**Gastric emptying.** Gastric emptying time is determined by the rate of the antral pumping contractions (three per minute) and the volume of material emptied into the duodenum by each antral contraction. The stroke volume of each antral contraction varies, depending upon the nature of the contents being pumped. Usually, however, this amounts to volumes of three to five millilitres for each antral contraction.

An ordinary meal is usually completely emptied from the stomach in two to three hours. Both the physical and chemical composition of the meal influence the emptying rate. Fluids are emptied more rapidly than solids, carbohydrates more rapidly than proteins, and proteins more rapidly than fats. Liquid meals that are isotonic to blood, that is, having the same osmotic pressure as blood, are emptied more rapidly than hypotonic or hypertonic liquids. Different substances are emptied from the stomach at differing rates because of the various neural and humoral factors that regulate gastric emptying.

When food is received into the stomach from the esophagus, it tends to form concentric layers. The contents at the periphery of the ingested meal are in contact with the gastric mucosa where they are mixed with the gastric secretions and subjected to the contracting waves of the wall of the stomach. As the peristaltic waves pass over the intragastric contents they tend to push the liquefied peripheral portion of the gastric contents into the **antrum**. When the **antrum** becomes compartmentalized from the body of the stomach, its liquid contents are pumped into the duodenum. The process is repetitive and constant until the stomach is emptied.

#### DIGESTION IN THE SMALL INTESTINE

The small intestine is the principal digestive organ of the human alimentary canal. Three principal activities within the small intestine are especially adapted for its role in digestion: (1) its motor activity allows both mixing and transport of intraluminal contents; (2) secretions into the small intestine provide the necessary enzymes and other constituents essential for normal digestion; (3) it has highly selective absorptive capabilities. These absorptive functions of the small intestine are made possible by the specialized structures of the intestinal mucosa that line the small bowel.

The morphology of the small intestine is arranged so that the inner mucosal surface, in contact with the intraluminal contents, greatly exceeds the external surface area. Some of the increased internal surface area is due to special folds in the intestinal mucosa known as plicae

Emptying  
time

Morphology of the  
small  
intestine

circulares. This internal area in addition is greatly increased by the presence of intestinal villi—small **finger-like** structures about one millimetre in height and one-tenth of a millimetre in diameter, projecting from the surface. The villi are covered by tall columnar epithelial cells. The luminal surface of the epithelial cells have microvilli that exponentially increase the absorptive surface presented to the intraluminal contents.

Anatomically the small intestine is divided into three parts: the duodenum, the jejunum, and the ileum. The most proximal portion of the duodenum communicates with the stomach through the pyloric valve. The duodenum is approximately 9 to 11 inches long and receives bile, secreted by the liver, from the gallbladder and also the secretions from the **pancreas**. The duodenal mucosa itself is the **origin** of a number of gastrointestinal hormones that regulate not only gastric and pancreatic secretion but also emptying of the stomach and gallbladder. The electrical "pacemaker" that regulates small intestinal motility also is located in the duodenum.

The jejunum is the upper third of the remainder of the small intestine. Its mucosal villi are tall and well developed. By the time ingested food has passed through this segment of the small intestine, most of the digestive processes are completed, as is the absorption of the products of digestion.

The ileum is the remaining two-thirds of the small intestine, similar in structure and function to the jejunum but with less well-developed intestinal villi. If for any reason normal digestive and absorptive processes are not completed in the jejunum, they are carried to completion in the proximal ileum. The ileum also provides a special site for the absorption of vitamin **B<sub>12</sub>** and bile salts.

**Small intestinal motility.** The primary purpose of the movements of the small intestine is to provide mixing and transport of intraluminal contents. Two types of motor activity have been recognized and designated as (1) segmenting contractions, and (2) peristaltic contractions. Characteristic of small intestinal motility is the inherent ability of the smooth muscle making up the wall of the intestine to contract spontaneously and rhythmically. This phenomenon is independent of any extrinsic nerve supply to the small intestine and creates pressure gradients from one adjacent segment of the intestine to another. The pressure gradients, in turn, are primarily responsible for transport within the small intestine.

The predominant motor action of the small intestine is the **segmenting** contraction. A segmenting contraction may be defined as a localized circumferential contraction, principally of the circular muscle of the intestinal wall: The contraction involves only a short segment of the bowel wall, usually less than one to two centimetres, and constricts the lumen, tending to divide its contents. The contractions occur at a maximum rate of 11 per minute in the duodenum and eight per minute in the lower ileum. Thus, from the duodenum to the ileum there is a gradual decrease in the maximal rate of segmenting contractions, from above downward. This has been described as the "gradient" of small intestinal motility. Most often segmenting contractions occur in an irregular manner. At times, however, they may occur in an extremely regular or rhythmic pattern, and at a maximum rate for that particular site of the small intestine. This type of recurring segmenting contraction has been termed rhythmic segmentation.

Rhythmic segmentation may occur in a localized segment of small intestine with the segmenting contractions being stationary; or such action **may** occur in a progressive manner, with each subsequent segmenting contraction occurring slightly distal to the preceding one. The latter type of rhythmic segmentation is known as progressive segmentation.

The rate of segmenting contractions is controlled by a pacemaker located in the duodenum in the **neighbourhood** of the ampulla of Vater, a swelling or pouch in the duodenal wall (see below). This pacemaker sends electrical impulses down the small intestine at a rate of 11 cycles per minute in the duodenum, gradually decreasing to eight cycles per minute in the ileum. These electrical

changes are propagated down the small intestine in the longitudinal muscle layer of the wall of the intestine. This cyclical slow-wave electrical activity is called basic electrical rhythm. Superimposed upon the slow-wave electrical activity may be fast, spikelike electrical changes. This type of electrical activity originates in the circular muscle layer of the intestinal wall and occurs when the circular layer contracts to form a segmenting contraction.

A peristaltic contraction may be defined as an advancing ring, or wave of contraction, passing along a segment of the small intestine. A peristaltic contraction normally occurs only over a short segment (a half-dozen or so centimetres) and moves at a rate of about one to two centimetres per minute. This type of small intestinal motor activity is primarily for transport of intraluminal contents from above downward, usually through one intestinal segment at a time.

When some inflammatory condition of the small bowel exists or when irritating substances are present in the **intraluminal** contents, a peristaltic contraction may travel over a considerable distance of the small intestine. This type of peristaltic contraction has been termed the peristaltic rush. Common infectious diarrhea is frequently associated with peristaltic rushes. Most cathartics produce their diarrheal effect by irritating the intestinal **mucosa** or increasing the contents, particularly with fluid. Either will induce a peristaltic rush.

**Digestive secretions into the small intestine.** The sources of digestive secretions into the small intestine are numerous. The gastric chyme that is emptied into the duodenum contains gastric secretions that continue their digestive processes while in the small intestine. One of the major sources of digestive secretion, however, is the pancreas, a large gland that produces both digestive enzymes and hormones (see DIGESTIVE SYSTEM, HUMAN), which empties its "juice" into the duodenum through both the major pancreatic duct at the ampulla of Vater and the accessory pancreatic duct a few centimetres proximal to the ampulla. Pancreatic juice contains enzymes that digest proteins, fats, and carbohydrates. The common bile duct delivers secretions of the liver, via the gall bladder, to the duodenum through the ampulla of Vater. Secretion from the mucosal surface of the small intestine is minimal and usually is no more than a few millilitres per hour for any one segment of intestine.

Secretions into the small intestine are under both neural (vagus) and hormonal control.

**Secretions from the small bowel.** Secretions from the small intestine are known as succus entericus. Except in the duodenum, the quantity of fluid secreted by the small intestine is never very great, even under conditions of stimulation.

The composition of the fluids secreted by the intestinal mucous membrane varies somewhat in the different parts of the intestine. In the duodenum, for example, where the mucous glands of Brunner are located, the secretion contains more mucus than is found elsewhere. In general the secretion of the small intestine is a thin, colourless, or slightly straw-coloured fluid, somewhat opalescent, and containing flecks of mucus. The intestinal juice consists of water, inorganic salts, and organic material. The inorganic salts are those commonly present in body fluids, with the bicarbonate concentration higher than it is in blood. The organic matter of the juice consists of mucus, enzymes, and cellular debris.

A great many enzymes have been reported as occurring in intestinal secretion. These include a pepsin-like protease (from the duodenum only), an amylase, a lipase, at least two peptidases, sucrase (invertase), maltase, lactase, enterokinase, alkaline phosphatase, nucleophosphatases and nucleocytases, and others (see also ENZYME).

Stimulation of the vagus nerve in experimental animals causes a moderate secretion of juice from the duodenum and smaller amounts from the rest of the small intestine after a latent period of one to one and one-half hours. Stimulation of sympathetic nerves supplying the small intestine causes no secretion, but cutting the nerves results in an increase in secretion.

Peristaltic contractions

Segmenting contractions

Composition of fluids

The most effective stimulus for secretion of succus entericus is local mechanical or chemical stimulation of the intestinal mucous membrane. Such stimuli are always present in the digesting intestine in the form of chyme and the food particles that it contains.

A hormone called enterocrinin, extracted from intestinal mucosa, when injected intravenously or subcutaneously, causes a denervated jejunal loop to secrete intestinal juice.

**Secretions from the pancreas.** The volume of the pancreatic juice may vary from 500 to 1,000 millilitres per day. Pancreatic juice is colourless, odourless, of low viscosity, and alkaline due to the presence of sodium bicarbonate. The pH of pancreatic juice is usually 8.0 to 8.3. Pancreatic digestive secretions consist mostly of water, sodium bicarbonate, and organic constituents—mostly enzymes—and inorganic components, including small amounts of calcium, magnesium, zinc, potassium, chloride, phosphate, and sulfate.

The principal enzymes secreted by the pancreas include trypsin and chymotrypsin, which digest protein; lipase, which acts on fats; and amylase, which digests starch. In addition to trypsin and chymotrypsin, other proteolytic enzymes are also present. These include carboxypeptidase, ribonuclease, elastase, and a collagenase. In addition to pancreatic lipase, pancreatic juice also contains two phospholipases known as phospholipase A and B.

Regulation is provided by both neural and hormonal stimulation. Vagal stimulation causes the pancreas to secrete a juice rich in enzymes. The secretion of water and sodium bicarbonate is mainly under the control of the gastrointestinal hormone secretin, elaborated in the duodenal mucosa, released into the bloodstream, and carried to the pancreas where it stimulates the centroacinar cells to secrete water and sodium bicarbonate. The concentration of the sodium bicarbonate secreted by these cells is approximately 150–160 milliequivalents per litre. In its passage through the pancreatic ducts to the duodenum, some bicarbonate is exchanged for chloride. It is thought that the bicarbonate in pancreatic juice is dependent upon flow rate and that the greater the flow rate, the higher the concentration of bicarbonate.

Pancreatic enzymes are elaborated in the acinar (or exocrine) cells of the pancreatic glands and stored in the form of zymogen granules until released into the lumen of the acinus. The release of the zymogen granules is also under the control of both neural and humoral mechanisms. Cholinergic or vagal stimulation enhances the effect of the gastrointestinal hormone pancreozymin. This hormone, like secretin, is also elaborated within the duodenal mucosa, released into the bloodstream, and carried to its target organ, the acinar cells, and there stimulates them to release pancreatic enzymes.

Both secretin and pancreozymin have been isolated and purified. In man they can be used to test the exocrine function of the pancreas. Both are administered intravenously, and pancreatic juice is collected from the duodenum by a long intestinal tube. After stimulation of the pancreas with secretin, the volume of juice secreted increases greatly, and the concentration of bicarbonate goes up with increased flow rate. After an intravenous injection of pancreozymin, the secreted juice is rich in proteins, including the principal enzymes trypsin, lipase, and amylase.

**Secretions from the liver.** The secretions from the liver are contained in bile. Bile is formed by the hepatocytes of the liver. Initially it is collected within the biliary canaliculi located between adjacent liver cells. These small bile ducts join together to form larger ones, and ultimately the bile is collected into the two main hepatic ducts and then into the common bile duct. Under normal conditions, bile is stored in the gallbladder, where it becomes concentrated as the gallbladder mucosa absorbs water and some salts from the hepatic bile. The steady flow of bile from the liver serves as an avenue for the secretion of substances important in digestion and for the excretion of certain others.

Liver bile consists of about 97.5 percent water and 2.5 percent solids. The main constituents of the solids that

make up bile are bile salts. Other important constituents include certain inorganic salts, as are found in blood plasma, cholesterol, bile pigments, and small amounts of fatty acids, lecithin, and fats. The pH of the liver bile is slightly alkaline, being 8.0 to 8.6; gallbladder bile is usually neutral. Gallbladder bile contains a much higher concentration of organic solids than does liver bile, and the concentration of individual bile constituents may vary widely.

When gastric chyme is introduced into the duodenum it causes the duodenal mucosa to release a gastrointestinal hormone called cholecystokinin (now thought by some investigators to be the same as pancreozymin) that causes the gallbladder to contract. Thus, as gastric emptying occurs, the contraction of the gallbladder empties the concentrated bile into the small bowel to be mixed with the gastric chyme.

The bile salts are the most important constituents of bile as far as digestion is concerned. In man, four bile acids have been identified: cholic, chenodeoxycholic, deoxycholic, and lithocholic acids. The bile salts are composed of the corresponding bile acid combined with sodium. They are important to digestion because they activate pancreatic lipase, produce emulsification of fats, and promote the absorption of fats by combining with the products of fat digestion to form fat micelles, colloid-like particles. Although fat is absorbed primarily in the jejunum, the bile salts are not reabsorbed until they reach the lower ileum. Of all the bile salts delivered into the duodenum, approximately 90 percent are reabsorbed from the terminal ileum. There is thus a recirculation of bile salts back to the liver where they are subsequently resecreted into the duodenum. This is known as the enterohepatic circulation of bile salts.

Of the many products excreted by the liver in the bile, bilirubin is one of the most important. Bilirubin, a bile pigment, is an end product of hemoglobin breakdown and of porphyrin metabolism. In the liver it is conjugated with glucuronic acid and excreted in the conjugated form. In the small intestine, bilirubin is reduced to urobilinogen and absorbed back into the blood, carried to the kidney, and excreted in the urine. Bacterial action in the small intestine and colon may unconjugate bilirubin, and the unconjugated bilirubin is absorbed into the blood and returned to the liver where it is re-excreted into the bile in the conjugated form. Thus, as in the case of bile salts, there is an enterohepatic circulation of bilirubin. Biliverdin, a green pigment, as the name implies, is also present in the bile but is of minor importance.

**Small intestine chemical digestion.** In the human diet the three principal components requiring digestion are carbohydrates, proteins, and fats. Most of the digestive processes that solubilize these substances and reduce them to relatively simple organic compounds occur in the proximal small intestine. The carbohydrates, fats, and proteins are substrates for the specific enzymes previously described.

**Digestion of carbohydrates.** Carbohydrates ordinarily make up about 50 to 60 percent of the total human diet. The amount eaten per day may range from 300 to 600 grams, representing 1,200 to 2,400 calories per day. Most of these carbohydrates are in the form of starches or polysaccharides—long-chain compounds containing many sugar molecules. The diet also contains some oligosaccharides, which are composed of two to ten simple sugars; disaccharides, compounds of two linked simple sugars, such as sucrose (common table sugar), maltose (malt sugar), and lactose (milk sugar); and monosaccharides or simple sugars such as glucose, or dextrose, and fructose.

Since carbohydrates are absorbed only in the form of monosaccharides or disaccharides, the polysaccharides and oligosaccharides must be reduced to these simpler components. This is accomplished by the enzyme amylase, which is secreted in the saliva by the parotid glands and in the pancreatic juice by the pancreas. The action of amylase on starch is to reduce it to maltose and glucose. On complete digestion of starch by amylase, starch is reduced to approximately 88 percent maltose and 12

Bile salts

Amylase action

Regulation of pancreatic secretion

Composition of bile

percent glucose. Amylase also acts on other **polysaccharides** and oligosaccharides and reduces them to **mono-** and disaccharides.

**Digestion of proteins.** The amount of protein in the diet usually amounts to about 50 to 75 grams per day. Adults require 0.5 to 0.7 gram of protein per kilogram of body weight per day to remain in nitrogen balance. Growing children may require as much as four to five times this amount. The products of protein digestion are amino acids. Proteins are absorbed only as amino acids.

In the gastric juice of man four pepsins have been identified. They initiate protein digestion in the stomach and reduce the ingested protein to simpler substances as proteoses and peptones, but only 10 to 15 percent of the ingested protein is reduced to amino acids by gastric digestion. In the small intestine, protein digestion is carried to completion by the action of pancreatic trypsin and chymotrypsin and by the proteases and peptidases that are released by the breakdown of epithelial cells peeled off the small bowel mucosa. Protein digestion is usually completed by the time the meal has passed through the first 100 centimetres of the proximal small intestine.

**Digestion of fats.** Little or no digestion of fats occurs in the stomach, and most ingested fats are delivered to the duodenum chemically unchanged. Ingested fat usually is from both animal and vegetable sources. The amount of fat in the diet varies with custom and the availability of fats. The average American or northern European diet contains from 50 to 100 grams of fat per day. In other parts of the world, particularly in colder climates, two to three times that amount may be consumed daily.

Because fats are insoluble in water, special digestive mechanisms are required to put them into solution and then to reduce them to simple absorbable units. Dietary fats consist mainly of triglycerides. A triglyceride is a fat molecule composed of a unit of glycerol linked to three units of fatty acids. The fatty acids in animal fat are mostly of the 16 or 18 carbon-atom-chain type. Pancreatic lipase hydrolyzes a triglyceride by splitting off the fatty acids that are connected to the ends of the glycerol molecule. This produces two molecules of fatty acids and a monoglyceride. Some triglycerides may be hydrolyzed completely into glycerol and fatty acids.

Bile salts **secreted** in the bile into the duodenum emulsify these products of fat digestion by combining with them to form fat micelles. Like carbohydrates and proteins, most fat is absorbed by the time it passes through the first 100 centimetres of the jejunum of the small intestine. A normal intestinal mucosa will absorb all dietary fat. If bile salts or pancreatic lipase are deficient, fat is not completely digested and will be excreted in the stool. Steatorrhea, an excess of fat in the stool, is a condition found in a number of diseases; *e.g.*, tropical sprue or adult celiac disease.

**Small intestine absorption.** Absorption of all food by the small intestine occurs principally in the upper part of that organ. The duodenum, although the shortest portion of the small intestine, plays an extremely important role in intestinal absorption. As noted previously, the duodenum is not only the receptor of the acid gastric chyme but is also the recipient of the pancreatic and liver secretions. It is in the duodenum that the intestinal contents are rendered isotonic with the blood plasma. The bicarbonate secreted by the pancreas neutralizes the acid secreted by the stomach. This brings the intestinal contents to the optimal pH, allowing the various enzymes to act on their substrates at peak efficiency. The duodenum is also the source of a number of important gastrointestinal hormones that regulate gastric emptying, gastric secretion, pancreatic secretion, and contraction of the gallbladder. These hormones, along with neural impulses from the autonomic nervous system, provide for autoregulatory mechanisms for normal digestive processes.

**Absorption of electrolytes and water.** Most salts and minerals, as well as water, are readily absorbed from all portions of the small intestine. Sodium, in the average daily diet to the extent of 12–15 grams, is absorbed by an active process, which means that an expenditure of

energy is required for absorption. The necessary metabolic energy is provided by the epithelial cells of the small intestinal mucosa. Sodium is moved from the lumen of the bowel across the mucosa against both a concentration gradient, or increase, and an electrochemical gradient. The ion is absorbed more readily from the jejunum than from other parts of the small intestine.

Potassium is absorbed at about 5 percent of the rate of sodium. It is thought that potassium moves across the intestinal mucosa in a passive manner or by diffusion as a consequence of water absorption. Chloride is readily absorbed in the small bowel and probably takes place as a consequence of sodium absorption.

Water appears to be dependent upon the absorption of electrolytes and occurs throughout the small intestine. The chief site of water absorption, however, is the jejunum. It has been shown by the use of isotopically labelled water that the upper small intestine absorbs approximately 95 percent of a 50-gram sample within ten minutes. Water, as mentioned previously, moves across the intestinal mucosa both ways. Thus, there is passage from the lumen of the intestine to the blood and from the blood to the lumen of the intestine. If the contents of the lumen are hypotonic, water moves more rapidly from the lumen to the blood. If the contents of the intestinal lumen are hypertonic, water moves more rapidly from the blood into the lumen. This two-way movement of water tends to maintain the intestinal contents in an isotonic state.

**Absorption of carbohydrates.** Carbohydrates are absorbed in the form of monosaccharides or disaccharides. Monosaccharides are absorbed more readily from the upper than from the lower small intestine. Glucose absorption is dependent upon the presence of sodium and is an active process; **thus** glucose can move across the intestinal mucosa against a concentration gradient. It is quite possible that there may be a specific pathway for the absorption of glucose and other monosaccharides that are actively transported across the mucosa, because certain structural requirements within the sugar molecule are necessary for the sugar to be accepted in the transport mechanism. Glucose and galactose have these structural requirements. Fructose, another simple sugar, is apparently absorbed by simple diffusion across the intestinal mucosa.

Disaccharides are absorbed subsequent to the action of specific enzymes, called disaccharidases, located within the microvilli of the epithelial cells. These enzymes split the disaccharides into simple sugars. Thus, sucrase hydrolyzes a molecule of sucrose into one molecule of glucose and one molecule of fructose. Maltase splits maltose into two molecules of glucose, and lactase converts lactose into glucose and galactose. The monosaccharides are then transported into the cells of the epithelium of the mucosa.

In certain individuals there is a deficiency or a congenital absence of one or more of the disaccharidases. The most common condition is that of a deficiency or absence of lactase. If **these** individuals drink milk, they cannot digest the milk sugar, lactose, and the **nonabsorbable** disaccharide remains in the intestine and frequently causes diarrhea. This is a common factor in so-called milk intolerance (see METABOLISM, DISEASES OF).

**Absorption of protein.** All digestible proteins are reduced by the proteolytic enzymes to amino acids and are absorbed as such. Amino acids may be classified into groups depending upon their optical rotatory characteristics (*i.e.*, whether they rotate polarized light to the left—**levo**; or to the right—**dextro**) and in terms of reactivity or pH. Amino acid absorption is an active process. **Levo**-rotatory amino acids are absorbed extremely rapidly—much more rapidly than are dextrorotatory amino acids—in fact, almost as quickly as they are released from protein or peptide. Neutral amino acids have certain structural requirements for active transport. If these specific structural arrangements are disturbed, active transport will not occur. Basic amino acids are transported at about 5 to 10 percent of the rate of neutral levorotatory amino acids.

**Absorption of fats.** The products of fat digestion are glycerol, free fatty acids, and monoglycerides. The glycerol is absorbed directly through the cell wall of the epithelial cells lining the mucosa. As explained previously, the free fatty acids and monoglycerides are combined with bile salts to form fat micelles. The fatty acids and monoglycerides are then absorbed from the micelles by the epithelial cells. Inside the cell the glycerol and fatty acids, as well as the monoglycerides, are reconstituted into new triglycerides or fat, the structure of which is characteristic of the species—in this case, of man. Molecules of triglycerides are then combined to form chylomicrons, which are microspheres of triglyceride coated with a layer of phospholipid. In this form they are transported by the lymph out of the intestinal mucosa and into the lymphatic system. Glycerol and free fatty acids that are not reconstituted into triglycerides within the mucosal cells are transported from the cells via the portal blood to and from the liver. The bile salts left behind in the upper small intestine move, along with other digestive residue, to the lower ileum, where they are absorbed and then recirculated through the liver.

**Absorption of other substances.** Calcium is absorbed from the small intestine by an active process. Apparently the amount of calcium absorbed from the intestine is controlled to meet the metabolic needs of calcium by the body. Parathormone, the hormone of the parathyroid glands, and vitamin D increase calcium absorption. The absorption of calcium appears to be a two-step process. First there is the uptake of calcium by the epithelial cells of the mucosa. The second step is the accumulation of calcium within the epithelial cells. Thus the calcium is not transported immediately across the mucosa into the blood. The entry of calcium into the cell is related, within certain limits, to the concentration of calcium within the lumen of the bowel. It appears that transport of calcium from the cells to the blood has a limiting rate, and if the calcium is not needed by the body it will be returned to the intestinal lumen when the epithelial cell is desquamated.

Iron in the amounts of 10 to 20 milligrams per day is contained in the average diet, of which only 0.5 to 1.0 milligram is absorbed. The absorption of iron is an active process and, like calcium, apparently occurs in a two-step fashion, first by entry into the cell and, second, storage in the cell with a slow release to the blood. The transfer of iron from the cells to the blood is regulated by the bodily need for iron. The total body store of iron is approximately four grams. Excessive amounts of iron stored in the epithelial cells of the mucosa are returned to the gut by desquamation of the epithelial cells. In the case of blood loss or during menstruation, the amount of iron absorbed a day may reach 1.0 to 1.5 milligrams.

Vitamin  $B_{12}$  is absorbed only in the terminal ileum. It first must be bound with the intrinsic factor of Castle, which, as noted above, is elaborated by the parietal cells of the gastric mucosa. The exact mechanism whereby vitamin  $B_{12}$  enters the intestinal mucosa is not known. The average diet contains adequate amounts of vitamin  $B_{12}$  and the normal requirement is only about one microgram per day.

#### DIGESTION IN THE LARGE INTESTINE

The large intestine or colon receives from the small intestine approximately one pint (500 millilitres) of intestinal chyme per day. This is ultimately reduced, in the colon, to approximately 150 millilitres, representing the volume of feces excreted each day. The primary function of the colon is to absorb water, sodium, and chloride from the digestive residue as it passes through.

**Large intestinal motility.** Twenty-four to 48 hours after oral administration of barium chloride, the opaque material commonly used in X-ray examination of the alimentary canal, the large intestine, or colon, will be filled with the substance and visible under fluoroscopy. A few minutes' observation shows no colonic motility. With longer periods of study using cineradiographic equipment, colonic segmenting contractions can be seen occurring at a rate of about two per minute in any one

segment. The segmenting contractions are similar to those of the small intestine and produce sacculations, or recesses, called haustra. These contractions primarily serve the purpose of mixing the colon contents to aid in the absorption of water, sodium, and chloride.

Another movement of the large intestine transports the intraluminal contents. This type of motor activity is termed mass movement and usually occurs only two or three times per day; it is frequently associated with eating and thought to be initiated by what is called the gastrocolic reflex. When mass movements occur, materials in the cecum (ascending colon) may be transported to the transverse colon, or material in the transverse colon transported to the descending colon. When mass movements occur in the descending colon, the intestinal contents fill the rectum and initiate the defecation reflex. Since the primary function of the colon is an absorptive one in man, the types of motility it exhibits are particularly adapted to enhance this function.

**Large intestinal secretion.** The large intestinal mucosa does not have the villi observed in the mucosa of the small intestine but is more glandular, with many crypts. The surface of the mucosa is covered by tall columnar epithelial cells. The crypts are lined with mucous glands. The principal substances secreted by the colon are mucus, potassium, and bicarbonate. The mucus aids in lubricating the intestinal contents and facilitates their transport by the mass movement contractions.

**Large intestinal chemical digestion.** In a normal individual, digestion of carbohydrates, proteins, and fats is completed in the upper part of the small intestine. Thus, by the time that the intestinal contents have reached the ileocecal valve, all normal digestive and absorptive processes of foodstuffs have occurred. The intestinal chyme delivered to the colon is isotonic and consists mainly of nonabsorbable substances such as cellulose and other fibrous materials. Man has no enzymes that adequately digest cellulose. Cellulose and pectin taken in the diet may be broken down by colonic bacteria. The large intestine of man contains large numbers of bacteria as well as yeast and fungi. These micro-organisms, referred to as intestinal flora, serve the function of reducing undigested food and undigestible items in the diet to substances suitable for elimination in the feces. Only in abnormal conditions where there is a deficiency or lack of intestinal enzymes or bile, as occurs in some diseases of pancreas, liver, or small intestine, does a significant amount of undigested food reach the colon. When this does occur, the undigested material is broken down by the intestinal flora.

**Large intestinal absorption.** Absorption of water and storage of fecal material until elimination by defecation are the main functions of the colon. The net absorption of water by the colon represents about 350 millilitres per day. The capacity of the colon to absorb water, however, has been determined to be two to three litres per day, and in the process of absorbing water the contents of the large intestine remain isotonic.

In addition to water, significant amounts of salt and chloride are absorbed through the colonic mucosa. Isotonicity is maintained as the colon mucosa secretes potassium and bicarbonate while sodium and chloride are absorbed. Colonic absorption results in the daily formation of about 150 millilitres of fecal material. Fecal material is composed of about one-third solids and two-thirds water. Bacteria make up 10 to 20 percent of the total weight of solids excreted in the feces each day.

#### ELIMINATION

Normally the digestive tract of man contains from 100 to 200 millilitres of gas. Approximately one-third of this amount is found in the stomach and two-thirds in the large intestine. Not much gas is normally present in the small bowel. Gas in the digestive tract comes primarily from air swallowed with meals. The amount of air ingested with meals varies greatly but may be as great as 500 millilitres in some individuals. Air ingested with meals is usually eructated but may pass on down through the small intestine to the colon. Some of the gases in the

Mass movement

Absorption of iron

Sources of gas in the digestive tract

large intestine are the result of bacterial action on the intraluminal contents. The composition of gas in the stomach depends on when it was swallowed. Immediately after eating, the composition of stomach gas is very similar to that of ordinary air; that is, 20 percent oxygen and 80 percent nitrogen. After remaining in the stomach for a period of time, however, the composition approaches that of expired air from the lungs; that is, 15 to 16 percent oxygen, 5 to 9 percent carbon dioxide, and the remainder nitrogen. In the colon approximately half of the gas has its origin from swallowed air; the remainder is that produced by the colonic bacteria. The composition of colonic gas is made up mostly of nitrogen and carbon dioxide, with nitrogen representing 50 to 60 percent and carbon dioxide 30 to 40 percent, and the remaining 5 to 10 percent is composed of hydrogen sulfide, methane, and hydrogen. Colonic gas is normally expelled by the act of flatulation. Movement of gas in the digestive tract produces gurgling sounds known as borborygmus.

**Defecation.** The transformation of ileal contents to fecal material by the colon has been described previously. When mass movements of the colon force fecal material into the rectum, the defecation reflex is initiated. The rectum is normally empty, but when it is filled with gas, liquids, or solids to the extent that the intraluminal pressure is raised to 15 to 20 centimetres of water, the impulse to defecate occurs.

The act of defecation is, in the adult, preceded by a voluntary effort consisting of assuming an appropriate posture, voluntary relaxation of the external anal sphincter, and usually compression of the abdominal contents by means of straining efforts. These movements, in turn, probably give rise to stimuli that augment the visceral reflexes, although these originate primarily in the distended rectum. Centres that control defecation reflexes are found in the hypothalamus of the brain, in two regions of the spinal cord, and in the ganglionic plexus of the intestine. As the result of these reflexes, the internal anal sphincter relaxes. The mass contraction of the colon carries its contents into the pelvic colon, which in turn transfers them into the rectum, eventually to be evacuated by way of the anus. Thus, the entire distal colon from the splenic flexure to the anus may be emptied at one time. A prominent mechanical feature of the final act of defecation is contraction of the longitudinal muscles of the distal and pelvic colon. The shortening of the distal colon tends to elevate the pelvic colon and obliterate the angle that it normally makes with the rectum. The straightening and shortening of the passage facilitates evacuation.

The act of defecation is a reflex that is under some degree of voluntary control. The voluntary regulation consists of the ability to inhibit the reflex under normal circumstances and to initiate it voluntarily provided the necessary visceral stimulus (recent distension of the rectum) is still present. If the impulse to defecate is ignored, it will disappear but reoccur as the pressure increases. Eventually involuntary reflex action takes over and defecation is no longer under voluntary control.

**Formation and composition of feces.** As mentioned previously, by the time food material has progressed through the small intestine, practically all the digestible material has been absorbed and carried away by the blood or lymph. The residue consists of water, small amounts of undigested and unabsorbed food, the remains of desquamated mucosal cells, and the undigestible and unabsorbable fractions of the digestive secretion. In addition, there may be present various species of bacteria and the products of their metabolism. This material is emptied from the terminal ileum into the colon, where it is subjected to further alteration through absorption of water and the action of bacteria.

Food residues provide an excellent culture medium for bacteria, and the interior of the colon is a nearly ideal environment for their growth; in consequence they multiply enormously, so that from 10 to 20 percent of the solid weight of the feces may be made up of bacterial cells. The colonic contents are further modified by absorption of water and inorganic salts, so that of the 75 to 180 grams of feces daily excreted only about 60 to 70 per-

cent is normally water; this proportion varies a great deal, however, according to the consistency of the feces.

Feces normally contain from 5 to 25 percent of fatty material, including such substances as neutral fats, free fatty acids, soaps, and sterols. Fats are present in appreciable amounts even on a fat-free diet, proving that some fat is excreted through the intestine. About one-third of the fecal lipid consists of sterols, chiefly cholesterol. The daily output of feces contains from 0.5 to 1.5 grams of nitrogen as nitrogen compounds. About half the nitrogen represents nitrogenous constituents of the fecal bacteria; the rest represents unabsorbed intestinal secretions and digestive fluids, mucus, desquamated mucosal epithelial cells, and a small amount of food residue; some digestive enzymes also may be present. Usually absorption and digestion of protein are so nearly complete that only small amounts of food protein nitrogen escape into the feces; likewise, only small quantities of digestive enzymes are normally present, since they are usually destroyed by other enzymes or by the action of bacteria. Digestive enzymes may be increased in the stool in diarrhea and may then cause severe skin irritations.

Since the pH of the feces is usually between 7.0 and 7.5, the inorganic constituents are mainly substances that are poorly soluble in alkaline pH ranges; these are chiefly calcium phosphate and oxalate and iron phosphate. Small amounts of magnesium, potassium, and sodium salts are also present in the stool. Since cellulose and lignin are not digested, they may be found in the feces whenever they are present in the diet, particularly in fibrous foods. The total volume of the feces may be considerably influenced by the amount of cellulose or lignin ingested.

The dark brown colour of the normal stool is due chiefly to stercobilin and urobilin, reduction products of the action of bacteria on the red bile pigment, bilirubin. The main cause of odour is the presence of skatole and indole, produced by bacterial action, and, to a lesser degree, the presence of hydrogen sulfide and methyl mercaptan. The odour is more pronounced on a high protein diet because of the formation of larger quantities of these odoriferous substances.

Even when no food is taken, about seven to eight grams of feces are excreted daily. This consists of desquamated mucosal cells, digestive secretions, bacteria, and bacterial residue. For the fate of ingested foods after digestion and absorption, see **METABOLISM**.

## Digestion and Digestive Systems

In order to sustain themselves all organisms must obtain nutrients from the surrounding environment. Some nutrients serve as raw materials for the synthesis of cellular material; others (*e.g.*, many vitamins) act as regulators of chemical reactions in living cells; and still others, upon oxidation in living cells, yield energy. Not all nutrients, however, are in a form suitable for immediate use by an organism; some must undergo physical and chemical changes before they can serve as energy or cell substance. This article deals with digestion and digestive systems generally, referring to specific organisms to clarify the account; it emphasizes the vertebrate condition in the latter half. For aspects strictly concerning human digestion see **DIGESTIVE SYSTEM, HUMAN; DIGESTIVE SYSTEM DISEASES**.

### GENERAL FEATURES

**Distinctions and definitions.** Through the act of eating, or ingestion, nutrients are taken from the environ-

The  
defecation  
reflex

ment. Many nutrient molecules are so large and complex that they must be split into smaller molecules before they can be used by the organism. This process of breaking down food into molecular particles of usable size and content is called digestion. Unusable components are expelled from the organism by a process called egestion. Some plants, many micro-organisms, and all animals perform these three functions—ingestion, digestion, and egestion (often grouped under the term **alimentation**)—but, as expected, the details differ considerably from group to group.

Auto-  
troph  
and  
hetero-  
troph

The problems associated with nutrient intake and processing differ greatly depending on whether the organism is autotrophic or heterotrophic. Autotrophic organisms are those that can manufacture the large energy-rich organic compounds necessary for life from simple inorganic raw materials; consequently, they require only simple nutrients from the environment. By contrast, heterotrophic organisms cannot manufacture complex organic compounds from simple inorganic ones, and so they must obtain preformed organic molecules directly from the environment.

Green plants constitute by far the majority of the Earth's autotrophic organisms. During the process of photosynthesis, they use light energy to synthesize organic materials from carbon dioxide and water. Both compounds can be absorbed easily across the membranes of cells—in a typical land plant, carbon dioxide is absorbed from the air by leaf cells, and water is absorbed from the soil by root cells—and used directly in photosynthesis; *i.e.*, neither of them requires digestion. The only other nutrients needed by most green plants are minerals such as nitrogen, phosphorus, and potassium, which also can be absorbed directly and require no digestion. There are, however, a few green plants (*e.g.*, sundew, Venus' flytrap, pitcher plant) that supplement their inorganic diet with organic compounds (particularly protein) obtained by trapping and digesting insects and other small animals.

Heterotrophy characterizes all animals, most micro-organisms, and plants and plantlike organisms (*e.g.*, fungi) that lack the pigment chlorophyll, which is necessary for photosynthesis. These organisms must ingest organic nutrients—carbohydrates, proteins, and lipids (fats)—and, by digestion, rearrange them into a form suitable for their own particular needs.

**Ingestion.** As already explained, the nutrients procured by most green plants are small inorganic molecules that can move with relative ease across cell membranes. Heterotrophic organisms such as bacteria and fungi, which require organic nutrients yet lack adaptations for ingesting bulk food, also rely on direct absorption of small nutrient molecules across cell membranes; molecules of carbohydrates, proteins, or lipids, however, are too large and complex to move easily across cell membranes. Bacteria and fungi circumvent this problem by secreting digestive enzymes onto the food material; these enzymes catalyze the splitting of the large molecules into smaller units that are then absorbed into the cells. In other words, the bacteria and fungi perform **extracellular digestion**—digestion outside cells—before ingesting the food. This method of feeding is often referred to as **osmotrophic nutrition**.

Like bacteria, protozoans are unicellular organisms, but their method of feeding is quite different. They ingest relatively large particles of food and carry out intracellular digestion—digestion inside cells—a method of feeding called **phagotrophic nutrition**. To a lesser degree many protozoans also are osmotrophic. Some organisms (*e.g.*, *Amoeba*) put out pseudopodia ("false feet"), which flow around the food particle until it is completely enclosed in a membrane-bounded chamber called a **food vacuole**; this process (Figure 1A) is called **phagocytosis**. Other protozoans (*e.g.*, *Paramecium*) pinch off food vacuoles from the end of a prominent oral groove into which food particles are drawn by the beating of numerous small, hairlike projections (cilia). In still other cases of phagotrophic nutrition, tiny particles of food adhere to the membranous surface of the cell, which then folds

Ingestion  
by simple  
cells

**Figure 1. The ingestion of food by cells.** (A) Phagocytosis, or the engulfment of a food particle; (B) two forms of pinocytosis, or the pinching off of food vacuoles. Adapted from (A) James G. Hirsch in A.E. Nourse, *The Body*; (B) From W.T. Keeton, *Biological Science*. © 1967 by W.W. Norton & Company, Inc.

inward and is pinched off as a vacuole; this process (Figure 1B) is called **pinocytosis**. The food particles contained in vacuoles formed through phagocytosis or pinocytosis have not entered the cell in the fullest sense until they are digested into molecules able to cross the membrane of the vacuole and become incorporated into the cellular substance.

Most multicellular animals possess some sort of digestive cavity—a chamber opening to the exterior via a mouth—in which digestion takes place. Large particles of food are broken down to units of more manageable size within the cavity before being taken into cells and reassembled (or assimilated) as cellular substance.

**Digestion.** The enzymatic splitting of large and complex molecules into smaller ones is effective only if the enzyme molecules come into direct contact with the molecules of the material they are to digest. In animals that ingest very large pieces of food, only the molecules at the surface are exposed to the digestive enzymes. Digestion can proceed more efficiently, therefore, if the bulk food is first mechanically broken down, exposing more molecules for digestion. Among the variety of devices that have evolved to perform such mechanical processing of food are the chewing teeth of mammals and the muscular gizzards of birds.

The chemical reactions involved in digestion can be clarified by an account of the digestion of maltose sugar. Maltose is, technically, a double sugar, since it is composed of two molecules of the simple sugar glucose bonded together. The digestive enzyme maltase catalyzes a reaction in which a molecule of water is inserted at the point at which the two glucose units are linked, thereby disconnecting them, as illustrated in the following structural diagrams.

The  
chemical  
basis of  
digestion

In chemical terms, the maltose has been hydrolyzed. All digestive enzymes act in a similar way and thus are hydrolyzing enzymes.

Many other nutrient molecules are much more complex, being polymers, or long chains of simple component units. Starch, for example, is a carbohydrate, like maltose, but its molecules are composed of thousands of glucose units bonded together. Even so, the digestion of starch is essentially the same as the digestion of maltose: each linkage between adjacent glucose units is hydrolyzed, with the result that the starch molecule is split into thousands of glucose molecules. Protein molecules also are polymers, but their constituent units are amino acids instead of simple sugars. Proteolytic (*i.e.*, protein-digesting) enzymes split the protein chains by hydrolyzing the bonds between adjacent amino acids. Because as many as 20 different kinds of amino acids may act as building blocks for proteins, the complete digestion of a protein into its amino acids requires the concerted action of several different proteolytic enzymes, each capable of hydrolyzing the bonds between particular pairs of amino acids. Fat molecules, too, are composed of smaller building-block units (the alcohol glycerol plus three fatty acid groups); they are hydrolyzed by the enzyme lipase.

Various other classes of compounds are digested by hydrolytic enzymes specific for them. Not all of these occur in every organism; for example, few animals possess cellulase (cellulose-digesting enzyme), despite the fact that cellulose constitutes a high percentage of the total bulk of the food ingested by plant-eating animals (herbivores). Some herbivores, nonetheless, benefit from the cellulose in their diet because their digestive tracts contain micro-organisms (known as symbionts) capable of digesting cellulose; the herbivores absorb some of the products of their symbionts' digestive activity.

So far, emphasis has been placed on the role of digestion in converting large complex molecules into smaller simpler ones that can move across membranes, thus permitting absorption of food into cells. The same processes occur when substances must be moved from cell to cell within a multicellular organism. Thus, green plants, which do not have to digest incoming nutrients, digest stored material, such as starch, before it can be transported from storage organs (tubers, bulbs, corms) to points of utilization, such as growing buds.

**Egestion.** Animals that ingest bulk food unavoidably take in some matter that they are incapable of using; for example, since man lacks cellulase, the cellulose he ingests in vegetables and fruits is indigestible. It cannot be absorbed from the digestive tract and must be expelled from the body.

In the case of unicellular organisms that form food vacuoles, the vacuoles eventually fuse with the cell membrane and then rupture, releasing indigestible wastes to the outside (Figure 2). Multicellular animals periodically release such waste from their digestive tracts either by regurgitating it through the mouth or by eliminating it as feces through the anus.

#### INVERTEBRATE DIGESTIVE SYSTEMS

**Vacuolar systems.** Unicellular organisms that ingest food particles via vacuoles rely on intracellular digestion to prepare the nutrients for use. The enzymes that catalyze this digestion, being very potent chemicals capable of breaking down the cell substance itself, are held until needed in special packets, or vesicles, called lysosomes; the membrane of a lysosome is both impermeable to the enzymes and capable of resisting their hydrolytic action. Soon after a food vacuole is formed, a lysosome fuses with it (Figure 2). Food material and digestive enzymes are mixed in the resulting composite vesicle, which is sometimes called a digestive vacuole. This vacuole moves in an orderly fashion through the cell, during which passage the products of digestion are absorbed, leaving the indigestible material, which is eventually expelled.

Vacuolar digestion is not restricted to unicellular organisms, however. Many multicellular invertebrates partly digest their food extracellularly before phagocytizing the remainder, which is then digested intracellularly by the same process described in the preceding paragraph.

**Channel-networksystem.** The sponges, among the simplest multicellular organisms, have what amounts to diversionary water channels that serve to bring water and food to their component cells. The channels are lined with special cells bearing whiplike structures called flagella that create water currents. A steady flow of water inward through smaller secondary channels and then out the main, or excurrent canal, carries with it bits of food. The lining cells capture the food particles and enclose them in food vacuoles, wherein the matter is digested as in protozoans, by intracellular means.

**Saccular systems.** With the evolution of multicellular organisms came a corresponding evolution of cellular specialization, resulting in a division of labour among cells; in this way, certain cells became specialized to perform the function of digestion for the entire organism. Cnidarians, especially hydra, provide a comparatively simple example. These radially symmetrical animals have a saclike body composed of two principal layers of cells (Figure 3B). The cells of the outer layer function as a

The gastro-vascular cavity

protective and sensory covering (epithelium); those of the inner layer, or gastrodermis, which lines the central cavity of the body, act as a nutritive epithelium. The central cavity, which functions as a digestive cavity, has only one opening to the outside; the opening acts both as a mouth for ingestion of food and as an anus for egestion of wastes. Such a digestive cavity is called a gastrovascular cavity, because in many animals it has vessel-like branches that convey the contents to all parts of the body.

Once prey, captured by a hydra's tentacles, has been passed through the mouth into the gastrovascular cavity, digestive enzymes are secreted into the cavity by the gastrodermal cells, and extracellular digestion begins. In cnidarians, this extracellular digestion is limited largely to partial hydrolysis of proteins. As soon as the food has been partially disintegrated, the gastrodermal cells engulf the fragments by phagocytosis, and digestion is completed intracellularly within food vacuoles.

Many flatworms (phylum Platyhelminthes) also have gastrovascular cavities, even though their bodies are in many other ways much more complex than those of cnidarians. In planarians, for example, the mouth opens into a tubular chamber called the pharynx, which in turn leads into an extensively branched gastrovascular cavity that ramifies throughout the body (Figure 3A). As in cnidarians, some extracellular digestion occurs in the planarian gastrovascular cavity, with the small food particles then being engulfed by gastrodermal cells and digested intracellularly. The additional process of extracellular digestion frees cnidarians and flatworms from exclusive reliance on intracellular digestion.

**Tubular systems.** Most animals above the level of cnidarians and flatworms have a complete digestive tract;

*i.e.*, a tube with two openings—a mouth and an anus. There are obvious advantages of such a system over a gastrovascular cavity, among them the fact that food moves in one direction through the tubular system, which can be divided into a series of distinct sections, each specialized for a different function. A section may be specialized for mechanical breakdown of bulk food, for temporary storage, for enzymatic digestion, for absorption of the products of digestion, for reabsorption of water, and for storage of wastes. The overall result is greater efficiency, as well as the potential for special evolutionary modifications for different modes of existence.

The digestive system of an earthworm is an example of a tubular system (Figure 4C). Food, in the form of decaying organic matter mixed with soil, is drawn into the mouth by the sucking action of a muscular pharynx. From the pharynx and then through a connecting passage called the esophagus, the food enters a relatively thin-walled storage chamber, or crop. Next, the food enters the gizzard, a compartment with thick muscular walls, and is ground up by a churning action, the grinding often being facilitated by bits of stone taken in with the food. The pulverized food, suspended in water, then passes into the long intestine, in which digestion and absorption take place. Most of the digestion is extracellular; cells of the intestinal lining secrete hydrolytic enzymes into the cavity of the intestine, and the end products of digestion, the simple compounds from which large molecules are formed, are absorbed. Finally, toward the rear of the intestine, some of the water is reabsorbed, and the indigestible residue is ultimately eliminated through the anus.

Not all large animals eat and grind up large pieces of food. Many are filter feeders; *i.e.*, they strain small particles of organic matter from water. Clams and many other mollusks filter water through tiny pores in their gills and trap microscopic food particles in streams of mucus that flow along the gills and enter the mouth; the mucus is kept moving by beating cilia. In such mollusks, digestion is largely intracellular, as might be expected in animals that eat microscopic food. Current theory holds that the earliest vertebrates were filter feeders. Some of the largest whales are examples of modern-day filter-feeding vertebrates; they strain small planktonic organisms from vast quantities of water.

Possession of a storage organ, such as the crop of the earthworm, enables an animal to take in large amounts of readily available food in a short time and to draw upon this stored matter over an extended period. Such a discontinuous feeding habit makes it possible for an animal to devote time to activities other than feeding. The majority of higher animals have evolved adaptations for discontinuous feeding, thereby gaining time for a behaviorally more varied existence.

Discontinuous feeding is frequently also of adaptive advantage in the feeding process itself. An animal's proper food, for example, may occur only in widely scattered locations; if it had to eat constantly to maintain itself, the animal would be unable to spend time searching for a new food supply or capturing more prey when the original supply had been depleted. The animal would thus have to live in an area in which there was an essentially unlimited and continuous source of food.

Animal food-storage organs are quite variable. In some animals they take the form of blind sacs (diverticula) branching off the digestive tract. Female mosquitoes, for example, have a large diverticulum that opens off the anterior portion of the digestive tract and runs posteriorly, occupying much of the abdominal cavity. The female mosquito locates a suitable animal, pierces its skin, and sucks blood until the diverticulum is filled. One large meal may suffice for the entire process of locating a site and laying her eggs—a matter of four or five days.

Food storage in mosquitoes

#### THE VERTEBRATE DIGESTIVE SYSTEM

The account below, based on the digestive system of higher mammals, proceeds compartmentally from the mouth to the anus. Other vertebrates are mentioned when they illustrate some important departure from the model.

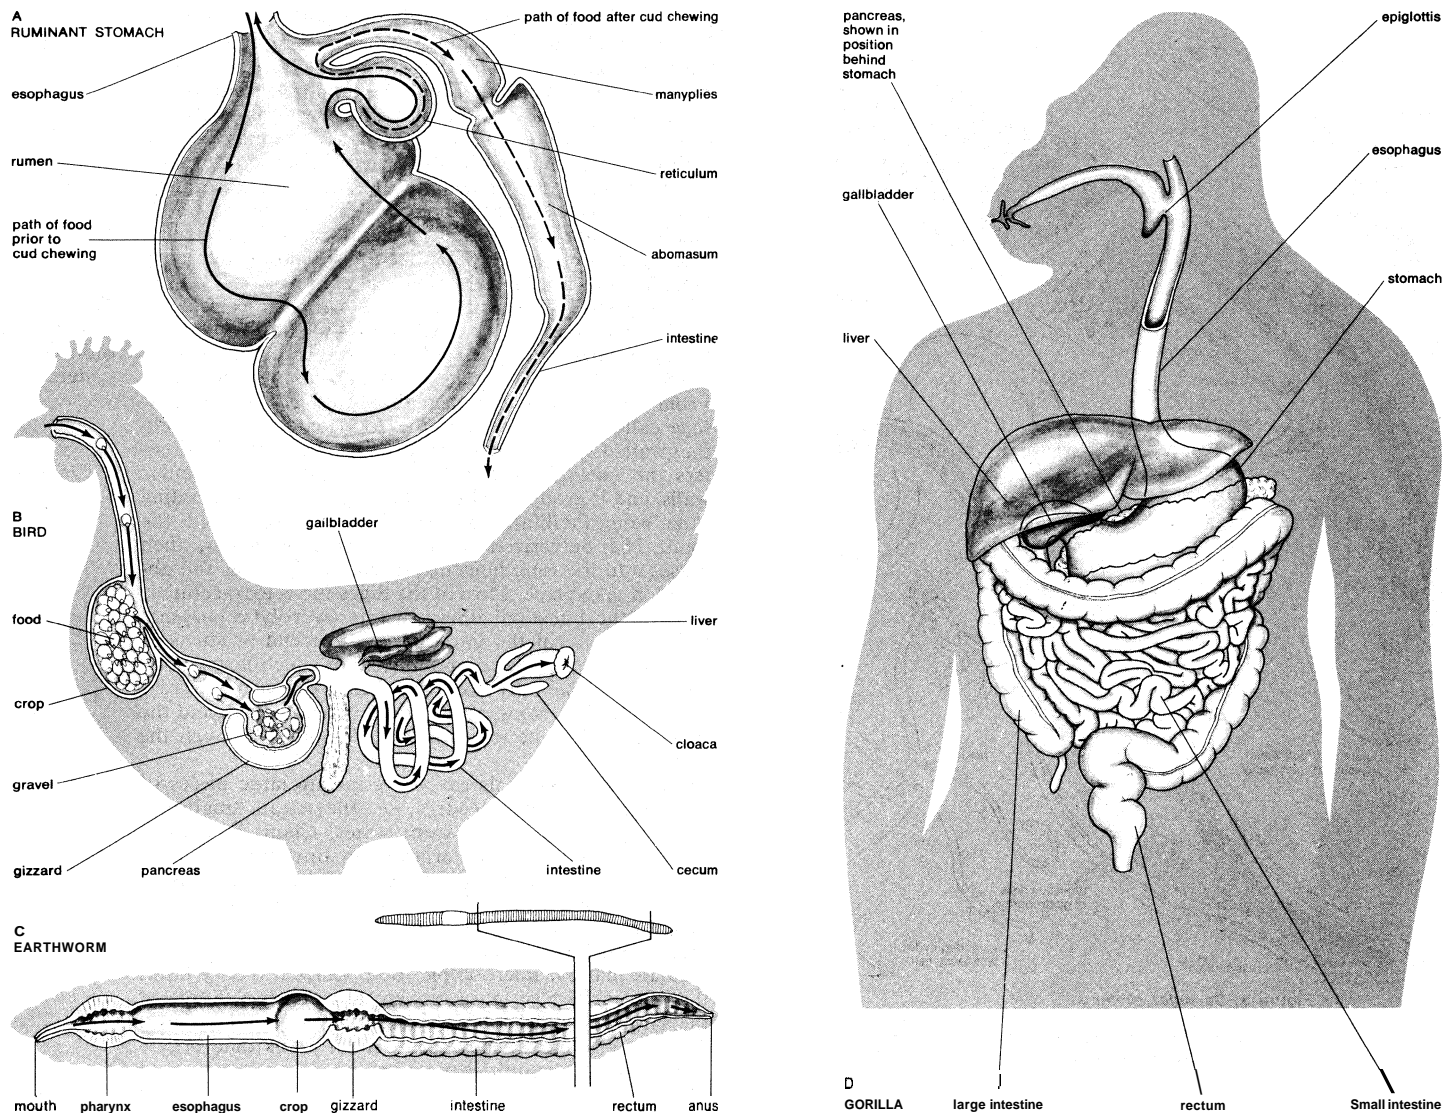

Figure 4: Vertebrate and invertebrate digestive systems

The oral cavity and pharynx. The first chamber of the typical mammalian digestive tract is the oral cavity, which contains teeth that function in the mechanical breakdown of food by biting, shearing, and chewing.

Mammalian teeth are of several different types, each adapted to a different function. In front are the chisel-shaped incisors used for biting. Beside them are the more pointed canine teeth, specialized for tearing food. Behind the canines are premolars and molars with flattened, ridged surfaces, which function in grinding, pounding, and crushing food.

#### Teeth specialization

The teeth of different vertebrate species are specialized in a variety of ways. The teeth of snakes, for example, are very thin and sharp and usually curve backward; they function in capturing prey but not in chewing, for snakes swallow their food whole. The teeth of carnivorous mammals, such as cats and dogs, are more pointed than those of primates, including man; the canines are long, and the premolars lack flat grinding surfaces, being more adapted to cutting and shearing (often the more posterior molars are lost). On the other hand, such herbivores as cows and horses have very large, flat premolars and molars with complex ridges and cusps; the canines are often totally absent. Sharp pointed teeth, poorly adapted for chewing, generally characterize meat eaters such as snakes, dogs, and cats; and broad flat teeth, well adapted for chewing, characterize vegetarians. Why the difference? Very few animals can digest cellulose, yet the plant cells used as food by herbivores are enclosed in cellulose cell walls that must be broken down before the cell contents can be exposed to the action of digestive enzymes. By contrast,

the animal cells in meat are not encased in nondigestible matter and can be acted upon directly by digestive enzymes. Consequently, chewing is not so essential for carnivores as for herbivores. Dogs gulp their food; cows and horses spend much time chewing. Carnivores have other problems, however—they must capture and kill prey, for which their sharp teeth, capable of piercing, cutting, and tearing, are well adapted. Man, an omnivore (an eater of plant and animal tissue), has teeth that belong, functionally and structurally, somewhere between the extremes of specialization attained by the teeth of carnivores and herbivores.

One class of vertebrates—the birds—have no true teeth. Mechanical breakdown of food is accomplished in these animals in a muscular gizzard (Figure 4B), located behind the stomach; in the gizzard, hard food is ground with grit formed of ingested rocks and pebbles.

The oral cavity has other functions in addition to those associated with the teeth. It is here that food is tasted and smelled, mixed with saliva secreted by several sets of salivary glands. The saliva dissolves some of the food and acts as a lubricant, facilitating passage through the subsequent portions of the digestive tract. The saliva of some mammals, including man, also contains a starch-digesting enzyme called amylase (ptyalin), which initiates the process of enzymatic hydrolysis; it splits starch into molecules of the double sugar maltose. Many carnivores, such as dogs and cats, have no amylase in their saliva, since their natural diet contains very little starch.

The muscular tongue of mammals manipulates the food as it is chewed, forming it into a mass called a bolus in

Function  
of the  
tongue

preparation for swallowing. The tongue pushes the bolus backward through the pharynx and into the esophagus. Food and air cross in the pharynx, which functions also as part of the respiratory passageway (see RESPIRATION; RESPIRATORY SYSTEMS). Consequently, swallowing involves a complex set of reflexes that closes off the opening into the nasal passages and trachea (windpipe), thereby forcing the food to move into the esophagus. When these reflexes do not occur in proper sequence, food enters the wrong passage, causing gagging or choking.

**The esophagus.** The esophagus, a tube in the upper portion of the abdominal cavity, extends from the pharynx through the neck and chest to the stomach. Food moves quickly through the esophagus, pushed along by waves of muscular contraction in a process called peristalsis. The contraction of circular muscles in the wall of the esophagus just behind the food bolus squeezes the food along the digestive tract.

At the junction between the esophagus and the stomach is a special ring of muscle called a sphincter, which, when contracted, closes the entrance to the stomach. It is normally closed, thus preventing the contents of the stomach from moving back into the esophagus, but it opens when a peristaltic contraction from the esophagus reaches it.

In some vertebrates, the esophagus is not merely a tubular connection between the pharynx and the stomach. In many birds, for example, an expanded region of the esophagus anterior to the stomach forms a thin-walled crop (Figure 4B), functionally analogous to the earthworm's crop, which, rather than the stomach, is the bird's principal organ for the temporary storage of food. Some birds also use the crop to carry food to their young; they fill it with food and then fly to the nest, whereupon they disgorge the food for their young.

Ruminant mammals, such as the cow, are often said to have four "stomachs" (Figure 4A). Actually, the first three of these chambers—rumen, reticulum, and omasum—are thought to be derived from sections of the esophagus. Vast numbers of bacteria and protozoans live in the rumen and reticulum. When food enters these chambers, the microbes begin to digest and ferment it, breaking down not only protein, starch, and fats, but cellulose as well. The larger, coarser material is periodically regurgitated as the cud; after further chewing, the cud is reswallowed. Slowly the products of microbial action, and some of the microbes themselves, move into the cow's true stomach and intestine, in which further digestion and absorption take place. Since the cow, like other mammals, has no cellulose-digesting enzymes of its own, it relies upon the digestive activity of these symbiotic microbes in its digestive tract. Much of the cellulose in the cow's herbivorous diet, which otherwise would have no nutritive value, is thereby made available to the cow.

**The stomach.** The primate stomach lies in the upper portion of the abdomen, just below the lower ribs (Figure 4D). It is a muscular sac, with a wall composed of three layers: an inner mucous membrane of connective tissue and many glands, a thick middle layer of smooth muscle, and an outer layer of connective tissue. The muscle layer contains fibres running around the stomach, others running longitudinally, and still others oriented diagonally. Thus, the stomach is capable of a great variety of movements. When it contains food, the stomach is swept by powerful waves of contraction, which churn the food, mixing and breaking it. In this manner, the stomach supplements the mechanical action of the teeth.

The glands of the stomach lining are of several types. Some secrete mucus, which covers the stomach lining (hence the name mucosa, or mucous membrane, for the inner layer of the stomach wall); others secrete gastric juice, a mixture of hydrochloric acid and digestive enzymes.

The principal enzyme of the gastric juice is pepsin, which digests protein. Unlike most protein-digesting enzymes, pepsin functions only in a strongly acid medium. This acidic requirement is characteristic of vertebrates; most invertebrates do not have proteolytic enzymes that are active in strongly acid solutions. Pepsin does not completely hydrolyze protein to its amino acid compo-

nents. It splits the so-called peptide bonds that link certain amino acids, particularly tyrosine and phenylalanine. Proteolytic enzymes such as pepsin are relatively specific for certain amino acids; that is, they will react only with certain ones. This is because enzymes have a specific region, called the active site, at which the catalytic action of the enzyme occurs. The fit between an enzyme, such as pepsin, and an amino acid, such as tyrosine, must be a good one, therefore, or the reaction cannot take place. The structural configuration around the various peptide bonds in a protein varies, depending on which two amino acids are joined by the bond. Consequently, some bonds may not fit the active site of a particular enzyme.

Discussion of protein digestion immediately raises the question of why the digestive tract itself—composed mostly of protein—is not digested by the proteolytic enzymes. There are two reasons. First, the gastric glands do not secrete active pepsin; instead, they secrete pepsinogen, which has no proteolytic activity and which, so long as it is stored in the glands of the stomach wall, poses no threat to that wall. Pepsinogen is changed to active pepsin only after exposure to acid in the lumen (cavity) of the stomach. Second, the wall of the digestive tract is covered with mucus, which apparently shields it from the enzymes it secretes. Sometimes, however, this defense breaks down, and the enzymes do begin to eat away at the lining; the resulting sore is known as an ulcer.

In addition to pepsin, the gastric juice of some mammals—e.g., calves (but not humans)—contains another enzyme, rennin, which clumps milk proteins, thus taking them out of solution and making them more susceptible to the action of proteolytic enzymes. Few animals other than mammals have such an enzyme. Although rennin aids digestion, it is not itself a digestive enzyme, since it does not catalyze a hydrolysis reaction.

**The small intestine and the pancreas.** Upon leaving the stomach, the partially digested food, in a soupy mixture called chyme, passes through the pyloric sphincter into the small intestine, that portion of the digestive tract in which most of the digestion and absorption takes place. The first section of the small intestine, attached to the stomach, is called the duodenum; it leads into a long, coiled section lying lower in the abdominal cavity. The relative length of the small intestine differs in different species. It is usually very long and much coiled in herbivores, shorter in carnivores, and of medium length in omnivores. These differences, like those of the teeth, are correlated with the difficulty of digesting plant material. Even if the cellulose of plant cells has been well broken down, it is mixed with the digestible portions of the cells and interferes with their disintegration by digestive enzymes. This interference makes digestion and absorption of plant material much less efficient than animal material, with the result that, in animals with a herbivorous diet, a long intestine is an adaptive advantage because a maximum amount of nutrients can be extracted.

In primates, the small intestine, where absorption of the products of digestion occurs, has special structural adaptations that increase its absorptive surface area. Clearly, its great length plays a role. But examination of its internal surface (Figure 5A) reveals three other modifications that increase the surface area to an even greater degree: (1) the lining of the intestine is thrown into numerous folds and ridges; (2) small, fingerlike outgrowths, called villi, cover the entire surface of the mucosa; and (3) the individual epithelial cells covering the folds and villi have a border consisting of countless, closely packed, cylindrical projections called microvilli. Microvilli are revealed only by the electron microscope. Thus, the total internal surface of the small intestine, including folds, villi, and microvilli, is extremely large.

Other vertebrates show other adaptations for increasing the absorptive surface area of the small intestine. For instance, it is not unusual for special blind sacs, called ceca, to branch from the anterior end of the small intestine in certain fishes and from the posterior end in many birds (Figure 4B). Another adaptation is the spiral valve of many primitive fishes, including sharks (Figure 5B). The spiral valve is an epithelial fold extending the length of

the intestine. Like a screw tightly enclosed in a tube, it forms a spiral in the intestine, to whose wall its base is attached; hence, food cannot move in a straight path but follows the spiral of the valve, thereby contacting more epithelial surface than it could by moving straight through a smooth tubular intestine of the same length.

When partially digested food passes from the stomach into the duodenum, it stimulates the release of a large number of different digestive enzymes into the lumen of the intestine. These enzymes are secreted from two principal sources, the pancreas and the intestinal glands. The pancreas is a soft glandular organ lying posterior to the stomach; it originates in the embryo as an outgrowth of the digestive tract and retains a connection to the duodenum via the pancreatic duct. When food enters the duodenum, the pancreas secretes a mixture of enzymes that flow through the pancreatic duct into the duodenum. Included in this mixture are enzymes that digest all three principal classes of foods—carbohydrates, fats, and proteins—as well as some that digest nucleic acids.

One of the pancreatic enzymes is pancreatic amylase (sometimes also called diastase, or amylopsin), which acts like salivary amylase, splitting starch into maltose. It is far more important than salivary amylase, however, for it digests most of the starch. Lipase is the fat-digesting enzyme of the pancreas. It splits molecules of fat into glycerol and fatty acids; most fat digestion is catalyzed by this pancreatic enzyme. Two important proteolytic en-

zymes from the pancreas are trypsin and chymotrypsin. Like pepsin, they are incapable of splitting all the linkages between the amino acids in a protein molecule. Each cleaves only the linkages adjacent to certain specific amino acids: trypsin splits the **peptide** bonds adjacent to lysine and arginine; chymotrypsin, those adjacent to tyrosine, phenylalanine, tryptophan, methionine, and **leucine**. Like pepsin, both trypsin and chymotrypsin are secreted in inactive forms, called trypsinogen and chymotrypsinogen, respectively. Trypsinogen is converted into active trypsin in the intestine by enterokinase, an enzyme secreted by intestinal glands. Chymotrypsinogen is converted into active chymotrypsin by trypsin.

The combined action of pepsin in the stomach and of trypsin and chymotrypsin in the intestine results in a splitting of proteins into fragments of varying lengths but does not produce many free amino acids. A great variety of other enzymes, each highly specific in its action, completes the digestion of proteins. One, for example, cuts off the amino acid at one end of a chain; another hydrolyzes the linkage of the amino acid at the other end. Still others break apart pairs of amino acids in specific ways. Most of these enzymes are secreted by glands in the intestine, but some are produced in the pancreas.

Just as certain enzymes from the intestinal glands complete the digestion of protein, other intestinal enzymes complete the digestion of carbohydrate begun by salivary and pancreatic amylase. These enzymes split double sugars into simple sugars. For example, maltase splits maltose, sucrase splits sucrose, and lactase splits lactose.

The **liver**. The liver is a relatively large organ occupying much of the space in the upper part of the abdomen (Figure 4D). It performs many important functions, among them the production of bile, which aids in fat digestion. Bile, produced throughout the liver, is collected by a series of branching ducts; it empties into a small storage organ, the gallbladder, located on the surface of the liver. When food enters the duodenum, the muscular wall of the gallbladder is stimulated to contract, and bile is forced down the gall duct into the duodenum. Bile is not a digestive enzyme; it is a complex solution of bile salts, bile pigments, and cholesterol. The bile salts act as emulsifying agents, causing large fat droplets to separate into many tiny droplets suspended in water (an action much like that of a detergent). The many small fat droplets expose much more surface area to the action of lipase than would a few large droplets. Bile salts apparently also aid in fat absorption. The bile pigments and cholesterol play no obvious role in digestion. The pigments, produced by destruction of red blood cells in the liver, give the characteristic brown colour to feces.

The function of bile salts

The large intestine. In primates the small intestine joins the large intestine (or colon) usually in the lower right portion of the abdominal cavity (Figure 4D). A blind sac, the colic cecum, projects from the large intestine near the point of juncture. A small fingerlike process, the appendix, extends from the tip of the cecum. The cecum of some mammals, particularly herbivores (e.g., horses), is large and contains many micro-organisms capable of digesting cellulose.

From the cecum, the large intestine ascends on the right side to the midregion of the abdominal cavity, then crosses to the left side, and descends again. The three sections thus formed are frequently termed the ascending, transverse, and descending colons. The details of shape and length vary greatly from species to species.

One of the chief functions of the colon is reabsorption of much of the water resulting from the digestive process. Occasionally, the intestine becomes irritated, and abnormally strong peristalsis moves material through it too fast for sufficient water to be reabsorbed, resulting in watery stools, or diarrhea. Conversely, if material is moved too slowly, excessive water is reabsorbed, and constipation results. A good diet contains sufficient roughage (indigestible material, primarily cellulose) to provide the bulk needed to stimulate sufficient peristalsis in the large intestine to prevent constipation. A second function of the colon is the excretion of certain salts, such as those of calcium and iron, when their **concentra-**

Pancreatic enzymes

tion in the blood is too high; the salts are excreted into the colon and are eliminated from the body in the feces.

The large intestine contains large numbers of bacteria, which live on the undigested food in the colon. Their significance is not yet fully understood; about half the dry weight of the feces consists of masses of bacteria.

The rectum  
and cloaca

The last portion of the large intestine functions as a storage chamber for the feces until defecation. In most mammals (including man) this chamber, called the rectum, is exclusively a part of the digestive system and terminates in a muscular sphincter that controls the anal opening. In many other vertebrates (e.g., amphibians, reptiles, birds), however, the digestive, excretory, and reproductive systems share one terminal chamber; the walls of the chamber, called a cloaca (Figure 4B), frequently have very powerful water reabsorbing properties.

#### EMBRYOLOGY AND EVOLUTION OF THE VERTEBRATE DIGESTIVE SYSTEM

**Embryonic development.** In amphioxus, an invertebrate member of the Chordata (the phylum to which all vertebrates belong), early divisions of the fertilized egg cell give rise to an embryo that is hollow and nearly spherical. Then an invagination (infolding) of cells at the vegetal (yolk) pole of the embryo converts the initially single-layered embryo into a two-layered one, a process called gastrulation. The new inner layer of cells, called endoderm (sometimes entoderm), surrounds a cavity, the archenteron, which has an opening to the exterior at the point at which invagination occurred; this opening is called the blastopore. The archenteron eventually becomes the cavity of the digestive tract, and the blastopore becomes the anus; the mouth arises as a new opening. In some invertebrates the reverse is true: the blastopore becomes the mouth, and the anus is the new opening.

The early stages of embryonic development in most vertebrates are not as simple as in amphioxus, largely because the egg cells contain much yolk or, in mammals, undergo specialized changes preparatory to implantation in the uterus. Thus, gastrulation is seldom a simple involution at the vegetal pole, and the blastopore, if indeed a "pore" really appears at all, usually becomes overgrown with cells. Nevertheless, in all vertebrate embryos, an endodermal-lined cavity arises by some process that may be regarded as analogous to gastrulation in amphioxus, and this cavity develops into the digestive tract. Ordinarily, endoderm lines the yolk sac; forms a tube, called the foregut, that pushes forward into the head; and forms a second tube, the hindgut, that pushes into the posterior part of the embryonic body. Eventually, the surface tissue (ectoderm) of the embryo forms a small anterior invagination, the stomodeum, that meets the end of the foregut, and a similar posterior invagination, the proctodeum, that meets the end of the hindgut. Rupture of the tissues separating the stomodeum from the foregut and the proctodeum from the hindgut forms a digestive tract with two openings to the exterior.

Embryonic  
derivations

It is apparent from the above description that short sections at both the anterior and the posterior ends of the digestive tract are of ectodermal origin. These correspond roughly to the oral cavity and to the anal canal, respectively. All the rest of the digestive tract, from the pharynx through the large intestine, is of endodermal origin. However, only the lining of the digestive tract is endodermal; the walls contain layers of muscle and connective tissue, which are of middle layer (mesodermal) origin. The endodermal lining gives rise by outpocketing to numerous organs, including the thyroid gland, gills or lungs, thymus, liver, pancreas, and urinary bladder.

**Evolutionary development.** In amphioxus, the digestive tract consists of only three components: the oral cavity, the pharynx, and a tubular postpharyngeal gut without subdivisions. The same condition holds in the most primitive living vertebrates, the cyclostomes (lampreys and hagfishes). In higher vertebrates, however, the postpharyngeal gut is almost always subdivided into a series of regions both anatomically and functionally distinct. By far the most common is the esophagus—stomach—small intestine—large intestine—rectum sequence.

The oral cavity and pharynx vary considerably among the vertebrate classes. The variation correlates with the evolutionary changes in the respiratory system that accompanied the rise of terrestrial forms from aquatic ancestors. In most modern-day bony fishes, the nares (corresponding to a mammal's nostrils) function only as entrances to the olfactory organs, there being no connection between them and the mouth, as occurs in mammals. The structure called the palate, which in mammals separates the nasal and oral cavities, does not exist in fishes. Respiratory water is taken directly into the mouth and then forced back into the pharynx, where it flows across gills located in a series of slits leading from the pharynx to the exterior. Thus, the pharynx, with its gills, is an extremely important chamber in these animals.

The terrestrial vertebrates, which must extract oxygen from air instead of from water, evolved a second major function for the nares that they inherited from their piscine ancestors. While retaining a smell function, these openings became the principal entrance of air for breathing. In amphibians—the earliest land vertebrates—air enters the external nares (nasal openings) and then passes through the internal nares, which are evolutionarily newer openings, into the front of the oral cavity, whence it moves into the pharynx and then into the trachea. There being no palate, no separate nasal cavity exists in these animals; both the oral cavity and the pharynx are common passages for the digestive and respiratory systems.

In most reptiles and birds, a pair of longitudinal folds in the roof of the oral cavity forms a passage that leads air from the internal nares to the pharynx. Complete separation of nasal and oral cavities by a palate, however, is found only in crocodilians and in mammals. In mammals, the bony, hard palate is supplemented posteriorly by a thick, membranous, soft palate.

Having lost its gills and its former importance as the area of gas exchange, the pharynx of terrestrial vertebrates is usually a short and relatively unimportant link in the digestive tract, simply leading to the esophagus. In most bony fishes, the esophagus is a short connecting link between the large pharynx and the stomach, but during evolution, with the reduction of the pharynx in land vertebrates and the relegation of the stomach to the abdominal portion of the trunk, posterior to the lungs, the esophagus became longer and more prominent. It is usually a simple tube, however, except in the case of the avian crop and the ruminant extra "stomachs."

Changes  
in the  
esophagus

Most vertebrates above the level of the cyclostomes have a stomach (though there is none in such fishes as the chimaeras, lungfishes, and a few bony fishes), but its size and shape are quite variable. Perhaps the greatest departure from the general plan is seen in birds, in which the anterior storage part of the stomach is small (the crop taking over most of this function), and the posterior part is specialized as the thick-walled muscular gizzard.

The intestine varies greatly among the various vertebrates in length, in specializations for increasing absorptive surface area, and in the degree of distinction between small intestine and large intestine. The chief functions, however, remain enzymatic digestion and absorption. In all cases, the liver and the pancreas, both of which arise as outpocketings from the anterior part of the small intestine just posterior to its junction with the stomach, play major roles in the digestive process.

The final chamber of the digestive tract is a common cloaca in elasmobranch fishes and in lungfishes, but in most ray-finned fishes there is a rectum instead; *i.e.*, the urinary and reproductive tubes, which do not join the digestive tube, have their own separate opening to the exterior. In this regard, then, the modern-day ray-finned fishes are more specialized than amphibians, reptiles, and birds, which retain a cloaca, presumably inherited from a primitive fish ancestor. A cloaca is also retained in the egg-laying mammals (monotremes), and, in a much reduced form, in the pouched mammals (marsupials). Even in placental mammals, a short-lived cloaca appears in the embryo, but the urogenital ducts eventually develop their own openings, and, as a consequence of this, mammalian adults have a rectum rather than a cloaca.

## BIODYNAMICS OF THE VERTEBRATE DIGESTIVE SYSTEM

Control of salivary secretion. The salivary glands are controlled by the two divisions of the autonomic nervous system (sympathetic and parasympathetic), and it is generally held that this innervation is exclusively responsible for regulation of the glands' secretory activity. No hormone appears to be involved.

There is normally some secretion of saliva all the time, whether or not food is in the mouth. When something touches the gums, the tongue, or some region of the mouth lining, or when chewing occurs, however, the rate of secretion rises. The stimulating substance need not be food—dry sand in the mouth, or even simply moving the jaws and tongue when the mouth is empty, are effective in increasing the salivary flow. This coupling of direct stimulation to the oral mucosa with increased salivation is known as the unconditioned salivary reflex. When an individual learns that a particular sight, sound, smell, or other stimulus is regularly associated with food, that stimulus alone may suffice to stimulate increased salivary flow. In other words, the mouth waters without any direct stimulation of the oral mucosa; this response is known as the conditioned salivary reflex.

Drugs that  
affect  
salivary  
flow

A variety of drugs are capable of increasing or decreasing salivary flow. Among those increasing the flow are sympathomimetic agents, drugs that produce effects similar to those elicited by the sympathetic nervous system (e.g., adrenaline, noradrenaline, amphetamine), and parasympathomimetic agents, drugs that mimic the effects of the parasympathetic nervous system (e.g., acetylcholine, pilocarpine). Among the drugs that decrease salivary flow are antagonists of adrenaline and noradrenaline (e.g., ergotamine, dibenamine) and antagonists of acetylcholine (e.g., atropine, scopolamine).

Control of gastric secretion. The secretion of gastric juice is regulated by both neural and hormonal mechanisms. Among the former are parasympathetic pathways (from the vagus nerve), which provide direct stimulation to the gastric mucosa, and sympathetic pathways, which influence gastric secretion indirectly via their control over the blood vessels that supply the mucosa. The hormonal control primarily results from the stimulatory action of gastrin, a hormone produced by certain cells in the mucosa of the pyloric region of the stomach, and from the inhibitory action of enterogastrone, a hormone produced by cells in the wall of the duodenum upon their stimulation by fats.

Control of gastric secretion in response to ingested food is customarily divided into three phases—cephalic, gastric, and intestinal. During the cephalic phase, stimulation of the mucosal glands is caused entirely by nervous impulses from the vagus nerve. The flow of gastric juice may be initiated by a variety of stimuli, even by merely thinking about food. If the vagus nerve is cut, this phase of gastric secretion is eliminated.

The gastric phase begins after food has reached the stomach. It is apparently controlled by gastrin and, to a lesser extent, by the vagus nerve. Among the most effective stimuli for gastrin release are various compounds from partly digested meat; however, mechanical stimulation by indigestible food particles or, in laboratory experiments, simple distension of the stomach by a balloon results in some release of gastrin. Though produced by cells that are located near its target cells, gastrin does not move directly from the one to the other; instead, it is picked up by the blood and carried to the gastric glands, where it stimulates increased secretion of gastric juice.

In the intestinal phase of gastric secretion, certain food substances in the duodenum stimulate release of regulatory chemicals that influence the gastric mucosa. This function was mentioned earlier, regarding the action of fats in stimulating release of enterogastrone, which inhibits secretion of gastric juice. Other food materials apparently cause release of a substance that stimulates secretion of gastric juice, but its nature is not yet known.

The  
influence of  
emotions

In many mammals, emotional states may markedly affect gastric secretion; fear, anger, or frustration, for example, may inhibit gastric flow. Chronic anxiety, however, tends to increase the flow, with the result that the

stomach contents become more acid, which may lead to formation of gastric or duodenal (peptic) ulcers. Though both gastric and duodenal ulcers can be produced experimentally by exposure of the mucosa to a constant drip of hydrochloric acid, or by treatment with the compound histamine, which stimulates the acid-secreting cells, the causative connection in nonexperimental situations between high gastric acidity and ulceration is much clearer in duodenal ulcers than in gastric ulcers.

Control of pancreatic secretion. The secretion of pancreatic juice is regulated by both neural and hormonal mechanisms. Neural mechanisms, dependent upon sympathetic and parasympathetic pathways, can elicit increased flow both before and after food reaches the duodenum. By contrast, hormonal mechanisms act only after certain substances move into the duodenum and stimulate specific cells of the duodenal mucosa.

The hormones produced by the duodenal mucosa are secretin and pancreozymin. Secretin is released in response to dilute hydrochloric acid, whereas release of pancreozymin is initiated by various products of partial protein digestion. Secretin stimulates the pancreas to secrete the water and bicarbonate components of pancreatic juice, and pancreozymin stimulates secretion of the enzyme components.

Control of intestinal enzyme secretion. Local mechanical or chemical stimulation of the intestinal mucosa is the most effective stimulus for secretion of intestinal juices. Parasympathetic nerves are probably the chief elements involved in bringing about the response. There is some evidence, however, that a hormone, tentatively called enterocrinin, may also play a role.

Control of intestinal movements. The intestine undergoes varied movements, of which three are described below: rhythmic segmenting contractions, peristalsis, and mass movements.

Segmenting contractions, especially prominent in the small intestine, are rhythmic alternations of contraction and relaxation at regularly spaced intervals along the intestine. They function in agitating the gut contents, thereby facilitating the subdivision of food particles, the mixing of food with intestinal secretions, and the bringing of digestive products into direct contact with the absorptive mucosa. These contractions appear to be myogenic; i.e., they originate in muscular tissue without the necessity of nervous stimulation (although nervous stimulation may increase or decrease the amplitude of such contractions).

Stationary  
intestinal  
contrac-  
tions

Peristaltic movements, which have already been described, are waves of contraction that move along the intestine. They push the gut contents along their prescribed path. Peristaltic movements do not occur as smooth waves progressing along a relaxed intestine from one end to the other at regular intervals. The movement is actually superimposed upon the rhythmic segmenting contractions, the individual waves often travelling only a few inches or a few feet and the waves appearing at irregular intervals. Both mechanical and chemical stimuli can promote peristalsis; their effectiveness is related, in part, to the irritability of the intestine and its muscle tone. Irritant cathartic drugs may trigger several successive, unusually strong peristaltic waves that sweep without interruption along the entire length of the intestine.

Mass movements are the principal propulsive movements of the large intestine. They involve simultaneous contractions of large segments of the colon and hence are not true peristaltic waves. The contractions are exceedingly powerful and can therefore push along hard, dry feces. When a mass movement pushes feces into the rectum, the increase in pressure within the rectum stimulates the urge to defecate. Since eating is a powerful stimulant to mass movements in the colon, the desire to defecate often occurs shortly after food is taken.

## Digestive System, Human

The digestive system consists of (1) the digestive tract—the series of structures and organs through which food passes during its processing into forms absorbable into the bloodstream and also the structures through which solid wastes pass in the process of elimination—and (2) other organs that contribute juices necessary for the digestive process.

The digestive tract begins at the lips and ends at the anus. It consists of the mouth, or oral cavity, with its teeth, for grinding the food, and its tongue, which serves to knead the food, mix it with saliva, and start it on its way to the stomach; the throat, or pharynx; the esophagus, or gullet; the stomach; the small intestine, consisting of the duodenum, the jejunum, and the ileum; and the large intestine, consisting of the cecum, a closed-end sac connecting with the ileum, the ascending colon, the transverse colon, the descending colon, and the sigmoid colon, which terminates in the rectum. Glands contributing digestive juices include the salivary glands, the gastric glands in the stomach lining, the pancreas, and the liver and its adjuncts—the gallbladder and bile ducts.

Digestive systems in animals other than man are described in the article DIGESTION AND DIGESTIVE SYSTEMS. That article and the article DIGESTION, HUMAN contain descriptions of the processes of digestion, including the hormonal control of the secretion of digestive juices. The articles ENDOCRINE SYSTEM, HUMAN; HORMONE; and ENDOCRINE SYSTEMS also touch upon hormonal control of digestion. The present article is focussed on the form and structure of the parts of the human digestive system.

### MOUTH AND ORAL STRUCTURES

**The mouth.** The mouth, or oral cavity, forms the entrance to the alimentary, or digestive, canal, also called the digestive tract. The structures within the mouth and the walls of the oral cavity are highly specialized in order to serve the functions of chewing food, mixing it with saliva, tasting it, and initiating the process of swallowing. (Another function for which the structures of the mouth have been adapted is speaking.) The exterior opening of the mouth is bordered by the lips. Behind, the oral cavity opens into the pharynx, or throat. The walls of the mouth are formed by the lips in front and the cheeks on each side. The roof is composed of the hard and the soft palate. The floor of the mouth is formed by the tongue, the tissue beneath it, and the lower jaw (mandible).

**The lips.** The lips are the fleshy folds surrounding the opening of the mouth. At their corners, on either side, they are continuous with the cheeks. The muscle of the lips, the orbicularis oris, accounts for the extreme mobil-

ity of these structures. The outer surface of the lips is covered with skin; the inner surface, with mucous membrane. The red margin of the lips, called the vermilion border, has a covering that is intermediate between skin and mucous membrane. The mucous membrane, or **mucosa**, of the lips and cheek has a characteristic reddish hue that is caused by the rich network of blood vessels that is visible through the thick but transparent covering layers of squamous, or scalelike, cells. The tissue beneath the covering of the lips contains numerous glands. Each lip at its midline is connected to the gum with a fold of mucous membrane, called a frenulum. The **frenula** of the lips can be felt with the tip of the tongue and can easily be seen when the lips are rolled back.

The lips are extremely sensitive; the upper and lower lips obtain their nerve supply, respectively, from branches of the maxillary and mandibular divisions of the trigeminal, or fifth cranial, nerve. There is a bountiful supply of arterial blood, from branches of the labial (lip) and buccal (cheek) arteries. Venous drainage is provided by tributaries of the anterior facial vein. The lips are also supplied with lymphatic vessels.

**The cheeks.** The cheeks, the sides of the mouth, are continuous with the lips and have a similar structure; the muscle of the cheeks is the buccinator (the "trumpeter") muscle. A distinct fat pad is found in the subcutaneous tissue (the tissue beneath the skin) of the cheek; this pad is especially large in infants and is known as the sucking pad. On the inner surface of each cheek, opposite the second upper molar tooth (the second grinder tooth from the end), is the slight elevation that marks the opening of the parotid duct, leading from the parotid salivary gland, which is located in front of the ear. Just behind are four to five mucus-secreting glands, the ducts of which open opposite the last molar tooth. The mucous membrane of the cheek, like that of the rest of the mouth, is composed of stratified squamous epithelium (a covering composed of layers of scalelike cells) and continues onto the gums.

**The roof of the mouth.** The roof of the mouth is concave both from side to side and from front to back and is formed by the hard and soft palate. The hard palate is formed by the horizontal portions of the two palatine bones and the palatine portions of the maxillae, or upper jaws. The hard palate is covered by a thick, somewhat pale mucous membrane that is continuous with that of the gums and is bound to the upper jaw and palate bones by firm fibrous tissue. In the midline is a slight ridge, the palatine raphe, which ends in front in a small elevation, the palatine papilla; this marks the position of the anterior palatine canal, which carries an artery. From the anterior part of the raphe, five or six transverse ridges, or rugae, of the mucous membrane run outward.

The soft palate is continuous with the hard palate in front and posteriorly has a free margin. The uvula, which varies greatly in size and shape, is a projection of the soft palate and hangs free from its rear margin. The soft palate is composed of a strong, thin, fibrous sheet, the palatine aponeurosis, and the glossopalatine and pharyngopalatine muscles. Both the oral and pharyngeal (mouth and throat) surfaces are covered by mucous membrane that contains many mucous glands.

**The floor of the mouth.** The floor of the mouth can be seen only when the tongue is raised. In the midline is a prominent fold (frenulum linguae) like that which binds each lip to the gums, and on each side of this is a slight elevation called a sublingual papilla, onto the summit of which the ducts of the submaxillary salivary glands open. Running outward and backward from this is a ridge (the plica sublingualis) that marks the upper edge of the sublingual (under the tongue) salivary gland and onto which most of the ducts of that gland open.

**The gums and teeth.** **The gums.** The gums consist of mucous membranes connected by thick fibrous tissue to the membrane surrounding the bones of the jaw. Around the base of the crown (exposed portion) of each tooth the gum membrane rises to form a little collar. The gum tissues are rich in blood vessels, receiving branches from the alveolar arteries; these vessels, called alveolar from their relationship to the alveoli dentales, or tooth sockets,

The hard and soft palates

The walls, roof, and floor of the mouth

also supply the teeth and the spongy bone of the upper and lower jaws, in which the teeth are lodged. The veins and lymphatics correspond essentially to the arteries.

**Teeth.** The teeth are hard white structures found in the mouth of man and many animals and are used for mastication of food, seizing and holding objects, combat, cutting, chiselling, and other purposes. Each tooth consists of a crown and one or more roots. The crown is the functional part that is visible above the gum. The root is the unseen portion that supports and fastens the tooth in the jawbone. The shapes of the crowns and the roots vary in the different parts of the mouth and from one animal to another. Man normally has two sets of teeth during his lifetime. The first set is acquired gradually between the ages of six months and two years. As the jaws grow and expand, these teeth are replaced one by one by the teeth of the secondary set. The first set is known as the milk, deciduous, or primary dentition. The teeth on one side of the jaw are essentially a mirror image of those located on the opposite side. The upper teeth differ from the lower and are complementary to them. There are five deciduous teeth and eight permanent teeth in each quarter of the mouth, making a total of 32 permanent teeth to succeed the 20 deciduous ones.

The deciduous dentition differs from the permanent in its smaller size, whiter colour, greater constriction of the necks of the teeth, and in the fact that the roots of the molars are widely spread to provide a wider base in order to accommodate the developing permanent teeth (the molars of the deciduous dentition are replaced by the permanent premolars). In the permanent dentition there are two incisors in each quarter of the mouth. These are used primarily for biting and cutting and have a delicate tactile sense that enables them to be used for identifying objects in the mouth by nibbling. The biting portion is wide and thin, in a sort of chisel shape or cutting edge. The upper central incisor is the largest. The lateral incisor, next in line, is smaller and sometimes irregular in form. The lower incisors are smaller and similar to each other. They bite against the upper incisors either edge to edge or slightly inward on the tongue side. An edge-to-edge biting position is acquired more and more as the teeth wear down. The cuspids, four in number, are next to the incisors and at the corner of the mouth, the third tooth from the midline. The cuspid, or canine, is frequently pointed and rather peglike in shape. It is absent in many mammals that have developed protective horns; in some other animals, it is a great defensive weapon by virtue of its use. In man it has the function of cutting and tearing. Its length and position are such that it does not normally protrude beyond the level of the other teeth, and this permits a side to side chewing motion that is not possible in the other primates, which have long canines. The two bicuspid, or premolars (total number, eight), are next in line. They replace the baby molars but have a somewhat different function. Each has two cusps, or elevations; the lower second bicuspid frequently has a small third cusp. The upper first bicuspid generally has two roots and sometimes one; the second generally has one root, sometimes two; the lower bicuspid generally have one root each. The three molars in each quadrant (total number, 12), the teeth farthest back in the mouth, are used exclusively for grinding. The upper molars have four (sometimes three) cusps, whereas the lowers have five (sometimes four). The number and position of the cusps and the character of the grooves between them differ among individuals. Generally, the upper molars have three roots and the lowers two. In persons of European origin, the first molar usually is large, the second smaller, and the third the smallest. In some other groups the third molar is larger than the second, though smaller than the first (see TEETH AND GUMS, HUMAN).

**Tongue.** The tongue, a muscular organ located on the floor of the mouth, in man is an extremely mobile structure and an important accessory organ in such motor functions as speech, chewing, and swallowing. In conjunction with the cheeks it is able to guide and maintain food between the upper and lower teeth until mastication is completed. In persons whose tongues have been ex-

cised, speech is defective. The tongue's motility aids in creating a negative pressure within the oral cavity, thus enabling mammals to suckle.

The mucous membrane that covers the tongue varies greatly. Especially important as a peripheral sense organ, it contains groups of specialized epithelial cells, known as taste buds, that carry stimuli from the oral cavity to the central nervous system. Furthermore, the tongue's glands produce some of the saliva necessary for swallowing.

The general appearance of the mucous membrane has interested physicians for centuries, and the custom of having the patient stick out his tongue during an examination is of some use, since certain changes in its appearance reflect disturbances in other organs and systems.

The mammalian tongue consists of a mass of interwoven, striated (striped) muscles covered with mucous membrane and interspersed with some glands and a variable amount of fat. By its extrinsic muscles, the tongue is attached to the lower jaw, the hyoid bone (a U-shaped bone between the lower jaw and the larynx), the skull, the soft palate, and the pharynx. It is bound to the floor of the mouth and to the epiglottis (a plate of cartilage that serves as a lid for the larynx) by folds of its mucous membrane.

The tongue presents on its upper surface a median groove, which traced posteriorly ends in a small pit, the foramen cecum linguae, which is the point of origin of the thyroid gland and forms the apex of a V-shaped groove, the terminal sulcus. The terminal sulcus marks the division of the tongue into two parts. The larger part, called the body of the tongue, is in front and belongs to the floor of the mouth, while the smaller posterior part, or root, forms the forward wall of the oral pharynx. (The pharynx and its divisions are taken up in a later section.)

The upper surface of the body of the tongue, called the dorsum, is rough in appearance because of numerous small projections, the lingual papillae, of which several kinds are recognized. Filiform (thread-shaped) and conical papillae are arranged in V-shaped rows, being numerous over the whole of the dorsum. Each contains a core of fibrous tissue with minute blood vessels. Fungiform papillae, similar in structure but less numerous, are easily distinguished by their larger size and reddish colour. They are found immediately in front of, and parallel to, the terminal sulcus. On most of the fungiform papillae are taste buds, usually seven to 11 in number. Each fungiform papilla consists of a flat central mound surrounded by a depression resembling a moat. On the sides of the moat are taste buds, and into the bottom of the fossa open ducts of Ebner's glands (which secrete a watery fluid that aids in forming saliva). Foliate papillae, rudimentary in man, are represented by three to eight vertical folds at the side of the hinder part of the dorsum.

The undersurface of the body of the tongue is covered in its free portion by a thin, smooth, mucous membrane. A prominent median fold, the frenulum linguae, connects the tongue with the mandible, lower jaw, and the floor of the mouth; on each side of this structure is an irregular, fringed fold, the plica fimbriata. Between the frenulum and the plica fimbriata, on each side, the lingual vein side shines through the mucosa.

The root of the tongue, which is thought of as part of the oral pharynx, differs from the body in several respects, including structure and appearance. In appearance, the mucous membrane of the root is warty because of the underlying nodules of lymphoid tissue, the lingual follicles, collectively designated as the lingual tonsil. The mucosa is not firmly adherent to the underlying structures, and a loose median fold of mucous membrane passes from the root of the tongue to the epiglottis and separates the valleculae, or little valleys, in which foreign bodies often become lodged. The lateral boundaries of the valleculae are two folds of mucous membrane.

The substance of the tongue is composed chiefly of interlacing striated muscle fibres arranged symmetrically on each side of a median fibrous septum, or partition. They are innervated by the hypoglossal (under the tongue) nerve. Four muscles lie entirely within the

Distinctions between deciduous and permanent dentitions

The lingual papillae

Functions of the tongue

The  
extrinsic  
muscles

tongue on each side, the superior and inferior longitudinal, the vertical, and the transverse muscles. These muscles, known as the intrinsic muscles, on contracting, change the length, width, and breadth of the tongue and protrude it. Moreover, when contracted on one side only, they cause the tongue's tip to bend in the opposite direction. A special branch of the hypoglossal nerve, known as the end branch, innervates these muscles. Other muscles—the pairs of hypoglossus, chondroglossus, styloglossus, and genioglossus muscles—come from skeletal parts and are attached to the substance of the tongue on either side. They are known as the extrinsic muscles. With the exception of the genioglossus muscle, the extrinsic muscles are retractors of the tongue. The genioglossus muscle can protrude the tongue a small amount, but its main function is to build a fulcrum around which the intrinsic muscles function. The arteries of the tongue are derived mainly from the lingual (tongue) branches of the external carotid arteries, which supply blood to the exterior of the head, to the face, and to much of the neck. The lingual veins return the blood from the tongue to the internal jugular veins, which receive blood from the brain, the face, and the neck.

### SALIVARY GLANDS

Besides the many minute glands that secrete saliva, there are three major pairs of salivary glands: the parotid, the submaxillary, and the sublingual glands.

**Size, form, and location.** The parotid glands, the largest of the salivary glands, in the adult weigh from 20 to 30 grams (from about 0.7 to one ounce) each. They are located at the side of the face, below and in front of each ear, in back touching the mastoid bone (which is behind the ear) and the sternomastoid muscle, the prominent muscle of each side of the neck, and in front shaped around the ascending portion of the bone of the lower jaw. The parotid glands are enclosed in sheaths that limit the extent of their swelling when inflamed, as in mumps.

The submaxillary glands, each of which in the adult weighs from eight to ten grams (from about 0.3 to 0.4 ounce), lie near the inner side of the lower jawbone, not far in front of the sternomastoid muscle. They are rounded in shape, with a flattened forward side.

The sublingual glands, which are elongated in shape, weigh from two to three grams (from 0.07 to 0.11 ounce). They lie directly under the mucous membrane covering the floor of the mouth beneath the tongue.

**Structure.** *Gross structure.* The salivary glands are of the type called racemose, from the Latin *racemosus* ("full of clusters"), because of the clusterlike arrangement of their secreting cells in rounded sacs, called acini, attached to freely branching systems of ducts.

The ducts of each parotid gland empty into successively larger ducts until they reach one large duct, as do the ducts of each submaxillary gland. The main duct of the parotid gland is known as Stensen's duct; that of the submaxillary gland, as Wharton's duct. Stensen's duct opens into the mouth at a point in the cheek opposite the crown of the second upper molar; Wharton's duct opens on the summit of the soft elevation known as the *caruncula sublingualis*, beside the frenulum of the tongue.

The sublingual glands, unlike the other two types, are drained by a number of small, short ducts rather than one large one. The short ducts, called the ducts of Rivinus, open on papillae along the side of the tongue. In many cases the forward part of the sublingual gland is drained by a single, large duct that opens alongside the opening of the submaxillary duct; *i.e.*, Wharton's duct.

**Microscopic structure.** The walls of the acini surround a small central cavity known as an alveolus. In the walls are one or two types of somewhat pyramidal secreting cells and, besides the secreting cells, some flat, star-shaped cells called myoepithelial, or basket, cells. The latter cells are thought to contract, like the similar myoepithelial cells of the breast, which by their contraction expel milk from the milk ducts.

The secreting cells may be of the serous or the mucous type. The latter type secretes mucin, the chief constituent of mucus; the former, a watery fluid containing an en-

Human digestive system.

zyme, amylase, which is also known as ptyalin. The secreting cells of the parotid glands are of the serous type; those of the submaxillary glands, of both serous and mucous types, with the serous cells outnumbering the mucous cells by four to one. The acini of the sublingual glands are composed primarily of mucous cells.

The ducts of the salivary glands are lined with several different types of cells. Cube-shaped cells that are largely nuclei line the smallest ducts, those leading from the acini. Larger ducts, called intralobular ducts, are lined with columnar, or rod-shaped, cells that resemble the cells lining the kidney tubules, the minute tubes of the nephrons, or functioning elements, of the kidneys. The next grade of duct, the interlobular, has a lining composed of two layers; the superficial layer is of columnar cells and the deeper layer of flattened cells. Near the termination of the interlobular ducts the lining changes to stratified squamous epithelium—a covering made up of layers of scalelike cells.

**Innervation.** The nerves controlling the salivary glands in man belong both to the parasympathetic and to the sympathetic divisions of the autonomic nervous system (the autonomic nervous system has to do with reactions that are independent of voluntary control). The parasympathetic nerve supply regulates secretion by the acinar cells and causes the blood vessels to dilate. Functions regulated by the sympathetic nerves include secretion by the acinar cells, constriction of blood vessels, and, presumably, contraction of the myoepithelial cells.

The parasympathetic nerves governing the salivary glands originate in the inferior and superior salivary nuclei, groups of nerve cells in the medulla oblongata, a centre in the brainstem just above the spinal cord.

The sympathetic nerve supply to the salivary glands originates in nerve cells near the top of the spinal cord (in the lateral horn of the first and second thoracic segments of the spinal cord).

Nerve fibres that carry pain impulses from the salivary glands to the brain form part of the *chorda tympani* (a branch of the facial, or seventh cranial, nerve and of the glossopharyngeal, or ninth cranial, nerve).

### PHARYNX

The pharynx, or throat, is the passageway leading from the mouth and nose to the esophagus and larynx. The pharynx permits the passage of swallowed solids and liquids into the esophagus, or gullet, and conducts air to and from the trachea, or windpipe, during respiration. The pharynx also connects on either side with the cavity of the middle ear by way of the eustachian tube and provides for equalization of air pressure on the eardrum

Functions  
of the  
pharynx

Types of  
secreting  
cells

membrane, which separates the cavity of the middle ear from the external ear canal.

The pharynx has roughly the form of a funnel flattened from front to back. It is about 13 centimetres (five inches) in length and narrows from a width of about five centimetres (two inches) at the top to about one inch at its junction with the esophagus. The walls of the pharynx are attached by its connective tissue and muscles to the surrounding structures. The attachment in most areas is loose enough in organization to permit gliding of the pharyngeal wall, in the movements of swallowing, against the surrounding structures.

Three main divisions of the pharynx are distinguished: the oral pharynx, the nasal pharynx, and the laryngeal pharynx. The latter two are airways, whereas the oral pharynx is shared by both the respiratory and alimentary (digestive) tracts. On either side of the opening between the mouth cavity and the oral pharynx is a tonsil called a palatine tonsil because of its proximity to the palate. Each palatine tonsil is between two vertical folds of mucous membrane (behind the glossopalatine arch and in front of the pharyngopalatine arch). The glossopalatine arches, located on the sides of the pharynx and an imaginary line back of the front two-thirds of the tongue, are approximately where the mouth cavity and oral pharynx meet. The nasal pharynx, above, is separated from the oral pharynx by the soft palate. The laryngeal pharynx and the lower part of the oral pharynx are hidden by the bulging root of the tongue. An important feature of this obscured region is the epiglottis, or laryngeal flap, which acts as a deflector between the laryngeal pharynx and the lowermost oral pharynx.

The principal layers of the walls of the throat, from within outward, are (1) a mucous membrane, consisting of epithelium (covering), numerous mucous glands, and fibrous connective tissue, of which the outermost part is a tough membrane called the pharyngeal aponeurosis; (2) the pharyngeal muscles; and (3) connective tissue. The pharyngeal muscles are concerned in the mechanics of swallowing. The principal muscles of the pharynx are the three pharyngeal constrictors. These pharyngeal constrictor muscles overlap each other slightly, from below upward, and form the primary musculature of the side and rear pharyngeal walls.

The tonsils

The pharynx is the seat of the tonsils. The term tonsil may suggest only the palatine tonsils, mentioned above, but these are only components of a series of tonsils encircling the wall of the pharynx. On either side, in addition to the palatine tonsil, is the tubal tonsil, near the opening of the eustachian tube. On the roof of the nasopharynx is the pharyngeal tonsil, which is frequently so enlarged in children as to obstruct the airway. (The tonsils are then known as adenoids.) On the floor of the mouth cavity, in the back one-third of the tongue, is the lingual tonsil. The tonsils are masses of lymphoid tissue embedded in the mucous membrane; this tissue is composed principally of lymphocytes, a variety of white blood cell. The tonsils are usually smaller in adults.

#### ESOPHAGUS

The esophagus, that portion of the alimentary canal that extends from the pharynx to the stomach, is about 25 centimetres (ten inches) in length; the width varies from one and one-half to two centimetres. The esophagus contains the four typical layers of the alimentary canal—mucosa (or mucous membrane), submucosa, muscularis, and tunica adventitia. The mucosa is made up of stratified squamous epithelium containing numerous mucous glands. The submucosa is a thick, loose fibrous layer connecting the mucosa to the muscularis. The mucosa and submucosa form long longitudinal folds so that a cross section of the esophagus opening would be star-shaped. The muscularis is composed of an inner layer in which the fibres are circular and an outer layer of longitudinal fibres. The outer layer of the esophagus, the tunica adventitia, is composed of loose fibrous tissue that connects the esophagus with neighbouring structures. Except during the act of swallowing, the esophagus is normally empty, and its lumen, or channel, is essentially blocked

by the longitudinal folds of the mucosal and the submucosal layers.

The esophagus can be divided into cervical (neck), thoracic (chest), and abdominal portions. The cervical portion lies immediately in front of the vertebral column and behind the trachea. The thoracic portion of the esophagus is that part within the mediastinum, the space between the two lungs. Within the thoracic cavity the esophagus passes behind the fork of the trachea, where it divides with the right and left main bronchi, and the right pulmonary artery (the artery that carries blood low in oxygen from behind the heart to the right lung). In the lower portion of the mediastinum, the esophagus passes between the aorta and the pericardium, the membranous sac that encloses the heart. The esophagus passes out of the thoracic cavity through the diaphragmatic hiatus, the opening in the muscular partition between the chest and the abdomen. The abdominal portion of the esophagus is that short portion (two to three centimetres) that extends from the diaphragm to the stomach.

Another way of dividing the esophagus is into upper, middle, and lower thirds. The upper third of the esophagus is composed of striated muscle, the middle third of a mixture of striated and smooth (involuntary) muscle, the lower third only of smooth muscle.

The esophagus has two sphincters. (Sphincters are circular muscles that act like drawstrings in closing channels.) The upper esophageal sphincter is located at the level of the cricoid cartilage (a single ringlike cartilage forming the lower part of the larynx wall). This sphincter is called the cricopharyngeus muscle. The lower esophageal sphincter encircles the three to four centimetres of the esophagus that pass through the diaphragmatic hiatus and is thus located partly above and partly below the diaphragm. Both sphincters normally remain closed except during the act of swallowing.

The arterial blood supply to the esophagus is derived mainly from the esophageal branches of the aorta. The veins that drain the esophagus accompany the arteries. The esophagus is supplied by both sympathetic and parasympathetic nerves, which terminate in two networks called plexuses. Of these, Meissner's plexus is located in the submucosa, whereas Auerbach's plexus is located between the circular and longitudinal muscle coats.

#### STOMACH

The stomach serves as a reservoir and receives ingested food and liquids from the esophagus and retains them for admixing with the gastric juice in order that digestion can begin. It is located in the left upper part of the abdomen immediately below the diaphragm. In front of the stomach are the liver, part of the diaphragm, and the forward abdominal wall. Behind it are the pancreas, the left kidney, the left adrenal, the spleen, and the colon. When the stomach is empty, it contracts, and the transverse colon ascends to occupy the vacated space.

The size, shape, and position of the stomach vary extremely and depend upon the extent of its contents as well as upon the tension in the muscles of its walls. The average capacity of the stomach is approximately one quart (one litre). The organ is more or less concave on its right side, convex on its left. The concave border is called the lesser curvature; the convex border, on the left and below, the greater curvature. The opening from the esophagus into the stomach is the cardia, while the outlet from the stomach into the duodenum is the pylorus.

The various parts of the stomach may be summarized as follows. The uppermost part, located above the entrance of the esophagus, is the fundus; it frequently contains a gas bubble, especially after a meal. The cardia is that portion of the stomach surrounding the opening from the esophagus. The largest part of the stomach is the body; it serves primarily as a reservoir for ingested food and liquids. The antrum, the lowermost part of the stomach, is somewhat funnel-shaped, with its wide end joining the lower part of the body of the stomach and its small end connecting with the pyloric canal, which empties into the duodenum. The pyloric portion (antrum plus pyloric canal) of the stomach tends to curve to the

Course of the esophagus

The parts of the stomach

right and slightly upward and backward and thus gives the stomach its J-shaped appearance. The pylorus, the narrowest portion of the stomach, is approximately two centimetres (0.8 inch) in diameter.

The stomach is lined with mucosa, or mucous membrane. When the stomach is empty, the lining is thrown into numerous longitudinal folds, known as *rugae*; these tend to disappear when the stomach is distended.

The surface of the gastric (stomach) mucosa is always covered by a thin layer of thick tenacious mucus that is secreted by the columnar cells in the surface epithelium. Beneath the surface epithelium various types of gastric glands are located that, in different parts of the stomach, vary in structure and in composition of their secretion. Thus, each area of the gastric mucosa is characterized by its glandular structure. When the gastric mucus is removed from the surface epithelium, small pits, called *foveolae gastricae*, may be observed with a hand magnifying glass. There are approximately 90 to 100 gastric pits per square millimetre (58,000 to 65,000 per square inch) of surface epithelium. Into each gastric pit from three to seven individual gastric glands empty their secretions.

The gastric mucosa contains five different types of cells. In addition to the tall columnar surface epithelial cells previously mentioned, there are three common cell types found in the various gastric glands and a rare cell type occasionally observed: (1) *Mucoid cells*—cells that secrete mucus—are common to all types of gastric glands. *Mucoid cells* are usually the only cell type found in the gastric glands in the cardiac and pyloric areas of the stomach. The necks of the glands in the body and fundic parts of the stomach are lined with mucoid cells. (2) Other cells, called *zymogenic*, or *chief*, cells, are located predominantly in the gastric glands in the body and **fundic** portions of the stomach. These cells secrete **pepsinogen**, from which the enzyme **pepsin** is formed. (3) Cells called *parietal*, or *oxyntic*, cells, in the glands of the body and fundic portions of the stomach, secrete hydrochloric acid and also most of the water found in gastric juice. (4) Another type of cell occasionally found in these glands is known as the **argentaffin** cell. Its exact function is not known.

Beneath the gastric mucosa is a thin layer of smooth muscle fibres called the *muscularis mucosa*, and below this, in turn, is loose connective tissue, the *submucosa*, which attaches the gastric mucosa to the muscles in the walls of the stomach.

The muscles of the gastric wall are arranged in three layers, or coats. The innermost layer of smooth muscle of the gastric wall, called the *oblique muscular layer*, is strongest in the region of the gastric fundus and progressively weaker as it approaches the pylorus.

The middle or circular muscular layer, the strongest of the three muscular layers, completely covers the stomach. The circular fibres of this coat are best developed in the lower portion of the stomach, particularly over the **antrum** and the pylorus.

The external coat, called the *longitudinal muscle layer*, is formed from the longitudinal muscle coat of the esophagus. The longitudinal muscle fibres are divided at the cardia into two broad strips. The one on the right, the strongest, spreads out to cover the lesser curvature and the adjacent posterior and anterior walls of the stomach. The longitudinal fibres on the left sweep from the esophagus over the dome of the **fundus** of the stomach to cover the greater curvature and continue on to the pylorus, where they join the longitudinal muscle fibres coming down over the lesser curvature.

At the pyloric end of the stomach the middle layer of muscle, the circular layer, becomes greatly thickened to form the pyloric sphincter. This muscular ring is slightly separated from the circular muscle of the duodenum by connective tissue. The outer muscle layer of the stomach, the longitudinal layer, continues on into the duodenum, forming the longitudinal muscle of the small bowel.

Many branches of the celiac trunk bring arterial blood to the stomach. The celiac trunk is a short, wide artery that branches from the abdominal portion of the aorta, the main vessel conveying arterial blood from the heart

to the systemic circulation. Blood from the stomach is returned to the venous system into the portal vein, which carries the blood to the liver.

The nerve supply to the stomach is provided by both the parasympathetic and sympathetic divisions of the autonomic nervous system. The parasympathetic nerve fibres are carried in the vagus, or tenth cranial, nerves. As the vagus nerves pass through the opening in the diaphragm with the esophagus, branches of the right vagus nerve spread over the posterior part of the stomach, while the left vagus supplies the anterior part. Sympathetic branches from a nerve network called the celiac, or solar, plexus accompany the arteries of the stomach into the muscular wall.

#### SMALL INTESTINE

The small intestine, which is 670–760 centimetres (22 to 25 feet) in length, is the longest part of the digestive tract of man. It begins at the pylorus, the juncture with the stomach, and ends at the **ileocecal valve**, the juncture with the colon. The parts of the small intestine are the duodenum, jejunum, and ileum.

**The three parts of the small intestine.** The duodenum is 23–28 centimetres (nine to 11 inches) long and forms a horseshoe, or C-shaped, curve that encircles the head of the pancreas. Unlike the rest of the intestine, it is **retroperitoneal** (that is, it is behind the peritoneum, the membrane lining the abdominal wall). Its first part, known as the *duodenal bulb*, is the widest part of the small intestine. It is horizontal, passing backward and to the right from the pylorus, and lies somewhat behind the wide end of the gallbladder. The second part runs **vertically** downward in front of the hilum of the right kidney (the point of entrance or exit for blood vessels, nerves, and the ureters), and into this part of the duodenum, at the *ampulla of Vater*, pancreatic juices and bile flow. The third part runs horizontally to the left in front of the aorta and the inferior vena cava (the principal channel for return to the heart of venous blood from the lower part of the body and the legs), while the fourth part ascends to the left side of the second lumbar vertebra (at the level of the small of the back), then bends sharply downward and forward to join the second part of the small intestine, the jejunum. An acute angle, called the *duodenojejunal flexure*, is formed by the suspension of this part of the small intestine by the ligament of Treitz.

The jejunum forms the upper two-fifths of the rest of the small intestine; it, like the ileum, has numerous convolutions and is attached to the posterior abdominal wall by mesentery, a fold of serous—clear-fluid-secreting—membrane.

The ileum is the remaining three-fifths of the small intestine, though there is no absolute point at which the jejunum ends and the ileum begins. In broad terms, the jejunum occupies the upper and left part of the abdomen below the subcostal plane (*i.e.*, from a plane just above the floating ribs), while the ileum is located in the lower and right part. **At** its termination the ileum opens into the large intestine.

**The small bowel mucosa.** The mucosa lining the small intestine is a remarkable structure in that it provides a tremendous absorptive surface to the intestinal contents. Although the small intestine is only three to four centimetres (1.2–1.6 inches) in diameter and approximately 7.32 metres (24 feet) in length, it has been estimated that the total absorptive area of the human small intestine is approximately 4,500 square metres (5,400 square yards). This enormous absorptive surface is provided by the unique structure of the mucosa. Within the small intestine, the mucosa is arranged in concentric folds that have the appearance of transverse ridges. These folds, or ridges, are approximately five to six centimetres (two to 2.4 inches) in length and about 3.2 millimetres (about one-eighth inch) thick. They are known as *plicae circulares*. These mucosal folds are present throughout the small bowel except in the first portion, or bulb, of the duodenum. The mucosa of the duodenal bulb is characteristically flat and smooth, except for a few longitudinal folds. The *plicae circulares* are largest in the lower

The muscles of the stomach wall

The jejunum and ileum

Arterial and venous supply

part of the duodenum and in the upper part of the jejunum. They become smaller and finally disappear in the lower part of the ileum. It has been estimated that the small intestine of man contains approximately 800 plicae circulares and that they increase the surface area of the lining of the small bowel by five to eight times the outer surface of the small intestine.

Another feature of the small bowel mucosa that greatly multiplies its surface area is that of the tiny projections called mucosal villi. These mucosal villi usually vary from 0.5 to one millimetre (0.02–0.04 inch) in height. Their diameters vary from approximately one-eighth to one-third their height. The villi are covered by a single layer of tall **columnar—rodlike—cells**. Goblet cells, so-called because of their rough resemblances to empty goblets after they have discharged their contents, are also found scattered among the surface cells. The goblet cells are a source of mucin, the chief constituent of mucus.

At the base of the mucosal villi are depressions called intestinal glands, or the crypts of Lieberkühn. The cells that line the crypts continue up and over the surface of the villi. In the bottom of the crypts, the epithelial cells are filled with alpha granules, or eosinophilic granules, so-called because they take up the rose-coloured stain eosin. These cells have been termed the cells of Paneth.

In the duodenum the villi are dense and large and frequently are **leaflike** in shape. In the jejunum the individual villus measures between 350 and 600 microns in height (there are about 25,000 microns in an inch) and has a diameter of 110 to 135 microns. The appearance and shape of the villi vary in different levels of the small intestine. The inner structure of the individual villus consists of loose connective tissue containing a rich network of blood vessels, a central lacteal, or channel for lymph, smooth muscle fibres, and scattered cells of various types. The smooth muscle cells surround the central lacteal and provide for the pumping action of the villi.

A small central arteriole (minute artery) branches at the tip of the villus to form a capillary network (the capillaries are the smallest of the blood vessels); the capillaries, in turn, empty into a collecting venule, or minute vein, that extends to the bottom of the villus.

The most remarkable feature of the small bowel mucosa is the rough surface of the epithelial cells, the cells covering the villi. This surface, called a brush border, is now known to consist of individual microvilli. The **microvilli** are approximately one-tenth micron in diameter and one micron in height; each epithelial cell may have as many as 1,000 microvilli. The microvilli, now known to play an important role in absorption of intestinal contents, enlarge the absorbing surface approximately 25 times and contain a number of enzymes.

Beneath the mucosa of the small intestine, as beneath that of the stomach, are the muscularis mucosae and the submucosa. The submucosa consists of loose connective tissue and contains many blood vessels and lymphatics. In the submucosa of the duodenum are located the glands of Brunner, composed of acini (round sacs) and tubules that are twisting and have multiple branching. Brunner's glands empty into the base of the crypts of Lieberkühn in the duodenum. Their exact function is not known, but they do secrete a scanty clear fluid that contains mucus and a relatively weak proteolytic (**protein-splitting**) enzyme. In the submucosa of the jejunum, solitary nodules (lumps) of lymphatic tissue are located. There is more lymphatic tissue in the ileum, in aggregates of nodules known as Peyer's patches.

The arrangement of the muscular coats of the small intestine is uniform throughout the length of the intestine. There is an inner, circular layer that is thicker than the outer, longitudinal layer. The outermost covering of the small intestine is the peritoneum, a single layer of flattened epithelial cells.

The blood supply of the small intestine is from the superior mesenteric artery (a branch of the abdominal aorta) and from the superior pancreaticoduodenal artery (a branch of the hepatic artery). These vessels run between layers of the mesentery and give off large branches that form a row or series of connecting arches from

which branches enter the wall of the small bowel. The blood from the intestine is returned by means of the superior mesenteric vein, which, with the splenic vein, forms the portal vein, which drains into the liver.

The small intestine has both sympathetic and parasympathetic innervation. The vagus nerves **provide** the parasympathetic innervation. The sympathetic is provided by branches from the superior mesenteric plexus, a nerve network close under the solar plexus, which follow the blood vessels into the small intestine and finally terminate in the two plexuses, or networks—Auerbach's, located between the circular and longitudinal muscle coats, and Meissner's, which is located in the submucosa.

#### **LARGE INTESTINE**

The large intestine serves as a reservoir for the liquids emptied into it, through the ileocecal valve, from the small intestine. The large intestine, or colon, may be divided into the cecum, ascending colon, transverse colon, descending colon, and sigmoid colon. The primary function of the colon is to absorb water and electrolytes (substances, such as salts, that in solution take on an electrical charge) from the ileal contents and to store fecal material until it can be evacuated by defecation.

The cecum, the first part of the large intestine, is a sac with a closed end. It occupies the right iliac fossa, the hollow on the inner side of the ilium (the upper part of the hipbone). Guarding the opening of the ileum into the cecum is the ileocecal valve. Most textbooks of anatomy describe the ileocecal valve as consisting of two folds or flaps of mucous membrane on the cecal side and above and below the ileal opening. The ileocecal junction does have this appearance commonly after death. During life, however, the ileocecal junction appears much different in that the terminal portion of the ileum doubles into the cecum; from the cecal side the ileocecal valve greatly resembles the cervix, the projection of the uterus into the vagina. The circular muscle fibres of the ileum and those of the cecum combine to form the circular sphincter muscle of the ileocecal valve.

The ascending colon extends up from the cecum at the level of the ileocecal valve to the bend in the colon called the hepatic flexure, which is located beneath and behind the right lobe of the liver. The ascending colon is about 20 centimetres (eight inches) long. In back it is in contact with the rear abdominal wall and the right kidney. The ascending colon is covered by peritoneum except on its posterior surface.

The transverse colon is variable in position, depending largely on the distention of the stomach, but usually is located in the subcostal plane; that is, at the level of the tenth rib. On the left side of the abdomen it ascends to the bend called the splenic flexure, which may make an indentation in the spleen. The transverse colon is bound to the diaphragm opposite the eleventh rib by a fold of peritoneum.

The descending colon passes down and in front of the left kidney and the left side of the posterior abdominal wall to the iliac crest, the upper border of the hipbone. The descending colon is about 15–20 centimetres (six to eight inches) in length, and it is more likely than the ascending colon to be surrounded by peritoneum.

The sigmoid colon is commonly divided into iliac and pelvic parts. The iliac colon stretches from the crest of the ilium, or upper border of the hipbone, to the inner border of the psoas muscle, which lies in the left iliac fossa. Like the descending colon, the iliac colon is usually covered by peritoneum. It is about 15 centimetres (six inches) in length. The pelvic colon lies in the true pelvis (lower part of the pelvis) and forms one or two loops, reaching across to the right side of the pelvis and then bending back and, at the midline, turning sharply downward to the point where it becomes the rectum.

The layers that make up the wall of the colon are similar in some respects to those of the small bowel; there are distinct differences, however. The external aspect of the colon differs markedly from that of the small bowel because of features known as the haustra, taeniae, and appendices epiploicae.

**Parts and function of colon**

The microvilli

**Haustra  
and  
taeniae**

The haustra, bulges or sacculations, are formed by constricting circular furrows of varying depths. The three taeniae are long, narrow bands of longitudinal muscle fibres, about one centimetre (0.4 inch) in width, that are approximately equally spaced around the circumference of the colon. Between the thick bands of the taeniae there is a thin coating of longitudinal muscle fibres.

The appendices epiploicae are collections of fatty tissue beneath the covering membrane. On the ascending and descending colon they are usually found in two rows, whereas on the transverse colon they form only one row.

The mucous membrane of the colon has a characteristic structure. It lacks the villi and the folds known as plicae circulares characteristic of the small intestine. It contains many solitary lymphatic nodules but no Peyer's patches. The surface epithelium is columnar, and there are many goblet cells. Characteristic of the colonic mucosa are deep tubular pits, increasing in depth toward the rectum. The submucosa contains numerous solitary lymphatic nodules, blood vessels, lymphatics, and submucosal nerve networks known as Meissner's plexuses.

The arterial blood supply to the large intestine is supplied by branches of the superior and inferior mesenteric arteries (both of which are branches of the abdominal aorta) and the hypogastric branch of the internal iliac (which supplies blood to the pelvic walls and viscera, the genital organs, the buttocks, and the inside of the thighs). The vessels form a continuous row of arches from which vessels arise to enter the large intestine. Venous blood is drained from the colon from branches that form venous arches similar to those of the arteries. These eventually drain into the superior and inferior mesenteric veins, which ultimately join with the splenic vein to form the portal vein (which carries venous blood to the liver).

The innervation of the large intestine is similar to that of the small intestine.

**RECTUM AND ANUS**

The rectum, which is a continuation of the sigmoid colon, begins in front of the midsacrum (the sacrum is the triangular bone near the base of the spine and between the two hipbones). It ends in a dilated portion called the rectal ampulla, which in front is in contact with the rear surface of the prostate in the male and with the posterior vaginal wall in the female. Posteriorly, the rectal ampulla is in front of the tip of the coccyx (the small bone at the very base of the spine).

At the end of the pelvic colon, the mesocolon, the fold of peritoneum that attaches the colon to the rear wall of the abdomen and pelvis, ceases, and the rectum is then covered by peritoneum only at its sides and in front; lower down, the rectum gradually loses the covering on its sides, until only the front is covered. At about the junction of the middle and lower thirds of the rectum, about 7.5 centimetres (three inches) from the anus, the anterior peritoneal covering is also folded back onto the bladder and the prostate or the vagina.

Near the termination of the sigmoid colon and the beginning of the rectum, the colonic taeniae spread out to form a wide external longitudinal muscle coat. At the lower end of the rectum muscle fibres of the longitudinal and circular coats tend to intermix. The internal circular muscle coat terminates in the thick rounded internal anal sphincter muscle. The smooth muscle fibres of the external longitudinal muscle coat of the rectum terminate by interweaving with striated muscle fibres of the levator ani, a broad muscle that forms the floor of the pelvis. A second sphincter, the external anal sphincter, is composed of striated muscle and is divided into three parts known as the subcutaneous, superficial, and deep external sphincters. Thus, the internal sphincter is composed of smooth muscle and is innervated by the autonomic nervous system, while the external sphincters are of striated muscle and have somatic (voluntary) innervation provided by nerves called the pudendal nerves.

The mucosal lining of the rectum is similar to that of the sigmoid colon but becomes thicker and better supplied with blood vessels, particularly in the lower rectum. In the rectal ampulla are two to three large crescentlike

folds known as rectal valves. These folds, or valves, are caused by an invagination, or infolding, of the circular muscle and submucosa. The columnar epithelium of the rectal mucosa changes to the stratified squamous (scale-like) type in the lower rectum a few centimetres above the pectinate line, which is the junction between squamous mucous membrane of the lower rectum and the skin lining the lower portion of the anal canal.

Arterial blood is supplied by branches from the inferior mesenteric artery and the right and left internal iliac arteries. Venous drainage from the anal canal and rectum is provided by a rich network of veins called the internal and external hemorrhoidal veins.

**ASSOCIATED GLANDS AND STRUCTURES**

**Pancreas.** The pancreas is both an exocrine (ducted) and endocrine (ductless) gland. The exocrine functions consist of providing the digestive system with water, bicarbonate, and enzymes. The endocrine functions consist primarily of providing the bloodstream with two hormones—insulin and glucagon—necessary for carbohydrate regulation and metabolism.

In man, the pancreas is a large gland located behind the stomach. The largest portion of the gland, known as the head, is within the curve of the duodenum and firmly attached to it. An extension of the head of the gland downward and to the left, a portion called the uncinate process (*i.e.*, hooked projection) lies immediately above the transverse portion of the duodenum. Extending to the left from the head of the gland there is a short neck and then the body and tail of the pancreas. The tail of the pancreas extends to the spleen.

The pancreas is completely retroperitoneal (behind the peritoneum). In front, it is covered almost in its entirety by the stomach. Posteriorly, the head is in contact with the inferior vena cava and the aorta. The body of the pancreas covers the splenic artery and vein, while the tail of the pancreas covers the upper portion of the left kidney. The pancreas is drained by a large main duct, the duct of Wirsung, which runs the entire length of the gland and, in the wall of the second part of the duodenum, joins usually with the common bile duct at a sac called the ampulla of Vater. This empties its mixture of bile and pancreatic juices into the duodenum. A smaller accessory pancreatic duct, the duct of Santorini, branches from the main pancreatic duct at a level near the junction of the head and neck of the gland and empties directly into the second portion of the duodenum at a point near the ampulla of Vater.

Like the salivary glands, the pancreas is a racemose (cluster-filled) gland. When studied microscopically, the pancreas is seen to be made up chiefly of cell groups, called acini, that are hollow and tend to be spherical or oval in shape. Groups of acini form primary lobules. These in turn combine to form larger secondary lobules. The secondary lobules are completely surrounded by connective tissue and can be dissected out as separate structures connected to the rest of the gland by ducts, nerve fibres, lymphatic vessels, and blood vessels.

The cells in each acinus tend to be pyramidal in shape, with the apex of the pyramid directed toward the hollow (lumen) in the centre of the sphere. The cells are large, with a well-developed nucleus, and have an abundant granular cytoplasm. The granules in the cytoplasm, called zymogen granules, tend to be more abundant in the part of the cell near the lumen of the acinus.

Besides the clusters of acini joined by ducts, there are, scattered through the pancreas, many thousands of microscopic groups of cells, known as the islets of Langerhans, that serve the endocrine functions of the pancreas. In the islets there are three types of cells: alpha cells, the sources of glucagon; beta cells, the sources of insulin; and D-cells, of unknown function.

Sympathetic nerve fibres accompany the blood vessels to all parts of the pancreas. Parasympathetic innervation is provided from both the vagus nerves.

**Liver, gallbladder, and bile ducts.** **Liver.** All invertebrate animals possess a liver, and the livers of all adult vertebrates are essentially alike, though among verte-

The rectal  
valves

Acini and  
lobules

brate animals some 20 modes of liver development have been found. The structure, functions, and disorders of the human liver, gallbladder, and bile ducts are covered at length in the article **LIVER, HUMAN**.

In man, the liver is the largest gland in the body; it is located in the upper right part of the abdominal cavity beneath the right diaphragm. Its weight is approximately one and one-half kilograms (3.3 pounds), representing about one-fortieth of the total body weight. In the living state, the liver is soft and compressible. Surrounding organs in contact with the liver push in its surface and leave impressions. When the liver is removed from the body, however, these depressions disappear.

Relation-  
ship of the  
liver to  
adjacent  
structures

The anterior, or **forward**, surface of the liver is divided into a large right lobe and a smaller left lobe by a thick ligament called the falciform ligament, which attaches the anterior surface of the liver to the abdominal wall. The upper and posterior surfaces of the liver are attached to the diaphragm and to the rear abdominal wall by a ligament called the coronary ligament. The inferior surface of the liver has many depressions from adjacent organs, the right kidney, the hepatic flexure of the colon, and the duodenum. The inferior surface of the smaller left lobe of the liver usually shows a depression produced by the **fundus** of the stomach.

The liver has a wide variety of functions, including the destruction of worn-out red cells, the production of the proteins that make up most of the clotting factors in the blood, the storage of carbohydrates and some fats and proteins, the production of urea, and the detoxification or modification of some drugs and poisons.

Only one activity of the liver seems directly concerned in the functioning of the digestive system. This is the production of bile salts, which aid in the digestion and absorption of fats in the small intestine. The bile salts are produced by the cells called variously hepatocytes, liver cells, and hepatic cells. They are arranged in close conjunction with microscopic blood and bile channels, in plates forming complex honeycomb-like structures.

**Bile ducts and gallbladder.** The gallbladder, and the system of ducts that carry bile from the liver to the gallbladder for concentration and storage and from the liver and the gallbladder to the duodenum, are described in **LIVER, HUMAN**.

Ducts from the right and left lobes of the liver unite to form the common hepatic duct. From the side of this a duct, called the cystic duct, leads to the gallbladder.

The common bile duct, formed by the union of the hepatic and cystic ducts, is like the vertical portion of the letter Y. It passes down through the head of the pancreas and then penetrates obliquely the muscular wall of the duodenum. Within the wall of the duodenum the common bile duct and the main pancreatic duct join and empty into the duodenum through the ampulla of Vater. The ampulla of Vater is surrounded near its outlet into the duodenum by a ring of muscle fibres, the sphincter of Oddi. (This muscle closes the passage through the ampulla of Vater and causes bile to back up into the gallbladder except when there is fat in the duodenum.)

The human gallbladder has a capacity of approximately 50 millilitres (three cubic inches). The wall of the gallbladder is composed of a thin layer of smooth muscle fibres and fibroelastic tissue. The gallbladder mucosa is composed of three types of cells—tall columnar cells, the most common, and two other types called pencil cells and basal cells.

The columnar epithelium of the gallbladder has many characteristics of an active absorbing membrane, including a border of microvilli on the surfaces of the cells next to the cavity of the organ, like the microvilli on the cells lining the small intestine. The lateral walls of the adjacent cells are interlocked into each other by folds of plasma membrane (the membrane enclosing the cell). This interlocking is thought to prevent material in the gallbladder cavity from penetrating between the cells, leaving the main route of absorption through the cells themselves.

## Digestive System Diseases

The ingestion of food and fluid is a prerequisite for man's growth; his digestive system represents one of his most ancient and essential vital pathways for survival. The system has evolved in such a way that great discriminatory powers are concentrated at the mouth, governing the amount and type of material ingested, and at the lower end providing for orderly expulsion of what is no longer needed. In between these two highly sensitive areas the tract has feebly developed sensors to the brain, but highly developed neurohumoral reflexes—reflexes dependent upon chemical substances released at nerve **endings**—which provide for the proper mixing of foodstuffs with those enzymes, hormones, emulsifiers, and electrolytes whose interaction constitutes what is called digestion and absorption. This article considers the derangements that may occur in the human digestive tract as a result of congenital, infectious, environmental, cancerous, or inflammatory processes.

### MOUTH AND PHARYNX

This uppermost section of the digestive tract extends from the lips to the point at which the pharynx, or throat, meets the esophagus, a muscular tube extending to the stomach. It is designed to smell, taste, masticate, and swallow materials, processes in which the individual gains experience as he ages. It may be damaged because it is poorly provided with sensors—as in the blind, or in those unable to smell or taste properly—or because (from inexperience) it allows matter too hot or too cold to come into contact with its mucous membranes, or because it is deceived by poisons masquerading as nutrients—*e.g.*, poisonous plants or meats carrying botulinus toxin.

The most important of the inborn defects involve failures in fusion of the palate—the bones and soft tissues of the roof of the mouth—thus impairing the ability to produce a closed, high-pressure cavity behind the lips and teeth. Other defects relate to defective apposition of the teeth and the jaws, resulting in inefficient mastication, and to the absence of one or more of the salivary glands, which may lessen the amount and quality of saliva that they produce. Neurological defects that provide inadequate motor power to the muscles of the tongue and the pharynx can seriously impair powers of mastication and even of swallowing; sensory-innervation defects may not allow the usual reflexes to mesh smoothly or may permit harmful ingestants to pass by undetected.

The mouth is in constant contact with the external environment, and through kissing and the use of shared feeding utensils may provide an easy source of entry for infectious agents into the abundant lymphoid tissues that form the tonsils, or through the esophagus and stomach into the small intestine from which they are disseminated. These agents can produce characteristic signs in the mucous membranes of the mouth and throat such as the Koplik spots that are the first signs of measles, the inflammation of the inside of the cheek at the point where Stensen's duct opens into the mouth in mumps, or the various ulcerations of the palate seen in chickenpox or smallpox.

In addition to the mouth lesions, some infections produce their major or most dramatic manifestations in the mouth and throat. Among the serious disorders of this type are moniliasis and histoplasmosis, fungous infections that produce ulcerative breakdown of the mucous membranes and often intense enlargement of the lymph glands of the tonsillar and tongue areas. Tuberculosis and syphilis produce a variety of reactions in this region, depending on the stages of the infection. These vary from white mucous patches on the mucous membrane of the cheek to deep ulceration of tongue, lip, or palate; or to

Infectious  
processes

accumulations of nodules, or small lumps. Infection with the common pyogenic bacteria produces acute redness and swelling of the posterior pharynx, from which the surface exudate is found to be loaded with streptococcus or staphylococcus organisms. Swollen, bleeding, malodorous gums are often the site of invasion by the organisms that cause "trench mouth" in mouths rendered insufficiently resistant by general ill health, malnutrition, or poor hygiene. Among the commonest diseases of this area is the multiple vesicular and ulcerative disease, **aphthous stomatitis** (canker sores), affecting the mucous membrane of the mouth and often the adjacent skin of the lips. Many skin diseases, both acute and chronic, have associated eruptive phases in the mucous membranes of mouth and pharynx.

As the mouth normally contains a variety of bacteria living in peaceful coexistence, it is apparent that adequate resistance to them can be maintained by properly nourished mucous membranes. Whenever the nutritional status of this barrier mucosa is lessened by whatever cause, disease becomes apparent as inflammation and easy bleeding of gums and mucous membranes, swelling and loss of papillae of the tongue, changes in colour of lips and tongue, and breakdown of the thin skin of the lips. These and other changes may be brought out more sharply whenever trauma—as in toothbrushing or denture irritation—is exerted or when infections damage the surface or increase metabolic needs. The best documented evidences of nutritional deficiency in the mouth and throat are: the easy bleeding of gums often seen in ascorbic-acid deficiency, the smooth, red tongue of pernicious anemia, the bright red tongue noted in niacin deficiency, and the inflammation at the corners of the mouth in riboflavine and perhaps other B-vitamin deficiencies. In Addison's disease the mucous membrane of the cheeks becomes infiltrated with a brownish **pigmentation**.

Certain toxins found in foods can produce devastating effects on the function of the oropharynx without leaving visible lesions. Botulinus toxin causes such damage to the nervous system centres governing the 9th, 10th, and 12th cranial nerves that swallowing is usually badly deranged, and coordination of respiration with swallowing may be impossible.

Ingestion of lead characteristically results in a dark line along the margins of gums rendered susceptible by poor hygiene; mercury inhalation or ingestion leads to an ulcerative inflammation of the gums and mouth, often of great severity. Such disorders are now rare, and instead it is more reasonable to attribute gum hypertrophy and inflammation to certain chronically ingested therapeutic agents, in particular anticonvulsants and antibiotics. Again, these lesions are most frequent and most severe in mouths subjected to poor hygiene.

A black, hairy tongue is most often a result of antibiotic sensitivity, but it is also seen in those who use excessive amounts of peroxide mouthwashes, smoke or chew excessively, or constantly chew on various medicaments. The mouth can be burned by caustics and by exposure to extremes of temperature.

Tumours involving the blood-forming organs often interfere with the body's ability to control bleeding, and such bleeding is often first manifest in the mouth and throat, either as diffuse oozing from the gums or as multiple ulcerations of the entire buccal mucosa and tongue. Any disorder that causes a decreased effective circulation of blood platelets may result in the same kind of oozing from the gums. The serious disorder known as **agranulocytosis**, usually the result of a sensitivity to drugs, is suspected when ulcerative lesions of the mouth fail to heal and become secondarily infected. In this condition there is a sudden failure to produce white blood cells (leucocytes), so that the normal resistance of mucous membranes to their indigenous bacterial population cannot be maintained. In addition to these oral manifestations of diseases seated elsewhere, tumours may arise in the mouth and throat. Of these, cancers of the salivary glands and of the mucous membranes of the cheeks may be

first observed from their effect on the mouth, where they may cause pain, bleeding, or difficulty in swallowing. The lymphomas and other tumours of lymphoid origin may first manifest themselves in the tonsillar or pharyngeal lymph nodes; these can usually be seen by direct inspection of the mouth and pharynx. Cancer of the tongue and of the bony structures of the hard palate or sinuses may project into the mouth or may burrow deep into the surrounding tissues. A precancerous lesion most often picked up by dentists is leukoplakia, a whitish discoloration of the mucous membrane of the mouth.

Any disorders of the bony framework of the mouth, including the lower and upper jaws and the hard palate, may produce difficulties with mastication or swallowing or may injure the oral mucous membranes. Differentiation of benign from malignant lesions in the oral cavity is the special area of expertise of dentists, but there is an overlap in the fields covered by otolaryngologists, who treat disorders of the ears and upper respiratory tract, by plastic surgeons, and by neurologists in solving complaints of persons suffering from dysfunction of this highly complex portion of the body. In the same way, pain or disability originating in the jaws, gums, and teeth may seem, when first complained of, to be pain associated with other disorders. Within relatively recent medical history teeth were suspected as the cause of many chronic disorders, especially arthritis, and were extracted for that reason rather than for any intrinsic dental disorder. Now, although careful inspections are made of the teeth and jaws of patients complaining of various chronic disorders, there is less willingness to extract teeth not obviously diseased.

Inflammation of the posterior wall of the mouth and of the tonsils and adjoining tissue on each side of the oropharynx, the **central** area of the pharynx, is very common especially in the young. Mention has already been made of streptococcal and staphylococcal infections of this area, but it should be emphasized that as many diffuse inflammatory responses of these tissues result from viral infections as from invasion by pyogenic bacteria. In viral pharyngitis the tissue is usually less violently red and swollen with fluid than is streptococcal pharyngitis and is less often covered by a whitish crust of even consistency. In acute streptococcal tonsillitis, both tonsils are swollen, pitted, and covered with whitish exudate; the soft palate is swollen and red, and there is much exudate seen streaming about the posterior pharyngeal wall. Other tonsillar tissue in the upper part of the pharynx and at the root of the tongue may be similarly involved. In diphtheritic pharyngitis the membranous exudate is more diffuse than in other types of pharyngitis, tougher, and extends over a much larger part of the mucous membrane of the mouth and nose. One of the complications of any tonsillitis or pharyngitis may be a peritonsillar abscess adjacent to one tonsil; this abscess is associated with bulging of the posterior pharyngeal mucosa over it. Surgical evacuation of such abscesses is usually required for healing.

**Summary.** The mouth and pharynx, being rather easily visualized by the physician, can be well characterized when diseases involve them. Symptoms of such disorders are usually localized by the patient, since this portion of his body is very heavily supplied with sensing devices, is geared for rapid action in eating and rejecting, and must carry out carefully coordinated actions, such as the simple ones of swallowing and breathing. As the first barrier that must be passed by ingestants or fluids, the area often suffers a variety of injuries from the environment, but its efforts are generally effective in reducing the variety of hostile agents that could attack the rest of the gastrointestinal tract.

#### THE ESOPHAGUS

This organ, a far less complex structure than the oropharynx, is designed to deliver to the stomach those materials that have successfully passed the pharynx. The esophagus does nothing to alter the physical or chemical composition of the material it receives, and it is poorly

Primary disorders of teeth and gums

equipped to reject materials that have got past the intricate sensors of the mouth and throat. Consequently, it is peculiarly vulnerable to mucosal injury from ingestants, as well as to materials that return into its lower segment from the stomach. Although its muscle coats are thick, it is not protected with a covering of serous membrane, as are neighbouring organs in the chest.

Inborn defects of the esophagus may be very serious; they are most often seen in infancy, primarily as a failure to develop normal passageways, often occurring between esophagus and trachea. Babies born with these openings cannot survive without early surgery. The lower end of the esophagus is subject to various developmental anomalies resulting in shortening of the organ so that the stomach may be pulled up into the thoracic cavity. Anomalies of the diaphragm may contribute to such an outcome.

#### Inflammatory disorders

Inflammatory disorders of the esophagus result from ingestion of noxious materials, as in lye or acid burns, from lodgment of foreign bodies, or from a complex of events associated with **reflux** of gastric contents from the stomach into the lower esophagus. All types of trauma produce damage to the mucous membrane of the esophagus. Inflammation resulting from surface injury by caustics is called corrosive esophagitis. When the problem is associated with **reflux**, the term peptic esophagitis is applied to the inflammation, which involves both the mucous membrane and the submucosal layer in a generally mild process. A number of other diseases may cause inflammation of the esophagus; *e.g.*, scleroderma, a disease in which the smooth muscle of the organ degenerates and is eventually replaced by fibrous tissue; and generalized **moniliasis**, in which the esophagus is often involved in a septic process characterized by many small abscesses and ulcerations throughout its entire length.

A straight tube of smooth muscle, the esophagus responds to localized inflammation by narrowing its passageway and, depending on the severity of the inflammation, producing a localized stricture. Such strictures have been known to be a consequence of ingesting lye or acid. They are readily seen by X-ray and by direct viewing with the esophagoscope, an instrument designed for this purpose. Treatment, after control of the infection, is surgical. With strictures brought about by interference with the emptying ability of the esophagus after inflammation caused by stomach juices, treatment is more complicated because it must involve control of the **still-present** causative processes, including acid-peptic stomach action and various structural variants of the lower esophagus.

An interesting disease of the esophagus is achalasia, formerly called **cardiospasm**. In this disorder a primary **disturbance** in the **peristaltic** action of the esophagus results in failure to empty the organ of its ingested and swallowed contents. The lower sphincteric portion of the esophagus does not receive its customary signal to relax and, over the months and years, may become hypertonic. A vicious cycle is thus set up in which the main portion of the esophagus slowly becomes distended, holding a column of fluid and food that it cannot propel downward, and the lower exit valve mechanism stays closed because of a failure in its information-feedback system. In most patients with this disorder there is a shortage of the ganglion cells of the intermuscular plexus (**Auerbach's plexus**) or they are diseased, so that coordinated peristalsis becomes impossible. In Chagas' disease, the infecting trypanosomes invade the neural tissue and directly destroy the ganglion cells. These organisms are not present in the temperate zones of the world, however, and the reason for ganglion cell degeneration in achalasia is unknown. Effective treatment is achieved by destroying the ability of the lower segment of the esophagus to contract; this may be done by dilating the esophagus with an inflated balloon or by surgery.

#### Tumours

Tumours of the esophagus may be benign or malignant. Generally, benign tumours originate in the submucosal tissues, and principally are leiomyomas, or tumours composed of smooth muscle tissue, or **lipomas**, which are of

adipose tissue. Malignant tumours are either epidermoid cancers, made up of unorganized aggregates of cells, or adenocarcinomas, in which there are glandlike formations. Cancers arising from squamous tissues are found at all levels of the organ, whereas adenocarcinomas are more common at the lower end where a number of glands of gastric origin are normally present. Tumours generally make their presence known by producing difficulty in swallowing, particularly of solid foods. They are much more common in men than in women, and seem to vary widely in their worldwide distribution. Some correlations with the alcohol or tobacco consumption of the population have been established, suggesting that continued ingestion or inhalation of these materials may predispose to malignant change, as, apparently, does previous stricture formation. Treatment by surgery or by irradiation is largely palliative at present.

Disturbances of the esophagogastric junction, the point where esophagus and stomach meet, are both common and important. In many persons material from the stomach flows back into the esophagus, only to be immediately swept down into the stomach once again. New methods of measuring the pressure in the lumen or passageway of the esophagus and stomach have led to the belief that there is an effective barrier to such **reflux** from the stomach, and that this barrier is inherent in the musculature of the last few centimetres of esophagus. It is not clear whether anatomical displacement of the junction is in itself enough to efface the pressure barrier, but there is little question that an intrinsic mechanism of the esophagus does function to prevent gastric **reflux** and that in many patients in whom the radiologist can demonstrate a definite hiatus **hernia**—*i.e.*, a protrusion of a portion of upper stomach through the opening in the diaphragm—there is no **reflux** of gastric juice. On the other hand, most patients with **reflux** do have some evidence of hiatus hernia. The principal **symptoms** of the **reflux** syndrome are heartburn, a moving burning sensation under the breastbone, made worse by bending over or lying down and usually relieved rapidly by antacid medication. Some of such patients show reddening of the mucous membrane in the lower esophagus, but many do not.

Biopsies of the area may or may not show inflammation, and rarely is there good correlation between symptoms and intensity of inflammation. Treatment by hourly use of antacids, by small meals, by raising the head of the bed for sleeping, and by weight reduction in the usually obese patient has usually been quite successful. In some patients these measures do not suffice, or there is in addition some difficulty in swallowing; it is in such patients that surgical correction of the hernia is indicated. Many antispasmodic drugs, by interfering with the normal motor function of the esophagus, may make the symptoms worse; furthermore, since they slow down gastric emptying, the esophagogastric junction may then more likely be breached by **reflux** of juice from the distended stomach.

Diverticula of the gastrointestinal tract—pouches in the walls of the structures in the digestive system—occur wherever weak spots may exist between adjacent muscle layers. In the upper esophagus there is such an area: the striated-constrictor muscles of the pharynx merge with the upper smooth muscle of the esophagus just below the larynx. Some males over age 50 will show protrusion of a small sac of pharyngeal mucous membrane through the space between these muscles. As aging continues, or if there is motor disturbance in the area, this sac may become distended and actually fill with food or saliva. It usually projects to the left of the midline, and may demonstrate its presence by producing bubbling and crunching sounds during eating; **often** the patient can feel it in the left side of the neck as a lump, which can be reduced by pressure of the finger. Sometimes the sac may get so large it compresses the esophagus adjacent to it, producing a true obstruction. The treatment is surgical. Small diverticula just above the diaphragm sometimes are found after introduction of surgical instruments into the esophagus.

#### Diverticula

The stomach juices are much less likely to ulcerate the esophagus than to cause inflammation. Ulcers occur only in esophageal tissue next to glands of gastric origin in the esophagus, glands that secrete acid and pepsin. Because the esophagus is not protected by serous membranes, such ulcers may penetrate to neighbouring structures, most commonly the aorta, and can thus produce fatal hemorrhages. A serious injury to the esophagus is spontaneous rupture, a catastrophe that can occur in patients who have been vomiting or retching and often in debilitated elderly persons with chronic lung disease. Emergency surgical repair of the perforation is required,

#### THE STOMACH AND DUODENUM

In areas of the stomach and adjacent small intestine exposed to the action of gastric secretion, the mucous membrane may become ulcerated. If this breakdown of the mucosa is acute in onset and superficial in extent—i.e., if it does not extend into the muscular coat of the stomach or intestine—it is called an erosion or acute superficial ulceration. If the damage extends more deeply into the wall of the organ, with resultant fusion of mucosa, submucosa, and muscularis into a chronic inflammation, it is known as peptic ulceration.

Under certain not completely understood circumstances the action of the gastric juice is directed at the tissues lining the stomach and intestine, resulting in either erosion or peptic ulceration. The present belief is that there is a rather delicate balance between the aggressive action of acid-pepsin and the resistance to this action maintained by healthy mucous membranes. The membranes of the stomach consist of epithelial cells covered with a flowing stream of mucus. The gastric glands secrete into the lumen of the stomach a number of products, including acid, pepsin, and various soluble forms of mucus. (See DIGESTION, HUMAN.) It is apparent that a complex neurohumoral regulatory system controls not only the secretion of gastric juice but also the compensatory defense mechanisms of the mucous membrane. Studies of persons who have peptic ulcers show that they differ in some ways from healthy persons, but that none of these differences is really unique. Thus persons with stomach ulcers are more likely to belong to blood group A, whereas those with duodenal ulcers are more likely to belong to blood group O. Persons with ulcers in the stomach have total rates of gastric acid secretion no different from a normal population, whereas those with duodenal ulcers as a group have rates of acid production greater than those of the general population.

Peptic  
ulcer

Peptic ulcer of the stomach occurs about equally in men and women, tends to occur above age 35, and to be a complicating factor in the lives of persons suffering from other disorders—in particular diseases of the nervous system and the lungs. Duodenal ulcer is much more common in men, generally makes its presence known from age 15 to 25, and does not often arise as a complication of other disorders. Persons with these diseases complain usually of pain in the upper portion of the abdomen and in the midline; the pain usually is absent on arising in the morning, tends to become troublesome in the late morning, is relieved by eating, only to return about one or two hours later after the stomach has emptied. Such episodes may occur infrequently and last only a few days or may become persistent for many weeks. As the ulcer becomes more active, inflammatory reaction around it usually interferes somewhat with the emptying of the stomach or duodenum producing retention of gastric contents. If this progresses, the patient may begin to vomit large quantities of retained food and to complain of unpleasant sour taste and more severe pain shortly after eating. About one-quarter of all patients with peptic ulcer will have blood in the stools at some time in the course of the disease; acute and massive bleeding occurs when the burrowing of the base of the ulcer strikes an artery of some size. In a few patients massive vomiting of blood may be the manner in which the ulcer first makes itself known. The burrowing of the ulcer deep into the wall of stomach or duodenum is known as pene-

tration, and its ultimate result is perforation, permitting the leakage of stomach contents into the general peritoneal cavity. When this happens, either a local peritonitis with walling-off of the leak occurs, or a more general peritonitis ensues. Such patients are extremely ill and need emergency surgical care.

Peptic ulcer is a common disease in the Western World, being found in about 10 percent of all men, and in about two percent of women over the age of 50. It is generally a benign process that responds to conservative management with frequent feeding and the use of antacid medications. It is recurrent and episodic, often related to increased emotional tension, fatigue, or at a time when a person has an acute attack of another disease. In the gastric ulcer patient the differential diagnosis is complicated by the possibility of malignancy in the area of the ulcer, and thus the management of such cases is more often carried out in hospitals where direct viewing of the stomach lining with a gastroscope, study of cells in gastric juice, and frequent study of the stools for blood loss can be performed. Gastric ulcers can bleed massively and often interfere with eating to a degree not often noted with duodenal ulcer; thus gastric ulcer is treated by direct surgical excision more often than is duodenal ulcer. In about 15 percent of all cases, ulcers in the duodenum do not respond to medical treatment and it may be necessary to add to this treatment surgical measures to remove the vagus nerve fibres, which normally stimulate secretion of acid by the stomach. Treatment of the secretory portion of the stomach with X-rays can accomplish this in patients thought not to be good risks for surgery. The overall death rate for peptic ulcer in the U.S. and the Western countries is about four per 100,000. This is a low case-fatality rate for a common disorder, producing much hospitalization and a total cost in work time lost and direct costs estimated at \$1,000,000,000 annually in the U.S. alone.

Diffuse or patchy inflammations not ascribable to invasion by bacteria, viruses, or parasites are quite common in the stomachs of persons, whether apparently healthy or complaining of a variety of digestive symptoms. The inflammation of stomach mucosa is known as gastritis. It is described in different terms depending on whether it is seen through a gastroscope, by X-ray, or by microscopic study of a biopsy obtained from the stomach. Except for atrophic gastritis and for acute erosive gastritis, in which large portions of the mucous membrane have been destroyed by caustic agents, drugs, or by unknown causes, none of the other types of inflammation can be said to be associated with any consistent symptoms or long-term complications. Thus at the present time the general term gastritis has no medical meaning and should not be used to denote a clinical disorder. It is now thought that at least part of the atrophic process, relative to the mucous membrane, is immunologic—that is, various antibodies to specific cells or products of the stomach glands can be demonstrated in the biopsies, in the gastric juice, and in the circulating blood. In pernicious anemia, in which atrophy of the gastric mucosa is usual, there are present antibodies to the material intrinsic factor, a mucoprotein necessary for the absorption of vitamin B<sub>12</sub>, a substance essential for the manufacture of red blood cells.

Gastritis

Malignant tumours of the stomach are common throughout the world but show remarkable variations, probably involving both genetic and environmental factors, in incidence from country to country. Cancer of the stomach often occurs in older persons whose stomachs are capable of making only small quantities of acid. Whether this indicates that the same process that results in acid-secretory depression is also neoplastic or that gastric cancer is inhibited normally by acid-peptic secretion cannot be answered at present. Gastric cancer affects men more than women and currently accounts for about 20 percent of all deaths from cancers of the gastrointestinal tract in the U.S. In Japan it accounts for nearly 70 percent of such cancers.

Other malignant tumours that involve the stomach are

tumours ordinarily made up of lymphoid and connective tissue respectively. Benign tumours, especially leiomyomas, are common and may, when large, cause massive hemorrhage. Polyps of the stomach are not common except in the presence of gastric atrophy. Treatment for all these tumours, benign or malignant, is surgical.

Symptoms produced by tumours of the stomach are highly variable, and there are no truly characteristic evidences of disease in the early stages of the tumours. Most often the patients have loss of appetite, some weight loss, and symptoms ascribable to an anemia, which is frequently present and is due to blood loss into the stools, constant but usually so minimal as to escape notice by the patient. As the tumour grows, or if it is situated in the lower part of the stomach, obstructive symptoms brought on by eating may be noted, and tumours high in the stomach may obstruct the esophageal entry into the stomach, producing difficulty in swallowing. Pain is usually mild but, on the other hand, may be the most impressive feature. Stomach cancers often spread to neighbouring lymph nodes or to the liver very early, accounting for the very low percentage of surgical cures.

Diseases of  
the  
duodenum

The duodenum, aside from being the site of duodenal peptic ulceration, is otherwise not an important seat of disease. It is, however, often involved by diseases of its neighbours, in particular the pancreas and the biliary tract. Primary cancer of the duodenum is an infrequent problem. Benign tumours, particularly polyps and carcinoids, are more frequent. Cancers of the common bile duct or of the pancreas are important causes of death and may make their presence known by what they do to the duodenum, particularly in terms of obstruction and pain. It is because of their encroachment on the duodenum that these entities often are diagnosed by upper intestinal X-ray studies. Benign anomalies of the organs of this area, like an encircling ring of pancreas, may also encroach upon the duodenum. Parasites, particularly roundworms and tapeworms, are often found anchored in the duodenum. In inflammations of the pancreas, the neighbouring duodenum is often involved in such a way as to produce impairment of motility, and occasionally ulceration with hemorrhage.

#### THE SMALL INTESTINE AND APPENDIX

Congenital malformations of the small intestine consist of various duplications, which are infrequent, and of Meckel's diverticulum, which is common. The latter occurs when the duct leading from the navel to the small intestine fails to atrophy. In the fetus the duct serves as a principal channel for nourishment from the mother. The diverticulum in the child or adult may range from a small nubbin to a tube a foot or more in length, and it contains cells derived from the stomach glands that can secrete acid and pepsin. If such secretion occurs near the normal intestinal mucosa, which is totally non-resistant to such acid-peptic aggression, the mucosa will ulcerate and often bleed. Thus a peptic ulceration can develop at a site far distant from stomach or duodenum, can give rise to pain, bleeding, or obstruction, and must be treated surgically. A third congenital problem in the small intestine is the presence of multiple diverticula—outpouchings of mucosa and serosa. These are usually seen in elderly persons, although occasionally one may be the site of acute inflammation in a young adult. In the elderly, bacteria flourish in these diverticula which have no motor activity and cannot empty themselves. The bacteria eat nutrients otherwise destined for the body's own economy and may produce serious malabsorption.

The commonest of acute inflammations of the small intestine is acute enteritis, usually viral. This extraordinarily common ailment is manifested as acute malaise, fever, and diarrhea, often with severe cramps and pain. If there is vomiting as well, one calls the illness gastroenteritis. The disease is ordinarily short-lived but may produce serious disturbances of dehydration in infants and cause elderly subjects suffering from other disorders

to become seriously ill. Species of the genus *Salmonella* cause acute bacterial infections of the small bowel; typhoid fever is the best known of these. Stool culture usually establishes the diagnosis of bacterial infections, which may require specific antibiotic treatment. Many of these infections, however, are self-limited and require no treatment other than replacement of fluids and salts.

Chronic inflammations of the small intestine include tuberculosis, now fortunately infrequent, and regional enteritis (Crohn's disease), currently on the increase. These disturbances are difficult to diagnose early, since their initial symptoms are often vague. Generally fever of low grade is present; there is a tendency toward loose stools and weight loss; and there may be episodes of crampy abdominal pain due to obstruction of the lumen and interference with normal muscular activity by the inflammation of the bowel wall. Diagnosis is usually suggested by the X-ray appearance of the intestine. Differentiation of tuberculosis from Crohn's disease is not always simple but usually can be accomplished using standard techniques. There is specific drug therapy for tuberculosis. In Crohn's disease anti-inflammatory, nonspecific drugs are quite helpful. Surgical excision or bypass of the offending segments of bowel may be necessary.

Appendicitis, inflammation of the vermiform appendix, may be caused by infection or partial or total obstruction. It is still a major cause of intra-abdominal pain, principally attacking those under 35. Fortunately, it is easily diagnosed, and, with current surgical practice, the mortality from the acute process in young adults and children has dropped to very low levels. Widespread use of antibiotics for upper respiratory and other diseases may have actually lessened the incidence of the acute form of this disorder, so that more cases of later-developing appendiceal abscess are now being reported. Parasitic worms also can contribute to its incidence. In a woman of the childbearing age the differential diagnosis of appendicitis is still difficult, and many such patients are operated on because the necessary distinction cannot be made otherwise.

Appendi-  
citis

Intestinal obstruction may occur from pressure on the lumen of the bowel by tumour, inflammation, or local areas of adhesion, or from twists of the intestine on the folds of membrane that support it, or as a result of the devitalization of the intestinal wall by diminished blood supply. Such episodes of obstruction may develop slowly or with alarming rapidity. Recognition depends on clinical acumen plus laboratory assistance, of which the X-ray film is of the greatest importance. In all instances the condition is a grave one and demands immediate treatment. When generalized vascular disease—i.e., heart failure or severe degenerative disease of the major vessels—exists, management may be best exercised by inserting tubes into the intestine and leaving them there; these relieve the distended segments of gas and fluid. Otherwise, the pressure is relieved by surgical treatment, and the offending segment or tumour is removed when possible.

Malabsorption occurs because the small intestine is unable to carry out its specialized functions of transporting properly prepared digestive materials from the lumen of the bowel into the lymphatics or mesenteric veins, from which they are distributed to the rest of the body. Such defects in transport occur either because the intestinal absorptive cells lack certain enzymes, whether by birth defect or by acquired disease, or because they are hindered in their work by other disease processes that infiltrate the tissues, disturb motility, permit bacteria to overpopulate the bowel, or block the pathways over which transport normally proceeds. A special case is that of inadequate bowel surface due to surgical resection, an increasingly common problem as life is maintained longer in persons with degenerative diseases.

#### THE LARGE INTESTINE

The function of the large intestine, or colon, is to transport the fluid contents it receives from the small intestine, while dehydrating them sufficiently to permit

Disturb-  
ances of  
motility

the passage of solid feces under controlled conditions. The proximal, or right, side of the colon is peculiarly fitted to carry out this absorptive function, during which sodium is reabsorbed, potassium and bicarbonate are secreted into the lumen, and about 400–500 millilitres (about a pint) of water is withdrawn.

Disturbance of motor and absorptive function is produced by a number of conditions involving the large intestine. Imperfect fetal development may result in an anus that has no opening; this defect may require major plastic surgery to correct. Abnormal rotation of the colon is fairly frequent, and may lead to no, or to serious, disorders. Long mesenteries supporting the cecum (right-sided tip of the colon) or the sigmoid colon (that section of colon just above the rectum) may permit recurrent twisting, which affects the blood supply to the involved loop, and the loop may itself be completely obstructed by the rotation. Such difficulties are usually seen in elderly patients and particularly in those with a long history of constipation.

A disease which has some analogy with achalasia of the esophagus is idiopathic (cause unknown) aganglionic megacolon, or Hirschsprung's disease. In this condition there is defective neuromuscular transmission in the Auerbach's plexus of autonomic nerves, usually only in the lower segment of the bowel, but occasionally involving most, or even all, of the organ. In areas thus poorly innervated, peristaltic waves do not progress, and a "functional obstruction" occurs. The area of normal bowel above the obstruction tries harder to push the fecal contents distally, and eventually thickening of the muscle of the normal segments occurs. The entire colon thus slowly becomes more and more distended and thick-walled. This kind of colonic obstruction must be differentiated by X-ray from "acquired megacolon," usually a psychiatric problem due to inhibition of defecation. In the latter there is no obstructed segment of colon but only a hugely dilated upper rectum and a tight anus. Various surgical procedures have been devised to help patients with Hirschsprung's disease. Psychiatric measures usually can completely relieve acquired megacolon.

Arteries penetrate the muscular walls of the colon from its outside covering, the serosa, and distribute themselves in the submucosa. The channels in which these arteries lie may be regarded as potential hernia tunnels. With aging, and perhaps in predisposed persons, these channels become larger. If the peristaltic activity of the colon maintains a high pressure within its lumen, as in patients straining at stool, the mucous membrane of the colon may slowly be driven into these channels and eventually follow the arteries back to their site of colonic entrance in the serosa. At such time the outward-pushing mucosa will become a budding sac, or diverticulum, on the antimesenteric border of the colon but with a connection to the lumen. In the Western world (but not in the Orient) multiple colonic diverticula occur in as many as 30 percent of the over-50 population. In the presence of the irritable colon syndrome a different form of diverticulosis is seen accompanied by a peculiar hypertrophy of colonic muscle. Diverticulosis is common in populations consuming a low-roughage diet, and rare in those with a high-roughage intake.

The principal dangers of diverticulosis are massive hemorrhage and inflammation (diverticulitis). Hemorrhage results from trauma of hard stools against those small arteries of the colon which are exposed and have lost their support due to diverticula. As the arteries age, they become less elastic, less able to contract after bleeding begins, and more susceptible to damage. Diverticulitis, on the other hand, occurs because the narrow necks of the diverticula may become plugged with debris or inedible foodstuff, and bacterial proliferation in the blind sacs proceeds uninhibited by the usual motor activity that keeps the bowel clean. When such abscesses enlarge, the bowel wall next to them becomes inflamed and irritable, muscle spasm occurs, and the patient has abdominal pain and fever. If the abscesses continue to enlarge they may rupture freely into the peritoneum, giv-

ing rise to peritonitis. More commonly they fix themselves to neighbouring organs and produce localized abscesses, which may prove very difficult to handle surgically. Mild diverticulitis responds well to conservative measures and to antibiotics; massive hemorrhage often requires emergency surgery; recurrent diverticulitis now is thought to warrant resection.

The colon may become inflamed because of invasion by pathogenic bacteria or parasites. A variety of species of *Shigella*, for example, attack the mucous membrane of the colon producing a very intense but rather superficial hemorrhagic response. In infants and in the elderly the amount of fluid and protein lost by the intense inflammatory response may be fatal, but ordinarily such symptoms are readily survived by otherwise healthy persons. *Salmonella* species, responsible for severe generalized infections originating from invasion of the small intestine, may cause damage in the lymph follicles of the colon but do not produce a diffuse colitis. The virus of lymphopathia venereum, on the other hand, can cause a diffuse superficial colitis. The most important parasite invading the colon and producing human disease there is the protozoan *Endamoeba histolytica*. This widely distributed parasite enters via the mouth and ordinarily lodges in the cecum and ascending colon of man. This usually results in irritability of the right colon and failure to absorb water properly, so that intermittent watery diarrhea ensues. The amoebae undermine the mucosal coat and may create large ulcerations that bleed impressively. Thus the stools contain blood, often much blood, but there is little pus or other evidence of reaction by the colon to the invading organism. In more generalized amoebic colitis, the rectum and sigmoid colon become invaded, and on direct visualization through the sigmoidoscope manifest their presence by numerous discrete ulcerations separated from each other by relatively normal-appearing mucous membrane. After identification of the parasites by direct smears from the margins of the ulcers, or from the stools, treatment with a combination of amoebicidal drugs plus a broad-spectrum antibiotic is carried out.

The colon can become the site of diffuse inflammation in which no invading organisms can be identified as causal. When this inflammation is confined to the mucosa and submucosa, the mucous membrane becoming diffusely reddened and bleeding at the slightest touch of a cotton swab, the term ulcerative colitis, either acute or chronic, is used to describe it. If the reaction is a proliferative one, the wall of the colon becoming thickened and all coats of the wall inflamed, the mucosa least of all, the term Crohn's disease of the colon is applied. These two diseases are not common but are disabling. As there is no specific etiology, a combination of anti-inflammatory drugs and other approaches to the patient must be used to help him over the worst episodes. Often it is necessary to resort to surgical techniques for partial or complete removal of the diseased bowel. The entire colon can be removed, and the small intestine brought out to the skin as an ileostomy, an opening to serve as a substitute for the anus, with generally acceptable results. When ulcerative colitis occurs in children, a high incidence of cancer of the colon is noted. In adults this relationship is less striking although still present.

Chronic overusage of laxatives can also produce mild inflammatory changes in the colon. Persons who have had constipation for many years often have elongated colons, occasionally with the mucous membrane bearing dark brown to black pigmentary deposits (melanosis coli), which have no pathological significance.

Tumours of the colon are usually polyps or cancers. The tendency of some persons to form polyps is nowhere more strikingly exemplified than in the rare disorder known as congenital polyposis, in which the colon may be studded with hundreds or thousands of small polyps. The kind of colon that can produce so many polyps eventually produces cancers as well; therefore, these patients should have their colons removed surgically as soon as the diagnosis is made. Another peculiar form

Infections  
of the  
colon

Diverticu-  
losis and  
diverticuli-  
tis

of polyp is the villous adenoma, often a slowly growing, fern-like structure that spreads along the surface for some distance. It possesses the potential for local recurrence after being locally resected, or it may develop into a full-blown cancer. Cancer of the colon is in the Western world a more common tumour than is cancer of the stomach, and it occurs in both sexes about equally. Symptoms are highly variable, the main unifying feature being blood in the stools, but this may be only detectable by chemical testing. Cancers compress the colonic lumen to produce obstruction, they attach to neighbouring structures to produce pain, and they perforate to give rise to peritonitis. They also may metastasize to distant organs before causing local symptoms. Nevertheless, the outlook for patients with this tumour is considerably better than is the case with cancer of the stomach. About half the patients who have colonic cancer removed surgically will live at least five years. Some patients must have colostomy, an opening from the colon to the skin, but this is usually easily managed.

Anorectal problems

Problems related to defecation are more common in the Western world than elsewhere. Whether this distribution is related to diet, exercise, or to social customs inhibiting the natural gratification of the defecation urge is not clear. In any case, anal problems plague Western persons from childhood on. These usually take the form of fissures—cuts or cracks in the skin or mucous membrane at the junction of the anal mucous membrane with the skin between the thighs. Sometimes these fissures become chronically infected and resistant to simple sitz baths and local medication. Under such circumstances they require surgical correction. Anal fistulas occur sometimes as complications of serious bowel disease, as in tuberculosis or Crohn's disease of the bowel, or in certain parasitic diseases. This complication requires surgical treatment. A more general form of disturbance is the enlargement of veins of the rectum and anus. The dilated veins become either external or internal hemorrhoids, or both. Probably half the adult population in the West have such venous enlargement, but only a small number of persons suffer significant symptoms from their presence. Hemorrhoids protrude, are associated with anal itching and pain, and they bleed, especially when in contact with hard stools. Most of the time these symptoms can be controlled by conservative measures, but occasionally they persist or cause so much acute distress that surgical removal of the enlarged and dilated veins is necessary.

In the past, poor obstetrical and postnatal care resulted in severe loss of support of the pelvic floor in parturient women, and prolapse of the rectum, as well as of the uterus and bladder, was common. Present day obstetrical practice has largely eliminated such complications; rectal prolapse is still seen in conditions such as fibrocystic disease of the pancreas in children or in aged persons with certain neurological disorders.

Abscesses in the perianal area, complicating any of the above conditions, are common. Hygiene is difficult to maintain in the elderly, the obese, or the feeble confined to chairs and bed. Careful control of skin bacteria and avoidance of trauma to the perineum are difficult to assure even under optimal conditions. Fungous infections of this moist and poorly cleansed area are common, permitting maceration of tissue and invasion by skin and colonic bacteria. In the diabetic patient, who is so susceptible to skin infection, scrupulous perianal hygiene is of great importance.

Primary cancer of the anus is fortunately a rare disease. Chronic involvement of perianal skin by the wart-like lesions of syphilis or the scarring of the venereal disease lymphopathia venereum are well-known but less frequent than formerly. Crohn's disease of the colon and intestine has a predilection for producing anal involvement with stricture.

#### THE DIGESTIVE GLANDS

The salivary glands contribute their secretions to mix with the food being masticated. Consequently, any inter-

ference with their function by inflammation, tumour, or calculous obstruction will lessen the amount of secretion available. The patient may have a dry mouth, swelling of one of the glands, or pain in the region of the duct and the gland supplying it. The virus disease, epidemic parotitis, or mumps, involves one or both parotids. The other glands are more often inflamed because a small stone has become impacted in the orifice of the secretory duct, and the resultant stasis may have allowed bacteria to proliferate in the stagnant stream. Thus abscesses in the blocked duct-gland system are common under these conditions and must be surgically repaired. The parotid glands, the salivary glands below and in front of the ears, which are very active in the synthesis of enzymes, are also subject to peculiar enlargement or swelling in the presence of severe malnutrition and other debilitating diseases, especially sarcoidosis, a chronic inflammatory disease of unknown cause. A disorder of connective tissue metabolism known as Sjogren's syndrome is associated with generalized dryness of the mouth as a result of involvement of these glands.

The salivary glands are also subject to neoplastic changes. The commonest tumour, the mixed tumour of the parotid, is a relatively slow-growing malignancy that produces a very hard swelling at the angle of the jaw below the ear. Various lymphomas may also invade the parotid and submandibular glands; in leukemias more than one gland may be infiltrated.

The liver is the largest single gland in the body, accounting for one-fortieth the body weight. The interaction between gut and liver is an important bodily regulatory function, and diseases in either organ can affect the function of the other. Disease processes involving the gut can cause the leakage of such quantities of protein into its lumen that the liver's synthetic abilities for making albumin are exceeded, leading to a generalized deficiency in this circulating plasma protein. Primary inflammations of the liver are often preceded by a period of nausea, diarrhea, and abdominal discomfort. Both acute and chronic inflammations of the liver result in a defective output of bile, leading to poor absorption of fat from the gut, and the appearance of excessive fat in the stools. Stools become light in colour if bile is prevented from entering the duodenum either because of liver disease or of blocks in the biliary ducts. Primary infections of the intestinal tract can permit their causative agents to get into the portal blood flow and travel to the liver, where they set up habitation and produce abscesses and various reactive processes. The commonest examples of this are the amoebic abscess of the liver and the purulent liver abscess secondary to appendicitis or diverticulitis. Cancers of the stomach, pancreas, and colon ultimately metastasize to the liver, which they enlarge and often make tender and painful. A consequence of chronic liver disease, as in cirrhosis, is an obstruction to the inflow from the veins draining the intestines. This leads to enlargement of these veins and of the spleen; the most serious complication of this process is rupture of veins into the stomach or esophagus, producing usually severe blood loss, with vomiting of blood and the passage of black or bloody stools (see also LIVER, HUMAN).

The gallbladder in the human is so frequently removed because of disease that ample proof of its dispensability is available. The principal factors underlying gallbladder disease in man are concerned with the results of the concentration of the bile that takes place in the gallbladder. The bile contains in an aqueous medium a number of substances that are difficult to keep water-soluble. These include cholesterol, lecithin, and bile salts. The proper combination of these three entities is importantly concerned with rendering cholesterol soluble as it flows from the liver to the gallbladder and down the common bile duct. Disturbance in the ratio of cholesterol to bile salts plus lecithin may permit cholesterol to precipitate. The cholesterol concentration in bile may rise, as seems to happen in late pregnancy, or the liver may not be

Liver diseases

Diseases of the gallbladder and bile ducts

able to manufacture sufficient bile salts or lecithin. Since the gallbladder usually empties after every meal, and perhaps more often, very small imbalances of this type may, over the years, lead to the slow deposition of cholesterol in the wall of the gallbladder and impair its function. Small amounts of precipitated cholesterol plus other materials probably underlie the formation of the cholesterol-calcium gallstones seen in human gallbladder disease. The disease occurs much more frequently in women than in men, but by age 70 its incidence in both sexes exceeds 15–20 percent in Western populations. The other main type of gallstone, the bilirubin stone, is unrelated to this process, being rather the product of excessive breakdown of hemoglobin, and most often related to hemolytic diseases.

In any case, the formation of gallstones, cholelithiasis, is related both to inflammation of the gallbladder, cholecystitis, and to the presence of gallstones in the common bile duct, choledocholithiasis. Acute cholecystitis can be a severe abdominal catastrophe, with gangrene and rupture of the gallbladder, or it can be a mild chronic problem diagnosed by recurrent episodes of discomfort under the right portion of the lower ribs. Gallstones, if small, can be pushed by contraction of the wall of the gallbladder into the conical neck of the organ, where they may become impacted. The gallbladder then is obliged to contract forcibly against an obstruction; this produces pain of recurrent or colicky type, often accompanied by vomiting. The pain is frequently referred to the back near the lower tip of the shoulder blades and occasionally to the tip of the right shoulder. The gallbladder may become chronically enlarged if the obstruction continues; this is called hydrops of the gallbladder if the contents of the organ remain uninfected; when infected, empyema of the gallbladder is produced, and usually fever and chills accompany the finding of the enlarged organ. In general, the treatment of these complications is entirely surgical.

Should the gallstones leave the gallbladder, they may become impacted at the lowest portion of the common bile duct in what is called its ampulla. This area occurs at the junction of the duct with the medial wall of the descending, or second, portion of the duodenum, near the entrance of the principal duct from the pancreas. A stone impacted in this narrow opening may completely or incompletely obstruct the flow of bile from the liver, producing jaundice, often with itching and chills. The liver may be unable to secrete the bile against the obstructing pressure, and the jaundice may rapidly increase. On the other hand, the stone may crack or disintegrate and be passed from the common duct into the duodenum, the bile flow resume, and the jaundice disappear over a period of a week or so. Proper diagnosis of this chain of events depends upon clinical observation, certain liver function tests, and radiologic demonstration of the gallbladder and the ducts.

Long-standing obstruction may result in scarring of the ducts or strictures. Sometimes the surgical intervention—necessary to remove the gallbladder or the offending gallstones—may lead to scarring and stricture. Strictures, or narrowed portions of these hollow tubes, present opportunities for more obstruction, either by newly formed gallstones or by inflammatory exudate and mucus. The strictures may require surgical correction. Administered antibiotics of many kinds are concentrated by the liver and excreted in the bile, so that serious infections in this area are not the problem they once were.

**Tumours** of the gallbladder and of the bile ducts are serious but infrequent problems. Cancer of the gallbladder occurs almost entirely in persons who suffered from cholecystitis and is more common in women than in men. It is hard to diagnose and its surgical treatment is not very satisfactory. Primary cancer of the bile ducts makes itself known by producing jaundice relatively early. Since it tends to be a slowly growing tumour, reasonably favourable results may be anticipated from surgical and radiation treatment.

The pancreas, a flat structure lying across the back of

the peritoneal cavity, secretes enzymes of digestive importance that are very powerful. Their liberation in areas outside the gastrointestinal tract may lead to serious destruction of normal tissue. Thus diseases of the pancreas may either deprive the intestinal lumen of enzymes needed to digest food properly, or may liberate them into the blood or peritoneal cavity, where they may digest normal fat and protein structures. Most importantly, inflammation within the substance of the pancreas itself may allow activated enzymes to attack the blood vessels of the organ, with the consequent production of hemorrhage into the substance of the gland.

The various possibilities are included within the concepts of pancreatitis, which may also be mild with swelling of the gland and none of the hemorrhagic or widespread destruction noted above. Attacks of edematous pancreatitis, often associated with gallbladder disease or acute alcoholic excesses, produce abdominal pain, fever, nausea, vomiting, and sometimes mild diabetic features. In acute hemorrhagic pancreatitis there is acute pain, shock, and hemorrhage within the gland. It is often fatal, since it occurs principally in persons with underlying vascular or renal disease. In alcoholic subjects repeated attacks of mild to severe nonhemorrhagic pancreatitis are associated with a chronic deterioration of pancreatic function. Sometimes the gland becomes laden with calcium deposits, sometimes a permanent diabetic state is produced, and sometimes the reduction of digestive enzymes produces a serious loss of nutrients in the frequent loose stools passed by such persons. Diagnosis of these various disorders is made by utilizing the clinical signs and symptoms, employing certain laboratory tests for pancreatic enzymes in the blood and duodenal juices, and by chemical analysis of the stools, which characteristically show increased amounts of unabsorbed fats and proteins. X-ray examination of the stomach and duodenum may also be helpful. The pancreas lies behind the stomach and is bounded by the duodenum; thus disturbance in its shape or configuration may be reflected by pressure on these neighbouring structures.

Although most cases of pancreatitis are the consequence of poorly understood metabolic derangements, direct trauma to the organ occasionally occurs, and may produce an inflammatory pancreatitis. In addition, several familial forms of the disease have occurred. An entirely different disorder of this organ is that associated with **mu**-covicidosis, a generalized disorder of the exocrine glands, that is, glands with ducts such as the mucous and sweat glands. This disease, also known as fibrocystic disease of the pancreas, occurs in infants and children in an inherited pattern characterized as autosomal recessive. As such, it is the most frequent lethal genetic disorder among the non-Negroid populations of the world. The secretions of the pancreas become thickened and plug the pancreatic ducts, leading to destruction of the organ. Similar processes cause chronic lung disease, with the bronchial lumina obstructed and then dilated behind the obstruction. Inability to control the loss of salt in the sweat leads to death in hot weather. Diagnosis in children is made by measuring the high concentrations of sodium and chloride in the sweat, and by demonstrating absence or great reduction in the amount of pancreatic enzymes in the duodenal juice.

Treatment of acute inflammatory diseases of the pancreas is principally supportive. Occasionally surgical intervention is necessary to drain blood clots or abscesses, or to remove diseased gallbladders when they coexist. Chronic pancreatitis is treated by trying to persuade the patients to discontinue alcohol consumption. There are available very good preparations of concentrated pancreatic enzymes, which can be fed to patients with poor enzyme output; such treatment can partially replace the deficiencies, make the patient eat better, and decrease the loss of foodstuffs into the stools.

**Fibrocystic** disease is treated with pancreatic replacement substances, with antibiotics for the pulmonary disease, and with various techniques for mechanically improving lung ventilation. The outlook is still poor for sur-

Diseases of  
the  
pancreas

vival, although now fewer children are dying of the disease at very early ages.

Cancer of the pancreas is one of the most rapidly increasing cancers in the U.S., having reached the same incidence as cancer of the stomach. The reasons for this are not clear, but there seems to be some association with better nutrition, or perhaps affluence, in the populations subject to the disease. On the other hand, cancers of all the digestive glands are thought to be more common in Africa, possibly as a result of protein deficiency in childhood.

**BIBLIOGRAPHY.** H.L. BOCKUS *et al.*, *Gastroenterology*, 2nd ed., 3 vol. (1963–65), a comprehensive and well-illustrated textbook with emphasis on diagnostic methods and treatment; M. PAULSON (ed.), *Gastroenterologic Medicine* (1969), deals comprehensively but not systematically with digestive diseases approached from a variety of disciplines; F.A. JONES *et al.*, *Clinical Gastroenterology*, 2nd ed. (1968), a shorter, easy-to-read textbook that covers all the important disease entities and is critical in its approach to diagnosis and therapy.

## Dilthey, Wilhelm

Wilhelm Dilthey was a German philosopher of the late 19th and early 20th century whose chief contribution to philosophy was the development of a distinct methodology for the humanities. He objected to the pervasive influence of the natural sciences and developed a philosophy of life that perceived man in his historicity; *i.e.*, in his historical contingency and changeability. Dilthey established a comprehensive treatment of history from the cultural viewpoint that has been of great consequence, particularly to the study of literature.

Dilthey was born on November 19, 1833, in Biebrich on the Rhine, the son of a Reformed Church theologian. After he finished grammar school in Wiesbaden, he began to study theology, first at Heidelberg, then at Berlin, where he soon transferred to philosophy. After completing exams in theology and philosophy, he taught for some time at secondary schools in Berlin but soon abandoned this to dedicate himself fully to scholarly endeavours.

Archiv für Kunst und Geschichte

Dilthey, oil painting by R. Lepsius, c. 1904. in a private collection.

During these years he was bursting with energy, and his investigations led him into diverse directions. In addition to extensive studies on the history of early Christianity and on the history of philosophy and literature, he had a strong interest in music, and he was eager to absorb everything that was being discovered in the unfolding empirical sciences of man: sociology and ethnology, psychology and physiology. Hundreds of reviews and essays testify to an almost inexhaustible productivity.

In 1864 he took his doctorate at Berlin and obtained the right to lecture. He was appointed to a chair at the University of Basel in 1866; appointments to Kiel, in 1868,

and Breslau, in 1871, followed. In 1882 he succeeded R.H. Lotze at the University of Berlin, where he spent the remainder of his life.

During these years Dilthey led the quiet life of a scholar, devoid of great external excitement and in total dedication to his work. He searched for the philosophical foundation of what he first and rather vaguely summarized as the "sciences of man, of society, and the state," which he later called *Geisteswissenschaften* ("human sciences")—a term that eventually gained general recognition. In 1883, as a result of these studies, the first volume of his *Einleitung in die Geisteswissenschaften* ("Introduction to Human Sciences") appeared. The second volume, on which he worked continually, never did appear. This introductory work yielded a series of important essays; one of these—his "Ideen über eine beschreibende und zergliedernde Psychologie" (1894; "Ideas Concerning a Descriptive and Analytical Psychology")—instigated the formation of a cognitive (*Verstehen*), or structural, psychology. During the last years of his life, Dilthey resumed this work on a new level in his treatise *Der Aufbau der geschichtlichen Welt in den Geisteswissenschaften* (1910; "The Structure of the Historical World in the Human Sciences"), which was also left unfinished.

Opposed to the trend in the historical sciences to approximate the methodological ideal of the natural sciences, Dilthey tried to establish the humanities as interpretative sciences in their own right. He considered as fundamental to this notion the interaction among personal experience (*Erleben*), its realization in creative expression, and the reflective understanding of this experience. He did not view the individual as isolated but always in the context of his environment. He emphasized that the essence of man cannot be grasped by introspection but only from a knowledge of all of history; this understanding, however, can never be final because history itself never is: "The prototype 'man' disintegrates during the process of history." For this reason, his philosophical works were closely connected to his historical studies. From these works later arose the encompassing scheme of his *Studien zur Geschichte des deutschen Geistes* ("Studies Concerning the History of the German Mind"); the notes for this work make up a complete coherent manuscript, but only parts have been published.

Dilthey did not have the ability for definitive formulation; he was suspicious of rationally constructed systems and preferred to leave questions unsettled, realizing that they involved complexity. For a long time, therefore, he was regarded primarily as a sensitive cultural historian who lacked the power of systematic thought. Only posthumously, through the editorial and interpretative work of his disciples, did the significance of the methodology of his historical philosophy of life emerge. Dilthey died on October 1, 1911, in Seis on the Schlern.

It is difficult to assess Dilthey the man. Even his more intimate disciples confessed to have known very little of his deeper feelings. Only the few invited to collaborate in his later years became somewhat familiar with him. They shared almost his entire day, reading to him, taking dictation, even drafting complete passages for him. They learned while being involved in various aspects of his work. And yet, each one perceived only one facet; nobody had full comprehension of the whole. Even to them, Dilthey remained the "strange mysterious old man."

**BIBLIOGRAPHY.** A detailed biography is lacking, although HANS-HERMANN GROTHOFF and ULRICH HERRMANN, "Wilhelm Dilthey: Persönlichkeit und Werk," in *Die Pädagogik Wilhelm Diltheys*, pp. 334–365 (1971), is a carefully executed recent work. A complete bibliography appears in ULRICH HERRMANN, *Ribliographie Wilhelm Dilthey* (1969). Dilthey's works are collected in his *Gesammelte Schriften*, 16 vol. (1923–72), with more volumes in preparation. Works on Dilthey in English include HERBERT ARTHUR HODGES, *Wilhelm Dilthey: An Introduction* (1944, reprinted 1969), with translations of selected excerpts; and *The Philosophy of Wilhelm Dilthey* (1952); and H. PETER RICKMAN, *Meaning in History: Wilhelm Dilthey's Thoughts on History and Society* (1961), which contains a general introduction and selected writings.

## Diocletian

Diocletian, Roman emperor from AD 284 to 305, restored efficient government to the empire after the near anarchy of the 3rd century. His reorganization of the fiscal, administrative, and military machinery of the empire laid the foundation for the Byzantine Empire in the East and temporarily shored up the decaying empire in the West. His reign is also noted for the last great persecution of the Christians.

Allinari

Diocletian, bust in the Capitoline Museum, Rome.

Diocletian's biography has been obscured by legends, rhetoric, the dubiousness of documents, and the hostility of his adversaries. He died at the age of 68 in his villa at Saloniae in Dalmatia in AD 313 or 316. As he is said to have died "after having returned to his homeland," it is possible he was born in that town in 245 or 248; little is known of his origins. His father was a scribe or the emancipated slave of a senator called Anullinus. Diocletian's complete name, found in official inscriptions, is given as Gaius Aurelius Valerius Diocletianus. He received the name Diocles first, then the name Valerius, after the name of his daughter, Valeria, who married Galerius in 293. The gens name Aurelius did not appear until March 1, 286; that is, until after his accession. Nothing is known of his wife Prisca other than what the contemporary Latin Christian writer Lactantius Firmianus says in his *De mortibus persecutorum*, which is of debatable veracity. Diocles, having adopted the name Diocletianus, entered history like so many of those emperors who emerged from the shadows through force of arms, brought to power by the army. The little that is known of his appearance is based on coin effigies and on sculptures. From these it appears that he was tall and thin, with a large forehead, a short, strong nose, a hard mouth, and a determined chin.

**Rise to power.** Up to the time of his accession, Diocletian had lived most of his life in military camps. These may have been either in Gaul, as reported in the *Historia Augusta*, or in Moesia. Or he may have been a member of the Roman emperor Carinus' bodyguard. The only definite fact known about Diocletian during this period is that he was among those army chiefs whom Carinus gathered, together with the Illyrians, to fight against the Persians. In 284, during that campaign, Numerian, Carinus' brother and co-emperor, was found dead in his litter, and his adoptive father, the praetorian prefect Aper, was accused of having killed him in order to seize power. When Diocletian, acclaimed as emperor by his soldiers, appeared for the first time in public dressed in the imperial purple, he declared himself innocent of Numerian's murder. He designated Aper as the criminal and killed him personally. Here again, rhetoric has ob-

scured the real events. Aper's guilt was accepted by contemporaries, but it was also true that a prediction had been made to Diocletian previously, telling him that he would become emperor on the day he killed a boar (Latin *aper*). And it was true, too, that he did not wish to wait much longer for the boar to come. In reality, Numerian had died either a natural death or from a stroke of lightning. By eliminating Aper, however, Diocletian rid himself of an eventual competitor and, retroactively, provided his act with sacred meaning.

Acclaimed emperor on November 17, 284, Diocletian had real power only in those countries dominated by his army (*i.e.*, in Asia Minor and possibly Syria). The rest of the empire was obedient to Numerian's brother, Carinus. After having put down a revolt by Julianus, a troop commander in Pannonia, whom he attacked and killed near Verona, Carinus next attacked Diocletian. An indecisive battle near the confluence of the Margus (modern Morava) and Danube rivers, not far from present-day Belgrade, would have been a defeat for Diocletian had Carinus not been assassinated by a group of soldiers. Thus, in midsummer of 285, Diocletian became master of the empire.

**Reorganization of the empire.** At the beginning of 286 Diocletian was in Nicomedia. In the interim, he and his lieutenants had calmed the stirrings of revolt among Roman troops stationed on the frontiers. From that point on, he dedicated himself to restoring civil order to the empire by removing the army from politics.

Although he came from the army's ranks, Diocletian was not, properly speaking, a soldier. He had scarcely come to power when he made an unexpected decision—to share the throne with a colleague of his choice. The empire was too great for one man to administer; nearly every week, either in Africa, or somewhere on the frontier that extended from Britain to the Persian Gulf, along the Rhine, the Danube, the Pontus Euxinus (Black Sea), and the Euphrates, he was forced to suppress a revolt or stop an invasion. Diocletian, who was more attracted to administration, required a man who was both a soldier and a faithful companion to take responsibility for military defense. In 286 he chose Maximian, an Illyrian, the son of a peasant from the area around Sirmium. A little later, though still keeping Rome as the official capital, he chose two other residences. Maximian, who was responsible for the West, was installed at Milan in northern Italy, in order to prevent German invasions. Diocletian established himself at Nicomedia, in western Anatolia, and close to the Persian frontier in order to keep watch on the East. Six years later, in 293, having taken the title of "Augustus" and given it to Maximian as well, he added two more colleagues: Galerius, a former herdsman, and Constantius I Chlorus, a Dardanian nobleman according to the legend of his house, but a rather rude countryman also. These additional collaborators were each given the title "Caesar" and attached to an Augustus. Constantius to Maximian (with a residence in Trier), and Galerius to Diocletian himself (with a residence in Sirmium). Thus, while the empire remained a *patrimonium indivisum* (undivided inheritance), it was nevertheless divided administratively: Diocletian, residing in Nicomedia, watched over Thrace, Asia, and Egypt; Galerius, residing in Sirmium, watched over Illyria, the Danubian provinces, and Achaia; Maximian, residing in Milan, over Italy, Sicily, and Africa; and Constantius I Chlorus, residing in Trier, over Gaul, Spain, and Britain. In order to strengthen the union of the colleagues, each Augustus adopted his Caesar. The relationships were further cemented when Galerius married Valeria, Diocletian's daughter, and Constantius I Chlorus repudiated his wife Helena, mother of the future emperor Constantine, in order to marry Theodora, Maximian's stepdaughter. The Empire now had four masters, celebrated by the authors of the *Historia Augusta* (a collection of biographies of Roman emperors and caesars, published in the 17th century) as the *quattuor principes mundi* ("four princes of the world"), and Diocletian consecrated this human unity by forming a religious bond. Because he believed that he had come to power through divine will, as revealed by the "fateful"

Division of responsibility

Personal appearance

boar, he regarded himself and Maximian as "sons of gods and creators of gods." After 287, he called himself Jovius (Jove) and Maximian was named Herculus (Hercules), signifying that they had been chosen by the gods and predestined as participants in the divine nature. Thus, they were charged with distributing the benefits of Providence, Diocletian through divine wisdom, and Maximian through heroic energy. Later designated as *dominus* et deus on coins and inscriptions, Diocletian surrounded himself with pomp and ceremony and regularly manifested his autocratic will. Under Diocletian, the empire took on the aspects of a theocracy.

#### Frontier revolts

Diocletian's reforms were successful; they put an end to domestic anarchy, and elsewhere they allowed Maximian to defeat the revolt in Gaul of the Bagaudae, bands of peasants who found the tribute oppressive. Then, with peace scarcely restored after a campaign against the Germans, Maximian had to battle Carausius, who, having fought for the empire in Britain against the Frankish and Saxon pirates, revolted and named himself emperor in Britain in 287. Carausius reigned in Britain for nearly ten years until Constantius I Chlorus succeeded in returning Britain to the empire in 296. Scarcely had troubles in Mauretania and in the Danubian regions been settled when Egypt declared itself independent under the usurper Achilleus. Diocletian reconquered the country in 296. Finally, in 297, he had to fight Narses, king of Persia, who had invaded Syria. Since he was still occupied in Egypt, he assigned this operation to Galerius, who, after a protracted campaign, finally won victory for the Romans. Tiridates, the king of Armenia and a protégé of the Romans, was able to return to his throne; the Tigris became the eastern border of the empire; and peace reigned in that part of the world until the reign of Constantine I (306–337).

**Domestic reforms.** Perhaps more important for the maintenance of the empire was Diocletian's program of domestic reform. He was not a complete innovator in this area, for his predecessors had made some tentative attempts in the same direction; the emperor Gallienus had excluded senators from the army and separated military from civil careers. The Senate had progressively been deprived of its privileges. Diocletian, however, systematized these arrangements in such a way that all his reforms led toward a kind of centralized and absolute monarchy that put effective means of action at his disposal. Thus, Diocletian designated the consuls; the senators no longer collaborated in the making of laws; the imperial counsellors (*consilia sacra*) were distributed among specialized offices, and their functions were strictly defined so that the power of the praetorian prefects (personal bodyguards to the emperor) was limited; the specialization of administrative work grew; and the number of bureaucrats increased. This was the beginning of the bureaucracy and technocracy that was eventually to overrun modern societies.

Such organization made it possible for administration to rely less on individual human beings and more on the application of legal texts. In fact, it was during Diocletian's reign that the Gregorian and Hermogenian codes, of which only fragments remain, were rewritten. But 1,200 extant rescripts show another aspect of the emperor's personality. A conservative, Diocletian was concerned with the preservation of the ancient virtues: the obligation of children to feed their parents in old age; of parents to treat their children justly; for spouses to respect the laws of marriage; for sons not to bear witness against their fathers, or slaves against their masters; and for private property, creditor's rights, and contract clauses to be protected. He forbade the use of torture if truth could be discovered otherwise and encouraged governors to be as autonomous as possible.

The army was also reorganized and brought back to the old discipline. Sedentary troops (local troops) were sent to the frontiers, and the ready army (main movable army) was made domestic. Troop strength was increased by a fourth, not multiplied by four as Lactantius claims. Here again, Diocletian's reforms were infused with a sense of human realities; he exempted soldiers from duty

after 20 years of service, and if he limited the price of commodities so as to reduce the cost of living, it was mainly to make life easier for the troops. If one is to believe Lactantius, Diocletian divided the provinces "so as to make himself more feared," but in fact it was to bring the governors closer to those they administered and, by fragmenting their power, to diminish their territorial strength. He undertook to facilitate economic development through a recovery of agriculture and a program of building.

Such policies were expensive, as were wars and the legacy of an unstable financial situation. Diocletian's fiscal solutions are still debated; they constitute a very difficult problem. Two new taxes were instituted, the *jugum* and the *capitatio*, the former being the tax on a unit of cultivable land, the latter, a tax on individuals. Taxes were levied on a proportional basis, the amount of the contribution being determined by the productivity and type of cultivation. As a rule, it was a sort of socioeconomic taxation based on the linkage between man and land in terms of either ownership or productivity. Assessments were made every five years; later, the system was consolidated into a cycle of 15 years called an *indictio*. This census of taxable adults gave rise to violent criticisms but had the theoretical advantage of replacing the arbitrary levies of the previous era. To be sure, the financial system was subject to excesses; but Diocletian's purpose was to obtain funds, and he did not even spare Italy, which had until then been free of land taxation.

This reform was accompanied by a monetary reform, including restoration of a sound gold and silver coinage of fixed design, creation of a new bronze coin, circulation of small coins to facilitate daily financial exchange, decentralization of minting, and an increase in the number of mints from eight to 15.

All of these measures tended to stave off financial crises. The famous edict *De Maximis Pretiis* was issued in AD 301, fixing wages and establishing maximum prices, so as to prevent inflation, abusive profits, and the exploitation of buyers. About 1,000 articles were enumerated, and violation was punishable by death; severe penalties were exacted of black marketeers. But even so, this regulation of prices and wages was not enforceable, and the edict was later revoked.

**Persecution of Christians.** The end of the reign was darkened by the last major persecution of the Christians. The reasons for this persecution are uncertain, but various explanations have been advanced: the possible influence of Galerius, a fanatic follower of the traditional Roman religion; the desire to restore complete unity, without tolerance of a foreign cult that was seen as separatist and of men who were forming a kind of state within the state; the influence of anti-Christian philosophers such as Porphyry and governors such as Hierocles on the scholarly class and on the imperial court; the fear of an alienation of rebellious armies from emperor worship; or perhaps the disturbances provoked by the Christians themselves, who were agitated by doctrinal controversies. At any rate, some or all of these factors led Diocletian to publish the four edicts of 303–304, promising all the while that he would not spill blood. His vow went unheeded, however, and the persecutions spread through the empire with an extreme violence that did not succeed in annihilating Christianity but caused the faith of the martyrs to blaze forth instead.

**Retirement.** Diocletian had aged prematurely through illness. Perhaps he decided that, after 20 years of reign, his abdication was also "fateful." Of his own volition he decided to entrust the affairs of the empire to younger men and returned first to Nicomedia, then to the neighbourhood of Salona, on the edge of the Adriatic, where he had a magnificent palace built (the modern town of Split, in Yugoslavia, occupies the site of its ruins). He abdicated May 1, 305, and his death occurred almost unnoticed.

Diocletian had reorganized the empire without political romanticism. His reforms had not proceeded from a premeditated plan but had imposed themselves out of historical necessity. He may be accused of several things: of

Tax reform

Freezing of wages and prices

having been cruel, but his harshness was not the act of deep-seated brutality; of being miserly, but this miserliness was inspired by the desire to obtain resources for the state; of cutting a slightly muddle-headed, visionary figure, but these were the traits that led him to reflect on better methods of governing an immense territory; of having paved the way to bureaucracy and technocracy, but this was done with greater efficiency in view. Personally, Diocletian was a religious man. No doubt he did not manifest any unusual piety, but he always thought that the gods of the emperors governed the world. He exercised an absolute, "divine right" monarchy and he surrounded it with an almost Oriental majesty.

Partially he failed in his task, and one can rightly say that the state he created was not "the new house he intended to build, but rather an emergency shelter," which offered protection against storms with the help of the gods. The fact remains that he was, in his actions, his religion, and his time, *vir rei publicae necessarius*, "the man whom the State needed."

## Diplomatics

Diplomatics, broadly speaking, is the study of documents. The term is derived from the Greek word *diploma*, meaning "doubled" or "folded." Besides the documents of legal and administrative import with which it is properly concerned, diplomatics also includes the study of other records such as bills, reports, cartularies, registers, and rolls. Diplomatics is therefore a basic and not simply an auxiliary historical science. This article deals with its development and practice in the Roman Empire and in Europe. During Roman antiquity certain documents containing different sorts of authorizations were engraved on a bronze diptych and then folded and sealed, in order to keep the contents secret—hence the term diploma. Rarely found during the Middle Ages, the word was used by the Renaissance Humanists to denote formal documents of ancient rulers. The interest in and description of such documents came to be called *res diplomatica* after the famous 17th-century work *De Re Diplomatica Libri VI*, by Jean Mabillon, a member of the scholarly Benedictine congregation of Saint-Maur. Mabillon's work first made the study of old documents a reputable science. The major task of diplomatics is to distinguish between genuine and false documents, and this involves detailed examination of their external and internal features. Diplomatic studies have been applied mainly to Western documents, usually medieval ones, because it requires less specialist training to analyze more recent documents.

#### HISTORY OF THE STUDY OF DOCUMENTS

**Medieval and Renaissance work.** The forging of documents took place on a vast scale during the earlier Middle Ages, partly because wars and disturbances so frequently upset possession and also because the increasing use of written records made it necessary for those whose title was, in fact, perfectly good in old unwritten "customary" law to give it written substantiation. Thus forgeries, partly intentionally honest, partly dishonest, occurred frequently, despite the fact that the Germanic tribes that settled in western Europe inherited, with other aspects of Roman law, the concept of forgery as a felony, which was soon also reinforced by the church's canon

law. This legal concept of forgery was, however, mainly applied to cases concerning property or inheritance; and literary forgeries, such as the famous Donation of Constantine, which purported to be the gift by the Roman emperor Constantine I the Great (died 337) to Pope Sylvester I of spiritual primacy throughout the church and of temporal power in Italy, were not concerned. Serious critical efforts to detect forgery did not begin in the Middle Ages, although obvious forgeries might be challenged in the course of a dispute. As early as the 6th century, the Merovingian king Chilperic II declared a charter recording the gift of land from himself to the Bishop of Reims a forgery on the simple ground that the royal official denied the signature on it to be his. Pope Innocent III (1198-1216) tried to establish infallible criteria for the detection of fraudulent papal documents, but knowledge of earlier documentary forms was totally inadequate. In the Renaissance the Humanists began to use philological and technical criteria; on these grounds Lorenzo Valla authoritatively pronounced the Donation of Constantine to be a forgery, though authenticity had already been questioned.

**Post-Renaissance scholarship.** Three events in the 17th century forced the development of more sophisticated standards of evaluation. The Thirty Years' War in Germany led to endless legal conflicts, and in France the nobility engaged in a concerted action known as the *bella diplomatica* ("diplomatic wars") to assert their ancient privileges against royal absolutism. The decisive impetus, however, came from a much more particularist dispute. Daniel van Papenbroeck, a member of the Jesuit commission known as the Bollandists (from another member, Jean Bolland), which was charged with the publication of the *Acta Sanctorum* ("Acts of the Saints,"), finding that some monastic documents he inspected were forgeries, assumed (1675) that this was true of almost all early-medieval documents. Since most of the monasteries with which the documents had been concerned were of the Benedictine Order, the Benedictines resented the suggestion, and Mabillon undertook to refute it. In his *De Re Diplomatica* (1681), Mabillon set out the fundamental principles of the science of verifying documents; Papenbroeck soon afterward acknowledged the correctness of his tenets. Nearly a century later, René-Prospér Tassin and Charles-François Toussaint published their six-volume *Nouveau traité de diplomatique* (1750-65; "New Treatise on Diplomatic"), a work that surpassed Mabillon's only in its greater wealth of material. Another important event in the history of the science of diplomatics was the founding of the École des Chartes (an institute for the training of French archivists) in Paris in 1821. During the next decades important collections of early-medieval French documents were printed in the *Recueil des actes* by a variety of eminent editors. But the greatest advances were made by German and Austrian scholars, among whom Julius von Ficker investigated the differentiation between *actum* and *datum* (that is, between verbal legal procedure and its formal documentation), and Theodor von Sickel defined a basic technique of studying and comparing the script of charters and thus of identifying the individual notaries or scribes. The diplomas of the Carolingian and the German kings and emperors were edited in the series of the *Monumenta Germaniae Historica* by members of the Institut für österreichische Geschichtsforschung (Institute of Austrian History Research), established by Sickel in 1854. Meanwhile, the *Regesta*, comprising short, synoptical condensations of the contents of papal documents down to 1198, published by Philipp Jaffé in 1851, gave a decisive momentum to the study of the papal chancery, while August Potthast covered the period from 1198 to 1304. Prominent scholars in the research of papal records in Germany at the beginning of the 20th century were Michael Tangl, Rudolf von Heckel, and, particularly, Paul Fridolin Kehr. In comparison with the amount of work done in France and Germany, historical scholarship in England long paid relatively little attention to legal, as opposed to literary, records. Although John Mitchell Kemble published his collection of Anglo-Saxon documents, the *Codex Diplo-*

*maticus Aevi Saxonici* (1839–48), an extensive study of Anglo-Saxon and Norman legal and administrative documents was delayed until the 20th century. Since then notable contributions have been made by scholars such as Helen Cam, H.W.C. Davis, Vivian Hunter Galbraith, Frank M. Stenton, Dorothy Whitelock, David Charles Douglas, and many others. Christopher Robert Cheney has made important contributions to the research of papal documents. In Italy Luigi Schiaparelli made vital contributions to the study of Lombard documents. From the 19th century, some study of documents has formed part of the medieval-history curriculum in most European universities.

#### DIPLOMATIC METHOD

Types of documents. Documents that have been preserved are either originals, drafts, or copies. Originals, of which many survive, are formal documents drawn up on the order of the sender or donor, and they were designated to serve the recipient or beneficiary as evidence of the transaction recorded. Handwritten copies of documents, made either before or after the deed was actually executed (sealed), are not classified as originals. If made before an "original," they were in fact rough drafts of it; if made afterward, they were copies. The particularly Anglo-Saxon method of chirography, however, gave the possibility of producing several "originals." By this process two or more specimens of a document were written on the same page of the vellum sheet, and the free space between the texts was filled in with the word *chyrographum* ("handwriting") or other words and symbols. Then the sheet was cut irregularly right through these words or symbols; the originals thus separated could later be reassembled, an exact fit being complete proof of authenticity. But to provide documents having the force of "originals," copies of the original were usually made and formally certified as such, by public notaries, or by high ecclesiastical or secular dignitaries. Copies certified in this way were accorded the same legal value as the originals. In practice, lack of critical judgment on the part of the certifiers often led to the certification of forged records. In documents known as transumpt, which recited earlier documents or charters as part of their text, it often happened that the earlier document was forged, but, being included in the new, it received validation. The original documents and copies considered above were issued at the request of the recipient or beneficiary or of his legal heir. It also happened quite often that the sender or donor wished for various reasons to retain a record of the documents issued by him. The chanceries (record offices) of secular rulers or great ecclesiastics therefore kept copies of outgoing documents in registers, and often of incoming documents, too. The popes were among the first to adopt the old Roman practice of keeping registers; although nearly all the earlier ones have been lost, an almost uninterrupted series of papal registers is extant from the pontificate of Innocent III onward. An important group of registers are the rolls kept by the medieval kings of England; the earliest extant rolls date from the 12th century. The keeping of registers in the chanceries of the French kings began about the year 1200, in Aragon about 1215, in Sicily under the Hohenstaufen emperor Frederick II (died 1250), and in the German imperial chancery from the early 14th century. Another manner of studying documents is in the formula books of the various chanceries. Notaries drawing up the various forms of medieval documents did not usually compose each new text afresh but, rather, copied from books in which such text formulas had been collected, a practice that can be traced back to Roman procedure. These model texts frequently contained only the legally relevant passages, while the individually applicable parts, such as names, figures, and dates, were either abridged or totally omitted. During the time of the Frankish kings, important collections were made, such as the *Formulae Marculfi* (early 8th century) and the *Formulae imperiales* (828–832). Significant collections of formulas serving as models for papal documents have been preserved from the 13th century.

Classification of documents. The documents of the Middle Ages are usually classified under two groups: public documents, which are those of emperors, kings, and popes, and private documents, which comprise all others. Another way of classifying documents is according to whether they are evidentiary or dispositive. The former merely record a valid legal act already executed orally, while the actual issuing of the latter forms in itself the legal act. This distinction, found among Roman documents from the 3rd century AD onward, gradually ceased to exist after the early Middle Ages. After the collapse of the Carolingian empire in the 9th century, private documents lost much of their function and were replaced by simple memorandums about legal acts and the witnesses to them. It was not until the late 11th and early 12th centuries that sealed charters of high secular or ecclesiastical dignitaries were again gradually considered as dispositive. Papal documents can be classified mainly as either letters or privileges, and royal documents can be classified as diplomas or mandates. Privileges and diplomas give evidence of legal transactions designed to be of long duration or even of permanent effect, while mandates and many papal letters contain commands.

Physical appearance of documents. *Material and ink.* Documents were written on a variety of material. In antiquity there were documents of stone, metal, wax, papyrus, and, occasionally, of parchment, but only papyrus and parchment (and, very occasionally, wax) were used during the Middle Ages. From the 12th to the 13th centuries, paper also was sometimes available. Papyrus, made from the stem of the papyrus plant, was produced mainly in Egypt; after the Arab conquest of Egypt in the 7th century, the import of papyrus to Europe became difficult. The Merovingian kings wrote their documents on papyrus until the second half of the 7th century, and the popes did so until far into the 11th century. North of the Alps papyrus had finally disappeared by the 8th century, when it was replaced by parchment. Parchment was made from animal hides and was thus easier to obtain. In southern Europe it was made mainly from sheep and goat hides; the insides of the skin were thoroughly smoothed and calcined, while the hairy sides were left rougher. In central and northern Europe, parchment was usually made from calves' skins, and both sides of the hides were thoroughly smoothed and calcined. Paper came originally from China. During the 8th century AD, it spread to the Arab world and from thence to Byzantium, where it was manufactured from linen and was used from the 11th to the 13th centuries for imperial documents. After that time ordinary paper was used in the Byzantine Empire. In the West the use of paper, most common at first in southern Italy and Spain, had begun to spread by the beginning of the 12th century. Germany and southern France began to import paper from Spain and Italy in the 13th century, and soon afterward it had reached England by way of Bordeaux. But paper did not altogether replace parchment, which long remained in use, especially for solemn documents. The medium for writing was ink, generally a mixture of oak gall and copper vitriol. Originally black, ink made north of the Alps sometimes shows a reddish-brown hue, while that made in Italy may contain tinges of brown and yellow. Over the centuries most of these colours have lightened as a result of atmospheric conditions. The Byzantine emperors used purple ink for their signatures. This custom was occasionally taken over by the Lombard rulers of Italy and, later, by the Norman kings of Sicily. Another custom of Byzantine origin is the use of gold lettering.

*Language, script, and abbreviations.* Throughout the entire Roman Empire, the language used in documents was primarily Latin. Greek was also used, and, during the latter part of the 6th century AD, it slowly superseded Latin in the East. From then onward, Greek was the language of Byzantine documents until the end of the Byzantine Empire (1453). In the West, the collapse of the empire and the establishment of barbarian kingdoms led to a vulgarization of Latin, written as well as spoken.

Introduc-  
tion  
of  
parchment

Use of  
formulas

Use of  
vernacular

Latin has always been used for papal documents and for most public and private charters, and it was used for international documents well into post-Renaissance times, until it was superseded by French as the language of diplomacy. In public and private documents, use of the vernacular alongside Latin gradually developed. Apart from its early and unique appearance in the documents of the Anglo-Saxons in England, no vernacular was used in charters before the 12th century. At the Norman Conquest (1066), use of Anglo-Saxon in English documents soon stopped, and no more vernacular was used there until some Norman French was introduced in the 13th century, and Middle English in the 15th century. There was an increasing use of the vernacular in Italian and French documents from the 12th century and in Germany from the 13th; but in medieval times Latin was never outstripped by the vernacular.

A correct assessment of the hand in which it was written is vital to ascertaining the provenance and authenticity of a document. Thus, the knowledge of paleography, different styles of ancient writing, is a skill essential to diplomatics. The broad basis of such knowledge begins with acquaintance with the general styles of writing current at particular times and places. This varied with the way the pen was held; whether the writing was cursive or had the letters formed separately; whether it was majuscule, all the letters being contained between a single pair of horizontal lines, or minuscule, with parts of the letters extending above and below the lines. There is a further distinction between what is called book hand and the business, or court, hand at one time used for documents (see CALLIGRAPHY).

In Europe the Roman capital letters, distinguished as rustic or square, uncial, and Roman majuscule and minuscule cursive, influenced all subsequent writing in the West. The Roman curial style (from the Curia, or papal court), used in the papal chancery until the 12th century, was a derivation of late Roman minuscule cursive. After the disintegration of the Western Empire, the Merovingian Franks used a Roman provincial script for their documents. Distinctive forms developed elsewhere, in Visigothic Spain and in Ireland. The Irish script, a half uncial (uncials are rounded letters) and a minuscule script, spread to Anglo-Saxon England and thence to the European continent. Under the Carolingian rulers, a particularly clear and attractive minuscule book hand was developed; modifications of this gradually became used in documents and eventually spread also to Italy, England, and Spain. A "Gothic," more pointed form of script developed since the 11th century in northern France and soon spread all over Europe, so that writing became more spidery in appearance. In the early years of the Renaissance, Italian scholars such as Poggio (Poggio Bracciolini) and Niccolò Niccoli developed a minuscule based on the Carolingian, and variants of this style were used by the Venetian Aldus Manutius and other pioneers of printing.

Abbreviations were used in both documents and books. Again, their particular characteristics would contribute to a correct assessment of the probable date and provenance of a document. Roughly two types were used: the suspension, involving the writing of only the first letter or syllable of a word; and the contraction, used first for Hebrew and Christian sacred names, the writing of only the first and last letter or letters of a word or syllable. The Carolingians sometimes used Tironian notes, a form of shorthand devised by Tiro, a freedman of the Roman orator Cicero.

**Validation of documents.** From Roman times the two most important methods of validating documents were by appending the signature or the seal of the sender or promulgator. The practice of using seals for this purpose (and not merely to close a document) was carried over from imperial usage and, by the 8th century, was current among the Lombards and other Germanic tribes in western Europe. Until about the 8th century, the signature of the Merovingian ruler or his delegate was also required for the validation of public documents, but thereafter the seal alone, together with the recognition

by a high chancery official, was held sufficient, the king's signature dwindling into a monogram or mere stroke (the "stroke of execution"). This change was probably accelerated because many medieval kings could not write. Thus, in England, King John sealed, and did not sign, the Magna Carta.

Seals were made of wax or of metal; if the latter, they were called bulls (hence, the use of this term for a certain group of papal documents). The Byzantine emperors used gold seals for their documents; Byzantine officials and ecclesiastics used lead and silver for their bulls. Papal seals were of lead or gold. Wax seals were increasingly used from about the 11th and 12th centuries, and wax was also used for the impression when, later, less formal documents were validated by use of the signet or privy seal. Seals could be two-sided, suspended from the document, or impressed upon it.

**Form and content of documents.** Normally, each document was divided into three distinct parts: the introduction (protocol), the main text (context), and the concluding formulas or final protocol. There were various subdivisions, and not all the parts here mentioned are necessarily found in every document. The introduction comprises, first, the invocation (invocatio) of God, either by name or through a symbol such as the cross; second, the superscription (intitulatio), giving the name and title of the sender; and third, the address (inscriptio), naming those to whom the document is directed, usually followed by a formula of greeting (salutatio). The actual text of the document can be divided into a number of parts. The first, known as the *arenga*, expresses in general terms the motive for the issue of the document. The notification (pronulgatio), briefly explaining the legal purpose of the document, is followed by the narratio, or exposition of the particular circumstances involved. In the dispositio the donor or promulgator firmly declares his purpose ("I hereby decree" or "I hereby give"); this clause is the vital core of the document, its legal decree of enactment. There usually followed the sanctio, a threat of punishment should the enactment be violated. The main text concluded with the corroboratio, a statement of the means to be used for validation of the document. The final protocol consisted of subscriptions or lists of names of all those, such as the scribe, who took part in the issue of the document and of witnesses to the enactment. The date and place of issue are given, and the final sentence, the *apprecatio*, is a short prayer for the realization of the contents of the charter. At the bottom of the document, the signs of validation (the recognition, monogram, seal) were then added.

The date given on a document might be either that of legal enactment (actum) or that of the issue of the document recording the (already performed) legal enactment (datum). The form in which dates are given in a document is of particular import in determining its provenance and authenticity. A wide variety of practices were followed at different places and times. For instance, days of the month could be given according to the old Roman system of calends, ides, and nones; by continuous counting throughout the month; or by reference to a saint's day. Years might be computed from the presumed time of the creation of the world; by the Roman indication, a 15-year cycle; by the names of officiating Roman consuls; by regnal years of emperor, king, or pope; or from the birth of Christ. Moreover, there were also a variety of ways to determine when the year began.

## DEVELOPMENT AND CHARACTERISTICS OF CHANCERIES

**The Roman and Byzantine empire.** Rulers, all of whom needed to issue directives and edicts, developed writing offices, or chanceries, in which formal documents were drawn up. The Roman imperial chancery, called the Office of Letters (ab epistulis), was subdivided into a Greek and a Latin department. In the 5th century four letter offices existed, all under the ultimate control of the *magister officiorum* ("master of offices"): the *scrinium epistolarum* ("letter office") handled mainly foreign, legal, and administrative affairs; the *scrinium libellorum*

## Seals

Problems  
of  
chronology

("petitions office") handled petitions and investigations; the *scrinium* memoriae ("memorandum office") composed shorter imperial decrees; and the *scrinium dispositionum* dealt with administration. From the 4th century, a group (*schola*) of notaries had come into being, some of whom served the emperor as personal secretaries. Two centuries later a special confidential (a *secretis*) secretary existed. In the Byzantine Empire in the 8th to 9th centuries, the *scrinium* epistolarum and the *scrinium libellorum* merged to form a new department under the *koiaistor* (a high palace official), while the secretaries had all come under the office of the *protoasekretis* (head of the secretaries). An official called the *mystikos* handled the emperor's secret correspondence. In preparing edicts or other laws, the *koiaistor*, after consulting the emperor, made a first draft of the bill, had the official copy drawn up by notaries, and then verified its accuracy before it was validated. From the 9th century onward other high court officials participated in the validation of Byzantine charters.

The important governmental documents of the late Roman and early Byzantine empires include laws, edicts, decrees (imperial decisions concerning civil and penal law), and rescripts (the emperor's replies to inquiries from corporate and administrative bodies or private persons). In the Byzantine era documents concerning more day-to-day affairs can be grouped under the headings of foreign letters, privileges, and administration. Foreign letters include correspondence with other rulers, treaties (regarded not as an agreement between equals but as an act of grace or privilege granted by the emperor, and made out as such), and letters accrediting imperial ambassadors. The most solemn and splendid form of privilege was the *chrysobullos logos*, so named because the word *logos*, meaning the emperor's solemn word, appeared in it three times, picked out in red ink. Written in the carefully embellished chancery script reserved for the emperor's personal documents, the text consists of the usual parts—that is, the *irrevocatio*, *intitulatio*, *inscriptio*, *arenga*, *narratio*, *dispositio*, *sanctio*, date, and the *subscriptio*. It was sealed with the golden bull. From about the 12th to the mid-14th century, a simplified form, the *chrysobullon sigillion*, was used for privileges of lesser importance. It was not signed by the emperor himself but was held to be validated by the insertion, by the emperor, in red ink of the *menologema*, a statement of month and indiction. It, too, was sealed with a golden bull. The administrative documents of the Byzantine imperial chancery include the *prostagma*, or *horismos*, a plain and short document known since the beginning of the 13th century. If directed to a single person, the document starts out with a short address, but, in all other cases, it begins immediately with the *narratio*, followed by the *dispositio*. The emperor replaced his signature with the *menologema*. Unlike the privileges, this document was not rolled up but, instead, was folded, and then closed by means of a wax seal stamped with the imprint of the imperial signet ring.

In addition to those emanating from the imperial offices, there were other types of documents issued in the Byzantine Empire. These include those issued by despots and imperial officials and, in the ecclesiastical sphere, by patriarchs and bishops. There were also private documents. The documents issued by the despots carried a silver seal, showing their intermediate status between that of imperial documents sealed with the gold seal and that of documents drawn up by imperial officials and sealed with lead bulls. Documents issued by imperial officials were simpler. They lacked the protocol, and the personal signature of the issuing official was written in black ink. The detailed date comprises the *menologema*. The documents of the Byzantine patriarchs are in many respects analogous to the imperial documents and symbolize the high status of the patriarch of Constantinople. They were, however, sealed with lead bulls. Byzantine private documents are almost exclusively notarial instruments. They are immediately recognizable by the crosses marked at the top of the documents. Used in lieu of the signature, the cross was the mark of the sender

and contained his name and official function in one of its angles. The document was either signed by witnesses, or at least the cross preceding their names is autograph. Following that is the signature of the notary. These documents were not usually sealed.

**The papal chancery.** Knowledge about early papal documents is scant because no originals survive from before the 9th century, and extant copies of earlier documents are often much abridged. But it is clear that the popes at first imitated the form of the letters of the Roman emperors. The papal protocol consisted only of the superscription and address and the final protocol of the pope's personal "signature"—not a mention of his name but merely a blessing. Toward the end of the 8th century, it became customary in certain documents to mention in the final clauses the name of the scribe responsible for the drawing up of the document; this was given with the date of issue, indicated by month and indiction, immediately following the subject matter of the document. There followed another clause, the great dating formula, *datum per manus* ("given by the hand of . . ."), naming a high chancery official and giving the date by reference to the regnal years of both emperor and pope. Both were used in documents containing decrees of permanent legal force, which came to be called privileges. Under Pope Leo IX (1049–54), the benediction written by the pope was changed into a monogram not written by him, but his signature was now introduced, placed in a round symbol, the *rota*. By the early 13th century, papal documents had evolved into two distinctive groups: solemn privileges and letters. Solemn privileges can be distinguished by their enlarged letters (*elongata*) of the first line, by the phrase *in perpetuum* ("in perpetuity") at the end of the address, by a threefold amen at the end of the text, by use of the *rota*, the pope's signature, the monogram, signatures of the cardinals, and by the *datum per manus*. Among letters, those whose bull was fastened on silken cords (*litterae cum serico*) brought some benefit to the recipient, while those with bulls fastened on a hempen cord (*litterae cum filo canapis*) contained either orders or the papal delegation in a dispute.

The number of solemn privileges began to decline from the mid-13th century, and eventually they were completely discontinued, their function being partly taken over by the *litterae cum serico*, which became increasingly elaborate in form. A new type of document also developed, the papal bull, distinguishable primarily by its use of formulas such as *ad perpetuam rei memoriam* ("that the matter may be perpetually known") in the superscription. Yet another new papal document appeared at the end of the 14th century, the *brief* (*breve*), used for the popes' private or even secret correspondence. Written not in the chancery but, instead, by papal secretaries (an office dating from about 1338), the *briefs* were sealed on wax with the imprint of the papal signet ring.

The papal chancery of the 4th to the 8th centuries was similar to the late-Roman imperial chancery. Its notaries (*notarii*, *scrinarii*), organized in a guild (*schola*), were headed by the *primicerius notariorum* and the *secundicerius notariorum* (first and second of notaries) and included the especially important notaries of Rome's seven ecclesiastical regions. But, during the 9th century, the *bibliothecarius*, the papal librarian, became the most important chancery official; a little later, various important bishops and dignitaries seem to have acted occasionally as *datarius* (the official named in the *datum per manus* formula). During the mid-11th century, a phase of German influence led to the temporary employment of notaries from the court of the emperor Henry III, who drew up papal privileges according to imperial formulas. A more important and permanent outcome of German influence was the gradual replacement of the *bibliothecarius* by a chancellor as the highest chancery official. The chancellor was invariably a cardinal, and in his absence another cardinal acted in his place as vice chancellor. Lesser chancery personnel still included the seven regional notaries; increasing business involved the use of lesser paid scribes in addition to the established notaries. From the late 11th century, a papal chapel,

Great  
dating  
formula

Imperial  
privileges

Chancery  
officials

modelled on those of contemporary emperors and kings, developed, and its staff was often employed in chancery tasks.

From the early 13th century, the vice chancellor became the permanent head of the chancery, the office of chancellor remaining vacant. During that century the vice chancellors were ordinary clerics, who renounced the office if elevated to the cardinalate; thus, the chancery became directly subordinate to the pope himself. Both the numbers and the official standing of the notaries in the chancery, which then functioned entirely separately from the chapel, gradually increased. Higher chancery officials were often distinguished canonists (legal experts), such as Sinibaldo Fieschi (later Pope Innocent IV), Godfrey of Trani, and Richard of Siena. From the beginning of the 14th century, bishops or cardinals filled the office of vice chancellor. During the Great Schism (1378–1417) there were two papal chanceries and two vice chancellors, one in Rome and one in Avignon.

Under Innocent III the procedure of the papal chancery had changed. Letters concerning matters of import to the papal Curia (*de Curia*) were drafted by the pope himself or else by a cardinal, the vice chancellor, or a notary. But the majority of the papal documents were elicited by their recipients, who had first to present to a notary the substance of their petition in a form the text of which largely anticipated the wording of the desired document. Professional proctors attached to the Curia assisted in the drafting and were also responsible for the documents during later stages of the procedure. Once a petition was approved, the notaries or the *abbreviatores* drafted a suitable document, drawing on a selection of formula books. After a final copy (engrossment) had been made and checked, it was read, if necessary, to the pope or in a special department of the chancery, the *Audientia litterarum contradictarum*. It was then passed to the Cistercian lay brothers who had charge of the papal bull, sealed, and given to the petitioner, who had had to pay a fee at almost every stage of the proceedings.

Insufficient research has so far been done on the papal chancery during the 14th and 15th centuries. Whereas formerly, when the vice chancellor was absent, one of the notaries had deputized for him, a new official, the *regens cancellariam*, was now created to fulfill this function. The number of notaries increased steadily, and, from the 13th century onward, an increasing number of public notaries worked in the papal administration. In order to distinguish between them and the papal notaries proper, the latter became unofficially known as protonotaries. The notaries were now in charge of the letters of justice, while the letters of grace were handled by the *abbreviatores*. The scribes remained in charge of the engrossments. A *computator*, aided by several assistants, was responsible for collecting fees.

The royal chanceries of medieval western Europe. Of the nations that held power in western Europe after the collapse of the Roman Empire there, the Ostrogoths, who occupied Italy from the late 5th to the mid-6th century, took over the ancient Roman imperial-chancery system in its entirety. Very little is known about the royal documents of the Lombards, their successors in Northern Italy, since not one of them has been preserved in its original form. But Lombard officials in charge of drawing up the documents were still trained in the Roman tradition. As well as *referendarii*, there were notaries who also acted as scribes. It is very likely that all of them were laymen.

Until the 12th century two main types of documents, diplomas and mandates, were produced north of the Alps, in the Merovingian, Carolingian, German, and French royal chanceries. Very little is known about the Merovingian royal chancery and its organization. The names of the scribes are never mentioned in the documents, but they were signed by high chancery officials, the *referendarii*.

*The Carolingian chancery.* When the Merovingian dynasty was supplanted by the Carolingians, chancery procedure changed drastically. In contrast to the Merovingian kings, the first Carolingian king, Pepin the

Short, was unable either to read or write. He therefore entrusted the responsibility for the correctness of the royal documents to an official of the court. At about the same time, the task of drawing up documents was taken over by those clerics whose original duty had been to look after the most important relic of the royal court, the coat (*cappa*) of St. Martin of Tours. Collectively named the *capella* (chapel), these clerics were individually called *capellani*, chaplains. This close connection between the court chapel and the chancery existed under the later Carolingians and at the German and French and other royal courts, including that of England. Until well into the 12th century, European chanceries were not bureaucratic offices in the modern sense but, rather, in most cases an assemblage of chaplains suited for the task of issuing documents and usually working under a cleric who was not the head of the chapel. Not all chaplains wrote documents, however, and the chapel and chancery thus remained separate institutions. From the reign of the emperor Louis I the Pious (814–840), the heads of the chancery were not personally involved in writing the documents, a task performed by unnamed and unknown scribes. At first the scribes were indiscriminately designated as either *notarii* or *cancellarii* (higher, Roman provincial officials of the 5th and 6th centuries, who stood at the barriers, *cancelli*, of the council rooms), but, by the 9th century, the title of *cancellarius* was gaining ground and was increasingly applied to the head of the chancery. The 9th century was a period of transition, during which, for a while, the archchaplain, the head of the chapel, became also the head of the clerks who wrote the charters.

*The German imperial chancery.* Under the Ottonian dynasty, which came to power in the eastern division of the original Carolingian empire early in the 10th century, the German royal chancery developed the organization that was to characterize it throughout the remainder of the Middle Ages. The heads of the chancery were the archchancellors, but the office was entirely honorary and soon came to be automatically held, as far as Germany was concerned, by whoever was archbishop of Mainz. When the German kings or emperors established administrations in Italy, Italian bishops were at first made archchancellors for Italy, but in 1031 the office was attached to the archbishopric of Cologne. From the 11th century, Burgundian bishops were archchancellors for Burgundy, but, in the second half of the 13th century, the archbishop of Trier took over the office.

The actual heads of the chancery were the chancellors. At first there was a chancellor, as well as an archchancellor, for each separate part of the empire — Germany, Italy, and Burgundy — but from 1118 there was only one chancellor for all three kingdoms. But even the chancellors, all of whom were clerics, were rarely involved in the actual composition and engrossing of documents, being usually engaged, as important advisers to the king or emperor, in much weightier matters. They do seem to have been especially concerned, however, with decisions about the granting of charters, and they supervised the work of the scribes or notaries. From among the ranks of these notaries, a group of protonotaries gradually developed after the mid-12th century, as a result of influence from the chancery of the Norman rulers of Sicily. Often called upon to deputize for the chancellor, the protonotaries, from the late 13th century onward, frequently titled themselves vice chancellors.

From the 12th century onward, the documents issued by the German royal chancery were divided into various classifications. The diploma, by then usually called a privilege, existed in two categories, the solemn and the simple privilege. A solemn privilege included the *invocatio*, the signum and recognition line, and a detailed dating or at least one of these three elements, which were entirely lacking in simple privileges. Gradually, simple privileges merged into documents called mandates; it is not always easy to distinguish between them, but, in general, privileges were concerned with rights in perpetuity, while the mandates dealt mainly with matters of only temporary importance. From the early 14th century, mandates

The  
*capella* of  
St. Martin

Imperial  
chancellors

were superseded by the use of letters patent and letters close (open or closed letters). Privileges continued to be sealed with a hanging seal; the seal on letters patent was impressed on the document and was used to seal up letters close.

As the power of the German kings declined during the later Middle Ages, so that of the archchancellors increased, and in the 14th century they attempted to win control of the chancery. But, despite fluctuations in the power struggle, the king retained control of the chancellor, who, by the end of the 15th century, held the title of imperial vice chancellor.

**The French chancery.** Under the Carolingians and the first Capetians in France, various bishops and archbishops, especially the archbishops of Reims, held the office of royal chancellor. But at that time the office was merely titular, and, by the end of the 11th century, it disappeared entirely. From the 12th century onward, the title of chancellor became reserved to the head of the chancery. These new chancellors became so powerful that in 1185 King Philip II Augustus left the office vacant, and, during almost the whole of the 13th century, the chancery was administered by subordinate officials. Chancellors, often laymen, were appointed again in the 14th century, however, and the office remained important until 1789. As in other parts of Europe, the French chancellor merely directed the work of the notaries, and it was they who were responsible for drawing up the documents. From 1350 onward, the notaries were called secretaries, and both their numbers and their importance steadily increased. From the 15th century, the tremendous expansion of business occupying the Grande Chancellerie led to the establishment of several subsidiary petites chancelleries, all issuing royal documents sealed with the king's signet. Until the reign of Henry I (1031–60), the old Frankish type of diploma was issued almost exclusively. Then, gradually, charters in the simpler form of letters began to replace the diplomas, and, during the 13th century, the lettres patentes became the common type of document. These lacked the invocatio, the monogram, and the signature of the high dignitaries, and they gave the simple form of dating. From the 14th century, two forms of lettres patentes existed: the charte, which was sealed with a green wax seal hanging on red and green silk cords; and the *lettre* patente, used mainly for administrative mandates, which was sealed with a yellow wax seal on double and single cord. Besides, lettres closes were used from the 13th century onward.

**The English chancery.** The English royal documents of the Anglo-Saxon period (before 1066) can be divided into two large groups: the charters, mostly written in Latin; and the writs, written in Old English. The charters, for the most part concerning grants of land, began with either a verbal or a symbolic invocatio (a cross or the monogram XP for Christ). There was an arenga but no intitulation. Charters were not sealed, the validation comprising the nonautographed signatures of the king and of ecclesiastic and secular dignitaries. Many of the extant charters of this era are forged or interpolated; the series of those apparently genuine starts shortly after the arrival in Canterbury (669) of the archbishop Theodore, and these show similarities with late-Roman private documents. It therefore seems probable that the Anglo-Saxon charters derive from Italian models brought to England by the Roman missionaries. Most of the charters were apparently written by the recipients. From the 11th century, the charters were gradually superseded by sealed writs, which became the most important type of document in medieval England. At first written in Anglo-Saxon, they were produced in Latin soon after the Norman Conquest. No continental document was anything like them. Written on a narrow strip of parchment, their entire text occupied only a few lines. A symbolic invocatio in the form of a cross was followed by the king's name and the address, which contained a salutation clause. There was no arenga, and the address was followed by a short description of the bequest, if the writ concerned a grant, or a directive, if the writ was a mandate. The Anglo-Saxon writs had no signatures of wit-

nesses and no date, but after 1066 these elements were added. The dating consisted at first only of a mention of the place of issue, days and month being usually given only toward the end of the 12th century. From the very beginning the writs were supplied with a pendant seal as a means of validation. From the reign of Henry II (1154–89), it is possible to distinguish mandate-like writs of the old type and charter writs, which mainly concerned questions of feudal enfeoffments and confirmations of privileges and were usually more carefully executed than the mandate writs. By the early 13th century, the charter writs had developed into a new form of charter. It contained the intitulation, including all the titles of the king; the general address; the dispositive text, which in most instances was introduced with the expression *sciatis* ("know that"); and the final clauses, consisting of the names of several witnesses and of the datum *per manus* clause mentioning the chancellor and giving the date and place of issue. During the final stage of its development, the great seal of green wax, pendant on silk cords, served as the means of validation. The ordinary writs further evolved into the common-law writs (containing orders to persons mentioned by name), the writs of summons, and, particularly, the letters patent (the latter eventually assuming the function of the charter writs, which disappeared at the end of the 13th century) and the letters close. The letters patent were furnished with a general address. Often introduced with the *sciatis*, the text concerns either limited grants or commissions to royal officials, introduced by the word *precipio* ("I order") or a similar expression. The dating begins with a series of witnesses and contains the place of issue, day, month, and year of the king's reign. Occasionally the dating is followed by the words "per N.," which are assumed to designate the household official transmitting to the scribe the royal order to issue the writ. The means of validation was the great seal in white wax, pendant on a single strip of parchment (simple-queue) or on a double strip of parchment or silk (double-queue). The letters close obtained their name from the fact that they were closed by means of the great seal. They contained either commands or information directed to a single individual or to several persons. Characteristic of these letters are the words *teste me ipso* ("witnessed myself") introducing the regular dating clause. These types of royal documents remained essentially unchanged throughout the Middle Ages and were imitated by both secular and ecclesiastic English magnates and dignitaries.

The English royal chancery grew out of the royal household. As on the Continent, it was at first merely a group of royal chaplains, and, until the Norman Conquest, there was no chancellor at their head. The chancellor was the keeper of the seal but usually took no part in the issuing of documents. During the 12th century the number of scribes was still low, between two and eight. At first this "chancery" travelled about with the king, only in the course of the 13th century establishing a permanent location at Westminster. At first English royal documents were not dispositive but merely evidentiary, confirming a previously arranged, orally discharged legal act, and the king's order for issuing the document was given orally. But, from the late 13th century, a royal secretariat came into existence, which was in charge of relaying to the chancellor, by warrant sealed with the privy seal, the royal order for issuing a writ under the great seal. In many ways the secretariat thus became a competitor of the chancery. In addition, during the first half of the 14th century, the Signet Office was established, so called after the small seal (signet). The king's secretary was also the head of this office. All these shifts made the issuing of royal documents increasingly complicated. From the end of the 14th century, the common procedure involved, first, the petitioner submitting a petition to the king. If the king approved of it, his secretary forwarded a warrant carrying the signet to the keeper of the privy seal with the request to send, in his turn, a warrant carrying the privy seal to the chancellor. The chancellor then ordered the issue of the document, which would bear the great seal. So far as the issuing of royal documents is con-

cerned, the fact that the secretariat developed into the secretariat of state is of great significance. The king's secretary (later on, there were two of them) became the centre of the royal administration. It was in his office that the state papers originated, which already under Henry VIII (died 1547) far surpassed in importance the old chancery records. Among the state papers there are in-letters, out-letters, drafts, reports, and schedules. The decline of the rolls (document registers) during the 16th century gave rise to yet another new office, the State Paper Office, headed since 1578 by the clerk of the papers. The second holder of this office, Sir Thomas Wilson, established the division of the state papers into foreign and domestic. As departments of state proliferated during the 18th and 19th centuries, they developed their own archives. In 1838 all the public archives became subject to an official called the master of the rolls.

*Other European chanceries.* Smaller European nations usually modelled their documents on those of the papacy, the empire, France, or England. The influence of papal letters and privileges can be observed particularly in Aragon, Castile, and Portugal, while German royal diplomas served as models in Bohemia (which was part of the empire), Hungary, and Poland. Because of the close political ties between the two kingdoms, Anglo-Saxon influence can be traced in the seal of the royal Danish documents during the 11th century, but, in the course of the 12th century, royal and princely German documents became the models for Danish as well as Swedish royal documents. Norwegian royal documents were modelled on Anglo-Saxon writs, probably as a result of the influence of English missionaries working in Norway from the early 11th century. The Norwegian writs were drawn up in the vernacular. The chancery of the Norman rulers of southern Italy and Sicily was highly developed. Influenced by the form of papal documents, the Norman documents comprise mainly privileges, either formal (with *rota*, witnesses, and gold bull) or simple (with *rota*, leaden bull, or wax seal), and mandates. They all have a detailed dateline that includes the name of the chancellor or other high court officials, the number of years since the birth of Christ, the regnal year of the king, and the *appraatio*. The mandates are more simply executed. They lack the *invocatio* and start out with a simple *intitulatio* and *inscriptio* that ends with a salutation clause. There is neither *arenga* nor *corroboratio*, but there is a command clause in the text. The dating consists only of the place of issue, the day of the month, and the *indictio*. There is no *rota* or signature. The seal is of red wax. The head of the royal chancery of the Norman kingdom of Sicily was the chancellor, a layman who was an influential court official. The notaries who drafted and wrote the documents were also laymen. Because the German Hohenstaufen emperors also ruled in Sicily from 1194 to 1250, Norman chancery practice influenced subsequent German documents.

**BIBLIOGRAPHY.** HARRY BRESSLAU, *Handbuch der Urkundenlehre für Deutschland und Italien*, 2nd ed., vol. 1 (1912), vol. 2, pt. 1 (1914), vol. 2, pt. 2, ed. by H.W. KLEWITZ (1931, all reprinted 1958, with separate index), although somewhat out of date, still the best handbook by far for Germany and Italy; OSWALD REDLICH, *Die Privaturkunden des Mittelalters* (1911, reprinted 1967), an excellent work on the private documents of the Middle Ages; LEO SANTIFALLER, *Beiträge zur Geschichte der Beschreibung des im Mittelalter*, pt. 1 (1953), the most up-to-date account of the history of writing materials during the Middle Ages; FRANZ DOLGER and JOHANNES KARAYANNOPULOS, *Byzantinische Urkundenlehre die Kaiserurkunden* (1968), the only study of the documents of the Byzantine emperors; C.R. CHENEY, *The Study of the Medieval Papal Chancery* (1966), an excellent general survey of modern research; R.L. POOLE, *Lectures on the History of the Papal Chancery down to the Time of Innocent III* (1915), the best book in English on this subject, though now out of date; PETER HERDE, *Beiträge zum päpstlichen Kanzlei- und Urkundenwesen im 13. Jahrhundert*, 2nd ed. (1967); and *Audientia litterarum contradictarum*, 2 vol. (1970), on papal letters of justice; WILHELM ERBEN, *Die Kaiser- und Königsurkunden des Mittelalters in Deutschland, Frankreich und Italien* (1907, reprinted 1967), an excellent supplement to Bresslau on the imperial and royal documents of the Middle Ages in Ger-

many, France, and Italy; GEORGES TESSIER, *Diplomatique royale française* (1962), the best and most up-to-date handbook on the royal French diplomatic; ALAIN DE BOUARD, *Manuel de diplomatique française et pontificale* (1929), a handbook on French and papal diplomatic; F.M. STENTON, *The Latin Charters of the Anglo-Saxon Period* (1955), a good brief survey on research since the 18th century; P.H. SAWYER, *Anglo-Saxon Charters* (1968), the most up-to-date annotated list and bibliography; R.C. VAN CAENEGEM, *Royal Writs in England from the Conquest to Glanvill* (1959), the best book on writs; V.H. GALBRAITH, *An Introduction to the Use of the Public Records* (1934) and *Studies in the Public Records* (1948), two works especially useful for the later periods; C.R. CHENEY, *The Records of Medieval England* (1956) and *English Bishops' Chanceries 1100–1250* (1950); T.F. TOUT, *Charters in the Administrative History of Medieval England*, 6 vol. (1920–33), the basic work on the subject, including the chancery; HARRY BRESSLAU, "Internationale Beziehungen im Urkundenwesen des Mittelalters," *Archiv für Urkundenforschung*, 6:19–76 (1918), the only survey on international relations in the documentary system of the Middle Ages; HORST ENZENSBERGER, *Beiträge zum Kanzlei- und Urkundenwesen der normannischen Herrscher Unteritaliens und Siziliens* (1971), the most up-to-date account of the chancery and documents of the Norman rulers in southern Italy and Sicily; H.O. MEISNER, *Archivalienkunde vom 16. Jahrhundert bis 1918* (1969), the best study of records from the 16th century through 1918 for central Europe, especially Germany; CHARLES CARTER, *The Western European Powers, 1500–1700* (1971), a very useful survey on archives and their records. All the cited works have comprehensive bibliographies, with some of them also containing bibliographies of editions and facsimiles of documents.

## Dipnoi

The Dipnoi comprise an order of fishes that first appeared in the Lower Devonian Period (about 370,000,000–395,000,000 years ago) and that today is represented by only six species. Some authorities recognize only three extant species. Known as lungfishes, the extant species occur in Africa, South America, and Australia. They are especially interesting because of their characteristic body forms, their generally large size, their erratic distribution over the tropical regions of the earth, and their peculiar mode of life.

The economic importance of the lungfishes is slight. Only in certain parts of Africa, because of their abundance and size, are they of any value to man as food. They are obtained from the mud of dried river bottoms. The South American lungfish, which is obtained in the same manner, is eaten locally.

Economic importance

Drawing by J. Helmer; from (B,C) J.R. Norman, *A History of Fishes* (1947); Hill & Wang Publishers, (D) A.S. Romer, *The Vertebrate Story*, Copyright 1933, 1939, 1941, 1959 by the University of Chicago

Living and fossil forms of Dipnoi fishes

**Size range and distribution.** Most species grow to substantial size. The Australian lungfish, *Neoceratodus forsteri*, attains weights of up to ten kilograms (about 22 pounds) and a length of 1.25 metres (about 50 inches). Of the African lungfishes, the yellow marbled Ethiopian species, *Protopterus aethiopicus*, is the largest, growing to a length of two metres (about 80 inches). The South American species, *Lepidosiren paradoxa*, reaches a length of 1.25 metres (about 50 inches).

The chancery of Norman rulers

The distribution of the Dipnoi strikingly parallels that of the unrelated osteoglossomorph fishes, another freshwater group. The Australian lungfish occurs in a very small region of Australia: in the marshes of Queensland, along Burnett River and St. Mary's River. Four species (*Protopterus*) occur in Africa, where they are chiefly concentrated in the equatorial belt, but occur as far north as Senegal and as far south as Mozambique. Within their areas of distribution, the African protopterids are abundant along the riverbanks, in submerged areas with plant cover, and in lakes. *Lepidosiren paradoxa*, the South American lungfish, is widely distributed in that continent. It is especially numerous and often associated with the eel *Synbranchus marmoratus* in the shallow and muddy watercourses of the Chaco River in Paraguay and in neighbouring areas.

**Natural history.** *Reproduction and life cycle.* The African lungfishes spawn in the last half of winter, coincident with the onset of the rainy season. *Protopterus* species build a nest in the form of a pit on the bottom of a watercourse. The egg is about 3.5 to four millimetres (about 0.14 inch) in diameter, and the tiny larvae emerge a week after the eggs are laid. The larvae have long, bright red tuftlike or fanlike external gills, which they use for breathing until the lungs are fully developed. The brood of young at first remain in the nest under the protection of the male.

The South American lungfishes dig a nest in the bottom in the form of a vertical passage, which frequently turns horizontally at the bottom. The male remains in the nest and guards the brood. During the spawning season, the pelvic fins of the male develop numerous tuft-shaped growths filled with small blood vessels (capillaries). These growths are believed to release oxygen from the blood, thereby oxygenating the water around the young.

The Australian lungfish lays gelatinous eggs among waterplants; the larvae, which have no external gills, breathe through internal gills.

**Behaviour and ecology.** Lungfishes are voracious, eating a variety of aquatic animals, including members of their own species. In captivity, African lungfishes eat earthworms, pieces of meat, tadpoles, small frogs, and small fish. The Ethiopian lungfish has at the front of the upper jaw two rather rounded teeth with a hard transverse (from side to side) bridge. The lower jaw has a number of crushing teeth. The prey is sucked in, crushed, and thoroughly chewed; such a manner of eating is rare among fishes.

**Form and function.** *General features.* The slim, eel-like African protopterids and the even slimmer South American *Lepidosiren paradoxa* have long stringy, very mobile pectoral and pelvic fins that are in a constant state of agitation—touching and sensing surroundings. The tips of these fins have a highly developed sense of touch, which, together with the fish's well-developed sensitivity to pressure and turbulence and its good sense of smell and taste, largely make up for the weakness of the eyes. The fish are almost blind with respect to the perception of form and movement. Pressure and turbulence are sensed by means of sensory structures called lateral lines. At the anterior, or head, end, the lateral lines are modified into a pattern of intricately interlaced bright lines, which are a series of tiny bud-shaped terminal organs. The highly individual patterns are used in distinguishing species.

The Australian lungfish has an entirely different appearance. It is more compactly built and has large, overlapping scales. The pectoral and pelvic fins are much broader. The African and South American lungfishes have paired lung sacs; in the Australian species the left lung sac atrophies.

**Adaptations for breathing.** There are a number of fishes that, in addition to or in place of gill breathing, have developed special organs through which they can breathe atmospheric air at the water surface. This phenomenon occurs almost exclusively in freshwater fishes. In lungfishes these organs for the intake of atmospheric air are, both in function and in structure, primitive lungs like those of amphibians. The name lungfish is thus well applied: these fishes have sac-shaped, pneumatic organs

that lie along the alimentary tract. The inner surfaces of these air-breathing organs are covered with a great number of honeycomb-like cavities covered with fine blood vessels. As in terrestrial higher vertebrates, gas exchange takes place in the tiny air vesicles.

In order to breathe, the fish swims upward and positions its head so that the tip of the snout barely touches the water surface. The mouth is then opened wide, and the fish sucks in air from just above the water—a process often accompanied by a characteristic sound. The Australian lungfish reportedly breathes air through the nasal openings, the mouth remaining closed. In contrast to the higher bony fishes, lungfishes have a particular opening (choana) that connects the nasal cavity with the mouth.

In the Australian lungfish, gill breathing predominates at least some of the time—namely, in times of normal water level when the water is well oxygenated. At such times the fish rises less often to the surface to breathe atmospheric air. When the water level goes down, which usually occurs in August or September, the fish is often found in isolated waterholes in which the oxygen content is greatly reduced. Other fishes in such pools often die from lack of oxygen, but the lungfish survives, having changed over to the breathing of atmospheric air. During such a dry period the Australian lungfish surfaces about every 40 to 50 minutes for air. African lungfishes surface for air about every 30 minutes or, in some cases, at longer intervals.

**Physiology and biochemistry.** African lungfishes bore into the bottom of a riverbed or lake bed for their "dry sleep." After burying themselves they become encased in a sheath that gradually hardens. Here they spend the dry season, during which the waterline becomes lower and the riverbed or lake bed finally dries out. The African lungfish generally digs in and encysts in this manner, even if there is sufficient time to swim to deeper waters. African lungfishes also burrow into mud and ensheath themselves under experimental conditions. They have been kept alive in such an induced state for more than two years.

The South American lungfish also bores into the mud in times of water shortage, but it forms no protective sheath. The Australian lungfish never buries itself in this manner.

Studies have shown that the "dry sleep" of the African lungfish is induced by a substance that inhibits the fish's normal metabolism (*i.e.*, together, all the internal physiological activities).

Extracts from the brains of such sleeping fish injected into rats have caused them to become lethargic; in addition, the body temperature of the rats falls 5° C, and the metabolic rate falls 33 percent. The day after receiving such injections, the rats stop eating. It is believed that the substance responsible for this effect is a protein-like substance.

**Evolution.** The oldest Dipnoi, from the Lower Devonian Period, had skull and dental features that are characteristically dipnoid but also had many similarities to the crossopterygians (*e.g.*, coelacanth). The Dipnoi was abundant until Triassic times (190,000,000–225,000,000 years ago), after which their numbers decreased.

*Dipterus*, one of the oldest lungfish, had leaflike pectoral and pelvic fins similar to those of the modern Australian lungfish, and it seems reasonable to assume that early forms also had functional lungs comparable with those of species living today. Hardened sections of clay, cylindrical in shape, have been found in Pennsylvanian (about 280,000,000–325,000,000 years old) and Permian (225,000,000–280,000,000 years old) deposits. Remains of the dipnoid *Gnathorhiza*, closely allied to the extant African and South American species, were imbedded in the clay, strongly suggesting that they passed unfavourable conditions buried in mud.

An evolutionary line can be traced from *Dipterus* to *Neoceratodus*, the extant Australian species. *Scaumenacia* and *Phaneropleuron*, common forms of the Upper Devonian (345,000,000–370,000,000 years ago), exhibited a much-reduced first dorsal fin (the first fin forward on the back); the second dorsal fin was enlarged and had

The "dry sleep"

Fins as sense organs

shifted further toward the tail. Lungfish of Permian times showed an apparent fusion of the fins along the back and the rest of the vertical midline into the so-called diphyccercal tail (*i.e.*, tapering to a point) present in modern lungfishes. Various side branches also occurred in the evolution of the Dipnoi, none of which has survived to modern times.

**Classification.** The annotated classification given below primarily relates to living forms; for a classification including the extinct forms see the critical appraisal below.

**Distinguishing taxonomic features.** The separation of Dipnoi as a discrete group is based largely on the structure and arrangement of the skull bones and the teeth. The suborders, of which there are two, are mutually distinguishable mainly by the number of lungs (one or two).

#### *Annotated classification.*

#### **SUBCLASS DIPNOI**

Lower Devonian (370,000,000–395,000,000 years ago) to Recent. Cranium not divided into movable parts; teeth in upper jaw reduced and lost in later members; some teeth fused into plates for eating shellfish. A single order.

##### **Order Sirenoidei**

##### *Suborder Monopneuma*

One functional lung.

**Family Ceratidae.** Pectoral and pelvic fins reduced but not tentacle-like; scales large; grows to about 1.25 metres (about 50 inches); 1 living species: *Neoceratodus forsteri* (Australian lungfish).

##### *Suborder Dipneuma*

Two functional lungs.

**Family Lepidosirenidae.** Body eel-like in form; scales small, pectoral and pelvic fins modified into slender tentacle-like structures; passes dry periods in mud of dried river and lake bottoms; grows to about 2 metres (about 80 inches); 2 living genera: *Lepidosiren* of South America (1 species: *L. paradoxus*) and *Protopterus* of Africa (4 species).

**Critical appraisal.** Some writers assign Dipnoi to the ordinal level, subsuming several families, mostly extinct, within that order.

The following alternate classification is according to A.S. Romer (1966), an American vertebrate paleontologist (extinct families represented only by fossils are indicated by a dagger [†]):

#### **ORDER DIPNOI**

##### †**Family Dipnorhynchidae**

Lower to Middle Devonian; Europe, Australia, North America.

##### †**Family Dipteridae**

Devonian; Europe, Greenland, North America, northern Asia, Australia.

##### †**Family Ctenodontidae**

Carboniferous (280,000,000–345,000,000 years ago); Europe, North America, Australia.

##### †**Family Phaneropleuridae**

Upper Devonian; North America, Greenland, Europe.

##### †**Family Sagenodontidae**

Mississippian to Lower Permian (250,000,000–280,000,000 years ago); North America, Europe.

##### †**Family Uronemidae**

Mississippian; Europe, North America (?).

##### †**Family Conchopomidae**

Pennsylvanian (280,000,000–325,000,000 years ago) to Lower Permian (250,000,000–280,060,000 years ago); North America, Europe.

##### **Family Ceratodontidae**

Lower Triassic (210,000,000–225,000,000 years ago) to Recent; one surviving species, *Neoceratodus forsteri*.

##### **Family Lepidosirenidae**

Pennsylvanian to Recent; 2 living genera, *Lepidosiren* and *Protopterus*.

## **Dipsacales**

The Dipsacales, or teasel order, is a small order of four families of flowering plants including about 1,100 species, chiefly herbs or shrubs and, rarely, small trees or climbers. Though distributed throughout the world, they are centred mainly in the temperate parts of the Northern Hemisphere, where they occur in many types of habitats. The order is primarily important for the large number of hardy ornamentals it contains; for example, those of the genera *Lonicera* (honeysuckles), *Viburnum* (guelder rose, arrowwoods, and wayfaring trees), and *Scabiosa* (scabious). A few species are noxious weeds.

#### **GENERAL FEATURES**

**Size range and diversity of structure.** The order Dipsacales, although predominantly herbs or small shrubs, includes quite diverse life forms ranging from small desert annuals to trees. It occurs in habitats from the Arctic to the tropics. Notable in the order are several species of the genus *Lonicera* that are characterized by their climbing and sometimes strangling habit, and some species of *Valeriana* that have large tap roots and a cushion (low, densely branched, matlike) growth form. There are, however, no succulents or parasitic plants in the order, and none that are normally epiphytic, (*i.e.*, not rooted in soil but living among the branches of trees).

**Utility and importance.** The Caprifoliaceae family contains many valuable and beautiful ornamentals, including many species of *Viburnum*, *Lonicera*, *Weigela*, *Abelia*, *Symplocarpos*, *Leycesteria*, and *Sambucus*. The hard wood of *Sambucus nigra* (elder) has been used in making musical instruments, and the large pith has been used for cleaning the pivots of delicate machinery. The fruits and flowers of this and other species of *Sambucus* are used for making jellies and wines. *Triosteum perfoliatum* (feverwort) roots are used as a mild cathartic. The dried and roasted fruits of this and other species have been used as a coffee substitute. *Lonicera japonica* (Japanese honeysuckle) introduced from Asia, is, in eastern North America, a pernicious and dangerous pest in woodlands, on roadbanks, and in hedgerows, overwhelming and strangling native flora. In China the leaves serve as a tea substitute, and in Japan and Vietnam extracts of the flowers and leaves are used as a diuretic.

In the family Valerianaceae there are no plants of great economic importance; a number are grown as orna-

Growth forms

Vegetative, floral, and fruiting structures of the order Dipsacales.

Drawing by M. Pahl

mentals as, for example, *Centranthus ruber* (red valerian), *Fedia eriocarpa* (African valerian), and *Valeriana officinalis* (common valerian or garden heliotrope). This latter species has been used as a source of the drug valerian sometimes used in the past in the treatment of functional nervous disorders and some cardiac ailments. Corn salad (*Valerianella locusta*), as its name implies, is used in salads. *Nardostachys jatamansi* (spikenard) is a native of high altitudes in Nepal, Bhutan, and other parts of the Himalayas extending into western Asia. The roots and spikelike woolly young stems, before the leaves unfold, are dried and yield an oil, which is used in perfumery. The spikenard referred to in the Bible is probably this plant. It was a popular perfume in Roman times and clearly costly, as the biblical references imply, due, no doubt, to the long distance it had to be imported from India. It is still used as a perfume in India, but the taste in perfume in western civilization has changed and spikenard might be considered disagreeable by some today.

The teasel family, Dipsacaceae, has a number of genera of horticultural interest, and *Scabiosa* in particular is widely cultivated for its ornamental value, especially *S. caucasica*. *Cephalalaria syriaca* can be a harmful weed in parts of the Middle East, the fruits contaminating grain and tainting flour. *Dipsacus*, the teasel, and the genus from which the order Dipsacales derives its name, consists of about 12 species in Europe, western Asia, and Africa. The name is from the Greek *dipsa*, "thirst," alluding to some species that have united, cup-shaped bases of the leaves that hold water. The genus contains the only member of economic importance, *Dipsacus sativus*, the fuller's teasel, so called because the ripened inflorescences (flowering heads) are used for fulling cloth. The heads are fixed to a cylinder that revolves slowly over the cloth while the plant's flexible receptacular bracts, which end in a stiff recurved spine, raise the nap or pile. The more appropriately named *D. fullonum* is very closely related, having erect receptacular bracts that are, however, too flexible for combing cloth. The fuller's teasel was widely cultivated in Europe and North America but the intro-

duction of "metal teasels" have to some extent replaced it. Some are still cultivated in parts of Europe and in the state of Oregon for fulling high-quality cloth.

Historically, the properties of the teasel as an instrument for fulling cloth were known in Roman times and records of its cultivation in Great Britain since Richard I (1199) are known. The word "teasel" occurs in pre-English Anglo-Saxon and is directly related to the word "tease" in the sense of the act of disentangling fibres.

#### NATURAL HISTORY

**Seed dispersal.** The order shows a wide variety of methods of seed dispersal. Fleshy berries and both fleshy and dry drupes (single stony-seeded fruits) occur in the family Caprifoliaceae, representing adaptations to bird dispersal. In the Valerianaceae family the fruits of some genera are provided with a plumed structure or are winged. In the Dipsacaceae family similar winged structures that occur are mechanisms or adaptations for wind dispersal. Some species in the family Dipsacaceae have bristles or burrs that cling to the coats of passing animals. Dry capsules, which split open explosively, and indehiscent (nonopening) fruits also occur in this family. Slugs are said to help the dispersal of the seeds of *Adoxa*.

**Pollination.** The flowers of the majority of genera in most of the families are generally adapted to pollination by insects. A few are reported to be pollinated by birds. There are no records of wind pollination.

The flowers manifest adaptations to insect pollination in a variety of ways. Many species have a fragrant or characteristic odour, and nectar is secreted in most genera of the order. Brightly coloured flowers are frequent and in some species are aggregated into a head sometimes with large, sterile ray flowers around the margin of the cluster, causing the whole inflorescence to resemble superficially a lone, large flower.

The flowers in the order are most commonly protandrous—that is, the male stamens mature and release pollen before the female stigma of the same flower becomes receptive—an adaptation that favours cross-pollination. There is, however, a large diversity of mechanisms for both self- and cross-pollination throughout the order. There is considerable sexual polymorphism (*i.e.*, the different sexes of flowers have different shapes and sizes) with frequent occurrence of gynodioecism, in which separate plants are of one sex, but some bisexual flowers occur on plants that normally bear mostly female flowers. Dioecism, male and female flowers occurring on different plants, is known, too, in at least one species, *Valeriana dioica* (Valerianaceae). *Sambucus* (Caprifoliaceae) has widely diverging stamens and extrorse anthers (*i.e.*, the anthers open away from the central axis and female parts of the flower) that render self-pollination difficult. In *Adoxa protogyn*, the condition in which the female parts mature before the male, is reported with the anthers at first remote from the stigmas and later inclined inward to allow self-pollination. Similar mechanisms to effect self-pollination, in the event of cross-pollination failing, are found in the genus *Lonicera* (Caprifoliaceae). Species of *Lonicera* with long corolla tubes are adapted to pollination by long-tongued insects, and in the western United States some species of this genus are pollinated by hummingbirds.

Self-pollination may occur in species of *Lonicera* that have pendulous flowers, and in some species in the order, especially *Valerianella*, automatic self-pollination results when the style elongates through the anthers during growth.

#### FORM AND FUNCTION

**Anatomy.** There are two general anatomical groups in the order, woody and herbaceous. The order has few distinctive anatomical characters but the occurrence of glandular hairs is almost a common feature.

The Caprifoliaceae family is predominantly woody and has characteristic xylem vessels (water-conducting tissues) with scalariform perforation plates (*i.e.*, the vessel end walls have ladderlike slotted openings), and its wood

Adaptations to insect pollination

The teasel

fibres have bordered pits. The genera *Sambucus* and *Viburnum*, however, differ from the rest of the family in having nectar-secreting organs located outside the flower. *Sambucus* is further distinct in having cellular crystals and thick-walled, long, narrow fibres and a large pith. It also has highly specialized secondary xylem. The genera *Alseuosmia*, *Carlemannia*, and *Silvianthus*, however, lack the characteristic anatomical features of the family.

The family Valerianaceae is characterized by the absence of parenchyma (a type of cell) and the presence of oil cells in the cortex and cork of the roots. Woody members have very small vessels.

The vascular system forms a closed ring early in development in the Dipsacaceae family, and a broad pith is a feature of the family.

**Pollen morphology.** The pollen in the order is variable. The families Valerianaceae, Dipsacaceae, and some members of Caprifoliaceae, however, show an overall pattern of similarity, most of their species having three-furrowed pollen, often with a pore in the furrow, and the pollen grain surfaces have spiny ornamentation.

The most common type of pollen in the Caprifoliaceae family is somewhat flattened with a spiny wall supported by densely packed rods, or bacula. The genera *Sambucus* and *Viburnum* have distinct pollen with a reticulate pattern of ornamentation on the wall. The genus *Abelia* is remarkable in having two distinct pollen types, typical Caprifoliaceae pollen and triangular pollen without ornamentation. *Adoxa* (family Adoxaceae) has pollen with reticulate sculpturing similar to *Sambucus*.

Two main types of pollen occur in the family Dipsacaceae, one that occurs in most genera of the family, in which the apertures have a surrounding halo and are usually covered with a lid and the surface has little spines or wartlike pegs; and a second type, found in the genus *Morina*, in which the apertures have no halo and a lid is usually absent and the surface has no spinules. The pollen morphology of the family Valerianaceae is not well known but generally resembles that of the family Dipsacaceae.

**Biochemistry.** The biochemistry of the order has not been studied extensively and only isolated facts are available. Volatile oils occur in the family Valerianaceae, especially in the roots and rhizome (a rootlike stem structure). The same oils are found in the genera *Sambucus* and *Viburnum*, members of the family Caprifoliaceae. The family Caprifoliaceae also contains several rather widespread cyanogenetic glycosides (toxic substances consisting of carbohydrates such as sugars combined with hydrocyanic acid), and rutin is reported. Alkaloids are rare and of little importance. Saponines are reported in the genus *Lonicera*. Some fruits of the family, especially in the genus *Sambucus*, are rich in pectin. The family Dipsacaceae is notable for the occurrence of pseudoalkaloids and pseudoindikases.

The serological correspondence in seed proteins—the measurement of the relative amounts of the major protein constituents of plant fluids—has been under investigation in the Caprifoliaceae, and the results are expected to prove important in the classification of the family.

**Chromosome number.** The chromosome number of the order is not well known although some genera have been investigated. The basic numbers in the order appear to be 7, 8, 9, and 10. Changes in chromosome number appear to have played only a small part in the differentiation of genera and species in the family Caprifoliaceae. Polyploidy—i.e., the existence of more than the basic two full sets of chromosomes—has played a major role, however, in speciation in some of the genera in the families Valerianaceae and Dipsacaceae.

#### EVOLUTION

**Fossil record.** The earliest remains assignable to the order appear to be leaf impressions described as *Viburnum vetus* found in Cretaceous deposits (about 100,000,000 years old) in Portugal. Fossil leaves of *Viburnum* are fairly widely reported from Upper Cretaceous deposits of the United States and Europe. This genus was exceed-

ingly widespread and characteristic of Tertiary times (between about 7,000,000 and 65,000,000 years ago), and both pollen and leaves occur in many American, European, and Asiatic deposits. Fossil pollen of *Sambucus* is reported from the Eocene (about 50,000,000 years ago) in Europe and North America, but it is by no means common. Fossil pollen of many members of the order has been reported, however, from Pliocene deposits (about 5,000,000 years old). Fossil leaves of *Sambucus*, *Lonicera*, and *Symphoricarpos* have been recognized in Miocene (about 20,000,000 years ago) and Pliocene deposits of Europe, Asia, and North America. Seeds of *Sambucus* have been identified from the Pliocene in Europe, and fruits apparently assignable to the genera *Valeriana* and *Valerianella* have also been reported.

**Phylogeny.** The adaptive significance of most of the characters that distinguish the Dipsacales order from other related orders is doubtful. Within the order there is a tendency for a progression from woody to herbaceous habit, from regular to irregular corolla, from several fertile locules (ovary chambers) to one, from numerous seeds to one, and from endospermous seeds to nonendospermous (endosperm is a starchy nutrient tissue for developing embryos)—a trend that has taken place in other orders of flowering plants. The family Caprifoliaceae seems clearly to be the most primitive family of the order, from which all the others have been derived. Several genera of the tribe Lonicereae are transitional toward the family Valerianaceae. The family Dipsacaceae, although specialized, is linked to Valerianaceae by *Triplostegia*, a genus first placed in the latter family but now accepted as a primitive member of the Dipsacaceae. The family Adoxaceae is a specialized herbaceous offshoot of the Caprifoliaceae.

#### CLASSIFICATION

Distinguishing taxonomic features. Dipsacales is an order occurring predominantly in the temperate parts of the world. It consists primarily of herbs or shrubs, characterized by opposite leaves that usually lack stipules. The flowers are gamopetalous (i.e., they have fused petals) and vary from being regular to irregular; the ovary is inferior.

Annotated classification.

#### ORDER DIPSALES

Herbs or shrubs, seldom small trees. Leaves in basal rosettes or opposite, very rarely alternate, usually lacking stipules. Flowers regular or irregular, bisexual or unisexual, rarely some sterile. Calyx (sepals) absent or poorly developed. An epicalyx sometimes well developed in fruit. Corolla sympetalous, 3- to 5-lobed. Stamens 1 to 5, usually 3 to 5, alternate with the corolla lobes; filaments attached to the corolla tube. Pollen trinucleate. Ovary syncarpous, inferior, 2- to 5-locular, locules with 1 to many anatropous ovules. Fruit various, endosperm present or absent, embryo straight. Four families, about 40 genera and 1,100 species, with worldwide distribution but more abundant in Northern Hemisphere temperate regions.

##### Family Caprifoliaceae

Deciduous or evergreen shrubs, sometimes small trees or vines, rarely herbs, with opposite or alternate, entire or divided, exstipulate or stipulate leaves. Inflorescence a corymb, cyme, thyrs, or spike of whorls, or flowers solitary or in pairs. Flowers regular or irregular, epigynous, bisexual, rarely some sterile. Floral tube adnate to the ovary, with a distinct constriction at the level of the 3 to 5 usually small calyx lobes. Corolla of fused petals, 3- to 5-lobed, salverform, rotate, campanulate, funnelform, or tubular, often bilabiate, sometimes gibbous at or near the base. Stamens 5 (sometimes 4), epipetalous, alternate with the corolla lobes; anthers 2-locular, opening longitudinally, versatile, dorsifixed, introrse or rarely extrorse; pollen tricolpate. Gynoecium of 1 to 5 fused carpels; style 1 or wanting; stigmas as many as the carpels, distinct or united; ovary inferior, 2- to 5-locular; locules with solitary to numerous, pendulous, anatropous ovules; placentation axile or parietal. Fruit a berry or drupe, rarely a capsule or achene, with 1 to many seeds or as many seeds as locules. Endosperm copious; embryo straight, small. About 18 genera and 500 species, distributed primarily in the North Temperate Zone, especially in China and the Himalayas, but extending to the mountains of the tropics, South America, and Australasia.

##### Family Adoxaceae

A glabrous, perennial, rhizomatous herb. Rhizomes creeping

Pollen  
shapes  
and orna-  
mentation

Evolution-  
ary trends

with fleshy white scales at the apex. Basal leaves 5-foliate or ternate, long petiolate, stem leaves ternate, exstipulate; leaflets divided into 2 or 3 stalked lobes. Inflorescence a capitulum-like cyme. Flowers regular, bisexual. Calyx 2- or 3-lobed. Corolla 4- or 5-lobed, imbricate, light green. Stamens 4 or 5, epipetalous, alternate with the corolla lobes, divided to the base and appearing as 8 or 10 each with 1 anther sac; anthers versatile, 2-locular, opening longitudinally; pollen tricolpate, reticulate. Gynoecium syncarpous, ovary semi-inferior, 3- to 5-locular with a solitary, pendulous, anatropous ovule; styles 3 to 5, stigmas capitate. Fruit a drupe with 3 to 5 pyrenes or nutlets. Seeds 3 to 5; endosperm copious; embryo small. One genus and one species (*Adoxa moschatellina*), occurring in moist, shady places throughout the North Temperate Zone.

#### Family Valerianaceae

Annual or perennial herbs, sometimes woody at base. Leaves in basal rosettes or opposite, pinnately divided or entire, exstipulate, the bases often sheathing. Inflorescence a monochasium, thyrse, or many-flowered compound dichasial cyme, sometimes condensed and capitate. Flowers irregular or almost regular, bisexual or unisexual. Calyx obsolete or developing late and becoming conspicuous only in fruit. Corolla tubular, 3-, 4-, or 5-lobed, imbricate, often basally spurred, or saccate or bilabiate. Stamens epipetalous and alternate with the corolla lobes, varying in number from 1 to 4; anthers versatile, 2- or 4-lobed, 4-locular, introrse, opening longitudinally; pollen tricolpate, echinate. Gynoecium syncarpous, ovary inferior, 3-locular, with 2 locules usually suppressed and 1 fertile, with a solitary, pendulous, anatropous ovule; style 1, stigma simple or lobed. Fruit dry, indehiscent, the calyx often developing into a winged, awned, or plumose pappus. Seed 1; endosperm absent; embryo large, straight. About 10 genera and 370 to 400 species distributed widely in the North Temperate Zone and well represented in the Andes Mountains of South America.

#### Family Dipsacaceae

Annual or perennial herbs, rarely small shrubs. Leaves opposite or rarely whorled, simple or compound, exstipulate. Inflorescence usually capitate or rarely a spike of false whorls or a panicle, bracts forming a calyx-like involucre. Flowers irregular or regular, bisexual with a calyx-like involucre of fused bracteoles borne in the axils of imbricate receptacular bracts. Calyx small, cuplike or tubular or divided into 5 to 10 papus-like segments. Corolla gamopetalous, 4- to 5-lobed, imbricate. Stamens usually 4, sometimes 2, 3, or 5, epipetalous, alternate with the corolla lobes; anthers versatile, 2-locular, introrse, opening longitudinally; pollen with 2 to 6 apertures, smooth or echinate. Gynoecium syncarpous, ovary inferior, 1-locular with a solitary, pendulous, anatropous ovule; style 1, stigma simple or 2-lobed. Fruit dry, indehiscent, one-seeded, enclosed in the involucre, often crowned by the persistent calyx. Seed 1, endosperm present, embryo straight. With about 8 to 12 genera and 250 to 300 species distributed chiefly in the Mediterranean area and Near East, extending to North Europe, East Asia, and South Africa.

**Critical appraisal.** The system of families followed here accords closely with the most recent classifications. Some authors have included the small, anomalous, tropical American family Calyceraceae in the order, but this seems unsatisfactory from the evidence available. The classification system of one important authority shows large differences from that presented here because it places the woody family Caprifoliaceae in a division called "Lignosae" near the family Cornaceae, in an order Araliales, far apart from the herbaceous family Adoxaceae, which is placed in the order Saxifragales of that system. The families Dipsacaceae, Valerianaceae, and Calyceraceae fall in a division called "Herbaceae" in an order Valerianales in that classification scheme. Such treatment, however, seems to result in concealing affinities within the order.

The inclusion of the family Rubiaceae with the families presented here as the order Dipsacales, as proposed by some earlier authors, appears to make a larger and more heterogeneous unit. Some early authors have advocated the merging of the Caprifoliaceae family with the Rubiaceae family, but this would appear to be undesirable because various Caprifoliaceae genera would then be assigned to different rubiaceae tribes and the identity of the family would be lost.

A number of anomalous plants are generally included in the family Caprifoliaceae. For example, it is problematic whether the New Zealand genus *Alseuosmia* and the New Caledonian genera *Pachydiscus* and *Periomphale*,

which have alternate leaves and valvate corolla lobes, belong strictly to the Caprifoliaceae family. These have been variously treated as a separate family, Alseuosmiaceae, either related to the Caprifoliaceae family or placed in the order Rosales near the families Pittosporaceae and Grossulariaceae. Similarly, the Asiatic genera *Carleman* and *Silvianthus*, which have been variously placed in the Rubiaceae family and in a separate family Carlemanaceae, are at times considered as doubtful members of the Caprifoliaceae family.

The position of the genera *Sambucus* and *Viburnum* is somewhat problematic as they stand apart from the rest of the family, with their regular flowers and short style. *Sambucus* is further distinct with pinnately compound leaves and extrorse anthers, and it has been treated in some classifications as a segregate family Sambucaceae. Relationships between the genus *Viburnum* and the families Hydrangeaceae and Cornaceae have been suggested. The most accepted treatment seems to be to regard the genera *Sambucus*, *Viburnum*, and the herbaceous genus *Triosteum* as three distinct tribes. The remaining genera in the family form a more or less well-defined fourth tribe named "Lonicerae."

The genus *Adoxa* has been assigned to the families Saxifragaceae, Araliaceae, and Caprifoliaceae but is now generally regarded as constituting an independent family. The relationships with the Araliaceae and Saxifragaceae families depend on the herbaceous habit and the interpretation of the floral parts as involucre and calyx with the corolla suppressed. Morphological, serological, and palynological (pollen structure) evidence support a relationship with the family Caprifoliaceae, especially with the genus *Sambucus* of that family.

Members of the family Valerianaceae often have a characteristic, somewhat unpleasant, odour, which also occurs in *Sambucus* and *Viburnum* of the Caprifoliaceae family and may indicate some affinity to it. Variation in fruit characters has formed the basis for the classification of species in a number of genera, notably *Valerianella*, but the discovery of dimorphism in the fruits of species of *Plectritis* suggests a need for further investigation. The family Valerianaceae is a very clearly defined family and is closely related to Dipsacaceae.

Dipsacaceae is mainly a natural family. The capitate inflorescence and involucre of bracts are characters that suggest affinities with the family Asteraceae (Compositae) but are considered also to be a result of parallel evolution. Differentiation has mainly taken place in the fruits of the family, and these together with variation in the receptacular bracts give good characters for taxonomic division into genera.

Two anomalous genera sometimes receive different treatment by various authorities. *Triplostegia*, with two species, is placed in the Valerianaceae by some workers while others treat it as a distinct family, *Triplostegiaceae*. *Morina*, a genus of about 15 species, is sometimes treated with the Dipsacaceae or as an independent family, *Morinaceae*.

Before the true affinities of the many anomalous genera in the various families of the order can be properly assessed, considerably more comparative work is needed to embrace detailed studies in such fields as palynology, cytology, anatomy, biochemistry, and phytoserology.

(I.K.F.)

## Diptera

Although many winged insects are commonly called flies, the name is strictly applicable only to members of the order Diptera, the two-winged, or "true," flies. Diptera, one of the largest insect orders, number more than 85,000 species that are relatively small, with soft bodies. Although the mouthparts of flies are of the sucking type, individuals show considerable variation in structure. Many flies are of great economic importance. Some blood-suckers are serious pests of man and other animals. These insects, along with many scavenging flies, are important vectors of disease; others are pests of cultivated plants. Flies are beneficial, too—as scavengers, predators or parasites of certain insect pests, pollinators of plants, and destroyers of weeds noxious to man. Dipterous larvae, often called maggots or grubs, are found in many habitats (e.g., in any kind of water, in plant tissue and soil, beneath bark or stones, in decaying plant and animal matter, even in pools of crude petroleum). Adults feed on plant or animal juices or other insects. Diptera fall into three large groups: Nematocera (e.g., crane flies, midges, gnats, mosquitoes), Brachycera (e.g., horse flies, robber flies, bee flies), and Cyclorrhapha (e.g., flies that breed in vegetable or animal material, both living and dead).

### GENERAL FEATURES

Flies range in size from midges of little more than one millimetre to robber flies more than seven centimetres long. In general the more primitive flies (e.g., mosquitoes, midges, fungus gnats) are fragile insects with delicate wings. The more advanced flies (e.g., blow flies, houseflies) are generally squat, sturdy and bristly; they fly in a more purposeful way than midges and gnats.

Diptera are abundant throughout the world: in the tropics, the subarctic, at sea level, and high on mountains. They colonize beaches to low-tide level, but few go into deeper water, and only one or two midges are truly marine (e.g., *Pontomyia natans* in the Pacific). On the other hand, migrating flies are found far out to sea.

### IMPORTANCE

The abundance, worldwide distribution, and habits of flies combine to make them a nuisance to man. Swarms of midges are a common annoyance. Sweat flies and face flies gather around the eyes, nose, and mouth and also suck blood and pus from wounds and sores. Such flies move constantly from one victim to the next; in so doing they can transfer disease-causing organisms.

The housefly (*Musca domestica*) is dangerous because it feeds on almost any food and moves from person to food, drink, or feces. By transferring infective organisms from the skin and intestine, houseflies are agents in transmitting typhoid, dysentery, cholera, summer diarrhea in children, and other intestinal virus- and bacteria-caused diseases. Eye gnats are a nuisance in warm countries. Although the larvae are plant feeders, the small active adults feed on physiological secretions, particularly those around the eyes. Other flies pierce the skin of vertebrates and feed on their blood. Mosquitoes, black flies, sand flies, biting midges, and horse flies have evolved mandibles and maxillae that are blade-like, piercing stylets.

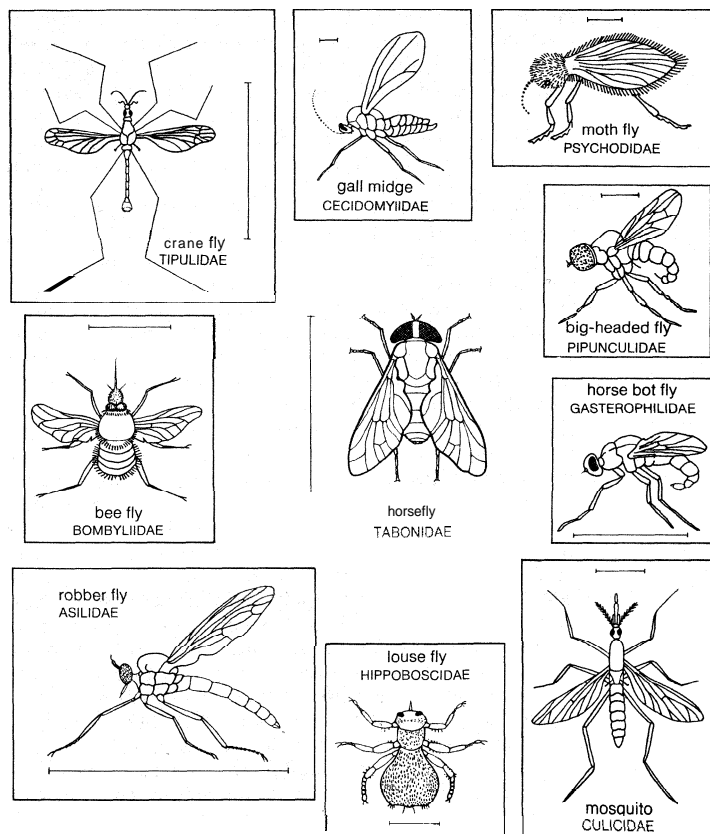

Figure 1: Diversity among Diptera. Line scales indicate the approximate size of each insect.

From *Invertebrate Identification Manual* by Richard A. Pimentel. © 1967 by Litton Educational Publishing, Inc. Reprinted by permission of Van Nostrand Reinhold Company

These piercing organs are developed only in females, which use blood protein in egg production. Males do not feed on blood. Other groups of flies have evolved different mechanisms for obtaining blood. Tsetse flies, stable flies or biting houseflies (*Stomoxys*), and certain parasitic flies have developed a hard drill-like labium to replace the soft spongelike one. Both males and females have evolved this labium; therefore both feed on blood. A few flies related to the housefly have a spongy proboscis equipped with small teeth for rasping skin around wounds and sores to increase the flow of blood and lymph. Other groups (e.g., robber flies) have developed a piercing proboscis used only against other insects.

Disease-causing organisms in the blood can be carried by a fly inserting its proboscis into successive victims. After piercing its victim's skin, a bloodsucking fly injects saliva into the wound; without the anticoagulant properties of this saliva, bloodsucking would be impossible since the tiny hole drilled by the proboscis would clog with clotted blood. If the mouthparts are contaminated with blood that contains micro-organisms, all are injected, along with the saliva, into the new victim. This is called direct, or mechanical, transmission of disease and occurs only if the fly, interrupted during a meal, finds a new victim before the micro-organisms die. One contagious disease that might be spread this way is tularemia, caused by a bacterium found in wild rodents. Trappers who cut themselves while skinning animals can contract the disease. In North America the bacterium is thought to be transmitted also by the deer fly (*Chrysops discalis*), common in wooded trapper country.

Surra, a disease of horses and camels in the Middle East and the Orient, is caused by *Trypanosoma evansi* and is transmitted by horse flies. Trypanosomes, transmitted by tsetse flies, cause sleeping sickness in man and nagana in animals throughout tropical Africa. These trypanosomes must spend part of their life cycle in the insect before they can infect a vertebrate; this is an example of cyclic disease transmission. The relationship between the parasitic dis-

ease organism and its two hosts, vertebrate and insect, is a result of evolutionary adaptation; however, it is not known whether the trypanosome was originally a fly parasite that spread to man and other vertebrates, or whether it was a human parasite that became adapted to living in a biting fly. An important cyclically transmitted disease is malaria. *Plasmodium*, the causative agent of human malaria, is an acellular protist nourished by red blood cells in the blood of man. Its reproductive cycles cause recurrent bouts of the disease. Occasionally sexual forms occur in the victim's blood; if this form finds its way into a suitable species of bloodsucking mosquito, another stage of the Plasmodium begins, preparing the organism to infect another human bitten by the mosquito host. Other diseases known to be cyclically transmitted include yellow fever, filariasis, and many viral diseases. It is likely that there are others not yet recognized.

Injuries to plants

Fly larvae are serious agricultural pests; they feed on young crop plants, retarding growth or killing them. Cultivated crops, because they provide pests with an almost unlimited food supply within a small area, can be devastated by uncontrolled population growth of a pest. On the other hand, wild food plants, because they are scattered and mixed with other varieties, do not usually provide so abundant a food supply and thus serve as a check on population growth. Frit flies can cause a 20 percent loss of an oat crop, and to the value of the lost oats must be added the cost of control measures necessary to save the remainder. Some crops, notably fruit trees and ornamental shrubs, are a financial loss if slightly disfigured by insect attack, though the life of the plant is not endangered. Fruit, although edible after attack by Mediterranean fruit flies, cannot be sold; a few infested fruits can result in loss of an entire consignment. Larvae of gall midges and leafminers lower the commercial value of ornamental plants.

#### NATURAL HISTORY

**Life cycle.** General features. The life cycle of a fly consists of four stages: egg, larva, pupa, and adult. Since larval forms, always morphologically distinct from adults, also occupy different habitats, flies in effect live two distinct lives and thus are able to adapt successfully to environmental changes. In some flies (e.g., robber flies) neither the larval nor the adult stage predominates; the larva feeds actively in soil, and adult flies of both sexes catch other insects in flight. Among mosquitoes, black flies, and related bloodsucking flies, the larvae have characteristic structures and live active lives under water; the complex mating process of the adults is followed (in the case of females) by bloodsucking and egg laying.

There are many flies in which one stage is predominant. Swarms of adult midges (Chironomidae), for example,

are conspicuous and troublesome; but the adult midge lives just long enough—usually less than a day—to mate and lay eggs. Thus, most of the life cycle is occupied under water by the larval stage. The larvae are wormlike in appearance. Some are adapted to oxygen-poor situations; the "bloodworm," for example, which lives in the mud of stagnant waters, uses hemoglobin as a respiratory pigment. Other midge larvae live in silken tubes, either filtering minute organisms from water for food or preying upon larger creatures. Some midge larvae have evolved an elaborate symbiosis, or mutualism, with other aquatic organisms; for example *Nostoc* (a genus of blue-green algae) and certain midge larvae utilize each other's excreta. Larval life as complex as this is not mere preparation for adult life; rather, the adult stage is a revitalizing and distributor-stage for the larval one. The adult stage is of relatively little importance in a few other groups, too.

At the opposite extreme are tsetse flies (*Glossina*) and three families of pupipara parasites (e.g., Hippoboscidae, which feed on the blood of mammals and birds; both Nycteribiidae and Streblidae feed only on bat blood). In these families a single egg is produced at one time and hatched internally. The larva, retained and nourished in a kind of womb, is expelled when it has matured and immediately forms a pupa. Thus, these flies have no free larval stage, no independent larval life. Since the pupa is immobile, the active life of the fly is passed as an adult. Most Hippoboscidae and Streblidae, and all tsetse flies, have wings and usually migrate to new hosts, but some species of these families, and all Nycteribiidae, cannot fly and often are wingless. Wingless flies can be identified as flies only after detailed morphological examination.

**Eggs.** The majority of flies lay eggs, which hatch into tiny larvae after a few hours or several days. The number of eggs laid by a female varies from 1 to about 250; however, a number of successive batches may be laid. The greenbottle fly (*Lucilia sericata*) has laid nearly 2,000 eggs in captivity; however, the total is probably fewer than 1,000 in the natural state when time and energy are lost looking for suitable places to lay. Egg-laying sites, chosen instinctively by the females, are related closely to larval habitats. Since many fly larvae feed in soft organic materials, many females have developed telescopic ovipositors, formed from the last three or four abdominal segments. The female uses the ovipositor to press the eggs into a mass of decaying material. Blow flies and houseflies push their eggs between the membranes of meat or into any convenient cavity in decaying organic material. The small fruit flies (*Drosophila*), which lay in rotting fruits and fermenting materials, also have this type of ovipositor; however, the large fruit flies (e.g., Mediterranean fruit fly), which lay eggs in the rind of growing fruits, have a stiffer ovipositor. Elaborate ovipositors found in the robber flies are used to push eggs into the interstices of flower heads and the axils of grasses, sometimes even into plant tissues, to conceal them and protect them from drying. When hatched, the larvae drop to the ground and burrow under the soil.

Egg-laying sites

**Larvae.** Fly larvae have one common characteristic: all lack true, jointed, thoracic legs. Many fly larvae have "false legs" (prolegs or pseudopods) similar to those that support the fleshy abdomen of a caterpillar. Flies, much more versatile in this respect than caterpillars, can have prolegs around any body segment. Prolegs help the larvae crawl through narrow spaces or push through soil.

The evolutionary trend among fly larvae has been toward structural simplification; thus, generally, larvae of primitive flies are more structured than are larvae of more highly evolved flies, which show greater physiological versatility. Larvae of most members of the suborder Nematocera (see below Annotated classification) have a well-developed head, with antennae, palpi, and complex mouthparts similar to those of many adult insects. Often they are so structurally adapted to their special way of life that they are unable to adapt to any other. This is, especially true among aquatic larvae (e.g., mosquitoes) and perhaps reaches the extreme in mountain midge larvae, which live in rushing torrents and crawl on sub-

Predominant stage in life cycle

Figure 2: Life cycle of the housefly.

merged rocks. Their body segments are equipped with clinging processes and suckers.

## Maggots

In contrast to highly specialized larvae, about half the fly species have larvae known as maggots. The maggot has lost the complicated head capsule of primitive flies; its pointed anterior end contains one or a pair of mouth hooks. The blunt posterior end has a pair of posterior spiracles (external airholes) that appear to the naked eye as black spots. Microscopically the spiracles are seen as a complex pattern of slits or pores that are useful in distinguishing species.

Although maggots show structural uniformity, they are diverse physiologically. Most maggots feed on decaying organic matter, but there are wide differences in the food preferences of different flies. Eight "waves" of maggots have been distinguished; each wave attacks dead animals in a strict sequence as decay progresses from the newly dead corpse through rigor and putrefaction to mummification. Although some maggots appear only during a clearly defined stage of animal decomposition, the large voracious maggots of many blow flies feed on any animal matter, including living tissues. The best-known blow flies are sheep blow flies, principally species of *Lucilia*. Maggots of *Lucilia* scricatn, for example, feed in small dead animals, abattoirs, and garbage cans; they oviposit in soiled wool around the anus of sheep or in the pus exuding from scratches and wounds, where they are important agents of sheep strike disease. These maggots sometimes occur in soil near buildings in cities; their food source is not known.

Other maggots feed in living or decaying vegetable matter. Larvae of the frit fly of oats and the gout fly of barley are maggots of flies that belong to the plant-feeding family Chloropidae. The hessian fly of wheat is the destructive larva of *Mayetiola* (*Phytophaga*) destructor of the nematoceran family Cecidomyiidae (the gall midges). Although the external structure of most nematoceran larvae is complex, the structure of the gall midges, which live completely immersed in plant tissue, has evolved in the direction of simplification; gall midges are among the most difficult fly larvae to identify. Also known as gall gnats because feeding larvae cause formation of disfiguring galls on leaves or stems, gall midges harm many kinds of plants. Thus they have evolved simplified structure and physiological diversity regarding food plants as have maggots of more advanced flies.

**Molts and larval stages.** Among insects in general, the evolutionary tendency has been toward decreasing the number of molts during development, and flies are no exception. The number of larval stages, or instars, is six or seven in black flies (Simuliidae) and four in most other Nematocera. Along the second line of evolution of flies, Brachycera have from five to eight instars while the maggots of the most advanced flies (Cyclorrhapha) have only three. One or two species have no molts. Sometimes molts occur before the larva hatches from the egg. Muscidae, for example, are arranged in three groups according to whether they are trimorphic (*i.e.*, have three free larval instars), dimorphic (*i.e.*, pass the first instar in the egg, have two free larval instars), or monomorphic (*i.e.*, pass the first two instars in the egg, have one free larval instar). Monomorphic larvae are always predatory; the others feed first on decaying matter (are saprophagous), but they may or may not be predatory in their final instar.

**Pupa.** The external features of the adult fly (*i.e.*, eyes, antennae, wings, legs) are clearly visible in the pupa. The pupa, however, is not always exposed to view; it may be enclosed either in a cocoon of extraneous matter (*e.g.*, soil, or silk, or a mixture of the two) or in a puparium, which is a case formed by the hardening of the larval skin. A puparium is formed in flies of the family Stratiomyidae and others that have maggots as larvae (all Cyclorrhapha). Many families of flies form cocoons sporadically; the cocoon has evolved as an adaptive device that provides extra protection to the pupa. The pupae of mosquitoes, of black flies (Simuliidae), and of a few aquatic midges swim actively. Many pupae that lie in soil

## Cocoons

or in wood have developed thorns and spines to help them work their way to the surface just before emergence of the adults.

**Adult.** The adult fly emerges from the pupa soft and crumpled with a colourless skin (integument) and perfectly formed (though not fully pigmented) hairs and bristles. The newly emergent adult swallows air to expand its body and wings and to force blood through its body. In the more advanced flies of the group Schizophora (see below), the ptilinum, an inflatable membranous sac in the head, is used to aid this process. The ptilinum shrivels away after it has performed its function; however, it leaves behind the ptilinal suture, a horseshoe-shaped groove that runs over and beside the antennal sockets and is only found in Schizophora.

**Ecology.** It has been said that there is hardly any life-supporting medium in which dipterous larvae have not been observed. It is not possible to discuss all dipteran habitats, but the annotated classification below provides many examples. Maggots, however, are the most important larvae, because they play an essential role in breaking down and redistributing organic matter. The waste products excreted by the larvae provide nutrients for molds, fungi, and plants. In addition, the bodies of larvae, pupae, and many adult flies are an important food source for higher animals. Examples are aquatic larvae of midges and mosquitoes, which are staple food for fish. The terrestrial maggots of many flies also have a role in food chains. Since a blow fly can lay one to two thousand eggs, the blow fly population would increase calamitously if more than a few of them survived. Most of the larvae die of malnutrition, desiccation, or drowning, or are consumed by birds. The adult flies are snapped up by birds, small mammals, frogs, and toads. Swallows, swifts, and martins devour large numbers of flies that have been carried up into the air by convection currents. Thus, the population is maintained at a constant level.

The most fundamental importance of flies, therefore, lies not in the few familiar families that contain mosqui-

Figure 3: Body plan of Diptera. (Top) Adult; (bottom) larva.

toes, tsetse flies, houseflies, and other nuisance insects, but rather in the large numbers of unfamiliar species that are an essential element in the food chains upon which all life depends.

#### FORM AND FUNCTION

**External features of adult.** General *appearance.* The thorax, abdomen, and legs of adult flies vary from long to short; the appearance of the fly is functional as well as decorative. Sometimes the bright colour and pattern of many flies is metallic (*e.g.*, blow flies), but most often the fly is covered with a fine coating called tomentum or dusting. Many flies, particularly those of more highly evolved families, are bristly; and the strongest bristles have a precise location, particularly on the thorax. The arrangement of bristles and the identification method based on them is called chaetotaxy.

**Wings.** Adult flies have only one pair of wings, on the mesothorax or second thoracic segment. The hind wings, modified into halteres, have a stalk and a knob, or club, that may be large and heavy relative to the size of the fly. The halteres vibrate up and down in time with the wings and act as gyroscopes in flight. If the fly yaws, rolls, or pitches during flight, the halteres, maintaining their original plane of movement, twist at their bases, where special nerve cells detect the twist and cause the fly to correct its flight attitude.

The wings of flies have a defined pattern of veins; each has a name and characteristic location, often of taxonomic value. Few true flies have a reticulation (*i.e.*, network of small veins) such as those in many other insects that are mistakenly called flies (*e.g.*, mayflies, dragonflies, dobsonflies). Primitive flies tend to have complex wing venation, while advanced ones have reduced and simplified venation. Some of the small midges (*e.g.*, Cecidomyiidae, Sciaridae, Mycetophilidae) have reduced wing venation also. Reduction or loss of wings occurs in many families, particularly those that inhabit windy places (*e.g.*, mountains, islands) or caves, or that are external parasites among fur and feathers.

**Eyes.** The eyes of flies often occupy most of the surface of the head, especially in males, where the eyes may meet in the middle line (holoptic). In female flies, with few exceptions, the eyes do not meet (dichoptic). In some families, notably robber flies and small acalyprate flies, both sexes are dichoptic. Parasitic flies, or those that live in secluded places, may have very small eyes or none at all. Typically, however, the compound eyes of flies contain many facets; for example, the housefly has 4,000 facets in each eye, about average for insects.

**Mouthparts.** The mouthparts of flies are adapted for sucking. Most flies have maxillae; many also have mandibles, elongate blades that overlie a groove in the labium and form a tubular channel for sucking liquids. In some females (*e.g.*, bloodsucking flies, mosquitoes) the mandibles act as piercing stylets for drawing blood. Mandibles became functionless or were lost entirely relatively early in fly evolution and therefore bloodsucking families that evolved later had to develop other piercing methods. Tsetse flies and stable flies use the hardened labium; robber flies and dance flies use the hypopharynx; and Dolichopodidae (small, metallic green flies with very long legs) envelop prey in the spongy labella of the labium and crush it with specially evolved teeth. Most flies suck their food; the few exceptions have reduced mouthparts and possibly do not feed at all as adults. Thus the food of flies must be liquid or solids that can be liquefied by saliva and stomach juices. Flies also have a pair of labial palpi equipped with sensory cells that act as organs of touch, taste, and smell. The palpi and the antennae are essential for examining possible food sources and suitable sites for egg laying.

**Antennae.** All flies have antennae. Members of the suborder Nematocera (*e.g.*, crane flies, various midges, and gnats) have whiplike antennae with two basal segments (scape and pedicel) and a flagellum of many similar segments. All other flies, properly called Brachycera, or short horns because the flagellum is contracted into a

compound third segment, have remnants of the terminal flagellar segments remaining as a pencil-like style or a bristle-like arista. Considerable antennal structural differences exist among related genera and species.

**Larval features.** Larvae of flies have no wings, show no external traces of wingbuds (endopterygote insects), and do not have segmented thoracic legs. Larvae of primitive flies (most Nematocera and Brachycera) have a well-developed head, with chewing mouthparts. Evolution has favoured reduction of the head capsule and replacement of chewing mouthparts with a pair of mouth hooks that move in a vertical plane. Larvae with adaptive external structures (*e.g.*, prolegs) generally belong to the Nematocera or Brachycera. The maggots of the Cyclorhapha have little external structure other than black mouth hooks and the posterior spiracles. Although a few of these larvae show secondary complexities (*e.g.*, some aquatic larvae of hover flies and shore flies), most cannot be identified beyond the family level.

**Nutritional requirements.** Adults. Nutrition involves balance between feeding habits of larval and adult flies. Primary feeding occurs during the larval stage; adult feeding serves to compensate the shortcomings of larval nourishment. At one extreme are nonbiting midges, with larvae that vigorously filter micro-organisms from water; the adults do not feed. Related to nonbiting midges are biting midges, mosquitoes, and black flies; adult females in these families must supplement an insufficient larval diet. Although one batch of eggs occasionally is laid without a meal of blood, blood is necessary to mature a second batch. Flies that lay one batch of eggs without blood are autogenous; those that cannot lay at all without blood are anautogenous. One species can have both types, possibly as a result of shifting populations or races arising from natural selection. For example, in the far north large populations of biting flies (*e.g.*, mosquitoes, biting midges, black flies, horse flies) occur during the short Arctic summer; obviously there are insufficient numbers of warm-blooded animals to provide food. If the flies find blood, they use it; if not, they still survive.

Most adult flies visit flowers, which provide water, nectar, and pollen. Pollen, more difficult for a sucking insect to obtain than blood, is rich in protein and is an important source of this nutrient. Certain hover flies crush pollen grains between hardened portions of the labella before swallowing them; many flies actively probe into flowers, covering their heads and eyes with pollen grains. Nectar from flowers contains carbohydrates, and most adult flies use this syrupy liquid. Although their role in pollination is less well known than that of bees, flies are important pollinators of flowers. Some plants (*e.g.*, spurge) are often covered with small flies of different families. Small flies also feed on honeydew from aphids (see HOMOPTERA). Although the name *Drosophila* means "lover of dew," this insect sucks water and any other obtainable fluid. Flies feed on dung and liquid products of either animal or vegetable decay. They obtain nutrients from farmyard manure heaps and garbage dumps. These places also harbour many larvae that feed either directly on available organic food or are carnivorous on other larvae. A familiar example is the yellow dung fly; adults prey on other insects visiting the dung.

Larvae. The adaptability of flies is evident in the wide range of foods that larvae eat. Apart from parasites, the most specialized feeders are larvae that live in plant tissues (*e.g.*, leafmining Agromyzidae, many restricted to one plant species or group). Generally agricultural and horticultural pests (*e.g.*, cabbage root fly) are versatile species, feeding on a variety of wild hosts and modifying their diets when presented with concentrated plantings of commercial crops. Many carnivorous fly larvae (*e.g.*, asilids) probably live in soil and eat vegetable or animal matter, whichever is available. Since adult asilids (robber flies), however, feed on other insects, the larval nourishment is presumed to be inadequate. Some larvae, particularly maggots, that feed on vegetable matter during the first and second instars, become carnivorous during the third instar, when most of the growth takes place.

## Respiration

Larval respiration is adapted to the medium in which the larvae live. Although a few parasitic larvae (*e.g.*, Pipunculidae, parasitic in froghoppers, and Drosophilidae, internal parasites of scale insects) get oxygen through the skin, most dipterous larvae need a tracheal system to distribute oxygen. Primitively, the tracheal system probably opened exteriorly by paired spiracles on each segment of the body. The soil dwellers, Bibionidae and Scatopsidae, retain this system, although most families have kept spiracles only on the thorax (one pair) and one at the tip of the abdomen. Even these are closed in some aquatic larvae (*e.g.*, luminous larvae of some fungus gnats and larvae of biting midges). However, mosquito larvae and those of most other water-living flies surface frequently to renew their oxygen supplies. Some larvae pierce the stems of underwater plants to obtain oxygen formed as a result of photosynthesis. Maggots of Cyclorrhapha rely heavily on complex posterior spiracles. Pupae respire through prothoracic spiracles that are sometimes equipped with long tubes extending outside the cocoon or puparium.

## EVOLUTION AND PALEONTOLOGY

Diptera belong to the panorpoid complex, which includes Mecoptera (scorpionflies), Trichoptera (caddisflies), Lepidoptera (butterflies and moths), Siphonaptera (fleas), and Diptera (true flies). All are believed to have evolved from an ancestor that lived in moss; four-winged insects that resemble crane flies have been preserved as fossils in Permian deposits (see FOSSIL RECORD). Strata of the Lias Period (Lower Jurassic) contain many true midges; early Brachycera began to appear in Mesozoic; Cyclorrhapha appear in the Cretaceous. By the end of the Eocene Epoch most modern families of flies had evolved. Flies in Oligocene amber and copal are similar to living genera.

## CLASSIFICATION

**Distinguishing taxonomic features.** The wings are the most distinctive feature of Diptera; they consist of a pair of functional forewings and reduced hind wings called halteres that serve as balancing organs. Except for male scale insects (see HOMOPTERA), only Diptera have hind wings modified into halteres. The thorax consists almost entirely of mesothorax filled with muscles that operate the forewings. This feature is useful in identifying wingless flies. The single pair of wings also distinguishes Diptera from other insects called flies (*e.g.*, caddisflies, dragonflies), while the posterior halteres separate the Diptera from other insects that have one pair of wings (*e.g.*, some mayflies and beetles).

Division into suborders is based on structure of antennae and wing venation. Another major feature is chaetotaxy, the arrangement of strong bristles, many in fixed positions and given individual or group names. Separation of Diptera into families is based on habitats and habits (*e.g.*, feeding) of larvae and adults. Genera and species are distinguished by details of head structure, shape and degree of separation of eyes, profile of head, and shape and proportions of leg segments. Abdominal shape often determines characteristic appearance of a genus, but it is difficult to define; the shape varies as the insect is starved, well fed, or pregnant (viviparous flies, such as tsetse).

## Annotated classification.

## ORDER DIPTERA

Size range one millimetre to 7.5 cm; wings, when present, number two; hind wings reduced to halteres; sucking mouthparts; 85,000 species; worldwide distribution; diverse habitats and diets in both larvae and adults.

## Suborder Nematocera

Antennae consist of scape, pedicel, and flagellum with numerous similar segments; maxillary palpi with more than three segments, often pendulous; anal cell of wing open; larvae usually with well-defined head, mandibles horizontally opposed.

Family Tipulidae (crane flies). Elongated body, wings, legs; slow-flying; larvae in soil (leatherjackets), moss, rotten wood, mud, fresh water, littoral, marine.

Family Mycetophilidae (fungus gnats). Fragile, slender; fly about in damp, shady places, among decaying vegetation.

Family Sciaridae. Similar to fungus gnats but more compact, more often indoors.

Family Bibionidae (march flies in northern hemisphere). Compact, well-armoured flies; strong spurs on legs; often abundant on spring blossoms; larvae in soil, sometimes found in a tangled mass near roots of plants.

Family Scatopsidae. Similar to march flies, more often indoors.

Family Cecidomyiidae (gall midges). Tiny flies seldom seen as adults; shapeless larvae burrow into plant tissues, cause formation of plant galls, and deform leaves, stems, and roots; some horticultural and agricultural pests.

Family Psychodidae (moth flies). Tiny, with hairy wings; often seen singly in kitchens, on windows above sinks; some larvae numerous in sewage sedimentation tanks; larvae mostly aquatic.

Family Phlebotomidae (sand flies). Closely related to Psychodidae; adult females suck blood, carry dermal and intestinal leishmaniasis and sand fly fever.

Family Ceratopogonidae (biting midges). Tiny, often with spotted wings (*e.g.*, Culicoides); adult females with irritating bite suck blood, carry some parasitic worms; Forcipomyia suck blood of insects.

Family Chironomidae (nonbiting midges). Related to biting midges, but females do not suck blood; larvae aquatic; important fish food; adults swarm near water.

Family Simuliidae (black flies). Also buffalo gnats; small, humpbacked, with short antennae; females suck blood, carry parasitic worms that cause "river blindness"; forms nodules under skin; larvae aquatic, filter feeders, attached to stones, underwater vegetation, or fresh-water crustaceans.

Family Culicidae (mosquitoes). Small; elongated; proboscis prominent; palpi often long; best recognized by scaly wings; many females suck blood, carry human diseases (Anophelini carry malaria; Culicini carry yellow fever, filariasis, dengue, viral encephalitis); larvae and pupae aquatic.

## Suborder Brachycera-Orthorrhapha

Name usually shortened to Brachycera; flagellum of antennae nearly always fused into a compound third segment, remaining diminutive segments form a stumpy "style" or bristle-like arista; anal cell of wing narrowed, nearly always closed on or before wing margin; palpi seldom with more than three segments, often two or one, held forward (porrect); larvae usually with well-defined head, mandibles move vertically or parallel, cannot be opposed; adult escapes from pupa by a rectangular slit ("Orthorrhapha").

Family Stratiomyidae (soldier flies). Colourful flies, found resting on vegetation with wings closed; males sometimes dance in air; larvae sometimes elongate, aquatic, active, carnivorous (Stratiomys); others in decaying vegetation (Hermetia).

Family Rhagionidae (snipe flies). Inconspicuous, usually rest on vegetation; some females (*e.g.*, *Symphoromyia*) suck blood; most larvae in soil or in water (some Atherix females form egg-laying swarms); some make pits in dust, like ant lions (*Vermileo*).

Family Pantophthalmidae. Large, archaic flies, now found only in tropical forests of South America; wood boring larval grubs sometimes damage commercial timber.

Family Tabanidae (horse flies, deer flies; march flies in Australia). Squat flies with big heads, brilliantly coloured eyes; some females (Chrysops, *Tabanus*, Haematopota) suck blood, are livestock pests; many primitive genera feed only from flowers; larvae in mud or wet soil, either vegetarian (*Chrysops*) or carnivorous (*Tabanus*, *Haematopota*).

Family Asilidae (robber flies). Adults catch other insects in flight, suck their blood; size varies from a few millimetres to eight centimetres (longest of all flies); characteristic "moustache" of bristles probably protects eyes from damage by fly's victim; larvae in soil or wood; eat any food.

Family Bombyliidae (bee flies). Hairy, scaly; superficially resemble bees, hover over flowers in similar way; often brightly patterned, pattern destroyed by rubbing scales; larvae scavenge in bee and wasp nests, or are parasitic (*e.g.*, locust egg pods, tsetse pupae).

Family Scenopinidae (window flies). Tiny black flies, on windows indoors; develop from larvae in carpets, feed on flea and clothes moth larvae; natural habitat, bird nests or similar dry debris.

*Family Therevidae* (stiletto flies). Adults resemble Asilidae, but not predatory; larvae like Scenopinidae, elongated, worm-like, carnivorous but sometimes attack plant roots.

*Family Nemestrinidae*. Rather like Bombyliidae; larvae parasitic in grasshoppers, locusts, perhaps beetles; remarkable for beautiful hovering.

*Family Acroceridae* (balloon flies). Grotesque; abdomen swollen, thorax small, head tiny; larvae parasitic in spiders.

*Family Empididae* (dance flies). Adults suck insect blood, also feed from flowers. *Hilara* darts over water, catches small insects; larvae in many habitats (e.g., marine and freshwater mud, decaying vegetation, fungi, running sap from trees).

*Family Dolichopodidae* (long-legged flies). Tiny, metallic, bristly flies; large numbers sit on leaves in wet places; predatory on other insects; larvae like Empididae, elongated, with little external head structure, same habitats.

#### Suborder Brachycera-Cyclorrhapha

Usually shortened to Cyclorrhapha; characteristically form pupa inside last larval skin as a puparium; adult fly pushes off a circular cap, hence the name Cyclorrhapha; most families (Schizophora) with a ptilinum (membranous sac inside head), which emerges from a horseshoe-shaped ptilinal suture (identifies adult Schizophora) above antennae, is puffed in and out to help fly escape from puparium or soil or to inflate fly's body; ptilinum atrophies and only ptilinal suture remains; a small group of Aschiza, without ptilinal suture, are recognized chiefly by their wing venation.

##### Series Aschiza

*Family Lonchopteridae*. Little known; notable for parthenogenesis; few species; worldwide; sometimes abundant.

*Family Phoridae* (coffin flies). Tiny flies sometimes numerous indoors; larvae live in any organic debris rich in protein or nitrogenous decay products and scavenge in nests of wasps, bees, ants, termites; breed in carrion; many adults wingless or with short wings (brachypterous).

*Family Pipunculidae*. Tiny flies; head spherical, noted for precise hovering; larvae parasitic in Homoptera.

*Family Platypezidae*. Small flies; peculiar legs; rarely seen; appear to dance in smoke of wood fires; larvae live in fungi.

*Family Syrphidae* (hover flies). Vena spuria in wing runs between third and fourth veins; familiar everywhere; hover over flowers, settle on leaves; some larvae aquatic ("rat-tailed" maggots); larvae of many species feed on aphids on plant stems and leaves.

*Family Conopidae* (thick-headed flies). Wasplike flies; larvae parasitic in bees and wasps; may be a separate evolutionary line.

##### Series Schizophora

All flies with a ptilinal suture in head; larvae with no external head structure, mouth hooks visible through cuticle, one pair of prothoracic spiracles and one pair of posterior spiracles, each with either three slits or a mass of small pores; larvae with fore end pointed and hind end truncate are called maggots; larvae with both ends blunt and fleshy, with bulges and tracts of spines, are called grubs.

##### Section Acalyptrata

Thoracic squamae (i.e., calypters that join base of wing to thorax) are small or evanescent; small soft-bodied flies; major families well established; placement of genera uncertain; families can be grouped according to food preferences of larvae.

*Flies breeding in vegetable compost and dung.*

*Family Lauxaniidae*. Larvae in decaying vegetable matter.

*Family Helomyzidae*. Like Lauxaniidae; most generalized of Acalyptrata.

*Family Dryomyzidae*. Like Lauxaniidae, but with wider range of food, including fungi; yellow flies often seen in winter.

*Family Chyromyiidae*. Yellow flies, 1 or 2 millimetres long; breed in debris of bud nests, mammal burrows, caves, cellars; seen singly on windows indoors.

*Family Celyphidae* (beetle flies). Scutellum enormously enlarged until it covers both abdomen and wings when at rest; tropical dung breeding.

*Family Mormotomyiidae*. Contains one wingless, African species; looks like a spider; known from only one locality in Kenya; breeds in bat dung.

*Family Coelopidae* (kelp flies, seaweed flies). Breed in wrack (i.e., heaps of decaying seaweed stranded on beaches) chiefly in temperate countries; adults of some species attracted by trichloroethylene; sometimes pests.

*Flies breeding in animal refuse, dung, carrion.*

*Family Sepsidae*. Small, black, roundhead flies, sometimes with spots at wing tips; may breed to infestation level in sewage sludge.

*Family Piophilidae* (cheese skippers). Larvae in cheese, ham, cured meats, dried fruits, preserved skins and pelts; natural habitat in mummifying carrion; called "skippers" because larvae move both by crawling and "skipping" (i.e., gripping the tip of the abdomen with mouth hooks and flipping the body through a relatively long distance).

*Family Micropezidae*. Large, long-legged flies; often with conspicuously patterned, blue-black wings; spectacular in tropics.

*Family Sphaeroceridae*. Tiny, black-brown flies; first tarsal segments of hind legs swollen; abundant throughout world in dunglike materials; some members live in seaweed on beaches; many short-winged or wingless species.

*Family Sciomyzidae*. Aquatic larvae eat both living and dead snails; may be valuable as controlling agents for injurious snails.

*Family Milichiidae*. Breed in dung; adults attach to predatory insects and spiders and feed on them; called "insect jackals"; *Madiza glabra* sometimes numerous indoors.

*Family Carnidae*. Scavenge in nests and burrows. Adults of *Carnus hemapterus* scavenge among bird feathers, break off wings.

*Family Neottiophilidae*. Nest-breeding; larvae suck blood of nestling birds.

*Family Thyreophoridae*. Among the rarest of flies; larvae in dead bodies of large animals.

*Family Chamaemyiidae*. Predatory larvae; known as controlling agents of aphids.

*Family Braulidae* (bee louse). *Braula caeca*, wingless fly, lives in beehives; larva feeds on wax and pollen stores; adult attaches to bee, may solicit nutritious saliva like other members of bee colony.

*Flies with plant-feeding larvae.*

*Family Ephydriidae* (shore flies). Transitional; wide range of larval habitats; no substance unpalatable for larvae (e.g., algae, sewage, excrement, carrion, urine, brine, hot springs, tar pools); carnivorous petroleum fly (*Psilopa petrolei*) lives in pools of crude petroleum seepage preying on trapped insects; many larvae feed in terrestrial and aquatic plants.

*Family Diopsidae* (stalkeyed flies). Some larvae live in decaying plant tissue, others mine in living plants.

*Family Chloropidae* (frit flies). Most important plant feeders; includes economic pests of cereal and other crops.

*Families Opomyzidae, Geomyzidae, Psilidae*. Small, usually yellow or grayish flies, plant feeders; *Psila rosae*, the carrot fly, an agricultural pest.

*Family Agromyzidae* (leafminers). Larvae feed in parenchymatous tissue of leaves, render epidermis transparent and produce either serpentine or "blotch" mines; rarely cause severe damage, but disfigure ornamental trees and shrubs.

*Flies with fruit-feeding larvae.*

*Family Trypetidae* (large fruit flies). Form galls in certain flowers particularly Compositae; many Trypetidae larvae feed in living fruits, and ruin them; now worldwide distribution; economic damage by several members (e.g., the Mediterranean fruit fly *Ceratitis capitata*) has resulted in worldwide quarantine laws to regulate entry of fruit into countries.

*Family Drosophilidae* (small fruit flies). Larvae in decaying and fermenting fruit or any sweet substance; includes *Drosophila melanogaster*, used in genetic studies.

A number of smaller families have been formed to accommodate genera closely related to the two above. Otitidae (Otitidae) and Lonchaeidae are the most clearly defined. Others such as Ulidiidae, Pallopteridae, Phytalmidae, Camilidae, and Diastatidae are debatable.

##### Section Calyptrata

Characterized by large squamae (calypters that join base of wing to thorax); Scatophagidae are transitional.

*Family Scatophagidae* (dung flies). Live around dung, other decaying materials; many also predacious as larvae and as adults.

*Family Muscidae* (housefly and allies). Many species include the housefly; some larvae carnivorous, especially in third instar; breed in decaying vegetable matter or dung; larvae of *Fannia*, the "lesser housefly" like materials soaked in urine; economically important muscid larvae feed on plant

stems and roots; subfamily (sometimes a separate family) Anthomyiinae contains dipteran plant pests; stable fly, *Stomoxys*, (biting proboscis in both sexes) may be placed in a separate family, Stomoxyidae; tsetse fly *Glossina*, confined to Africa, peculiar structurally and biologically, sometimes placed in the family Glossinidae, occurred in North America in the Miocene.

**Family Calliphoridae** (blow flies). Some bristly flies with carrion-feeding maggots; common blow flies, *Calliphora* (bluebottles), feed as larvae in dead meat; *Lucilia* (green-bottles) sometimes attack living flesh; screw-worms (*e.g.*, *Cochliomyia*, *Callitroga*) are dangerous feeders in living tissue.

**Family Cuterebridae**. Offshoot of Calliphoridae above; larvae are parasitic in rodents; one larva, *Dermatobia hominis* (human bot fly) also attacks man; eggs sometimes attached to mosquitoes and other biting flies and carried to their prospective prey.

**Family Oestridae** (bots and warbles). Larvae live under skin, in nose, and in other head cavities of large mammals; includes the sheep nostril fly (*Oestrus ovis*), warble flies of cattle (*Hypoderma bovis* and other species).

**Family Gasterophilidae** (horse bots). Larvae live in stomachs of horses, zebras, rhinos and elephants, attached to intestinal lining; relationship with other bot flies problematic; currently classified with other bot flies.

**Family Sarcophagidae** (flesh flies). Large, gray and black; common around refuse dumps; larval habits diverse, in living or dead animal matter; many viviparous species.

**Family Tachinidae** (tachinid flies). Ecologically important in balance of nature because larvae are parasites in other insects, spiders, woodlice, and centipedes; employed in biological control of pests.

#### Section Pupipara

Disputed group, families may merely be convergent in habit; lay living larvae, adults of both sexes feed exclusively on blood.

**Family Hippoboscidae** (louse flies). Feed as adults on blood of mammals and birds; many fly, some have wings reduced or lost (*e.g.*, sheep ked, *Melophagus ovinus*).

**Family Streblidae** (bat flies). Distinct, rounded head, wings often functional but fly little; cling closely to host.

**Family Nycteribiidae** (wingless bat flies). Always wingless; thorax weakened and de-sclerotized; live exclusively on bats; scarcely recognizable as flies.

Critical appraisal. Although there is general agreement concerning major groups of Diptera, disputes concerning relatively minor problems are not uncommon. After extensive study of relationships among families, probable lines of evolution within the order were traced in 1958. The order was surveyed according to the evidence of paleontology, and many fossil flies were illustrated in 1964; this resulted in subdividing the order into an unusually large number of families. Evolution of flesh-feeding maggots and classification and probable evolution of Oestridae has also been investigated.

## Dirac, P.A.M.

The English theoretical physicist P.A.M. Dirac played a prominent role in the mathematical restructuring of the science of physics early in the 20th century that advanced the understanding of atoms and made it possible to control their behaviour. An early practitioner of the mathematical methods that have come to characterize modern theoretical physics, Dirac applied these techniques with notable insight and originality. Physicists rank him as a theoretician with Albert Einstein and Niels Bohr.

Ramsey & Muspratt Ltd., Cambridge

Dirac. 1960.

Paul Dirac was born in Bristol, England, on August 8, 1902. His mathematical ability showed itself, as often happens, at an early age. At the school he attended in Bristol he was given rather advanced books on mathematics to study independently. His father, a Swiss by birth who was the French master at the same school, encouraged his son to develop his mathematical ability. He wished him also to become fluent in French, to the extent that, according to the son's report, the elder Dirac refused to speak to him unless he was addressed in the French language. This may have fostered Dirac's pronounced tendency to speak seldom and choose his words with utmost care. He avoided company, preferring to work alone. His chief pastime was solitary walks.

Toward the practical end of earning a living, Dirac studied engineering at the University of Bristol. The use of approximations that he learned in this study had a strong influence on his later work; it strengthened his confidence in the intuitive approach to problem solving. He came to believe that a theory expressing fundamental laws of nature could be constructed solely on the basis of approximations, guided by intuition rather than exact knowledge of the actualities. He declared that the actual phenomena were too complex ever to be pinned down in a precise way; a physicist must be satisfied to work only with approximate knowledge of reality.

Dirac's study of theoretical physics began only after he had received a degree in electrical engineering, had failed to find work in this field, and, aided by a grant, had entered St. John's College, Cambridge. From R.H. Fowler,

Training in mathematics and engineering

his faculty supervisor, who had collaborated with Niels Bohr in his pioneering work in atomic physics, Dirac learned the current state of that science.

In 1926, while still a graduate student, he made his first major contribution to physics by devising a form of quantum mechanics, the laws of motion that govern atomic particles. Other physicists (Max Born, Pascual Jordan) working in Germany anticipated Dirac in this achievement by only a few months. Dirac's version of quantum mechanics was distinguished, however, by its generality and logical simplicity.

With the object of formulating atomic laws in the most elegant mathematical language, Dirac applied to quantum mechanics the ideas of Einstein's special theory of relativity. He had the revolutionary idea that the electron could be described by four wave functions, satisfying four simultaneous differential equations. It followed from these equations that the electron must rotate on its axis, an idea that had been developed by other physicists, and also that there must be states of negative energy. The latter conclusion did not seem to correspond to physical reality. In a later paper, however, Dirac suggested that a deficiency of an electron in one of these states would be equivalent to a short-lived positively charged particle. This idea was confirmed when Carl David Anderson obtained cloud chamber photographs showing the existence of positrons—*i.e.*, particles equal to the electron in mass but positively charged. In the experimental confirmation of this phenomenon, an apparent difficulty of Dirac's theory was turned into a triumph.

In his book *The Principles of Quantum Mechanics* (4th ed., 1958), Dirac developed the so-called transformation theory of quantum mechanics that furnished a machinery for calculating the statistical distribution of certain variables when others are specified. He also stated his philosophical position with respect to theoretical physics. The fundamental laws of nature, he wrote, "control a substratum of which we cannot form a mental picture without introducing irrelevancies." In his own work Dirac avoided using any pictorial model or mental picture of the phenomena described by his mathematical symbols.

In addition to refining mathematical descriptions of matter on the atomic scale, Dirac introduced a quantum theory of radiation. He was co-inventor of the Fermi-Dirac statistics. In 1933 he was awarded the Nobel Prize for Physics (shared with Erwin Schrodinger) and in 1939 the medal of the Royal Society. Dirac taught at Cambridge after receiving his doctorate there, and in 1932 was appointed Lucasian Professor of Mathematics, the chair once held by Isaac Newton.

**BIBLIOGRAPHY.** An introduction to Dirac's work may be found in NIELS H. DE V. HEATHCOTE, *Nobel Prize Winners in Physics 1901–1950* (1953). A historical account of the development of modern atomic physics that stresses the disparate contributions of individual theoretical physicists is BARBARA LOVETT CLINE, *The Questioners: Physicists and the Quantum Theory* (1965).

(B.L.C.)

## Directing

The craft of controlling the evolution of a performance out of material composed or assembled by an author is called directing. The performance may be live, as in a theatre and in some broadcasts, or it may be recorded, as in motion pictures and the majority of broadcast material. The term is also used in film, television, and radio to describe the shaping of material that may not involve actors and may be no more than a collection of visual or aural images. Directing also may mean the instructing of anyone who takes part in any kind of radio or television program so as to make best use of what is said or done in front of the camera or microphone.

In the theatre a confusion has arisen between definitions as applied in England and in the United States. The director (as distinct from an old-time actor organizing rehearsals of a play in which he himself appears) emerged during the 19th century, and, like his actors, he worked for an employer who engaged both on contract. The employer, in England, came to be known as the manager,

while the person directing the action was known as the producer; in the United States the producer is in fact the one who engages the actors and finances the production, while the artist who directs the actors and shapes the performance is known as the director. With the advent of films these terms were applied to the new industry, and the American usage eventually found its way into the London theatre. Nevertheless, many British provincial repertory companies retained the old terms, and the British Broadcasting Corporation still refers to producers of plays and features. The American usage, however, is spreading in the United Kingdom and the rest of the world, and eventually it will no doubt become general.

The role of the director varies a great deal, not only according to the medium in which he works but also according to whether or not he works with actors. There is always common ground between directors of drama, whatever the medium, because their success depends not only upon knowledge of the specialized form but also upon understanding of acting and human nature. But there need be nothing in common between a maker of fictional films and one who makes abstract films, even though both are film directors; the latter may be an excellent artist, yet may regard people as no more than colours on a palette.

The nature of the medium affects the responsibilities of the director. He who is in charge of a play is responsible, artistically speaking, solely to that play in the same way in which a symphony conductor is responsible to the score. But a film or television director may have a greater social responsibility, for his audience is larger. A documentary-film maker may have a greater one still, since in the editing (an area close to the director's and almost inseparable from it) the meaning of what is photographed or recorded can very easily be transformed into the opposite of what was originally intended.

In all directing there is a tension between content and form. Because in the newer media there are many opportunities for jugglery with technical tricks, directors can be tempted toward virtuosity at the expense of meaning. The justification for this in theatre directing is highly debatable; in any event, the value of immediate effect must be balanced against that of enduring significance, for the two are often mutually exclusive.

Outside the Western world, the director, as part of a general process of westernization, is today established, though only insofar as Western plays and Western-type plays are performed. Indigenous Oriental theatre, as typified by the classical theatre of China and the Nô and Kabuki theatres of Japan, is rooted in tradition. The aim is not discovery but the perfect presentation of what has been discovered. Chinese actors hand down their techniques from father to son. In Nô and Kabuki the positions of the performers on their acting platforms, the precise moments when they make their stylized gestures, and the way in which they use their voices have all been fixed for centuries. For these the director is superfluous.

## DIRECTING FOR THE THEATRE

The director as a dominant force began to be recognized in the late decades of the 19th century. One of his functions, however (that of guiding the actors), was probably being regularly practiced as early as the time of the ancient Greek political orator Demosthenes (384–322 BC), who was said to have been given lessons in speech by an actor named Polus. It is a reasonable assumption that, from the beginning of the existence of an acting profession, it became customary for the most experienced performers to give advice and instruction to their less experienced colleagues: actors are seldom as confident as their performances can suggest, and they need repeated confirmation that their abilities approach their self-imposed standards. Such confirmation is likely to be sought from the most respected member of the company. There is a limit, however, to the value of the help given by a fellow actor; the perspective needed to see all the possibilities of performance is usually attainable only from a viewpoint outside the cast. The importance of this perspective is well illustrated in Hamlet's advice to the players, yet

Applica-  
tion of  
relativity  
to  
quantum  
mechanics

Role of  
the  
director

it was well over 200 years after Shakespeare's death before acting companies officially ceased to direct themselves from within.

**Nineteenth-century directing.** The first professional to coordinate the acting, decor, sound effects, and lighting of a production without performing in it herself was probably Madame Vestris, who in 1830 controlled the Olympic Theatre in London. At her injunction, the company abandoned certain restrictive traditions of dress that had encouraged staginess and artificiality by inhibiting individuality of characterization. At the same time, she introduced varying degrees of realism into her productions, such as interior settings with real doors and windows (instead of painted ones) and sophisticated stage machinery.

By the 1870s Augustin Daly, although a leading actor in America, was also achieving fame for the very personal direction he was giving his company in New York. Daly's even more famous successor David Belasco started his career as an actor and concentrated on directing and play doctoring, after the '80s. He had a flair for vivid staging and is probably the best known director in American theatre history, but he had little or no influence on acting. In common with a number of other early directors in the United States and England, he left behind him no tradition. It was left to an eccentric amateur in Germany to establish an acting company that was eventually to lead to profound changes in theatrical methods throughout the Western world. The Duke of Saxe-Meiningen's actors aimed to achieve a kind of psychological depth of characterization that was quite new for playgoers, and the company also paid a meticulous attention to detail in their settings and in the way they managed crowd scenes. In 1890 they toured Russia, where they greatly influenced Konstantin Stanislavsky, who was beginning to think along the same lines. A few years later, Stanislavsky and V.I. Nemirovich-Danchenko, who had established the Moscow Art Theatre, learned further from Anton Chekhov, a playwright so concerned with conveying the inner realities of human nature that his works could not be acted successfully except through entirely new directorial methods. Eventually, some two and a half decades later, similar methods seen through the independent mind of Theodore Komisarjevsky, who emigrated to England in 1919, were to affect the English theatre.

Meanwhile, in Scandinavia, France, England, and Germany there appeared realistic writers, very different from Chekhov, whose plays, however, also called for deeper and subtler acting; thus, a "theatre of significance" grew up alongside the "theatre of entertainment" in those countries, leading to the emergence of original and creative directors. Prominent among these were Harley Granville-Barker in England and André Antoine in France. By the turn of the century nearly all professional productions presented in Europe and America were directed by professional directors—though another two decades were to pass before directors were universally acknowledged in theatre programs.

**Twentieth-century directing.** The craft of the theatre director has become a matter of considerable diversity and complexity in the 20th century. His field includes the style of acting of his players, the interpretation of the play, guidance of the actors in the exploring of their parts, and sometimes, though controversially, a complete control over their performances. He also exercises overlordship in matters of decor, costuming, and lighting (sometimes he functions himself in these three areas, but union restrictions in certain countries, notably in the United States, prevent this, even though they allow him the final word). Incidental music, if any, and choreography in a musical play are also under his control, as are visual and sound effects.

These, the director's theatrical instruments, are more numerous and sophisticated than they were in the 19th century. Moreover, the actor is now much more aware than he used to be of the techniques of voice and speech, so that the director needs at least a theoretical knowledge of how a performer achieves the fully expressive tonal

octave of which he should be capable. He must also be sensitive to the rhythms and dynamics of speech and how these are affected by emotion and situation; through the contrasts resulting from these, he can create in performance a pattern that can appeal both to the mind and to the senses. Even pauses can be transformed into theatre magic by the director's skill. A great deal depends, too, upon the composition of his stage pictures, which must never remain static for long, and on how and when his actors move. The function of a modern director might be summed up like this: he creates a succession of focal points that must irresistibly attract the attention of the audience; then, through the quality of the acting, he tries to ensure that these focal points are as relevant as he can possibly make them.

**Directorial styles.** The backgrounds of individual directors—some have been actors, some stage managers, some have entered the theatre from other professions—have shaped their styles. Yet style in a director is difficult to gauge. It is much affected by his material, and he may be labelled by facile critics according to the kind of production with which he has been most obviously associated. Max Reinhardt (1873–1943) was famous in two continents as a "spectacular" director very largely because of *The Miracle* (premiered 1911), a play of no great distinction that owed much of its success to his spectacular treatment. His less publicized interpretation of Luigi Pirandello's *Six Characters in Search of an Author*, a psychological play requiring no scenery, was, however, at least as typical of this distinguished Viennese director. The name of Konstantin Stanislavsky is inextricably linked with that of Anton Chekhov, and he is commonly believed to have been the perfect interpreter of the great Russian playwright. The belief is, however, perhaps due less to a full understanding of Chekhov on the part of Stanislavsky than it is to the fact that Stanislavsky wrote repeatedly and at length about the kind of acting that Chekhov's plays needed. We know from the former's prompt script of *The Seagull* and from Chekhov's letters that the two men differed over some fundamental questions of artistic judgment. Chekhov's letters and Nemirovich-Danchenko's last production of *The Three Sisters* (1938), which held the stage for over 20 years, suggest that the Russian playwright was far better served by Stanislavsky's more reticent partner.

The success with which a director has carried out his task is not easily assessed by either playgoer or critic. Both can be deceived by exciting scenery or bold theatrical effects into overvaluing these tools of the trade and forgetting their purpose, which is to ensure an imaginative interpretation of what the author has written. Louis Jouvet, the distinguished 20th-century French director, once wrote:

There are two kinds of director: the one who expects everything from the play, for whom the play itself is essential; and the one who expects nothing except from himself.

There is much truth in this statement, provided the extremes are not taken too seriously. Peter Brook of the Royal Shakespeare Company seemed to expect little from the author when he did an outstanding production of *Titus Andronicus* in 1955. If he had put greater faith in Shakespeare and had not eked out the script with a multitude of happy theatrical inventions, the public would have been the poorer. On the other hand, Brook's treatment of Shakespeare's great plays have not invariably been happy; these do not need eking out and rather seem to ask that director and actors should build a testament to Shakespeare's poetry and grandeur.

Possibly the best directors cannot be made to fit into categories. Tyrone Guthrie (1900–71), in 45 years of directing every kind of play, progressed from an almost perverse disregard of authors to an ungrudging respect for them. His work ranged from Shakespeare to Aeschylus and took in Gilbert and Sullivan on the way. In viewing the totality of Guthrie's work, what emerges most strongly is an irrepressible comedic originality: here he showed the maturity that overtook him after his early productions. The ability to discern comedy inevitably lurking behind the obvious sorrows of existence is evi-

Comedic originality of Tyrone Guthrie

Early directors in America

Diversity and complexity of modern directing

dence of more than maturity; it also demonstrates the director's knowledge of dramatic ways and means, for the face behind the mask is in the best writers always discernible, and in the less good it is still there, to be forcibly exposed. The discovery of the comedy that is latent gives a highlight to good dialogue and the impression at least of an extra dimension to any writing that might otherwise seem featureless.

Jacques Charon of the Comédie-Française is noted for the positive yet subtle way in which he handles comedy and farce. His juxtaposition of the inevitable with the unexpected and his controlled yet apparently uninhibited comic invention put him in the topmost ranks of 20th-century directors. It is his strong technical discipline that makes him equally skillful and at home with French classical theatre as with modern drama. The same range of ability has been shown by the Englishman Sir Laurence Olivier, who is remarkable for his capacity to direct a play in which he is also acting the leading part. This is a rare talent. It is extremely difficult for the actor-director to maintain creative objectivity while becoming immersed at the same time in his own personal creation.

No inventory of outstanding modern directors would be complete without reference to the Swede Ingmar Bergman. His influence on films apart, that of his stage productions has been considerable. This work has spread over the years and is especially associated with the Royal Dramatic Theatre in Stockholm. He is a master of the art of drama in a multitude of forms and techniques, and probably the most profound director of modern times. His emendations to the classic plays of Europe and of his fellow Scandinavians are respectfully regarded even by those who do not agree with them. Part of the success of Bergman's productions is due to his handling of actors and the admiration that he inspires in them. Consequently, the best performers throughout the world have regarded an invitation to work for him as an accolade.

National conditions affect directorial vitality. The vast size of the United States and its hesitation to accept the cultural asset of professional drama, except in a very few cities, have polarized the American theatre in the post-World War II period. At one extreme is Broadway, highly professionalized but dependent upon the limited vision of speculative investors and demanding little of imaginative directors. Its intellectual sterility encourages the opposite extreme of "Off Broadway" and "Off Off Broadway," where there is often both experiment and imagination but also unfortunately much professional incompetence. Somewhere in between are a handful of resident theatres dotted about the country in and around the bigger centres of population. There the conditions imposed by union limitation of rehearsal hours do not encourage the emergence of directors of distinction.

The scarcity of good directors poses the question as to why modern dramatists should not direct their own plays. In the 17th century the great French dramatists Racine and Molière did so as a matter of course. Contemporary writers seem more introverted and tend to lack both the stagecraft and the desire to inspire a company of actors. The contemporary English playwright Harold Pinter is a notable exception. An actor himself, he is as good a director as he is a playwright. Other modern exceptions are the late Harley Granville-Baker and George Bernard Shaw, who saw to it that their plays were performed as they wished them to be. Moreover, they both had a marked effect on English acting and laid the foundations for its 20th-century pre-eminence in the English-speaking world. Shaw, in particular, inspired many a young performer with the understanding of stress, cadence, and rhythm, and even today his stage directions (with most dramatists these are no more than generalized indications and are useless for practical purposes) are models of instructive lucidity from which a director departs only at his peril.

The director's relation to the actor. A proper comprehension of and respect for the actor is indispensable to direction of the highest quality, since the acting in the theatre greatly outweighs such elements as settings, light-

ing effects, and visual ideas. On this point Louis Jouvet and George Bernard Shaw both have written aptly. The former said: "The profession of director suffers from the disease of immodesty." And the latter, hardly famous for underestimating his own abilities, advised in *The Art of Rehearsal*:

Do not forget that though at the first rehearsal you will know more about the parts than the actors, at the last rehearsal they ought to know more about them than you, and therefore have something to teach you about them.

If a director has antagonized his actors and has not, on the contrary, stimulated their imagination so that they have become confidently creative, then failure for him is almost inevitable.

The task is difficult. The best way to communicate with any particular group of actors needs the most balanced judgment. Unlike the orchestral conductor, to whose aims the theatrical director's are closely analogous, he cannot control actual performance. Neither can he, except rarely, tell his actors precisely and in every detail exactly what he wants of them. The minutiae are solely their concern, just as in a concerto they are the concern of the soloist (all actors, basically, are soloists, and their creative powers generally are inhibited by drill sergeant methods). Actors need at least the illusion that their own imaginations have full freedom. To direct by guile is therefore most often the key to success, as was demonstrated by the British productions of Theodore Komisarjevsky, the illustrious Russian director whose subtle yet powerful influence in the '20s and '30s complemented that of playwright-director Granville-Barker and helped to complete the ripening of English acting that took place in that period.

The rehearsal process. The results of the director's efforts are naturally affected by the length of time given to rehearsals. These vary according to economic pressures, national customs, and union rules. In some countries, notably the United States, the actors' union has used its powers to escalate salaries and limit working hours in the 20th century. The American director is consequently hard put to find enough time to achieve the depth and the polish to which he aspires. His limit may stretch to four weeks on Broadway and to a mere one or two weeks outside New York City. In many parts of Europe, subsidized theatre has been long established, and, particularly in eastern Europe and Scandinavia, conditions are better. Rehearsals can last five or six weeks and may even extend into months. Despite unionization, the length of the rehearsal day for serious drama in Great Britain is left to the discretion of the artists themselves. The working day is long there, and four weeks is usually considered enough time.

Directorial capacities for patience and self-control usually are put to the test in the last few days of rehearsal. For weeks the company has worked together, and hopefully it has at last reached a result that, as far as the acting is concerned, seems very close to fruitful consummation. The actors may have rehearsed, as in many European countries, on the very stage on which they are to perform. Alternatively, if they are working in Great Britain or the U.S., they may have worked in nothing better than a room. In either case, a time must come when scenery, probably incomplete, appears and almost inevitably looks unlike what was expected. The actors have scarcely adjusted themselves to this when the lighting has to be set and cues established. Suddenly, the marvellous magic world that the artists have built together and come to inhabit as their own is shattered: the technicians have arrived. There is a sense of retrogression and despondency as door handles come off in the actors' hands and complicated speeches written to be spoken to the dying rays of a setting sun are repeated over and over again while the sun obstinately refuses to set. At this point the entire production must be born again and all its disparate components brought together in rhythm and harmony. Once again, the best served theatre artists are those in eastern Europe and Scandinavia, who are given as much as a week or more, before

directing

the first dress rehearsal, in which they and the technicians can work together upon the stage. The British are fortunate if they have two days. The allotted time in the United States may be less than 24 hours.

There is a crucial responsibility at the other end of the production schedule, before rehearsals even begin. It is the casting process, which is often regarded as an art in itself. An error in casting can be fatal, no matter how much imagination, hard work, and money have been invested in the production. The responsibility should always be the director's, but it is often usurped by the producer in box-office-oriented theatres, and it has become a frequent habit with the latter to seek either the "right type" for the part or a well-publicized "name," irrespective of the ability to act. The wisest casting often works by opposites, so that a hot-blooded character is best played by an actor whose own personality is cool and objective. Then, as a director of the Royal Academy of Dramatic Art in London observed:

Two contrary elements fuse harmonically to create a character in depth [who] becomes "real" precisely because he is made up of opposite elements in the same way as people are in life.

Casting, the planning of schedules, and the coordination of differing streams of creativity become more complex in production outside the field of straight drama. The rehearsal period in musicals, for example, is longer, and the strain is greater not so much on the director's artistic resources (for he has a great many helpers) but on his powers of leadership. The presence of a choreographer, with a conductor and an orchestra, the cost of which in England and America prohibits the use of musicians before the dress rehearsal, in addition to a heightened emphasis on lighting and visual effects, all contribute to creating a vast potential for discord. The director must resolve these and even turn them to advantage.

Ice shows introduce another complication: dancing, singing, and acting capacity has to be injected into skaters by specialists, each of whom may compete with each other for precious rehearsal time and may vie with each other for precedence. All large-scale entertainments reach the ears of the audience by means of electronic amplification. This introduces the alien element of the sound engineer, who is likely to be more technocrat than artist and may require tactful handling.

Clearly, the director of live entertainment needs to be a man with many qualities, some of which are in conflict with each other. Of all the necessary characteristics, patience perhaps is one of the most important. Unlike directors in other media, he is both artist and maintenance man: in a long run it is his duty to watch the show at least every two or three weeks, thus ensuring that all that happens on the stage continues to be true to his original intentions. Such recurring watchfulness calls for critical balance and powers of endurance not easily found.

#### DIRECTING FOR THE MOTION PICTURE

In contrast to the theatre, the motion picture's roots are only partly in acting, with the complex heredity of that art in myth and ritual. The film director's ancestry is mundane: the original interest of film makers was in actuality reproduced as accurately as the technique of primitive photography would allow. The artifices that have always been inherent in drama and that gave it a potential for development into a sophisticated art developed only when the novelty of photographing movement began to fade. A new world was then discovered by the cinema. It was a childlike world of make-believe, whose inhabitants could achieve the impossible, such as multiplying themselves 50-fold in the flash of a second or vanishing like ghosts into nothingness.

Out of such conjuring tricks grew the more compelling magic sought by the technocrats of the films. These, the film editors (or cutters) and the film directors, developed the power to vary the duration of a film shot and the movement of the film camera. It was they, far more than the actors (who at first had little or no control of what they did in front of the lens), who controlled tim-

ing, suspense, and emphasis. When the motion picture finally became accepted as an art, the directors and editors emerged with a measure of artistic control incomparably greater than a theatre director has ever possessed: they had power over the shape of a manufactured product after the actors had completed their own contributions to it.

**The era of the silent film.** Rapid movement and sudden change for their own sakes were the staple ingredients of the early films, and so, when the Lumière brothers caused a sensation in 1895 by photographing the arrival of a train, they needed neither actors nor director. And when another Frenchman, Georges Méliès, made the film *Cinderella*, in 1899, though he used actors, his success was due less to them than to his own cinematic inspiration. Méliès invented multiple exposures, slow and rapid motion, and (by an accident) the fade-in and -out, as well as many other devices that seemed mysterious and fascinating to those seeing them for the first time. Such novelties could give substance to fairy tale and seemed to give the lie to "reality" itself. Méliès made altogether about 4,000 films, from which others learned: he can be fairly called the first film director.

Since the camera can see farther than the human eye and since what is most easily seen is movement, leading logically to action, incident, and conflict, the natural material of the motion picture became melodrama, together with melodrama's reverse image, farce. This did not require sophisticated actors. The early directors springing from among fairground showmen, photographic handymen, and inventive opportunists were not dramatically informed. They were concerned with inventive photogenic action, composing their frames as good photographers, and the better use of their cameras.

**Directors in the United States.** In 1903, the impact of a new innovator was felt in the United States. Edwin Porter, a photographer in Thomas Edison's laboratory, had carefully examined the achievements of Méliès. Méliès had invented out-of-sequence filming. He did this for economic reasons, since he could greatly reduce costs by keeping a set standing and shooting on it until it was completely exploited, regardless of chronological order. Porter, however, thought of deliberately interrupting the sequential flow of action so that it no longer appeared on the screen as one long scene, in the manner of the theatre, but had at certain moments other frames from different scenes cut into it. By this he heightened dramatic tension and pioneered the art of editing. Out-of-sequence filming subsequently has become standard practice, since the economic advantages outweigh its defects. The problems it raises for directors and actors, however, are very real. There have been occasional instances where the appearance of the actor and even the manner of the acting have betrayed the order in which the scenes were photographed. The "continuity girl" is employed for the sole purpose of taking accurate note of every detail of every shot so that mistakes may be avoided. Porter also invented the close-up in *The Great Train Robbery* (1903). Here he showed a huge head and shoulders of the villain pointing a revolver at the audience. The film made history, establishing the basic convention of the western and its prime climactic ingredient, the chase.

Although the French led the world in filming until World War I, and many pictures were made before that in Scandinavia, Italy, and Germany, the growing industry had not by then elevated the film director to prestigious and publicity-earning status. The first to reach that status was D.W. Griffith of the U.S.

Griffith began as an actor, and he brought an improved standard of acting into films. He looked on motion pictures, crude though they were, as something that had possibilities of form and content and so could be shaped into a kind of art. He was not too proud to learn techniques from Porter and Méliès, but he had an original cast of mind and carried innovation a great deal further. Before Griffith the screen was still thought of as a sort of proscenium or frame through which actors, viewed from a fixed position, moved and grouped them-

Griffith

selves exactly as they had always done upon the living stage. Griffith realized that a film audience was not bound to watch drama from a single point. By changing the placement of his camera—which he correctly saw as the audience's eye—they could be made to imagine that they were actually moving among the characters of the story. He thus discovered a new and tremendous power for contrast and emphasis. His camera moved during shots, it panned from side to side, it tilted up and down, it tracked into close-up and out again. This new flexibility of vision and particularly the new intimacy it gave to dramatic action elevated an unsophisticated mass audience to a position of privilege: now they could almost see the heartthrobs of their heroes and heroines.

Griffith invented the "language" of the motion picture. By varying the length of the scenes he shot, he made filmic rhythm possible. His ideas in general greatly influenced the growing motion-picture industry, and many of them havaprevalled throughout the 20th century.

By the end of World War I, which temporarily halted developments in Europe, America had a virtual monopoly in film making. The "star system," which Griffith had created by finding unknown performers and building them up with publicity, had become established. The convention of epic romance, of which *The Birth of a Nation* (1915) was an example, became a stereotype of the "big picture." There were other stereotypes, too; the western invented by Porter and the comedy (which was really film slapstick) made famous by the film producers Mack Sennett and Hal Roach. These stereotypes, which guaranteed success at the box office and were perfect instruments for building an industry based on unthinking mass audiences, did not (except for comedy) encourage creative directing. But they did make for slick technicians and continued technical development. The techniques of editing and directing became more and more intertwined. It came to be realized that clever editing could entirely transform what had been performed on the studio floor. A disaster of acting or directing could even on occasion be turned into success in the cutting room. In Hollywood the stars and the producers decided what should be made, but their ideas were seldom new ideas. The conditions were not healthy for growth of original directorial minds.

*European directors.* In Europe after the war, however, and particularly in Germany in a resurgent industry, the creative director was able to develop. There the market and the audience were smaller, but the tradition of stage drama was very much alive. Films inexpensively made with good actors on modest salaries could create a cinema that was individualistic, free from the obligation to appeal to the lowest common denominator of comprehension, and really a kind of extension of the legitimate theatre that the Germans had always appreciated so much.

Suddenly, the motion picture became respectable fare for bourgeois and intellectual society. The art of the film began to be the subject of critical analysis in the better class newspapers. Such German directors as Robert Wiene (*The Cabinet of Doctor Caligari*; 1919), F.W. Murnau (*The Last Laugh*; 1924), and American-born Arthur Robison (*Warming Shadows*) began to be talked about in circles where such discussions had formerly been limited to the fine arts. The directors of the new Soviet cinema contributed greatly to the general ferment over the new medium. Vsevolod Pudovkin appeared to transform peasants into actors; Sergey Eisenstein developed the cutter's art of montage so that documentary films and dramatic films merged into a single statement. In Sweden Mauritz Stiller discovered Greta Gustafsson and changed her in the United States into Greta Garbo.

By the middle of the 1920's the masters of the silent film had transfigured the primitive trickery of Méliès into a true magic art, backed by the most sophisticated technical achievement. Perhaps its most remarkable monument was *Warming Shadows*, in which Robison succeeded in reducing the subtitles to no more than four, of which only two actually broke into the story. At last the silent film almost literally spoke for itself.

**The sound film before World War II.** In 1928, recorded sound suddenly intoxicated the tycoons of the industry, and for a while all creative direction seemed to be abandoned. Camera technique retrogressed. Cameras were immobilized in soundproof booths to protect the conquering but undirectional microphones from the sound of their whirring motors. Shooting scripts were peppered with directions for inflicting the public with inappropriate noises, from the thunder of well-oiled locks to the patter of little canine feet.

In the United States the coming of sound killed the Hollywood film comedy, which posterity was to rank as a unique contribution to motion-picture art. Hal Roach and Mack Sennett had each taken hold of the American clichés of sentimentality and melodrama and had turned them upside down. The results were a long succession of remarkable inventions, described by the famous U.S. film critic James Agee as

such a majestic trajectory of pure anarchic motion that bathing girls, cops, comics, ~~dogs~~, cats, babies, automobiles, locomotives, innocent bystanders, sometimes what seemed like a whole city, an entire civilization, were hauled along head over heels in the wake of that energy Like dry leaves following an express train.

This was near to genius, even if Sennett had not given their first chance to the world-renowned comics Buster Keaton and Charlie Chaplin and others who developed the form to a high level of inspiration.

The tradition created by Sennett and Roach never really died, though they themselves went out of business when dialogue displaced the visual gag. René Clair, the first important director to use sound in an original way, owed much to Sennett. By the 1930s, cameras had become mobile again, and the satirically minded Frenchman seized his chance with both hands. He found new and unknown actors and formed them to his own style. He wrote his own dialogue. He used composers of reputable quality to write background music that made a witty commentary on the action and characterization at a time when Hollywood was still, on the whole, happy with Tin Pan Alley music. Clair was the first screen satirist of sound films. His *À Nous la Liberté* (1931; "Liberty for Us") was a technically innovative comic-poetic elegy for industrial civilization that immortalized the eccentric aspects of the Gallic personality.

France seemed to lead the world in cinema until World War II. Jean Renoir, the son of the great Impressionist painter and René Clair's contemporary, earned an enduring reputation with beautifully composed pictures, each frame of which plainly showed its ancestry. His films were of the very earth of France, deep and memorable. His camera examined men's natures rather than recorded their actions.

Hollywood directors, with their huge financial resources, maintained a technical lead, and there were exceptions to a general impression that they did no more than turn out a mass of glossy pictures without enduring substance. Ernst Lubitsch imported his Viennese sophistication and wit and kept up a consistent standard in his comedies. Frank Capra reconciled the qualities needed for creating light entertainment with an honest yet affectionate observation of American character. Preston Sturges, a sort of American René Clair, became a brilliant farcical satirist of middle America.

At this time and for some years after, a kind of stability had become established in the industry, and it seemed that the film makers' art and methods had permanently formed their conventions. Choice of story remained almost everywhere with the producers; and these were largely guided by the box office and what would tempt stars to work for them. The handling of the story was much influenced by the producer, although it was the domain of the director and the cutter, who were complementary to each other and were sometimes even the same person. The director's ability to obtain a good performance did not depend on a detailed knowledge of acting (scenes only needed to be sustained for brief periods in a succession of short shots and so did not call for the endurance and technical resource of stage

actors). What the director most needed was an instinct for making the performer seem real in front of the camera—by giving him the briefest instruction in the simplest possible terms. The classic example remains the injunction given to Garbo for her tragic closing shot in *Queen Christina* (1933): she was told to "think of nothing at all." If the dialogue was of unusual quality and made particular demands upon those who had to speak it, then a dialogue director was especially engaged and imported from the theatre or from the faculty of a drama school.

Photography had improved vastly over the years, but camera technique had not changed a great deal since the early days. The director still took his "master shot," covering everybody taking part in the scene. He then photographed portions of the same scene several times at closer range and from different angles. Finally, equipped with long shots, a number of three shots or two shots, and a couple of close-ups, he was able to give the editor ample footage from which to choose the best assemblage of frames. The conventions of dissolves and fade-outs to emphasize lapses of time or changes of locality remained the same as they had been for a long time. The biggest change, in the middle '30s, was the achievement of deep focus, which permitted for the first time a sharp image in the background of a close shot. It was used to good effect by the U.S. director Gregory La Cava in *My Man Godfrey* (1936).

**The sound film after World War II.** Then, in mid-century, films were rocked by television and social change. The mass public, which had loyally supported the movies even through the Depression years, drifted away to the new medium. Insecurity invaded the industry. Perpetuation of old clichés no longer guaranteed success. Producers lost some of the arrogance born of overconfidence and listened more to the views of directors. A new generation of directors was willing and able to take charge of their own destinies.

Even before television had taken hold, the revolution had begun. The U.S. actor-director Orson Welles struck the first blow with *Citizen Kane* (1941). This was something new for Hollywood: realism had sprung before out of its magazine-story romanticism, but it had been a realism that reflected the melodrama of the tabloid headlines or sustained, as in John Ford's *Grapes of Wrath* (1940), the national patriotic myths. Realism inside the home was something else.

**Postwar European directing.** The realities of World War II made nonsense of the romantic dream. Hitherto, Great Britain had counted for little in quality film making, excepting for contributions of Alfred Hitchcock and the documentaries of Robert Flaherty and Humphrey Jennings. Now British directors began to grow into prominence. Carol Reed came to maturity with *The Third Man* (1949). This film, with a story by the English novelist Graham Greene, revitalized the thriller tradition. Reed's roots were in the theatre, and most of his cast were theatre actors: the depth and subtlety of the acting of this film gave great support to a plot whose merit was that its presentation of the postwar world of disillusionment and the iron curtain might actually be true. Other British directors arrived on the scene and made reputations at Ealing Studios. They were not only prolific but also surprisingly eclectic, as exemplified by Robert Hamer's *Kind Hearts and Coronets* (1949)—the only filmed example of an artificial comedy in the Oscar Wilde tradition, especially written for the medium. The British film benefitted, too, from an influx of American directors, like Joseph Losey, displaced from Hollywood by the anti-Communist political pressures of the '50s.

In France there was also resurgence. At first the influences were literary. Only France would have given a writer such as Jean Cocteau the opportunity to direct a film. His *Belle et la Bête* (1946; *Beauty and the Beast*, released in the U.S. in 1947) established a tradition of highly articulate storytelling that has continued with René Clément, François Truffaut, and Claude Chabrol. France, too, gave repeated opportunities to the Spanish director Luis Buñuel, a passionate recorder of human

suffering whose films are not easy to forget because of the contrast between the beauty of their backgrounds and the harshness of the events depicted in front of them. In the same immediate postwar decade there suddenly appeared Jacques Tati, Chaplin's French counterpart. He, like Chaplin, was a brilliant director and comedian combined; both men spend years of meticulous thought between the films they write, direct, and dominate.

Sweden evolved a monolithic figure in Ingmar Bergman. He is imitated by many in a country where motion-picture standards have always been high. He is generally conceded as not having been surpassed in the postwar period, though, like all directors, he has had his failures. One mark of his genius is that in two remarkably fruitful decades he has hardly ever failed to produce the unexpected. Another is that it is almost impossible to judge where, in the many aspects of film making, his pre-eminence lies: he excels in them all—in the way he handles actors (with whom he spends weeks of preparation before he begins shooting), in his cutting and camera work, in always getting the right actor for the right part, and in the intellectual richness of his ideas.

Bergman continued his unpredictable course in the '60s and '70s, while the world of films changed around him. The mass audience had deserted to television, though it could still at intervals be lured back to the movie house, if the "big picture" was good enough and the star popular enough. On the other hand, the contradictions and upheavals that had affected every kind of art in the middle of the century—and which some thought mere perversity and others the road to an artistic utopia—created a climate of great opportunity for enterprising producers. They could risk adventures when the stakes were infinitesimally smaller than in the old days of the huge capitalizations of pictures intended for world consumption. Directors benefitted: they attained a freedom of which their predecessors had never dreamed, seeming to explore a multiplicity of paths in all directions at once.

The Italians were in the forefront not only of change but also of the new catholicity. Luchino Visconti, high stylist of direction in the opera house, made "operatic" pictures, in which elaborate and beautiful sets supported complicated emotional stories acted in depth by experienced and star-studded casts. His films were the *haute couture* of the industry—tasteful, traditional in form (if not always in technique), and magnificent. At the other extreme, Federico Fellini, Vittorio De Sica, and Pier Paolo Pasolini asserted their own directorial importance by deliberately diminishing that of the actor. They claimed that amateurs could more easily be "real people," and their pictures often sought to bridge the gap between fiction and the documentary film. Fellini and Michelangelo Antonioni in Italy and Alain Resnais in France, with younger directors François Truffaut and Jean-Luc Godard, ignored the old conventions of editing that had guided the public for decades and started something of a new fashion. Their avant-garde films darted hither and thither, through time and space, replacing the fade-out by the sudden jump cut, indicating contrasting psychological planes by changing from colour to black and white and back again, and emphasizing strong situations by the frozen frame, in which life seemed for a moment to stand stiff and still as in an old daguerreotype. Truffaut and Louis Malle (together with Fellini) were associated with the so-called "auteur theory," whereby a director assumed *total* responsibility for his picture, often doing without a script, and creating, as he directed, by improvisation. The success of such directors and their followers did a valuable service; it demonstrated that conventions and aesthetic principles are not the same, and that even when they are for the most part convenient and practical they may sometimes be flouted to advantage.

Outside Europe and the United States the film industry expanded, particularly in Japan and India, during the '50s and '60s. Kurosawa Akiwa evolved a great many styles, assimilating Western idioms and translating these into his own. The Indian Satyajit Ray's leisurely long films achieved the persuasiveness of good novel writing

and have achieved considerable success outside his native land.

Directing in the '60s and '70s. In the '60s and '70s there was a tendency for films to grow more subjective, many directors asserting a right for their work to express their personal attitudes. Continuing social evils throughout the world and the futilities of power politics led to films of social consciousness and protest. In the U.S. the virtual collapse of the great wealth and power of the big studios encouraged a striking break with the old Hollywood traditions of make-believe, although films of traditional sentimentality continued to be made and were highly successful. The documentary approach increased in popularity, stimulated by social violence in many countries. In France the phrase cinema *vérité* was coined to express an allegiance to the unglamorous truth. Such films were shot with the news photographer's "mini-camera," often held with a deliberately shaky hand to express the utmost dissociation with the motion picture's glossy past. In 1969 the American director Haskell Wexler solved formidable matching problems by successfully combining colour news film of the Chicago 1968 National Democratic Convention with fictional footage made with professional actors. The result was *Medium Cool*, a thinly disguised protest film.

From the quasi-documentary to the frankly propaganda film was the smallest of steps: from that to the underground film was smaller still. Ever since the 1940s, when the New York director Sidney Peterson made *The Cage*, there had been many purposeful individuals, some with genuine talent and others with none at all, eager to exploit the new and cheaper featherweight cameras in order to demonstrate their personal views. Needing minimal equipment, avoiding professional actors, and combining the function of director, cameraman, and editor, they could make films for small audiences at astonishingly low cost and in perfect freedom. Their subject matter ranged from Freudian obsessions of every kind to an anarchic contradiction of the very nature of the motion picture, the latter being well illustrated by the fixed camera shooting for several hours on a sleeping man done by the U.S. artist-director Andy Warhol in *Sleep* (1963). The ultimate in abstract pattern making brought the underground-film director almost to the position of the fabricator of the animated cartoon. Both were absolute dictators, and neither had any use for the actor as intermediary to help them communicate with their public.

In the United States the animator remains rooted in the Walt Disney tradition of the 1930s, somewhat wanting in taste and with an efficient but unadventurous technique. In Europe, however, animation has evolved, perhaps because there is it taken seriously. Cartoonists Jiří Trnka, Zdeněk Miler, and Jiří Brdečka in Czechoslovakia, with Gyula Macskassy and Gábor Kovács in Hungary, are all artists of originality, while in Italy Guglielmo Giannini and Emanuele Luzzati together showed in "The Thieving Magpie" that frivolity is not necessarily inconsistent with subtlety of colouring and a witty conception.

So very catholic are today's habitués of the movies that films of infinitely varied kinds hold the screen. Some, such as those of Alfred Hitchcock, seem to be directed almost exactly as they used to be three decades ago. Others, such as the U.S. director Stanley Kubrick's 2001: *A Space Odyssey*, range wide in philosophic and imaginative splendour or, as in John Schlesinger's *Midnight Cowboy*, dig deep into the psyche of ordinary people. In the main, directors have given good value in return for the freedom that the crumbling of the old tyrannical film empires has given them. Many of the most creative are now their own producers, and they have taken charge of their own destinies.

#### DIRECTING FOR TELEVISION

Although the output of theatre in audiovisual programs is greatly exceeded by other televised material, drama, particularly in the forms evolved for the motion picture, has put its stamp on direction for television. The television director, like his theatre colleague, should lead the eye of the audience to a succession of focal

points in a picture of meaningful activity. Like the film director, he should give composition to his images, achieving a variation of intimacy in the shots he chooses, as well as the rhythm that cutting can give to his sequences. It is arguable whether any director ever reaches the goal of his ideal; in the case of the television director, there is no doubt: he cannot do so. The reason lies both in the cost factor and in the very nature of the medium, which combine to deprive him of what every director needs—time in which to have enough second thoughts. Although he is allotted a period for pre-preparation, a most important and necessary part of his work is done at the very same time as his production is being recorded for subsequent screening—and sometimes, though rarely, as it is being screened "live."

Primarily because of high production costs, the choice of shots he uses—the kind of decision the film director-editor is able to make from a number of alternatives at leisure—has either to be incorporated beforehand in the camera script and adhered to within narrow limits or else it is improvised in the control room during recording, in a succession of decisions that must be immediate. Always, the actual moment of cutting away from one picture to another (to which the film cutter or director can give both time and thought in choosing the exact frame in the cutting room) is a choice boldly made during the action being photographed. The decision in a live show is irrevocable: in a recorded television program it is not entirely so. The director may stop the running of the videotape and re-record a section of it. But at best he can do no more than to repeat, with some improvements, the pictures he has already taken. But opportunity for alternative pictures is not available to him, since they do not exist. Occasions when he may stop the tape are limited by the total of hours agreed with the unions for each recording session. This allowance is neither parsimonious nor generous, and a director may well wish to exceed it. The cost of doing so, however, can be high.

In the case of a drama director, two kinds of experience are called for. He needs theatre knowledge, since he will want actors who can sustain character and technical power throughout the entire length of their parts. This means stage actors, not film actors, whose time in front of the camera is measured in seconds or minutes. Since, however, television essentially consists of pictures in motion, all directors must also have knowledge of film technique and the techniques of the cutting room. Early television directors were drawn from radio, films, and the theatre. Each discipline had its contribution to make, and radio experience proved particularly useful in the vast field of news, discussion programs, "participation" programs, competitions, music, interviews, and the whole realm of sports coverage.

The pioneers learned as they worked, making mistakes that were forgiven by a minority public easily fascinated by novelty. As demand increased, it began to be realized that the new medium must have a discipline of its own. Courses of training for direction were established. The lecturers often insisted that anyone trained to a sufficiently high standard for drama would be fully equal to dealing with television of other kinds. On the whole, this insistence was justified: a good director of a football telecast has to fulfill the drama director's function of "leading the eye to the focal points." He cannot guarantee their relevance, however, for he never knows beforehand where the most exciting television pictures need to be looked for. Such a director hopes, through experience and intuition, that his cameras will succeed more often than they fail in shooting in the right direction at the right time. Because of this unpredictable element, the sports director himself presses the buttons that determine which camera is on the air or is being recorded.

In drama and other scripted programs the movements of the participants have been rehearsed, and the shots have been planned, numbered, and laid down in the camera script. The unpredictability lies only in the minor yet important changes of camera work that the director may be able to make while the production is actually in progress or being taped. In a typical production the drama

Unique role of the television director

Requisites for drama directing

Directors of animated films

director sits in the control room with a vision mixer (British) or a technical director (American), who is connected by earphones with each of four to six cameras on the set and who "calls the shots" according to the script, unless ordered by the director to do otherwise. Others in the control room are the production assistant and the sound mixer, who is in touch with the various microphone boom operators on the set and who, fortunately for the director, ensures that voices and sounds are always of appropriate volume and quality. The director keeps his eyes on the half dozen or so monitor screens in front of him. One of these shows the shot that is being recorded or transmitted at any given moment: another, called the preview monitor, indicates the next shot to come. Others inform the director exactly what each of the cameras is "looking at." If camera one is "on transmission" it will indicate the same picture as the transmission monitor, and, if camera three has the next shot according to the camera script, it will duplicate the preview monitor: cameras two and five will show preparations for what is further ahead in the script. The director concentrates his attention on the picture that is being transmitted and also on the preview monitor, so that at the right moment he may cut from the first to the second and call the next shot on the cue as indicated in the camera script. This is where unpredictability enters, for if the director feels impelled to improve on the camera script he may alter the precise moment of the cut. He may even become aware that one of the camera monitors is showing a better picture for his next shot than the one that was planned and so change it. He is thus like a juggler keeping several balls in the air at once. An additional screen can be his concern from time to time. This is the monitor upon which film may be running at certain times so that it can be cut in and out at the appropriate cue.

#### Use of film in television directing

Films can be valuable aids to a television production. A script may call for a sequence that cannot be realized in the studio—some scenes, for example, might be taking place on a fishing boat entering a harbour. Or an actor could be required to make a complicated change of make-up and clothes between scenes separated by "script time" but connected in screen continuity, which could waste many precious minutes of recording time. In such cases, filmed footage shot prior to the recording of the production could fulfill the requirements. The use of film, however, also presents its problems: conditions for photography in two such contrasted media as film and television are very different. There are virtually no opportunities in television for altering lighting and thus extracting the best possible photographic advantage from each shot. Film shots, on the other hand, are separately lit, as there is always plenty of time between each in which to change the lighting setups, which differ according to whether they are close-ups or long shots. Thus, the quality of the picture varies from one media to the other.

Unsurprisingly, many television dramatic productions turn out to be substandard. A high degree of adaptability, strong nerves, unfailing picture sense, and an ability to make quick decisions are all called for in the television director—in addition to all the attributes of good theatrical direction.

In the current-affairs program, with its journalistic affinities, ephemerality is appropriate. But here there are responsibilities for the director that are both public and onerous. Because he is a director, he must be something of an artist, but he must also maintain at all times the objectivity of good reportage. Television is a public service, and the director must not bring his personal opinions to the screen. If his program depicts, for instance, a gathering of politicians whom he dislikes, or if he photographs two people in weighty argument, he must favour both sides equally with his angles and the closeness of his shots.

The obstacles in the television director's path mean perpetual and exciting challenge, for the medium is still evolving. The field, therefore, attracts young recruits, although it often fails to keep them. It is a useful stepping stone to the film industry, where there can be more time for aesthetic and creative considerations.

#### DIRECTING FOR RADIO

Although radio has in some ways become television's poor relation, directing for this medium can show qualities that provoke admiration. The range of programs calling for a director is far from narrow. Though the bulk of material that employs them consists of drama, there are also discussion programs, sound documentaries, interviews, and talk shows in which the director's function is vital.

The fact that sound is the sole means of conveying meaning has important consequences. The director, like a blind man whose other senses are heightened by affliction, acquires a highly sharpened sense of what is essential and what is not. The mistakes made in the early sound films were not repeated by the early radio directors, who knew how easily too much of anything spoils the effect. They also discovered a remarkable refinement in evoking reality through well-chosen music and by inventing strange and original sounds.

In good radio directors two qualities particularly stand out. They are, in a sense, pedants in the way they concentrate on minutiae in nuance of inflection and stress. Many a public speaker, thinking himself an expert in tonal variety, is humbled when he first rehearses a radio talk. In half an hour of professional instruction, his typed script has become pockmarked with a multitude of dactyls and spondees or their equivalent—all indicating how little that speaker had really explored the possibilities of expressive speech. The other interesting and paradoxical quality of the good radio director is the vividness of his visual imagination. In order to be confident that the microphone will convey everything possible in a play that will be heard but never seen, he himself must "see" the totality of that play in his mind's eye: he must be aware of all that the audience will gather only by implication. Thus, radio directing demands an unusually perceptive and retentive mind, as well as all the expected qualifications of a theatre director. Possibly this explains why, despite the decline in status of this vocation since the advent of television in the 1950s, the radio director is often a particularly dedicated individual who obstinately insists on remaining in the field, since there is nearly always enough rehearsal time to do his work well.

Qualities of a good radio director

## Disciples of Christ

The three major bodies of the Disciples of Christ stem from a common origin.

The Churches of Christ (1970 membership 2,400,000) emphasize rigorous adherence to the New Testament as the model for Christian faith, practice, and fellowship. They reject general religious institutions other than the congregation, practice a dynamic evangelism based on a literal view of the Bible, and remain aloof from interdenominational activities.

The Christian Church (Disciples of Christ), which reported 1,592,609 members in the U.S. and Canada in 1970, has developed organizations for missionary work and ecumenical involvement and accepts its status as a denomination (uniting a number of local organizations).

The congregations loosely related in the Undenominational Fellowship of Christian Churches and Churches of Christ (estimated membership in 1968 1,000,000) were formerly identified with the Disciples but refused to follow them into the Christian Church. They earlier had refused to follow the Churches of Christ in rejecting musical instruments in worship and missionary organizations as a matter of biblical principle; they later repudiated the openness of their fellow Disciples toward biblical criticism, theological liberalism, ecumenical involvement through "official" channels, and development of denominational institutions.

In a larger sense, Disciples of Christ includes "sister churches" in Britain, Australia, and New Zealand, known locally as Churches of Christ, with origins largely independent of America. It also denotes churches in other lands resulting from the missionary efforts of all these bodies.

### NATURE AND CHARACTERISTICS

The original ethos of the Disciples blended the independence and pragmatism of the American frontier with an uncomplicated biblical faith in the restoration of the "ancient order" in the church. They repudiated "human creeds" and traditions as requirements for Christian fellowship, understood Baptism as the immersion of believers only, and recognized no churchly authority beyond the congregation. This simple formula's typical "sectarianism" was combined with a strong catholic impulse: a plea for the union of all Christians, the regular celebration of the Lord's Supper in weekly worship, and the use of inclusive biblical names such as disciples, Christians, saints, and brethren, that would not distinguish them from other believers.

The original equilibrium among these varying emphases did not last for long. Without rigid structures of official dogma or government, Disciples of all persuasions have responded to historical influences by changing, wittingly or unwittingly, the original formulation

### HISTORY

**Origins.** The movement emerged on the American frontier through various efforts to cut through the complexities of sectarian dogma and find a basis for Christian fellowship. Out of the Great Western Revival (1801) in Kentucky arose the short-lived Springfield Presbytery, which dissolved in 1804 so that its members might "go free" simply as Christians. Their leader, Barton W. Stone, championed revivalism, a simple biblical and noncreedal faith, and Christian union. In the upper Ohio Valley, Presbyterian Thomas Campbell, a contemporary of Stone, organized the Christian Association of Washington (Pa.) in 1809 to plead for the "unity, peace, and purity" of the church. Soon its members formed the Brush Run Church and ordained his son Alexander, under whose leadership they accepted immersion of believers as the only scriptural form of baptism and entered the Redstone Baptist Association. Alexander Campbell rapidly gained influence as a reformer, winning fame as preacher, debater, editor (Christian Baptist), and champion of the new popular democracy. His colleague Walter Scott developed a reasonable, scriptural "plan of salva-

tion" based on "positive," or objective, steps into the church: faith, repentance, Baptism, remission of sins, gift of the Holy Spirit. The formula attracted thousands who longed for religious security but, perhaps because of temperament, did not "experience" the emotional crisis and subjective "assurance" that characterized the prevailing revivalism.

By 1830 the regular Baptists and the reformers parted company, the latter terming themselves Disciples. Two years later Stone and many of his followers joined with them, though continuing to use the name Christians.

Alexander Campbell from 1830 on turned to constructive churchmanship. He established Bethany College, then in Virginia (1840), for the education of leaders and agitated unsuccessfully for a general church organization based on congregational representation. The first general convention met at Cincinnati, Ohio, in 1849 and launched the American Christian Missionary Society as a "society of individuals" and not an ecclesiastical body. Similar cooperative organizations emerged in various states to support evangelists and to establish new churches. The Christian Woman's Board of Missions (1874) and the Foreign Christian Missionary Society (1875) initiated successful programs overseas, and other boards were soon founded to promote building loans for new churches, care for aged ministers, homes for orphans and the aged, temperance, and other "causes." The Centennial Convention at Pittsburgh in 1909 claimed an attendance of 30,000; they had come to celebrate a century of triumph for the New Reformation, or Restoration Movement.

**Controversy and separation.** Meanwhile, schism had begun to sunder the ranks, yet without shaking the confidence of the Disciples in their plea for union. They had held together during the controversy over slavery and through the Civil War, when major American denominations had divided. In the succeeding era of bitterness, however, the Disciples also suffered schism. New developments in response to growing urbanization and sophistication brought two sharply divergent responses. The conservatives regarded such developments as unauthorized "innovations," while the progressives (pejoratively termed digressives) looked on them as permissible "expedients."

Discord first arose over the "society principle" involving general missionary work. Alexander Campbell's biblical view of the church had kept pushing him toward a general church organization, but he could never find a convincing biblical text to support his proposals. Frontier independence and pragmatic popular biblicism prevailed. The "society principle" seemed to its advocates a legitimate solution: entertaining no ecclesiastical pretensions as a secular corporation, the missionary society provided a means by which individual Disciples could work in voluntary cooperation. But the opponents saw in it a repudiation of the Bible as the determining rule of practice.

The introduction of musical instruments (reed organs) into Christian worship concerned congregations much more directly and led to many local disputes. Other innovations added occasion for controversy—the infringement of the "one-man pastoral system" on the local ministry of elders, introduction of selected choirs, use of the title Reverend, and lesser issues.

In 1889 several rural churches in Illinois issued the Sand Creek Declaration, withdrawing fellowship from those practicing "innovations and corruptions." In 1904 a separate "preacher list" issued unofficially by some conservative leaders certified their preachers for discounts on railway tickets. The Federal Religious Census of 1906 acknowledged the separation between Churches of Christ and Disciples of Christ (who commonly took the name Christian Churches) even though many congregations did not decide which they were for some years.

The crucial issue centred in the manner of understanding biblical authority. Both conservatives and progressives accepted the New Testament as the only rule for the church. The conservatives, heavily concentrated in the South, applied a strict construction to Scripture; this

Plea for  
union

Dispute  
over  
music

Thomas  
and  
Alexander  
Campbell

required a specific New Testament precept to authorize any practice. The progressives tended toward a broader construction, accepting as expedient such measures as they found harmonious with Scripture or not in conflict with it.

**Disciples in the 20th century.** Disciples had experienced their most rapid growth in rural America. Their leaders undertook to respond to the passing of the frontier, the growth of cities, and the emergence of urban expectations. Whereas the Churches of Christ had opted for the practices established in the rural past, regarding them as biblical, the Disciples of Christ (progressives) were able to find some flexibility in the biblical rule. Nevertheless, rural and small-town Christian Churches predominated in numbers and membership even past midcentury, and the newer social and cultural influences did not affect all of them simultaneously.

Urban churches demanded full-time leadership, and Disciples gradually developed a professional ministry. In the first half of the century they worked hard to establish collegiate education as standard for ministers. As late as 1930, only 11 percent had graduate education, and the rapid growth of theological seminaries did not come till after World War II. The expanding corps of educated leadership reworked the inherited formulas, introducing both ideas and practices that troubled the more traditional.

The cooperative organizations underwent notable changes. In 1917 the old general convention, a week-long series of annual meetings of the various societies, gave way to the International Convention (U.S. and Canada), to which all cooperative agencies were expected to submit reports for review and advice. It consisted of two houses: a large Committee on Recommendations, constituted of delegates from state conventions, and a mass assembly; in 1967 it made the assembly a body of voting representatives from congregations.

Meanwhile, a number of the agencies had combined in 1920 to form the United Christian Missionary Society. Ten years later most state and national agencies entered Unified Promotion, a cooperative program of fund raising, with voluntarily accepted restraints on independent campaigns, and with distribution on the basis of agreed allocations. Thus they gradually evolved, in effect, one general budget. From the start the United Society drew intense criticism for ecclesiastical giantism and theological liberalism. There was especially intense opposition to reports of "Open Membership" in the China mission. (Open membership, increasingly practiced in the U.S., meant reception of unimmersed Christians from other denominations.)

In 1927 traditional forces established the North American Christian Convention. Many churches gave their support to "independent" missionaries in large numbers, as well as to "independent" Bible colleges, youth camps, district meetings, Bible school curriculum, various publications, and a yearbook—all of them explicitly denying official status—more or less parallel to the "cooperative" agencies. The power struggle focussed on the placement of ministers and resulted, on the cooperative side, in enhancing the leadership of the state secretaries and creating the pressure for delegate conventions in the states.

The cooperative conventions (state and international) also became instruments of ecumenical participation, electing representatives to the old Federal Council of Churches (and to the succeeding National Council and the World Council of Churches), as well as to the state councils, and to the Consultation on Church Union. Thus for the sake of their original catholic commitment, the "cooperatives" accepted status as a denomination, a compromise that the independents rejected.

A growing sense of moral obligation toward the common cause led in 1950 to the formation of the Council of Agencies, which included all organizations reporting to the International Convention. Legally independent, they sought by consultation to avoid overlapping and to develop a common mind. From the Council came a pro-

posal for a Commission on Restructure, appointed by the convention in 1960. In 1967 the convention approved the commission's Provisional Design for the Christian Church (Disciples of Christ), ratified in the ensuing year by all 40 area conventions and 15 national agencies. In 1968 the International Convention of Christian Churches reconstituted itself under the Design as the General Assembly of the Christian Church (Disciples of Christ). All general agencies became provisional administrative units of the Christian Church in the United States and Canada, and the state organizations became provisional regions. Congregations retained full legal independence, but the system provided for corporate unity through decisions by representatives from congregations and regions.

Fear of infringement on congregational freedom and theological opposition to the doctrine of the church underlying the restructure proposals led to active opposition. Many independent congregations formally requested withdrawal of their names from the Yearbook of Christian Churches (Disciples of Christ), and a campaign led many cooperative churches to follow suit. From 1967 to 1969 the number of congregations listed dropped from 8,046 to 5,278.

Meanwhile, a self-appointed Chaplaincy Endorsement Commission for the Undenominational Fellowship of Christian Churches and Churches of Christ asked recognition by the U.S. government to represent those congregations that had elected "to continue as free, independent, and completely autonomous local churches" apart from the restructured Christian Church.

The World Convention of Churches of Christ since 1930 has sponsored mass meetings for fellowship and inspiration at five-year intervals. It attracts both cooperative and independent Disciples from America and from many nations, but very few from the American Churches of Christ. As a world confessional body it appointed official observers to the second Vatican Council, but it exercises no administrative or programmatic functions.

**Churches of Christ in the 20th century.** The Churches of Christ continued to avoid any general organization and until midcentury at least had shown little interest in their own history; they centred attention on the New Testament and on the Restoration Movement (involving the restoration of the doctrines and practices of primitive Christianity) of the early 19th century. Records of their 20th-century history still remain as raw material in their journals.

In 1906 the vast preponderance of the members and leaders of the Churches of Christ lay in the South, with heaviest concentrations in Tennessee and Texas. The reported membership of 159,658 apparently did not include all who held their general position. In the ensuing half-century they have grown into the largest of the three Disciple groups. The migration from the rural South to urban centres has brought impressive membership gains in the North and the West—aided by a vigorous evangelism that has made intensive use of radio. Missionaries have established churches in Asia, Africa, Latin America, and Europe, winning converts especially from Roman Catholicism. Many churches now forward their missionary funds to an agent for disbursement, all the while making certain that the actual appointment of missionaries remains the prerogative of congregational elders.

The churches' doctrine permits individual initiative in certain types of religious (not ecclesiastical) enterprises. A vigorous journalism has flourished for more than a century, the most influential papers being the *Gospel Advocate* (Nashville, Tennessee) and *Firm Foundation* (Austin, Texas). Benevolent homes provide care for children and the aged. A number of churches conduct Christian day schools, while private colleges offer Christian higher education and receive support from churches. A graduate school of religion at Harding College in Memphis, Tennessee, offers a three-year Master of Theology degree.

Variations of conviction about specific practices (whether a single, "common" cup or many cups are to

Develop-  
ment of a  
profes-  
sional  
ministry

Schism

Missions

Ecumenical  
participation

be used in communion) and doctrines (especially millennial ones about the perfect age of Christ's reign on earth) have produced sharp controversies and withdrawal of fellowship, but the continuing absolute stand against any type of ecclesiastical structure makes it difficult to trace the effects of such discord.

After two generations of refusal to have fellowship with their divergent brethren, some leaders in the Churches of Christ took initiative in the 1960s to set up informal forums or conferences on unity with members of the Christian Churches, both coöperative and independent. With no official status, these meetings provided opportunity for a limited kind of ecumenical dialogue. Their doctrinal stance, in repudiation of ecclesiastical organization, prevents members of both the Churches of Christ and the Udenominal Fellowship of Christian Churches and Churches of Christ from official participation in ecumenical gatherings.

#### BELIEFS, WORSHIP, ORGANIZE

**Influences and relationships.** Alexander Campbell summarized his theology in *The Christian System* (1835), the most influential book in shaping Disciple thought. In it he outlined a commonsense biblical doctrine against the complex theories of the schools and the sects. The influence of Renaissance humanism on Campbell is evident in his insistence on going to the sources and his rules of biblical interpretation. He shared the presuppositions of the Enlightenment in its romantic primitivism and in its rationalism as tempered by John Locke, "the Christian philosopher," and by the Scottish Common Sense school, which opposed the paradoxes of subtle philosophies. From Locke he took over the political theory considered self-evident in the young American nation and readily transferred it to his doctrine of the church. He also followed Locke's theory of knowledge based on sense experience, which established the grounds for Christian faith in historical events and objective evidence (recorded in Scripture) rather than in mysticism or subjective religious "experience." He therefore repudiated the Calvinist (and revivalist) concept of miraculous conversion and the similar concept of miraculous call to the ministry. Debates on these issues, as well as on the damnation of unbaptized infants, which Disciples denied, led them to think of themselves as anti-Calvinist.

The general framework of their thought nevertheless followed Reformed (Calvinist) outlines, modified by the influence of British Independents (the originally Scottish Glasites—or Sandemanians—in practice a strictly New Testament sect, and the Congregationalists). Disciples shared the orthodox Protestant emphasis on the authority of Scripture. Their classic biblical position differs from that of other Protestants in being a product of the early 19th rather than of the 16th or 17th century.

**Characteristic doctrines.** Early Disciples understood their uniqueness to lie in the rigour, precision, and simplicity with which they set forth the biblical basis for the unity of all Christians. Campbell distinguished sharply between Old and New Covenants (Testaments), limiting to the latter any authority for "the original faith and order" of the church. Only explicit apostolic teaching or precedent belonged in the realm of faith, of the essential; all else, however logical or helpful, fell in the area of opinion and consequently of Christian liberty. Thus they rejected creeds as tests of fellowship; they believed such tests usurped the sole authority of the New Testament and set forth demands not found there. The popular Disciple bias against theology as a divisive preoccupation with human opinions—as well as Alexander Campbell's early protest against ecclesiastical institutions as unwarranted by Scripture and threatening to freedom—also was inferred from the New Testament.

Campbell saw the biblically authorized ministry as that of elders and deacons, ordained by the congregations, and of evangelists, who served the church at large. The latter provided the general leadership in his day; he succeeded in establishing no extracongregational procedure for their authorization and discipline.

He regarded immersion and "the breaking of bread" (*i.e.*, Baptism and communion) as ordinances of the Lord (Christ). While the insistence on believer's Baptism alone separated Disciples from the "paedobaptists" (those advocating Baptism of children), weekly communion served as a universal element in their worship and tempered their rationalist bent. Despite their memorialist doctrine (that communion is a commemoration of Christ's Last Supper involving no miracle of transubstantiation), they understood the service as present communion with their Lord.

**Internal differences.** The divisions in the movement expressed varying attitudes toward Scripture, as the norm of faith and practice: Churches of Christ construing it strictly, Disciples more loosely. Many who introduced organs in worship held the same view of biblical authority as those who refused to do so; their interpretation simply led to a different conclusion about the use of musical instruments in apostolic times. They provided the constituency for the "independent" Christian Churches, whereas Disciples tended to find more and more flexibility in the principle of expediency.

In the world of scholarship since the early 19th century, a revolution has occurred in the understanding of the biblical documents and the nature of their authority. In general, the Churches of Christ hold steadfastly to older views of the Scripture. Disciple leaders tend to accept the results of critical scholarship. While the "biblical theology" that flourished in the second quarter of the 20th century enabled some Disciples to work out a contemporary formulation of their tradition within the ecumenical context, the conservative biblical position of their forefathers has largely been eroded. Of the three groups, Disciples have been most influenced by the theological movements of the 20th century; *i.e.*, biblical criticism, liberalism, existentialism, ecumenism, neoliberalism. The independents have been much less influenced, the Churches of Christ least of all.

**Recent theological trends.** At the beginning of the 20th century, the most influential Disciple scholar was J.W. McGarvey, a champion of the traditional doctrines and view of the Bible and an opponent of the musical instrument in worship. Early in the century Herbert L. Willett, E.S. Ames, and C.C. Morrison led in a liberal reformulation of the plea, emphasizing a pragmatic and reasonable approach to faith, the repudiation of creeds, an openness to the scientific world view, and a commitment to Christian unity. The neo-orthodoxy that dominated Christian thought at midcentury had less appeal to most Disciples, but a leading English theologian, William Robinson, gained attention for neo-orthodoxy's emphasis on biblical doctrine. A Panel of Scholars appointed by two of the national agencies published three volumes of papers in 1963 showing the impact of the new mood. With the rapid growth of their theological seminaries and college faculties of religion and with their deep ecumenical involvement, Disciples went through a theological renaissance in the 1950s.

The institutional developments leading to restructuring were accompanied by a reformulation of the old doctrine of the church. The founders of the early movement had spoken of the Church of Christ as a local congregation; they recognized no other organization as a church. The new generation of Disciples could no longer deny the churchly character of the institutions that had been developed. They began to speak of three manifestations of the Christian Church—congregational, regional, general (U.S. and Canada). The name that they adopted in restructuring—the Christian Church (Disciples of Christ)—they found to have been dictated by their history. They saw that church manifesting itself organizationally "within the universal body of Christ" and as committed to "responsible ecumenical relationships."

**Worship.** After fruitless attempts to derive a stated order of worship from the New Testament, Disciples settled into an informal but relatively stable pattern composed of hymns, extemporaneous prayers, Scripture, sermon, and breaking of bread. Except for its omission of the Decalogue, the public confession of sin, and the

Controversies in biblical interpretation

Early 20th-century liberal leaders

Legacy of John Locke

Standards of apostolic teaching

creed, it resembled classic Reformed (or Presbyterian) worship, especially in its austerity of spirit. In the second half of the 19th century it took over more of the mood of popular revivalism, which still prevails among Churches of Christ and the independent Christian Churches.

Because many churches in the 19th century had the services of a preacher only occasionally but regularly observed the Lord's Supper (communion) after the Bible School (Sunday School) hour, the breaking of bread came to precede the sermon, which was simply added on when a preacher was present. At the Lord's Table, two local elders presided, one offering a prayer of thanksgiving for the bread and the other for the cup. The minister now commonly presides, but the elders ordinarily offer these prayers.

*Christian Worship: A Service Book* (1953), edited by G. Edwin Osborn, a semi-official manual for voluntary use, exerted wide influence in restoring and stabilizing the typical pattern, with an emphasis on much use of scriptural sentences. More recently Disciples have responded to the liturgical movement, with greater use of responsive readings (minister and people reciting alternate verses), affirmations of faith, and accommodation to the historic pattern of the Christian liturgy.

**Social issues.** On social questions Disciples have held positions characteristic of the American denominations of English background. Alexander Campbell applied his principles literally in the matter of slavery, admitting that Scripture and the law of the land permitted the practice, though as a matter of opinion he favoured emancipation. By this line he prevented schism. During the Civil War a number of leading Disciples, especially in the Border States, espoused pacifism on biblical grounds.

Liberal Disciples took up the Social Gospel (a theological movement that stressed the social this-worldly aspects of Jesus' teachings) early in the 20th century, whereas most Disciples, along with members of the Churches of Christ and the independent Christian Churches, held to the emphasis on personal salvation. Disciple representatives to the National Council of Churches and the World Council of Churches have supported those organizations' general stand on social issues but resisted the tendency to accept the new radicalism of the later 1960s.

(R.E.O.)

## Disease

Disease commonly is considered to be a departure from the normal physiological state of a living organism sufficient to produce overt signs, or symptoms. The concept applies to the mental, as well as the physical, state of the organism; thus, it is customary to speak of "mental" disease when referring to deranged thought processes.

The normal state of an organism represents a condition

of delicate physiological balance, or homeostasis (*q.v.*), in terms of chemical, physical, and functional processes, maintained by a complex of mechanisms that are not fully understood in their entirety. In a fundamental sense, therefore, disease represents the consequences of a breakdown of the homeostatic control mechanisms. In some instances the affected mechanisms are clearly indicated, but, in most cases, a complex of mechanisms is disturbed, initially or sequentially, and precise definition of the pathogenesis of the ensuing disease is elusive. Death in man, and other mammals, for example, often results directly from heart or lung failure, but the preceding sequence of events may be highly complex, involving disturbances of other organ systems and derangement of other control mechanisms.

The initial cause of the diseased state may lie within the individual organism itself, and the disease is then said to be idiopathic, innate, primary, or "essential." It may result from a course of medical treatment, either as an unavoidable side effect or because the treatment itself was ill-advised; in either case the disease is classed as iatrogenic. Finally, the disease may be caused by some agent external to the organism. This may be an inert but toxic agent, in which case the disease is **noncommunicable**; that is, it affects only the individual organism contacting it. The external agent may be itself a living organism capable of multiplying within the host and subsequently infecting other organisms; in this case the disease is said to be communicable.

#### NONCOMMUNICABLE DISEASE

**Metabolic defects.** Noncommunicable diseases arise from metabolic faults present at birth that leave the organism ill-equipped to deal with the natural materials it encounters in its daily life. In man, for example, the lack of a certain enzyme necessary for the metabolism of the common amino acid phenylalanine leads to the disease phenylketonuria (or PKU), which is often associated with mental retardation. Other metabolic defects may make their appearance only relatively late in life. Examples of this situation are the diseases gout and diabetes in man. Gout results from an accumulation within the tissues of uric acid, an end product of nucleic acid metabolism; and diabetes results from an impairment of the synthesis of insulin by the pancreas and a consequent inability to metabolize sugars and fats properly. Alternatively, the metabolic fault may be associated with aging and the concomitant deterioration of control mechanisms, as in the loss of calcium from bone in the condition known as osteoporosis. That these late-developing metabolic diseases have a genetic basis—that is, that there is an inherited tendency for the development of the metabolic faults involved—seems to be definitely indicated in some instances but remains uncertain in others.

**Environmental hazards.** Metabolic derangements also may result from the effects of external environmental factors, and this relationship may be suggested by the apparent confinement of a disease to sharply delimited geographic areas. Notable examples are goitre and mottled enamel of the teeth in man. The development of goitre is attributable to iodine deficiency in the diet, which leads to compensatory growth of the thyroid gland in a vain effort to overcome the deficiency. In the absence of deliberate inclusion of iodine in the diet in such standard items as table salt, the disease tends to occur in inland areas where seafood consumption is minimal. Mottled enamel of teeth is observed to result from consumption of excessive amounts of fluoride, usually in water supplies, but conversely, dental caries is found to occur to a greater extent in areas with water supplies deficient in fluoride. Analogous conditions in herbivorous domestic animals result from deficiencies in the so-called trace elements, such as zinc, in the soil of pastures and, therefore, also in plants making up the diet. Similarly, plant growth suffers from deficiencies in the soil of essential elements, particularly nitrogen, potassium, and phosphorus. The correction of these conditions by supplying salts to domestic animals, such as cattle, and the application of fertilizers to soil, is well known.

Disruption  
of phys-  
iological  
balance

Deficiency  
diseases

These, generally, are diseases of deficiency; there also are diseases resulting from toxic substances added to the environment in sufficient amount to produce symptoms of greater or lesser severity. Although best known in man, untoward effects of such contamination of the environment occur also in plants and animals. The problems caused by environmental toxic agents are largely, if not entirely, man-made. Best known of the environmental diseases, perhaps, are the occupational diseases, especially those of the respiratory tract, including asbestosis, silicosis, and byssinosis (caused, respectively, by inhalation of asbestos, silica, and cotton dust). Also important in this regard are metal poisoning, as with mercury, lead, and arsenic, poisoning with solvents used in industrial processes, and exposure to ionizing radiation. Of more importance to the population at large are the diseases that result from exposure to insecticides and atmospheric pollutants. Such diseases usually, though not invariably, are of a chronic nature, requiring prolonged exposure to the noxious agent and developing slowly. Environmental diseases of all kinds, however, also may predispose the individual to other diseases, notably tuberculosis in the case of respiratory diseases such as silicosis, and perhaps, in the longer view, to cancer.

#### COMMUNICABLE DISEASE

**Host-parasite relationships.** Communicable, or contagious, diseases are diseases transmitted from one organism to another; infectious diseases are diseases caused in the host by infection with living, and therefore replicating, micro-organisms such as animal parasites, bacteria, fungi, or viruses. Practically, these two classes of disease are the same, for infectious diseases generally are communicable, or transmissible, from one host to another, and the causative agent, therefore, is disseminated, directly or indirectly, through the host population. Such spread is an ecological phenomenon, the host serving as the environment in which the parasite lives; it becomes complex when the parasite occurs in more than one host species. The host-parasite relationship, therefore, must be considered not only with respect to the individual host-parasite interaction but also in terms of the interrelationship between the host and parasite populations, as well as those of any other host species involved.

The degrees of dependence of the parasite on the host form a continuous spectrum, ranging from the almost complete independence of free-living forms that survive on decaying matter (are saprophytic) and only incidentally to their own life history may produce disease in a host, to that of the highly adapted obligate intracellular parasites, which are capable of undergoing reproduction only within the cells of the host species. The causative agent of botulism in birds, and in mammals (including man), is a saprophytic inhabitant of the soil that is unable to invade host tissue. When it grows in foods, it produces a potent toxin, and disease in the host is a consequence of the ingestion of preformed toxin. The tetanus and gaseous gangrene bacilli also are essentially saprophytes, but they may live as "passengers," or commensals, in the large bowel of animals. There they are capable of setting up circumscribed foci of infection in previously injured host tissue, and disease results from the absorption of toxins produced during the growth of the micro-organisms.

The majority of the pathogenic bacteria are obligate parasites; that is, they are found only in association with their hosts. Some, such as staphylococci and streptococci, can proliferate outside the body of the host in nutritive materials infected from host sources. Within the tissues of the host, these organisms set up local infections that tend to spread throughout the body. Still other bacteria, such as the glanders bacillus, and the gonococci, meningococci, and pneumococci, are more closely adapted parasites, multiplying outside the body of the host only under the artificial conditions of the laboratory. All of these micro-organisms have complete cell structures and metabolic capabilities.

A greater degree of dependence upon the host is shown by the micro-organisms known as rickettsiae and viruses.

Rickettsiae have the cell structure of bacteria, and they exhibit a small degree of metabolic activity outside of cells, but they cannot grow in the absence of host tissue. The ultimate in parasitism, however, is that of the viruses, which have no conventional cell structure at all and consist only of nuclear material wrapped in a protective protein coat. Viruses are obligatory intracellular parasites, capable of multiplying only within the cells of the host, and they have no independent metabolic activity of their own. The viral nuclear material, containing directive information for the synthesis of virus materials and certain enzymes, enters the host cell, parasitizes its chemical processes, and directs them toward the synthesis of virus substances.

The occurrence of these various degrees of parasitism suggests that the host-parasite relationship is subject to continuing evolutionary change. The adaptation of the micro-organism to its parasitic existence, in this view, is accompanied by progressive loss in metabolic capability, with eventual complete physiological dependence of the parasite upon the host, as is the case with viruses.

**Parasite specificity.** The condition of obligate parasitism is associated with a degree of specificity of the parasite with regard to the host—that is, the parasite generally is more closely adapted to one species of host than to all others. This may represent the development of dependence of the parasite upon the chemistry of the host species, and it also may represent an adaptation of the host species to infection by the parasite. Micro-organisms adapted to plant hosts, with only rare exception, are unable to infect animal hosts, and conversely micro-organism parasites of animals rarely occur in plants. A number of host species may be susceptible to infection with a given parasite, and the pattern of host susceptibility need not correspond with taxonomic relationships, including, for example, hosts varying as widely as vertebrates and invertebrates.

The ability to produce consistently highly fatal disease in a host is clearly of negative survival value to the parasite, because it is quite likely to eliminate quickly all available hosts. Consistent with this, there is a tendency for disease resulting from infection to be less severe when adaptation of the parasite to the host has become close. A change in severity of a disease, presumably resulting from adaptation, has been observed in the case of the spirochete that causes syphilis, the disease in man being less severe today than it was in the 16th century.

Disease produced in related host species may be either milder or more severe than in the definitive host. In certain cases, adaptation is so close that the parasite is unable to infect any other hosts under natural conditions; this is true of many micro-organisms producing disease in man. On the other hand, natural infection of secondary hosts may occur, leading to severe or fatal disease. Rabies, for example, is a highly fatal disease in almost all animal hosts, but the virus persists in bats, presumably the natural host, as an asymptomatic infection. Similarly, spotted fever rickettsiae, which cause severe and sometimes fatal disease in man, appear to be so closely adapted to their tick host as to be congenitally transmitted. In this host they constitute a permanent, and apparently harmless, infection.

**Host resistance.** The specificity of pathogenic micro-organisms with regard to their hosts is an expression not only of differences in microbial character but of differing host resistance. The ability of a micro-organism to produce disease can be evaluated only in terms of the host reaction, and conversely the resistance, or immunity, of the host can be judged only with regard to its effect on the micro-organism. In short, the two are but different facets of the same phenomenon, and either may be evaluated by holding the other constant and varying it. Commonly, for example, virulence of an infective agent is determined experimentally by inoculating groups of hosts with graded doses of the agent and determining, by interpolation, the dose that produces a typical reaction in 50 percent of the host individuals inoculated. This dose is termed the 50-percent-effective dose, or ED<sub>50</sub>; it is related in inverse fashion to virulence and in a direct way to re-

Disease  
as an  
ecological  
problem

Pathogenic  
bacteria

Adaptation  
of parasite  
to host

sistance. In other words, in a given host, the higher the 50-percent-effective dose, the less virulent the infective organism; or with a micro-organism of known virulence, the higher the  $ED_{50}$  with the host it is tested against, the greater the resistance of that particular host. Customarily, in different host species, resistance is expressed as an  $n$ -fold increase or decrease (with  $n$  equal to a whole number) in the  $ED_{50}$  over that of the normal host species.

This kind of assay is possible because both virulence and resistance tend to occur in approximately normal, or bell-shaped, frequency distributions; that is, most members of the host and micro-organism populations occupy a central position with regard to these properties, exceptional individuals appearing at both extremes. With reference to host resistance, this explains the varied incidence of disease in a host population exposed to a statistically constant dose of the infectious agent. In most practical considerations, of course, the dose is only statistically constant, for it varies greatly from one host to another depending upon circumstances relating to transfer of the infectious agent. Individual variation in host resistance to infection, however, is due to more than mere numbers of infectious agents encountered; it is also clearly due to innate factors in the individual host organism. At any rate, the result of variation in host resistance is that not all individuals making up a population essentially universally susceptible to infection with a newly appearing infectious agent (such as the Asian strain of the influenza virus in 1957) will contract the disease on primary exposure.

**Apparent and inapparent infection.** Because infection is not an all-or-none affair, individual variation in resistance to disease also results in different degrees of reaction to the infectious agent; *i.e.*, the outcome of the interaction of host and parasite is variable in each individual instance. Some individual hosts show symptoms typical of the disease; they are readily recognized. Others, having greater resistance, exhibit symptoms of the disease in only a mild or atypical form, and these individuals are not clearly recognizable. Still other host organisms become infected with the invading parasite but show no symptoms of the disease. Distinction, therefore, must be made between infection and disease, the former occurring on occasion without any sign of the latter. There may be, of course, no such thing as totally symptomless infections. What are taken to be such may be, in fact, only those infections with symptoms occurring beneath the level of observation. Nonetheless, such inapparent infections, or "carrier" states, clearly exist and serve to transmit the infection to susceptible hosts.

The overt consequence of infection of a host population of relatively high resistance is the sporadic occurrence of cases of disease, and a high carrier-case ratio. The infection, in other words, is widely prevalent in the host population in asymptomatic form, and the relatively rare, observed cases of disease represent the highly susceptible few in the host population making up the extremes of the bell-shaped frequency distribution curve. Examples of human diseases of this kind are poliomyelitis, meningococcal meningitis, and cholera.

This type of irregularity in the occurrence of cases of disease tends to occur in host populations of high, but not too high, resistance to the infectious agent. If host resistance is too high, or too low, the disease will die out: in the former case, because the infective agent is unable to maintain itself and, in the latter, because it eliminates the host. One of the best known illustrations of the importance of relative host resistance to survival of the parasite is that of the plague bacillus. Plague is primarily a disease of rodents and persists as focuses of infection in these hosts. The black rat and the less susceptible gray sewer rat are commonly associated with this disease but are too susceptible to allow its persistence; *i.e.*, the host is destroyed. The infection persists, however, in relatively resistant wild rodents. In Kurdistan and adjacent areas four species of gerbils are involved, two resistant and two highly susceptible species, and the parasite population is maintained in permanent focuses through the infection and interaction of these rodent populations. In

Mesopotamia and India, focuses of infection persist for periods of up to several years but do not become permanent because the wild rodent population, also species of gerbils, in which the disease occurs is not sufficiently resistant. Plague continues to occur in these areas through reintroduction of the parasite from permanent focuses of infection elsewhere, usually by means of the highly susceptible rat, which transmits the infection to the indigenous gerbil population.

**Inheritance of resistance.** That there exists genetic control of resistance is suggested by the mere fact of host specificity, and such control has been demonstrated amply by experimental studies on both plant and animal hosts. The former, for example, had wide practical application in the development, by selective breeding, of strains and races of plants of economic importance, especially grains, that are resistant to a wide variety of plant diseases. Although similar studies on animal hosts have not had practical application, intensive investigation of lower animals has shown that resistance, or susceptibility, unquestionably is determined genetically.

In general, resistance developed by selective breeding is only partially specific; that is, the observed resistance to infection with pathogenic micro-organisms, and to the toxins of such organisms, is manifested toward groups of related micro-organisms producing similar diseases, and not to single organisms alone. Although resistance to disease has been found in a few instances to be a function of a single gene, in the majority of cases, several genes appear to be involved—as might be expected from the complex nature of resistance.

For many years there has been considerable interest in the possibility of differences in resistance to disease associated with the different races of man. While marked differences in morbidity and mortality occur between whites and nonwhites in the United States, for example, it is often difficult to rule out differences in exposure to infection, socio-economic factors, and differential application of preventive and therapeutic measures in accounting for them. Nevertheless, there are fragmentary indications that there may be sufficient genetic segregation among races of man to give differences in resistance to certain diseases. The case fatality rate in tuberculosis appears to be lower in Jews than in others, for example, and gonorrhea seems to be a less serious disease in the Negro than in the Caucasian.

**Epidemiology.** The interaction of host and parasite populations constitutes the subject matter of epidemiology (the term being more inclusive than suggested by its relation to the word epidemic). In most instances the epidemiology of infectious disease is characteristic of that disease and is an outgrowth of biological properties of the parasite and the host, including host specificity and the behaviour of the host populations as populations.

Aside from the saprophytic micro-organisms that occasionally produce disease, most pathogenic micro-organisms are adapted sufficiently closely to their hosts that they cannot compete successfully in the physical, chemical, and biological environment outside the host tissues. Exceptions to this generalization occur in the cases of those micro-organisms whose life history includes a resistant spore stage. This occurs with various fungi responsible for plant disease, as well as certain parasites of animals. Among the latter are species of the fungus *Coccidioides*, which infect both rodents and man (producing desert fever in man), and the anthrax bacillus, which causes disease in cattle, sheep, and other domestic animals, and occasionally infects man as well.

Survival of the parasite ordinarily requires transmission from an infected host organism to a susceptible one more or less directly. The precise route of infection often assumes primary importance, some micro-organisms requiring direct access to internal tissue, others being able to initiate infection on mucous membranes of the nose and throat, and still others able to establish primary infections in the intestinal tract. These particular modes of infection then generally demand transmission by way of, respectively, biting insects, coughing and sneezing, and contamination of food and water.

Distribution of resistance and virulence

Racial differences in man

Focuses of infection

The role of  
vector  
hosts

The occurrence of a given parasite in more than one host species may markedly affect its epidemiological character; it may persist, for example, in one or another of its hosts as a reservoir of infection, sallying forth to encounter the alternate host only on occasion. It is fairly common to find transmission of a parasite from one vertebrate or plant host to another by means of an insect carrier, or vector. Often animal parasites have intermediate hosts in which one or more phases of their life cycles occur; this results in an obligatory sequence of hosts in the life history of the parasite. With the disease schistosomiasis in man, for example, the blood flukes responsible for the disease spend one phase of their larval life in snails. Under such circumstances, and they are not uncommon, the dissemination of the parasite in a host population is dependent not only upon the interaction of the parasite population with that of the host population but also upon the interaction of the intermediate or vector host population with both parasite and host populations.

Such interrelationships may be the basis of geographical and seasonal differences in the incidence of disease. An insect-borne disease transmitted from one host species to another requires the simultaneous presence of all three populations in sufficient numbers for its dissemination. Such a circumstance may be sharply limited by location and season.

Behavioral patterns of host populations often have a very great effect on the transmission of infectious agents. Crowding, for example, facilitates the spread of infection. Bovine tuberculosis is largely a disease of domesticated cattle in barns, and the age incidence of the human diseases of childhood is lower in urban than in rural populations, suggesting that in the more crowded urban environment children are exposed to disease at an earlier age. That transmission of human childhood diseases is favoured by aggregation also is indicated by the prevalence of these diseases during the times when children are in school.

When a disease is prevalent in an area over long periods of time, it is considered to be endemic in that area. On the other hand, when the prevalence of disease is subject to wide fluctuations in time, it is considered to be epidemic during periods of high prevalence. Epidemics prevailing over wide geographical areas are called pandemics.

Epidemic prevalence of disease occurs in a wave, the number of cases rising to a peak and then declining. The period of rise occurs when each case gives rise to more than one additional case; *i.e.*, when the parasite population is growing more rapidly than the host population; and the decline occurs when each case gives rise to less than one new case; *i.e.*, when the parasite population begins to die off because it encounters only immune individuals among the host population. The rise and fall in epidemic prevalence of a disease is a probability phenomenon—the probability being that of transfer of an effective dose of the infectious agent from the infected individual to a susceptible one. After an epidemic wave has subsided, the affected host population contains a sufficiently small proportion of susceptible individuals that reintroduction of the infection will not result in a new epidemic. Since the parasite population cannot reproduce itself in such a host population, that host population as a whole is immune to the epidemic disease, a phenomenon termed "herd" immunity.

Herd  
immunity

Following such an epidemic, however, the host population immediately tends to revert to a condition of susceptibility because of (1) the deterioration of individual immunity, (2) the removal of immune individuals by death, and (3) the influx of susceptible individuals by birth. In time the population as a whole again reaches the point where it is susceptible to epidemic disease. This pattern of rising and falling herd immunity explains why epidemic diseases tend to occur in successive waves; *i.e.*, exhibit a periodicity in prevalence. The time elapsing between successive epidemic peaks is variable and differs from one disease to another. In human measles uncontrolled by immunization, the interval between periods of

epidemic prevalence is about two years and in meningococcal meningitis it is seven to eight years.

**Immunity.** An animal host reacts to the presence of parasites within its tissues by the formation of antibodies to the parasite and its products. Effective immunity to disease is a function of antibodies directed toward some, though not all, of the chemical substances (antigens) from the parasite. In general, such immunity is dual in nature, being made up of components active against the organism itself and against the toxins it produces. The relative importance of the two types differs from one kind of micro-organism to another. In those diseases that result largely from the action of microbial toxins, such as tetanus and diphtheria, the antitoxic element is of primary importance and the antimicrobial immune response is more or less irrelevant. When toxins are not formed by the micro-organism, or are of a low order of potency, antibodies to the cell substance of the micro-organism are predominant in effecting immunity to disease. The antimicrobial antibodies function in part by coating the microbial cells in such a way as to facilitate their destruction by the white blood cells of the host.

Although the immune mechanism is primarily defensive in nature, it may contribute in some cases to the toxic course of the disease. In rheumatic fever, for example, sensitivity to the causative streptococcus organism is associated with symptoms of the disease. The immune response to various environmental substances, including materials such as plant pollens and chemotherapeutic drugs, also is responsible for the diseases grouped under the general head of allergies. The immune response itself may become abnormal in such human diseases as multiple myeloma, macroglobulinemia, Hodgkin's disease, chronic lymphocytic leukemia, and infectious mononucleosis. Such abnormal immune responses, however, seem to be of minor significance to the course of these diseases.

One category of disease is associated with an immune response to antigenic components of the host itself (auto-antigens). The occurrence of such diseases, which are called auto-immune diseases, is firmly established on a laboratory basis. Diseases produced by the inoculation of experimental animals with extracts of their own organs and tissues include encephalitis, thyroiditis, hemolytic anemia, polyarthritis, myocarditis, and dermatitis. These experimental diseases mimic, to a greater or lesser degree, certain human diseases, the autoimmune nature of which is strongly implied, though unequivocal proof of this relationship is not available. Diseases of this kind include rheumatoid arthritis, systemic lupus erythematosus, polymyositis, thyroiditis, encephalopathy, encephalomyelitis, and multiple sclerosis. Certain of these diseases tend to merge into one another, and in all of them there is some evidence of the participation of immunological reactions in their pathogenesis. Generally, therapy with corticosteroids, which are known to suppress the immune response, alleviates their symptoms.

Auto-im-  
mune  
disease

#### CONTROL OF DISEASE

**Prevention.** Most diseases are preventable to a greater or lesser degree, the chief exceptions being the idiopathic diseases, such as metabolic defects. In the case of those diseases resulting from environmental factors, prevention is a matter of eliminating, or sharply reducing, the responsible material in the environment. Because these materials originate largely from human activities, prevention ought to be a simple matter of the application of well-established principles of industrial hygiene. In practice, however, this may be difficult to achieve.

The infectious diseases may be prevented in one or the other of two general ways: (1) by preventing contact, and therefore transmission of infection, between the susceptible host and the source of infection; and (2) by rendering the host unsuitable, either by selective breeding, or by induction of an effective artificial immunity. The nature of the specific preventive measures, and their efficacy, varies from one disease to another.

Quarantine, a theoretically effective method of preventing transmission of disease in principle, has had only

Quarantine

limited success in practice. It has served to control rabies in Britain and to exclude foot-and-mouth disease from the United States. Rigorous application of quarantine procedures also effectively prevented the occurrence of cholera in Japan in one of the great pandemics of this disease. Other than these instances, however, quarantine has not achieved prevention of the spread of disease across international borders, and quarantine of individual cases of disease in man has long been abandoned as ineffective.

It has not been possible to prevent effectively the dissemination of airborne disease, notably airborne fungus diseases of plants and human diseases of the upper respiratory tract. Nor is disease ordinarily controllable by elimination of reservoirs of infection, such as those that occur in wild animals. There are certain exceptions in which the reservoir of infection can be greatly reduced, however; for example, chemotherapy of human tuberculosis may render individual cases noninfectious, and slaughtering of infected cattle may reduce the incidence of bovine tuberculosis.

When infection is spread less directly, through the agency of living vectors or inanimate vehicles, it is often possible to break one or more of the links connecting the susceptible host with the source of infection. Malaria, for instance, can be controlled effectively by elimination of the mosquito vector, and louse-borne typhus in man can be regulated by disinfection methods. Similarly, diseases spread in epidemic form through the agency of water or milk are controlled by measures such as the chlorination of public water supplies and the pasteurization of milk.

Artificial immunization against certain diseases provides a solid immunity and may be utilized in these instances, particularly when other methods of control are impractical or ineffective. Mass immunization in childhood has been highly effective in the control of diphtheria, smallpox, and poliomyelitis, and, to a somewhat lesser extent, whooping cough. Under special circumstances, as in certain military populations, it has been possible to control with prophylactic medicinal agents the spread of disease for which effective vaccines have not been developed.

**Treatment.** Treatment of disease in the affected individual is twofold in nature, being directed (1) toward restoration of a normal physiological state and (2) toward removal of the causative agent. The diseased organism itself plays an active part in both respects, having the capacity for tissue proliferation to replace damaged tissue and to surround and wall off the noxious agent, as well as defense and detoxification mechanisms that remove the causative agent and its products or render them harmless. Therapy of disease supplements and reinforces these natural defense mechanisms.

Metabolic faults also may sometimes be corrected—for example, by the use of insulin in the treatment and control of diabetes—but more often specific therapeutic measures for idiopathic diseases are lacking. When disease is produced by environmental factors, there is commonly no specific treatment; removal of the affected individual from exposure to the agent generally allows normal detoxification responses to take over. Again, there are notable exceptions, as in the treatment of lead poisoning with ethylenediaminetetraacetic acid, an agent that forms complexes with lead that are excreted by the kidney. Similarly, mercury poisoning, and less effectively arsenic poisoning, may be treated with the substance dimercaprol, which forms inactive complexes with the metal atoms.

Treatment of infectious diseases is more effective in general; it assumes several different forms. Treatment of diphtheria with antitoxin, for example, neutralizes the toxin formed by the micro-organisms, and host defense mechanisms then rid the body of the causative micro-organisms. In other diseases, treatment is symptomatic in the sense of restoring normal body function. An outstanding example of this is in cholera, in which disease symptoms result from a massive loss of fluid and salts and from a metabolic acidosis; the highly effective treat-

ment consists of restoring water and salts, the latter including bicarbonates or lactates to combat acidosis. More often, however, therapy is directed against the infecting micro-organism by administration of drugs such as sulfonamides or antibiotics. These substances do not kill micro-organisms in the host but inhibit their proliferation and give host defenses an opportunity to function effectively. For other infectious diseases there is no specific therapy. There are, for example, very few antiviral chemotherapeutic agents; treatment of virus diseases is solely symptomatic in that it is directed toward relief of discomfort and pain, and recovery, if it ensues, is largely a matter of an effective defense against the invading virus by the host.

## Disease, Human

This article presents a general consideration of human disease and of necessity deals with health and its maintenance. A survey of the various forms of human diseases and their classification is presented, to provide some understanding of the complexities involved in the maintenance of health and the scope of the diseases that can affect it.

This article is divided into the following sections:

- I. Maintenance of health
  - Homeostasis
  - Adaptation
  - Defense against biotic invasion
  - Repair and regeneration
  - Hemostasis
  - Interrelationship of defensive mechanisms
- II. Disease: signs and symptoms
- III. The causes of disease
  - Diseases of genetic origin
  - Congenital malformations
  - Heredity and environment
  - Chemical and physical injury
  - Diseases of immune origin
  - Diseases of biotic origin
  - Abnormal growth of cells
  - Diseases of metabolic-endocrine origin
  - Diseases of nutrition
  - Diseases of psychogenic origin
  - Diseases of senescence
- IV. Classifications of diseases

Before human disease can be discussed, the meanings of the terms health, physical fitness, illness, and disease must be considered.

Health could be defined theoretically in terms of certain measured values; for example, a person having normal body temperature, pulse and breathing rates, blood pressure, height, weight, acuity of vision, sensitivity of hearing, and other normal measurable characteristics might be termed healthy. But what does normal mean and how is it established? It is well-known that if the temperatures are taken of a large number of active, presumably healthy, individuals the temperatures will all come close to 98.6° F (37° C). The great preponderance

The meaning of health

Artificial immunization

of these values will fall between 98.4° F and 98.8° F. Thus health could in part be defined as having a temperature within this narrow range. Similarly, a normal range can be established for pulse, blood pressure, and height. In some healthy individuals, however, the body temperature may range below 98.4° F or above 98.8° F. These low and high temperatures fall outside the limits defined above as normal and are instances of biological variability.

Biological criteria of normality are based on statistical concepts. Body height may be used as an example. If the heights of every individual in a large sample were plotted on a graph, the many points would fall on a bell-shaped curve. At one end of the curve would be the very short people and at the other extreme the few very tall people. The majority of the points of the sample population would fall on the dome of the bell-shaped curve. At the peak of the dome would be those individuals whose height approaches the average of all the heights. Scientists use curves in determining what they call normal criteria. By accepted statistical criteria, 95 percent of the population measured would be included in the normal range, that is, 47.5 percent above and 47.5 percent below the mean at the very centre of the bell. Looked at in another way, in any given normal biologic distribution 5 percent will be considered outside the normal range. Thus the seven-foot basketball player would be considered abnormally tall, but that which is abnormal must be distinguished from that which represents disease. The basketball player might be abnormally tall but still have excellent health. Thus, in any statistical analysis of health the possibility of biological variation must be recognized.

A better example than height of how problems can arise with biological variability is heart size. If the heart is subjected to a greater than normal burden over a long period, it can respond by growing larger (the process is known as hypertrophy). This occurs in certain forms of heart disease, especially in long-standing high blood pressure. A large heart, therefore, may be a sign of disease. On the other hand, it is not uncommon for athletes to have large hearts. Continuous strenuous exercise requires a greater output of blood to the tissues, and the heart meets this demand by becoming larger. The physician may have his diagnostic abilities taxed in deciding whether an abnormally large heart represents evidence of disease or is simply a biological variant.

The effects  
of age

The effects of age introduce yet another difficulty in the attempt to define health in theoretical measured norms. It is well-known that muscular strength diminishes in the advanced years of life, the bones become more delicate and more easily fractured, vision and hearing become less sharp, and a variety of other changes occur. There is some basis for considering this general deterioration as a disease, but, in view of the fact that it affects virtually everyone, it can be accepted as normal. Theoretical criteria for health, then, would have to be set for virtually every year of life. Thus one would have to say that it is normal for a man of 80 to be breathless after climbing two flights of stairs, while such breathlessness would be distinctly abnormal in an agile child of ten years of age. Moreover, an individual's general level of physical activity significantly alters his ability to respond to the ordinary demands of daily life. The amount of muscular strength possessed by an 80-year-old man who has remained physically active would be considerably more than that of his fragile friend who has led a confined life because of his dislike of activity. There are, therefore, many difficulties in establishing criteria for health in terms of absolute values.

Health might better be defined as the ability to function effectively in complete harmony with one's environment. Implied in such a definition is the capability of meeting—physically, emotionally, and mentally—the ordinary stresses of life. In this definition health is interpreted in terms of the individual's environment. Health to the construction worker would have a dimension different from health to the bookkeeper. The healthy construction worker expects to be able to do manual labour

all day, while the bookkeeper, although perfectly capable of performing his own sedentary work, would be totally incapable of such heavy labour and indeed might collapse from the physical strain; yet both individuals might be termed completely healthy in terms of their own way of life.

The term physical fitness, although frequently used, is also exceedingly difficult to define. In general it refers to the state of optimal maintenance of muscular strength, proper function of the internal organs, and youthful vigour. The champion athlete prepared to cope not only with the commonplace stresses of life but also with the unusual, illustrates the concept of physical fitness. To be in good physical condition is to have the ability to swim a mile to save one's life or to slog home through snow drifts when a car breaks down in a storm. Some experts in fitness insist that the state of health requires that the individual be in prime physical condition. They prefer to divide the spectrum of health and disease into (1) health, (2) absence of disease, and (3) disease. In their view, those who are not in prime condition and are not physically fit cannot be considered as healthy merely because they have no disease.

Physical  
fitness

Health involves more than physical fitness, since it also implies mental and emotional well-being. Should the angry, frustrated, emotionally unstable person in excellent physical condition be called healthy? Certainly he could not be characterized as effectively functioning in complete harmony with his environment: Indeed, such an individual is incapable of good judgment and rational response. Health, then, is not merely the absence of illness or disease but involves the ability to function in harmony with one's environment and to meet the usual and sometimes unusual demands of daily life.

The definitions of illness and disease are equally difficult problems. Despite the fact that these terms are often used interchangeably, illness is not to be equated with disease. A person may have a disease for many years without even being aware of its presence. Although he is diseased, he is not ill. Similarly, the diabetic person who has known disease and has received adequate insulin treatment is not ill. The cancer victim is often totally unaware of his disorder and is not ill until after long years of growth of the tumour, during which time it causes no symptoms. The term illness implies discomfort or inability to function optimally. Hence it is a subjective state of lack of well-being produced by disease. Regrettably, many diseases remain submerged for long years before they produce discomfort or impair function and, thus, escape detection and possible cure.

Disease, which can be defined at the simplest level as any deviation from normal form and function, may either be associated with illness or be submerged (latent). In the latter circumstance, the disease will either become apparent at some later time or will render the individual more susceptible to illness. The person who fractures an ankle has an injury—a disease—producing immediate illness. Both form and function have been impaired. The illness occurred at the instant of the development of the injury or disease. The child who is infected with measles, on the other hand, does not become ill for approximately ten days after exposure (the incubation period). During this incubation period the child is not ill but has a viral infectious disease that is incubating and will soon produce discomfort and illness. Some diseases render a person more susceptible to illness only when he is put under stress. Some diseases may consist only of extremely subtle defects in cells that render the cells more susceptible to injury in certain situations. The blood disease known as sickle-cell anemia, for example, results from a hereditary abnormality in the production of the red pigment (hemoglobin) of the red cells of the blood. The child of a mother and father both of whom have sickle-cell anemia will probably inherit an overt form of sickle-cell anemia and will have the same disease as his parents. If only one parent has sickle-cell anemia, however, the child may inherit only a tendency to sickle-cell anemia. This tendency is referred to by physicians as the sickle-cell trait. Individuals having such a trait are not anemic but have a

Illness and  
disease

greater likelihood of developing such a disease. When they climb a mountain and are exposed to lower levels of oxygen in the air, red blood cells are destroyed and anemia develops. This can serve as an example of a disease or a disease trait that renders the affected person more susceptible to illness.

Disease, defined as any deviation from normal form and function, may be trivial if the deviation is minimal. A minor skin infection might be considered trivial, for example. On the eyelid, however, such an infection could produce considerable discomfort or illness. Any departure from the state of health, then, is a disease, whether health be measured in the theoretic terms of normal measured values or in the more pragmatic terms of ability to function effectively in harmony with one's environment.

## I. Maintenance of health

Health is not a static condition but represents a fluid range of physical and emotional well-being continually subjected to internal and external challenges such as worry, overwork, varying external temperatures, bacteria, and viruses. These constantly changing conditions require the adjustment of the function of the various systems within the body. Mechanisms are continually at work to maintain a constant internal environment called by the French scientist Claude Bernard the milieu *intérieur*. The maintenance of this relatively constant internal environment is known as homeostasis. On a hot summer day, for example, the body is challenged to maintain its normal temperature of 98.6° F. Sweating represents a mechanism by which the skin is kept moist. By the evaporation of the moisture, heat is more rapidly lost. The hot day, therefore, represents a challenge to homeostasis. On a cold day gooseflesh may develop, an example of a homeostatic response that is a throwback to mechanisms in lower animals. In man's forbearing ancestors, cold external environments caused the individual hair shafts to rise and, in effect, produce a heavier, thicker insulation of the body against the external chill. Man still develops this primitive gooseflesh response but regrettably does not have the luxuriant pelt to protect himself.

Bacteria, viruses, and other microbiologic agents are obvious challenges to health. The body is able, to a considerable extent, to protect itself and adjust to challenges, and to the extent that it is successful, the state of health is maintained. While health is often thought of as fragile and at the mercy of all the evils to which man is exposed, it is, in fact, a ruggedly guarded state protected by a host of internal mechanisms. Few machines made by man could tolerate the abuse heaped on the human body and still be capable of functioning.

Some of the mechanisms vital to the maintenance of health include (1) the maintenance of the internal environment—*i.e.*, homeostasis; (2) adaptation to stress situations; (3) defense against microbiologic agents, such as bacteria and viruses; (4) repair and regeneration of damaged tissue or cells; and (5) clotting of the blood to prevent excessive bleeding. Each of these areas will be discussed briefly. Despite these separate considerations, the commonality of purpose—the preservation and maintenance of health—must not be lost sight of. In so far as each of these mechanisms works to maintain a constant internal environment, it can be considered as a homeostatic mechanism. Later, when disease is discussed, it will be apparent that to a considerable extent disease represents a failure of homeostasis and the other defensive responses listed above.

### HOMEOSTASIS

The term homeostasis refers to the maintenance of the internal environment of the body within narrow and rigidly controlled limits. The major functions important in the maintenance of homeostasis are fluid and electrolyte balance, acid–base regulation, thermoregulation, and metabolic control.

Fluid and electrolyte balance. This term refers to the controlled partition of water and major chemical constituents among the cells and the extracellular fluids of

the body. The human body is basically a collection of cells grouped together into organ systems and bathed in fluids, most notably the blood. The intracellular fluid is the fluid contained within cells. The extracellular fluid—the fluid outside the cells—is divided into that found within the blood and that found outside of the blood; the latter fluid is known as the interstitial fluid. These fluids are not simply water but contain varying amounts of solutes (electrolytes and other bio-active molecules). An electrolyte (sodium chloride, for example) is defined as any molecule that in solution separates into its ionic components and is capable of conducting an electric current. Cations are electrolytes that migrate toward the negative pole of an electric field; anions migrate toward the positive pole. The electrolyte composition of the various fluid compartments is summarized in Table 1.

**Intracellular and extracellular fluid**

**Table 1: Principal Electrolytes of the Body Fluids**

extracellular fluid*		intracellular fluid†	
Cations (+ electrical charge)			
Sodium (Na +)	142 mEq/l‡	sodium (Na +)	10 mEq/l
Potassium (K +)	4 mEq/l	potassium (K +)	160 mEq/l
Calcium (Ca ++)	5 mEq/l	magnesium (Mg ++)	35 mEq/l
Magnesium (Mg ++)	3 mEq/l		
Total	154 mEq/l	total	205 mEq/l
Anions (– electrical charge)			
Chloride (Cl –)	103 mEq/l	bicarbonate (Cl –(HCO <sub>3</sub> –))	3 mEq/l
Bicarbonate (HCO <sub>3</sub> –)	27 mEq/l	phosphate (PO <sub>4</sub> <sup>3–</sup> )	140 mEq/l
Phosphate (PO <sub>4</sub> <sup>3–</sup> )	2 mEq/l		
Sulfate (SO <sub>4</sub> <sup>2–</sup> )	1 mEq/l		
Protein	16 mEq/l		
Organic acid	5 mEq/l	protein	55 mEq/l
Total	154 mEq/l	total	205 mEq/l

\*Approximate values in the blood plasma. †Approximate values for the muscle cells. ‡mEq/l = milliequivalents per litre.

It is apparent from this table that the ionic compositions of the intracellular and extracellular fluids are significantly different. The major cation of extracellular fluid is sodium. The major anion of the extracellular fluid is chloride, while bicarbonate is the second most important. In contrast, the major cation of the intracellular fluid is potassium, and the major anions are proteins and organic phosphates. The intracellular and extracellular compartments are closely integrated and interdependent: changes in one have immediate effects on the other. It is extremely difficult to measure the ionic concentrations within cells; consequently, in clinical medicine, most measurements of electrolyte concentration are performed on the extracellular-fluid compartment, notably the blood serum. The values given in Table 1 remain fairly constant on a day-to-day basis, in spite of various dietary intakes of food and water.

It is the primary task of the kidneys to regulate the various ionic concentrations of the body. Any abnormality in these concentrations can produce serious disease; for instance, the normal sodium concentration in the serum (the blood minus its cells and clotting factors) ranges from 136 to 142 milliequivalents per litre, while the normal potassium level in the serum is kept within the narrow range of 3.5 to five milliequivalents per litre. A rise in the serum potassium to perhaps 6.2 milliequivalents per litre could cause serious abnormalities in the performance of the heart by disturbing the regularity of the nervous impulses that maintain the heart's rhythm.

The state of hydration. The total amount of body water is also maintained at fairly constant levels from day to day by the combined action of the central nervous system and the kidneys. If one were to refrain from drinking any water for a few days, the thirst centre, located in the hypothalamus deep within the brain, would send out messages that would be translated into the feeling of thirst. At the same time a hormone from the pituitary gland known as antidiuretic hormone (ADH) would be secreted. This hormone, released into the bloodstream, reaches the kidneys, where it signals the kidney to retain water and not excrete it. Should too much water be ingested, ADH secretion would be turned off, and the kidney would promptly excrete the excess amount.

**Antidiuretic hormone**

**Definition of homeostasis**

**Acid-base equilibrium.** The acidity of the body fluids is maintained within narrow limits. This acidity is expressed in terms of the pH of a solution, values exceeding 7 representing alkalinity and less than 7 acidity. The pH of a solution is an expression of the amount of hydrogen ion present. Increases in hydrogen-ion concentration cause a lowering of the pH, and, conversely, decreases in the hydrogen-ion concentration raise the pH. Any abnormal process raising the hydrogen-ion concentration in the body fluids produces a state of disease referred to as acidosis; one that causes the concentration to be lowered results in alkalosis.

In health, the blood is slightly alkaline, being kept at a pH of 7.35 to 7.45, a narrow range, the maintenance of which is required for the optimum operation of the many chemical reactions that go on constantly in the body. Alterations in the blood pH occur in many diseases, particularly of the lungs and kidneys, organs one of whose functions is the regulation of the body pH.

**Thermoregulation.** As has been said above, the temperature of the body is kept nearly constant at 98.6° F. Fluctuations within a few tenths of a degree are perfectly compatible with health. Wider swings in temperature are usually indicative of disease, and thus, body temperature is an important factor in assessing health. Body temperature is regulated by a thermostatic control centre in the hypothalamus. A rise in body temperature initiates a chain of events leading to an increase in the rate of breathing and in sweating, two processes that serve to lower the body temperature. Similarly, a decrease in body temperature, perhaps occasioned by a chilly winter walk, leads to increased heat-producing activity such as the muscular contractions of shivering—again mediated by the thermostatic control centre in the hypothalamus.

**Metabolic control.** In essence, metabolism involves all of the physical and chemical processes by which cells are produced and maintained. Included under this broad umbrella are the regulation of fluid and electrolytes, the maintenance of plasma-protein levels adequate for the building and repair of cells, and control of the amounts of sugar (glucose) and fats (lipids) in the blood so as to provide sufficient amounts for all of the energy-producing activities of the cells. (The main treatment of this subject is contained in the article METABOLISM.)

Blood-glucose level

The control of blood-glucose levels is a good example of homeostasis. Most of the glucose utilized by the body is derived from the dietary intake of various forms of sugars and starches. These are digested within the intestinal tract into the simplest forms of carbohydrate (monosaccharides). Glucose, galactose, and fructose are the principal monosaccharides. These are absorbed from the intestines into the blood and thence drain to the liver. Here all are eventually converted to glucose. The glucose may be utilized by the liver cells in part as a source of energy, but most of it enters the general circulation of the body and contributes to the blood-glucose level. Blood glucose may also be derived in times of need by the conversion of the stored glycogen into glucose.

When food is eaten there is a temporary rise in the blood-glucose level known as alimentary hyperglycemia (high blood-glucose level). Mechanisms are activated that stimulate the pancreas to secrete the hormone insulin. This hormone makes it possible for the cells of the body to utilize the glucose by facilitating its transport (carriage) across the membranes of cells into their interior, where it can enter the complex chemical reactions that ultimately provide the cell with energy. By virtue of insulin secretion, the cells receive adequate amounts of glucose, and the blood-glucose levels are returned to the normal range, somewhere between 80 and 120 milligrams per 100 millilitres of blood.

Metabolic controls are exerted similarly for fats and proteins. As will be noted later on, derangements of these controls can lead to serious disease. The state of health implies proper, smooth-running metabolic machinery.

#### ADAPTATION

Adaptation refers to the ability of cells to adjust to severe stresses and achieve altered states of equilibrium while

preserving their state of health. The process can be likened to adjusting the air supply to an engine. If a car normally travels at 40 miles per hour it requires a certain amount of air to be mixed with the gasoline for the most effective development of power. If the car now begins to travel at 60 miles per hour, it consumes more gasoline and must have additional air. If the air valve can open and provide adequate quantities the car may function perfectly well at this higher speed. In the human body, the large bulging muscles of the man engaged in heavy labour are good examples of cellular adaptation. Because of the heavy demand on these muscles each of the individual muscle cells within the labourer's arms and legs becomes larger (hypertrophies). They become larger by the formation of increased numbers of tiny fibres (myofilaments) that provide the contractile power of muscles. Thus, while the normal cell might have 2,000 myofilaments, for example, the hypertrophied cell might have 4,000 myofilaments. The work load can now be divided among twice as many myofilaments, and no one filament is overloaded. The cells are completely normal, and, in fact, are more robust than their fragile cousins. The individual can do heavy work all day without excessive fatigue, and no cell injury results from heavy work load. A new level of equilibrium has been achieved by the process of cellular hypertrophy, a form of adaptation. A person with this type of muscular development, in fact, can be considered to be in excellent physical condition, since he is capable of meeting emergency situations, such as running from a fire or catching a train, without the dangers that might be encountered by a person who has not undergone such a development.

The enlarged muscle cell

Inhabitants of high altitudes adapt to the lowered amounts of oxygen within the air by developing an increased number of red blood cells (a condition called secondary polycythemia). The greater number of red cells in the blood are capable of absorbing more oxygen from the air breathed into the lungs, and thus, the person who lives in high altitudes makes better use of the slender oxygen content of the air.

Other examples of adaptation can be given, such as the ability of the liver cells to increase their supply of enzymes, thereby enabling them to adapt to increased levels of chemicals to which they may be exposed.

Thus adaptation is a mechanism by which the body preserves and maintains its health by adjusting to alterations in the conditions under which it functions.

#### DEFENSE AGAINST BIOTIC INVASION

Man swims every day of his life in a sea of various types of microbiologic (biotic) organisms. Most of the various classes and types of these organisms are entirely harmless for man, and, indeed, some play an important role in helping man as, for example, by trapping nitrogen from the air and aiding in the decomposition of waste materials. Organisms capable of producing disease are known as pathogens. The maintenance of health requires defense against such possible biotic invasion. There are four levels of defense in the body: (1) the intact skin and linings of the various orifices of the body (such as the mouth, nose, throat), (2) a widely dispersed system of cells capable of destroying invaders, (3) the capability of mounting an inflammatory reaction that destroys offenders, and (4) the capability of developing an immune response that helps to bring about further neutralization and destroy any attackers.

Four levels of defense

Maintenance of the integrity of skin and mucosal linings. With rare exception, pathogenic organisms cannot penetrate the intact covering and linings of the body. Indeed, if one were to take samples of the bacteria found on the skin, one would find large numbers of potentially harmful organisms that represent no threat unless the skin is punctured or the linings of the body are in some way injured. There are exceptions to this generalization, and a few biotic agents can probably penetrate intact mucosal surfaces. The bacteria (*Salmonella typhosa*) that cause typhoid are thought to penetrate the normal lining of the gastrointestinal tract. Nevertheless, the intact skin and mucosal linings are primary protective

barriers in the maintenance of health. For centuries, mothers have wisely admonished their children to wash a cut. Potentially harmful bacteria can be introduced into a cut, which thus provides a portal of entry for organisms that may then cause an infection. By adequate washing at least sufficient numbers of bacteria are flushed out to prevent the infection. Irritation of the skin from any cause or irritation of the throat by habitual smoking impairs the integrity of these barriers and predisposes to invasion by potentially harmful organisms. The body has ingeniously contrived to place further roadblocks in the way of invaders. The saliva and the secretions in the stomach contain enzymes and acids that also destroy organisms. Thus, man has an effective enclosing barrier that protects him against biotic attack.

**Phagocytic cells of the body.** The term phagocytosis means "cell eating." In biologic terms it defines the capability of certain cells within the body of engulfing particulate material. When a phagocytic cell comes in contact with some particle such as a bacterium or even inert particulate matter such as a small splinter, the cytoplasm of the cell (the cell substance outside its nucleus) flows around the object and literally incorporates it within the body of the cell. Once engulfed, the intruder is subjected to the action of destructive enzymes within the cell. If the chemical composition of the foreign substance permits degradation by the enzymes, it is destroyed. In the case of bacteria, protein-digesting enzymes (proteases) digest and thereby destroy the micro-organism. Phagocytic cells abound in the body; they serve as a second line of defense against most biotic invasion.

There are two groups of phagocytic cells, white blood cells—polymorphonuclear neutrophils and monocytes—and tissue cells. The white blood cells are able to migrate through blood-vessel walls in areas of inflammation or infection, where they may phagocytize foreign material such as bacteria. Moreover, in inflammatory and infectious states, the total number of white cells in the body increases (leukocytosis). Thus the population of phagocytic cells is expanded when it is needed in the body's defense.

The second group of phagocytic cells found in the body are usually firmly fixed within tissues and are known as the reticuloendothelial system. The cells in this system go by a variety of names depending on their location (*e.g.*, Kupffer cells in the liver, macrophages or histiocytes in loose connective tissue). They are particularly abundant in the spleen, liver, lymph nodes, and bone marrow but are also scattered throughout the blood vessels and virtually all of the other tissues of the body. If, for example, bacteria do find a portal of entry, but the bacterial invasion is not too massive and the organisms are not too powerful, these phagocytic cells are capable of engulfing and destroying them before they can cause injury (see RETICULOENDOTHELIAL SYSTEM, HUMAN).

**The inflammatory response.** Whenever cells are damaged or destroyed in the body, a series of vascular and cellular events known as the inflammatory response is set in motion. This response is protective of health in that it destroys or walls off injurious influences and paves the way for the restoration of the state of normality. The sequence of events is as follows: in an area of injury (as in a bacterial infection), substances are released from cells that cause the small blood vessels in the affected area to become larger and thus increase the amount of blood flowing to the injured area; at the same time, clear fluid exudes out of the vessels into the area; this fluid tends to dilute any injurious substances in the area of injury; next, white corpuscles from the blood flow out of the blood vessels (emigrate) into the damaged area and begin to phagocytize the bacteria and destroyed cells; the resulting mixture of dead cellular debris and white blood cells is known as pus.

The major signs of inflammation are redness and increased heat (caused by blood-vessel engorgement and enlargement), swelling (resulting from the accumulation of fluid), and pain. The last of these signs (pain) is somewhat of a mystery. Although there is considerable doubt

as to its cause in inflammation, there is unanimous agreement that it is one of the cardinal signs of all inflammatory responses. Inflammation can be classified as either acute or chronic. Acute inflammation, such as seen around the skin cut, lasts for only a few days and is characterized microscopically by the presence of a certain type of white blood cell—the polymorphonuclear leukocyte. Chronic inflammation is of a longer duration and is characterized microscopically by the presence of lymphocytes, monocytes, and plasma cells and, in general, is associated with little fluid exudation.

Because of the pain and swelling, the inflammatory response is often viewed as an unwelcome event following injury. Yet it is important to recognize that it is the first step in the healing process and represents an important protective response in the maintenance of health (see INFLAMMATION).

**The immune response.** The immune reaction is one of the most important defense mechanisms against biotic invasion and is therefore vital to the preservation of health. It is a relatively recent development from an evolutionary point of view, being found only in vertebrates. This complex system, covered at length in the article INFLAMMATION, has, as its participants, antigens, antibodies, complement, and white blood cells. The interaction of these participants can perhaps be suggested by the following analogy: a potential criminal appears but is apprehended by the forces of law and order in the nick of time and is securely impounded in the local jail. In the analogy the villain represents an antigen, any substance capable of evoking an immune response. Most often the antigen is a protein or a polysaccharide (a complex carbohydrate), both of which are important constituents of many bacteria or viruses. In the analogy the police correspond to antibodies or immunologically reactive cells. Antibodies, complex protein structures that have the ability to bind to (form compounds with) antigens and neutralize them, are formed by plasma cells and released into the circulation; thus they are available throughout the body for reaction with antigens wherever they are present. Certain antigens do not evoke circulating antibodies but instead cause the generation of lymphocytes that are capable of an immune response and are known as immunologically competent cells. This special form of immune response is provoked largely by certain types of bacteria, such as those that cause tuberculosis (*Mycobacterium tuberculosis*). In either event, the intruder is neutralized by either antibodies or immunologically competent cells and so is prevented from doing further damage. Complement, a complex group of proteins found in the blood, facilitates the immune response by attracting phagocytic white cells to the area of the reaction and by creating a firmer union between the antigens and the antibodies. The subsequent phagocytosis (imprisonment) of the offending antigen by white cells completes the analogy.

Two of the remarkable qualities of the immune system are specificity and "memory." When an antigen enters the body it evokes a specific antibody or specific immunologically competent cells; that is, the antibody or the cells will neutralize only the antigen that evokes them. Furthermore, the system exhibits what appears to be memory: once challenged by an antigen, the body "remembers" it for years and perhaps for life. The child who has an attack of measles is immune for the rest of his life. When the specific antigen (such as the measles virus) appears at a later date, the immune system recognizes it and responds and thereby prevents a reinfection. Indeed, these two characteristics of the immune system, specificity and memory, serve as the basis for preventive immunization. By inoculation of infants or children with inactivated or attenuated biotic agents, the immune system is made alert to such an antigen should it appear at a later date. Poliomyelitis, for example, once dreaded as a cause of paralysis and death, has recently come under control with the development of the polio vaccine.

What has been said will aid in understanding why certain illnesses (such as measles, mumps, and chickenpox) seem to affect only children—and in fact, are referred to

Action of complement

Major signs of inflammation

as the childhood diseases. While these viral diseases can affect persons of any age, most adults have had previous exposure to the antigens (viruses) and are thus immune. Children with no previous exposure have no specific immunity to these invaders and consequently are able to develop the diseases.

Thus the immune system is a vital part of the defense against biotic invasion. The immune system may also be a cause of disease (see below Diseases of immune origin).

#### REPAIR AND REGENERATION

By the replacement of damaged or destroyed cells with healthy new cells, the processes of repair and regeneration work to restore an individual's health after injury and protect his future health. Unlike the salamander, which is capable of totally regenerating a limb if it is destroyed or cut off, man cannot regenerate whole organs or limbs. If one of the kidneys is totally destroyed by a disease process, it is permanently lost. Moreover, the many cell types of the body have varying capacities for regeneration.

Regeneration is the production of new cells exactly like those destroyed. Of the three categories of cells in man—(1) the labile cells, which continue to multiply throughout life; (2) the stable cells, which do not multiply continuously but have the capacity to do so when called upon to replace cells lost by injury or some destructive process; and (3) the permanent cells, incapable of multiplication in the adult—only the permanent cells are incapable of regeneration. These are the brain cells and the cells of the skeletal and heart muscles.

Labile cells comprise those of the bone marrow, the lymphoid tissues, the skin, and the linings of most of the ducts and hollow organs of the body.

Stable cells are found in the liver, in many of the glands of the body, such as the pancreas and salivary glands, in the lining of the kidney tubules, and in the connective tissues. Normally these cells do not divide unless some are destroyed by disease or injury and must be replaced.

If only a small area of liver (made up of stable cells) is damaged or destroyed, the cells can be replaced by regeneration of the still-living cells around the area of injury. When large areas of liver are destroyed, cellular regeneration cannot occur, and the area of cell loss is replaced by new healthy connective-tissue cells, which thus produce scars. When a person has a heart attack, a certain number of heart-muscle cells (permanent cells) are killed because of loss of their blood supply. Since heart-muscle cells cannot regenerate, the area of injury is replaced by a scar (if the patient survives). Such repair is by no means perfect, but it nonetheless permits restoration of reasonable heart function with perhaps only a slightly reduced level of health.

Cellular regeneration in man is limited by many other factors, such as the availability of blood supply and a supporting connective tissue. When the blood vessels and supporting cells (connective tissue) are destroyed in the liver along with the liver cells, perfect reconstitution of the liver is not possible. There may be some regrowth of liver cells, but they do not form the normal liver architecture, and the newly regenerated cells cannot function because they do not have an appropriate orientation to the blood vessels and bile ducts.

A review of the events that occur after a simple cut in the skin provides a good example of the processes of regeneration. At first, the area becomes red, swollen, and painful, because of the inflammatory reaction. A scab forms. Beneath the scab, while the inflammatory process is going on, the cells from the adjacent healthy skin begin to regenerate by dividing and growing over the damaged area. If the damage is minor, perfect reconstruction of the skin and its appendages is likely to result. If the damage has extended below the skin surface, deeper connective-tissue cells, notably the fibroblasts, proliferate and fill the area. These cells lay down collagen (connective-tissue protein) composed of tough, durable fibrils (minute fibres), and, eventually, scar formation ensues. Once scarring has occurred, it cannot be reversed, although considerable shrinking of the scar may occur.

#### HEMOSTASIS

Another mechanism of defense is hemostasis, the prevention of loss of blood from the blood vessels by formation of a clot. (This process is covered more at length in the article BLEEDING AND BLOOD CLOTTING.) Simply stated, a break in a blood vessel leads to the activation of a complex sequence of events leading to the formation of a solid plug of fibrin and blood cells (fibrin is a fibrous protein formed from fibrinogen). This plug, or clot, seals the damaged vessel and prevents further loss of blood (hemorrhage). The numerous components of the fluid blood called clotting factors contribute in sequential fashion to the formation of the clot. (The clotting factors are commonly referred to by a roman numeral rather than by name. Fibrinogen, for example, is clotting factor I.) These many factors are each important because abnormalities, such as the absence of one of the clotting factors (VIII), can lead to disorders of bleeding, such as that found in hemophiliacs.

#### INTERRELATIONSHIP OF DEFENSIVE MECHANISMS

The homeostatic and defensive mechanisms involved in maintaining a constant internal environment are complex and yet beautifully coordinated. Thus, the normal state of health is not a static condition but exists rather within a narrow range maintained by the coordinated responses of many systems and mechanisms. Health requires the proper function of all of these controls. Disease may begin in a single organ or system, but the interdependence and close coordination of the many bodily functions, which cooperate so beautifully in health, may be upset by a chain reaction when one breaks down. A disease of the kidney leading to abnormal retention of sodium, for example, can lead to hypertension (high blood pressure). Prolonged hypertension in turn can induce heart failure, and this can result in the abnormal collection of fluid in the lungs. The impairment of respiratory function may then result in a sudden rise in the level of carbon dioxide in the blood, which brings with it further complications. Similarly, if the normal inflammatory response malfunctions, a trivial skin infection (popularly known as a pimple) can enlarge into a boil (a furuncle). The responsible bacterial agents may proliferate in the local site and penetrate small blood vessels to seed the bloodstream, thus causing a generalized infection (septicemia or bacteremia). Such a generalized infection is extremely serious and may cause secondary infections of the heart (endocarditis) or of the coverings of the brain (meningitis).

Thus health implies the proper functioning of the homeostatic mechanisms just described, including those systems involved in the defense of health. The state of disease basically represents a failure of these mechanisms. Although one tends to think of disease in terms of offending agents, these agents are only able to produce disease by their ability to disrupt normal homeostasis, and it is precisely those disruptions that are the manifestations of disease.

#### II. Disease: signs and symptoms

Disease may be acute, chronic, malignant, or benign. Of these terms, chronic and acute have to do with the duration of a disease, malignant and benign with its potentiality for causing death.

An acute disease process usually begins abruptly and is over soon. Acute appendicitis, for example, is characterized by the sudden onset of nausea, vomiting, and pain usually localized in the lower right side of the abdomen. It usually requires immediate surgical treatment. The term chronic refers to a process that often begins very gradually and then persists over a long period. Peptic ulcer, for example—an ulcer usually of the stomach or duodenum—is a chronic disease. It may begin at any age and tends to persist indefinitely, although strict regulation of the diet and antacid therapy may result in good control.

The terms benign and malignant, most often used to describe tumours, can be used in a more general sense. Benign diseases are generally without complications, and a

What  
regenera-  
tion is

Chain  
reactions  
in disease

Repair of  
a cut

good prognosis (outcome) is usual. A wart on the skin, for example, is a benign tumour caused by a virus; it produces no illness and usually disappears spontaneously if given enough time (often many years). Malignancy implies a process that, if left alone, will result in fatal illness. Cancer is the general term for all malignant tumours.

Each disease entity has a constellation of signs and symptoms more or less uniquely its own; individual symptoms such as fever, however, may be found in a great number of diseases. Some of the common manifestations of disease—as they relate to an imbalance of normal homeostasis—are taken up in this section. They are covered more at length in the article **DIAGNOSIS**.

Fever is an abnormal rise in body temperature. It is most often a sign of infection but can be present whenever there is tissue destruction, as, for example, from a severe burn or when large amounts of tissue have died because of lack of blood supply. Body temperature is controlled by the thermostatic centre in the hypothalamus. Certain protein and polysaccharide substances called pyrogens, released either from bacteria or viruses or from destroyed cells of the body, are capable of raising the thermostat and causing a rise in body temperature. Fever is a highly significant indicator of disease.

Mention was made earlier of the phagocytic white blood cells and the process referred to as leukocytosis. The expansion of the number of circulating phagocytic white blood cells is one of the more common manifestations of disease. The stimulus for such an event may be any inflammatory process in the body, such as is caused by bacteria, viruses, or any process that leads to the destruction of cells. Such leukocytosis is reflected in the white-blood-cell count, which may be substantially elevated above the normal upper value of 10,000 cells per cubic millimetre of blood.

The pulse rate is another easily obtainable and important piece of information. The heart rate varies with the level of physical activity, beating faster during exercise and more slowly during rest. An inappropriate heart rate (or pulse) may be indicative of disease. The heart rate increases in the feverish patient. A weak, rapid pulse may be a sign of severe blood loss or of disease within the heart itself. Irregularity of the pulse (arrhythmia) is an important indicator of malfunction of the heart.

The respiratory rate (the rate of breathing) is modified by disease. People with fever have an increased respiratory rate (hyperventilation), which serves to lower body temperature (this rapid breathing is analogous to the panting of the dog). Hyperventilation is a common response to painful stress. Any condition leading to acidosis (lowering of body pH) similarly drives the respiratory rate upward. Diseases of the lungs—with accompanying inability to oxygenate the blood adequately—have a similar effect.

Thus it can be seen that temperature, pulse, and respiratory rate—called the vital signs—may be important manifestations of disease and are easily obtainable information for the physician. A fourth vital sign, blood pressure, is equally significant. Among other things, it indicates the amount of blood in circulation. A decrease in circulating blood volume, as is seen with severe bleeding, lowers the blood pressure and deprives the tissues of adequate blood flow. Reflexes are initiated that compensate for the reduced blood volume and blood pressure. The heart rate increases and compensates to some extent for the sudden reduction in blood volume and pressure; at the same time, peripheral blood vessels in such areas as the abdomen constrict, tending to divert the reduced blood volume to the more vital areas such as the brain and head. Unusual elevation of pressure (hypertension) is a disease by itself.

Fluid and electrolyte imbalances may be further consequences of homeostatic failure and additional significant manifestations of disease. The causes of these abnormalities are complex. Edema, or swelling, results from shifts in fluid distribution within body tissues. Edema may be localized, as when the leg veins are narrowed or obstructed by some disease process. The pressure of the

blood in the distended veins rises, and fluid is driven out of the vessels into the tissues, causing swelling of the extremity. Generalized edema is seen in renal (kidney) disease that causes abnormal retention of sodium and water. Heart failure is an additional cause of generalized edema, usually most manifest in the feet and ankles. Alterations such as dehydration, hyperventilation, and tissue destruction can all lead to varying fluid and electrolyte derangements. The levels of the serum electrolytes (sodium, potassium, carbonate, chlorine), determined relatively easily in the laboratory, provide the physician with valuable clues to deranged homeostasis induced by disease.

Finally, the determination of body pH and a number of blood tests designed to evaluate adequate (or inadequate) metabolic regulation provide diagnostic clues of homeostatic failure. These tests include determination of the levels of the blood sugar, blood urea nitrogen, and serum protein.

The disease diabetes mellitus provides an excellent example of such a failure of the homeostatic mechanisms. Diabetes is a common disease of metabolic-endocrine (ductless gland) origin involving a relative or absolute deficiency of insulin, a hormone that plays an important role in carbohydrate metabolism. Any or all of the above-mentioned homeostatic derangements can be found in this disease. Patients with a severe form of diabetes may at one time be dehydrated, because of obligatory excretion of water (osmotic diuresis); be acidotic, because of formation of increased amounts of keto acids; be hyperventilating, as a result of the acidosis; be comatose, because of high levels of blood sugar; have a weak pulse, because of severe dehydration; have electrolyte abnormalities; and so on. The signs and symptoms are numerous, all illustrating the interdependence of the homeostatic mechanisms, which, when not functioning properly, provide the manifestations of disease.

At the most elemental level, disease develops when any disruptive or adverse influence overcomes the homeostatic and defensive controls of the body. As will be seen, there are numerous influences that can tip the scales of health toward disease. Viruses and bacteria are obvious threats to health. There are a great many others, some so subtle as to be poorly understood. The following section focusses on the causes of disease rather than on a detailed description of each entity. It represents one method of classification. There is a considerable overlap in categories; certain diseases grouped as metabolic-endocrine in origin could also be classified as diseases of genetic origin. Indeed, the interdependence of the organ systems, the metabolic pathways, and the defense systems renders finite classification in medicine difficult. The human body acts as a unit—an individual—both in health and in disease.

### III. The causes of disease

The search for the causes (etiologies) of the many diseases of man goes back to antiquity. Hippocrates, a Greek physician of the 4th and 5th centuries BC, is credited with being the first to adopt the concept that disease is not a visitation of the gods but rather is caused by earthly influences. Scientists have since continually searched for the causes of disease and, indeed, have discovered the causes of many.

In the development of a disease (pathogenesis) more is involved than merely exposure to its agent. A room full of people may be exposed to a sufferer from a common cold. One or two of those exposed may later contract the cold, but the others do not. A number of individual host factors determine whether the cause will induce disease or not. Thus, in the pathogenesis of disease, the resistance, immunity, age, and nutritional state of the person exposed, as well as virulence and level of exposure, all play a role in determining whether the person develops a disease.

In the following sections the many types of human disease will be divided into a number of categories, and in each category only a few examples will be given to establish the nature of the process. These categories are divided on the basis of the presumed etiology of the dis-

Increased  
number of  
white  
blood cells

Causes of  
edema

Overlap in  
causal  
categories

ease. Many diseases are still of unknown (idiopathic) origin. With others the cause may be suspected but not yet definitively proved. In a few instances, the discovery of the etiology of a disease represents the individual achievement of a solitary investigator who may have worked long years on the problem. The story of Louis Pasteur and the discovery of the cause of anthrax is a classic example of this. More often the individual investigator who makes the final breakthrough stands on the shoulders of hundreds of earlier workers who provided bits and pieces of knowledge vital to the final understanding. Thousands of research workers have spent millions of man-hours attempting to elucidate the cause of cancer. Regrettably, cancer must still be listed as being of unknown cause.

#### DISEASES OF GENETIC ORIGIN

Congenital  
genetic  
disorders

Certain diseases of man are traceable to an abnormality (mutation) in genetic constitution (genome). The mutation, for example, may have altered the genetic coding necessary for the synthesis of a certain enzyme of vital importance in normal metabolism. Most genetic disorders can be detected at birth; the child is born with the defect or defects. Thus these abnormalities are congenital (at birth) genetic disorders. Surprisingly, a few genetic derangements do not become manifest until later life. An example is Huntington's chorea, a nervous-system disease in which the genetic defect requires years to become manifest. Hence it may be said that most but not all genetic diseases are congenital.

Conversely, some congenital diseases are not genetic in origin; they may arise from some direct injury to the developing fetus. When a mother contracts the viral disease **german measles** (rubella) during pregnancy, the virus may infect the fetus and alter its normal development, leading to some malformations, principally of the heart. These malformations constitute a congenital disease that is **not genetic** (see BIRTH DEFECTS AND CONGENITAL DISORDERS).

Further confusion often arises over the terms genetic and familial. A familial disease is hereditary, passed on from one generation to the next. It resides in a genetic mutation that is transmitted by mother or father (or both) through the gametes (sperm and egg) to their offspring. Not all genetic disorders are familial. The mutation may occur in the formation of the gametes or may arise during the early development of the fetus. Such an infant will have some genetic abnormality, though the parents themselves are completely normal. Perhaps the most illustrative disease is Down's syndrome (mongolism). Most of these unfortunate children are born of normal parents. During the formation of the gametes an error in the division of the chromosomes (see below) leads to the infant's having one too many chromosomes (known as trisomy). All of the defects of Down's syndrome arise out of this extra chromosome. It is extremely important to recognize that genetic disease need not be familial, because other children of the same parents may be entirely normal.

Each cell in the body contains 22 homologous (alike) pairs of chromosomes called autosomes and one pair of sex chromosomes (XX in the female and XY in the male), yielding a total of 46 chromosomes. Each chromosome is comprised of long double strands of deoxyribonucleic acid (DNA) wound in spiral fashion and forming a double helix. The smallest functional unit of the DNA strand is known as a gene. Specific hereditary traits are determined by one or more genes located at precisely corresponding points on each of the pair of homologous chromosomes. A pair of genes on homologous chromosomes controlling a single trait (such as eye colour) is referred to as an allele. Should the alleles on a given pair of chromosomes be identical for a trait, the individual is said to be **homozygous** for that trait. Should the alleles be different, the individual is said to be **heterozygous**. Furthermore, one of the genes in an allelic pair is said to be dominant if the trait controlled by that gene is expressed (*i.e.*, is manifested) in a heterozygous individual and recessive if it fails to express itself in a heterozygote. For example, with respect to eye colour, if an individual were **hetero-**

**zygous**, having received one brown allele from the mother and one blue allele from the father, he would have brown eyes because the brown allele is dominant and the blue allele is recessive. A blue-eyed person must have two blue alleles, because that trait must be homozygous to be expressed. Similarly, a disease resulting from a recessive gene (or allele) would be manifest only in the **homozygous** individual. Most diseases are inherited as recessive traits. Diseases controlled by dominant genes are much rarer, because persons carrying such a dominant gene would manifest the disease and so, in some instances, die very young, while those who survive tend not to marry and reproduce. This is an example of Darwin's theory of natural selection. The most desirable traits are selected for, and the most undesirable perish with their host.

Diseases of genetic origin can be divided conveniently into those with large mutations that produce demonstrable chromosomal abnormalities and those in which the mutation is at the level of a gene and is so subtle as to be inapparent with currently available methods of study of the chromosomes. This division, of course, is artificial, because the basic mechanism, alteration in genetic code, is common to both groups. Diseases with demonstrable chromosomal abnormalities have large genetic alterations and, in general, have more dramatic clinical presentations. On the other hand, diseases without demonstrable chromosomal abnormalities have very small genetic defects and, therefore, cause clinical derangements that are often more subtle.

The demonstration of chromosomal abnormalities involves the following process. Use is made of colchicine, a substance that is capable of stopping cell mitotic division when all the chromosomes are fully formed (this stage is called metaphase). By use of special stains, the chromosomes can readily be seen with a light microscope. Furthermore, they can be photographed and arranged pictorially into groups based on chromosome size and shape. Such an arrangement of chromosomes is referred to as a karyotype.

If no chromosomal abnormality can be seen, a disease can be determined to be genetic in origin only by a systematic study of the family of which the diseased person is a member. Successive generations in a family tree must be studied to determine whether the disease appears in the family pedigree and is presumably familial. Careful retrospective studies of such family trees not only can determine the genetic basis of a disease but also can illuminate the pattern of inheritance, such as dominance and recessiveness.

**Factors relating to genetic injury.** The causes of mutations are still poorly understood. Certain factors, however, are thought to be important. It is an accepted fact that maternal age plays an important role in predisposing toward genetic injury. The frequency of Down's syndrome and of congenital malformations increases with the age of the mother. All ova are formed during the fetal development of the female infant. They persist throughout the active reproductive life of the woman. It is hypothesized that the ova are continuously exposed to all the adverse influences, such as infections and nutritional deficiencies, suffered by the woman. The longer the exposure to such injury (*i.e.*, the older the mother), the greater the chance of genetic injury to the ova. No such relationship has been shown with the father's age. From a statistical point of view, the safest time for a woman to have children is before the age of **30**.

Radiation is a well-recognized cause of chromosomal damage. In Japan, the survivors of the atomic-bomb blasts in 1945 have shown definite chromosomal abnormalities in certain types of their circulating white blood cells. Indeed, a higher incidence of leukemia (a form of cancer of white cells) has been reported in this population, suggesting that the chromosomal changes may have played some role in the induction of the disease (see also RADIATION INJURY).

Viruses have been shown to cause mutations in human cells when the cells are grown in a tissue-culture flask, but there is no clear evidence that viral infections of man have caused genetic injury. It should be re-emphasized

Recessive  
inheritance  
of disease

Congenital  
defects and  
age of  
mother

that the virus of German measles (rubella) causes congenital malformations, but it has not been established that there is a genetic role to these disorders.

The role of drugs and chemicals in the induction of genetic mutations is a complicated one. Currently, there is great concern about the possible ill effects of lysergic acid diethylamide (LSD) on the offspring of habitual users. While there are many agents that cause chromosomal alterations in the human cells grown in culture, there is not yet any definitive evidence of drug- or chemical-induced genetic injury in the living host.

#### Diseases associated with abnormalities in the karyotype.

Demonstrable chromosomal abnormalities may arise through several pathways. These abnormalities may consist of an alteration in the structure of one or more chromosomes or an abnormal number of chromosomes. The mechanisms leading to alterations in number are nondisjunction and simple loss of a chromosome.

The normal chromosome count of man is 46. This number is referred to in genetics as the diploid mode. Before mitosis (division of cells into double the number of cells, each with 46 chromosomes) actually begins, there is synthesis of new deoxyribonucleic acid (DNA) until the cell about to divide contains double the normal amount of DNA and each of the 46 chromosomes also possesses twice the normal amount. During mitosis each of these large chromosomes divides in half; each half, called a chromatid, possesses as much DNA as a usual chromosome. During mitosis the chromatid doublet separates and the two halves migrate to the opposite poles of the cell about to be divided. In this fashion each daughter cell receives the usual diploid number of chromosomes. If a chromatid doublet fails to divide (nondisjunction), the resulting daughter cells receive an inappropriate number of chromosomes (*i.e.*, one cell might receive 47 chromosomes and the other 45) instead of the usual 46 chromosomes.

Simple loss of a chromosome occurs during metaphase, when a chromosome fails to line up properly along the equator of the cell. When cell division occurs the aberrant chromosome is lost, and daughter cells have unequal chromosomal composition.

Mechanisms leading to alterations in chromosomal structure include translocation and deletion. Translocation occurs when a chromosome fractures and a resulting fragment attaches itself to another chromosome. When a fragment fails to reattach itself to a chromosome, that segment is lost from the genetic pool, a process referred to as deletion (Figure 1).

Figure 1: Alterations in chromosome structure.

Diseases with demonstrable chromosomal abnormalities can involve either autosomal (nonsex) chromosomes or the sex chromosomes. Down's syndrome is an example of the former; Turner's syndrome is an example of the latter.

Down's syndrome (mongolism) is a relatively common genetic disorder, affecting approximately one out of every 700 births. Nowhere is the effect of maternal age on chromosomal abnormalities better illustrated than in this disorder. When the mother is less than 30 years of age

the incidence of this disorder is approximately one in every 3,000 births. In the age group 30–34 the incidence rises to one in 600. Mothers between the ages of 45 and 50 have a one in 40 chance of having a mongoloid child.

The basis of this disorder remained a mystery until 1959, when it was demonstrated that affected children have 47 chromosomes instead of the normal 46. The extra chromosome was found to be one of the smaller autosomal (nonsex) chromosomes. A rarer version of the same disorder is caused by a translocation of one chromosome to another (Figure 1).

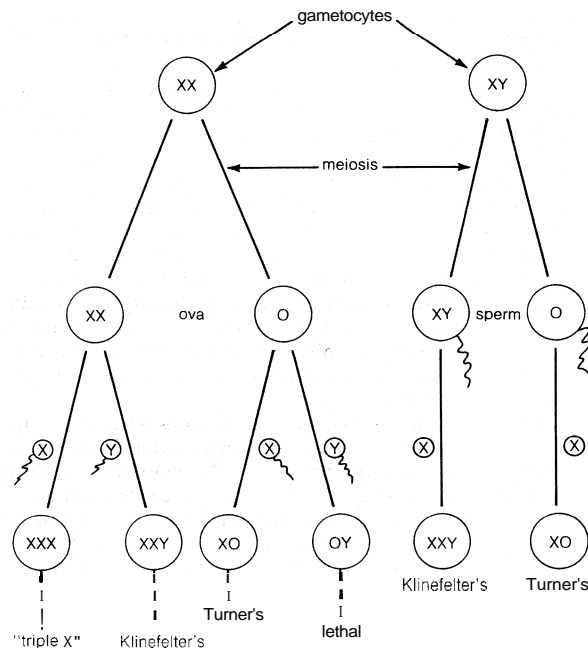

Figure 2: Nondisjunctional errors in gamete formation (see text).

The term mongolism is a misnomer, for while the child with Down's syndrome may seem to the casual observer to resemble somewhat the child of Mongolian descent, the latter bears none of the signs of the genetically defective child. These signs include mental retardation, below-average stature, slow reflexes, and abnormalities of the tongue, hands, feet, and eyes. Years ago, before the use of antibiotics, these children perished of pneumonia in infancy. Medical advances have provided them with a far better chance of surviving; indeed, they now account for a significant percentage of institutionalized children. Characteristically they are sweet, gentle children, and many, with training, can be significantly helped.

In the formation of sperm and ova—the sex cells, or gametes—a reduction division (meiosis) occurs. It differs from mitosis in that the daughter cells each contain exactly one-half the normal chromosomal number. Thus, each sperm or egg contains 23 single chromosomes (22 autosomes and one sex chromosome) instead of 46. During fertilization, when the gametes unite, they form a zygote (fertilized egg), which has 46 chromosomes, half from the father and half from the mother. Just as the 22 pairs of autosomes are divided in meiosis, so are the pair of sex chromosomes. In the production of spermatozoa, meiotic division can result in sperm containing either an X-chromosome or a Y. The production of female gametes, or ova, yields only cells containing an X.

Demonstrable abnormalities of the sex chromosomes are almost always the result of nondisjunction (see above) during meiosis. Thus one gamete may possess two sex chromosomes, while the other contains none. Repeated nondisjunctional errors in meiosis may yield gametes with three, four, or even five sex chromosomes contributed by one or both gametes. Thus zygotes may have too few or too many chromosomes and even two or three Y-chromosomes. A Y-chromosome determines the male sex of the fetus, however many X-chromosomes may be

Abnormalities of sex chromosomes

Nondisjunction, translocation, and deletion

present. It is the absence of a Y that specifies the female sex. The multi-X zygotes are female, as are those with a single X and no Y. The absence of both sex chromosomes or the presence of only a single Y-chromosome is incompatible with life. One of the more frequent patterns of abnormal meiotic division is illustrated in Figure 2. In this figure, during male spermatogenesis, nondisjunction has occurred, yielding one gamete with two sex chromosomes instead of one and the other gamete without sex chromosomes. The mating possibilities for these gametes would thus yield either an XXY zygote or an XO. This indeed does occur. People with an XXY chromosomal pattern have a disorder known as Klinefelter's syndrome. People with only one X-chromosome (XO) have a disease known as Turner's syndrome.

Turner's syndrome (XO) occurs in approximately one out of every 3,000 births. These female children lacking a second sex chromosome often are not recognized as suffering from some disorder until puberty, at which time the conspicuous absence of secondary sex characteristics (*i.e.*, pubic hair and breast formation) becomes evident. Children with Turner's syndrome are quite short in stature with a broad, weblike neck. The breasts are poorly developed and the internal sex organs are functionless. These girls fail to menstruate and usually are sterile. Klinefelter's syndrome is a disorder of persons who, in general, are male in physical configuration but have small testes, do not produce sperm, and display varying degrees of eunuchoidism.

**Diseases without demonstrable chromosomal abnormalities.** Enzymes are specialized proteins that facilitate the chemical reactions in the body. The synthesis of these proteins is dictated by the sequence of certain units (nucleotide bases) in the deoxyribonucleic acid (DNA) molecule within the chromosome. Mutations involving a portion of the DNA molecule can result in the defective production, or total absence, of one or more enzymes. More often than not, these mutations produce little or no disease. On occasion the absence of a critical enzyme can have far-reaching results. At present, several thousand distinct diseases have been ascribed to mutations that lead to the absence or relative lack of critical enzymes. Collectively these disorders are referred to as inborn errors of metabolism (see METABOLISM, DISEASES OF).

Disease  
due to lack  
of an  
enzyme

Table 2: Examples of Genetic Diseases with No Demonstrable Chromosomal Abnormalities		
metabolic defect	disease	mechanism
Defective enzyme synthesis		
Tyrosinase	albinism	blockage of synthesis of melanin
...	gout	excess production of uric acid
Defective synthesis of proteins not classified as enzymes		
Hemoglobin	sickle-cell anemia	abnormal hemoglobin leading to tendency to hemolysis
Factor VIII (AHF)	hemophilia	defective hemostasis leading to bleeding disorder
No metabolic defect known		
—	polydactylism	—
—	cleft palate	—

While most studies of these submicroscopic genetic abnormalities have concerned themselves with enzyme abnormalities, there are important exceptions. There are several diseases caused by probable mutations at the gene level in which no biochemical abnormality has been identified. The addition of one or more digits to the hand (polydactylism), for example, is a genetic disorder not associated with any known biochemical abnormality.

Finally, genetic mutations can produce disease by abnormal synthesis of proteins not classified as enzymes. Disorders involving hemoglobin, the protein responsible for carrying oxygen in the blood, have been clearly described (*e.g.*, sickle-cell anemia). Hemophilia is a sex-linked (carried on the sex chromosome) disorder similarly involving a protein not classified as an enzyme. Table 2 summarizes these classifications.

CONGENITAL MALFORMATIONS

Congenital malformations, any structural defects present at birth, range from those that have serious effect upon health to trivial alterations, such as an extra nipple (supernumerary nipple) or a "strawberry mole." Some of the more serious forms of malformation include blindness, the absence of a limb, cleft palate, and mental retardation. As many of the serious childhood diseases have been brought under control, congenital malformations have become major causes of death in newborn infants, accounting for about 15 percent of all mortality during the first year of life. Progress in preventing birth defects has been painfully slow because the mechanisms and arrangements that lead to such malformations are largely unknown. Nonetheless, the study of birth defects (teratology) and their causes has become a major area of current medical-biological research.

The overall incidence of congenital malformations lies in the range of 1-10 percent of all births. This wide range is partially the result of differences in defining the term malformation. Another variable is the age range employed in the analysis of congenital malformations. Some reports confine their analyses to the first month or first year of life, while others extend the time span of the study. The incidence of malformations varies also with the time span embraced, because some malformations are not discovered immediately after birth.

Congenital structural abnormalities must be viewed as the postnatal emergence of developmental defects that may have originated at any time in the development of the fetus, beginning with the fertilization of the ovum. The malformations encountered in living children represent the mildest forms of developmental defects. The more severe malformations are not compatible with survival of the fetus. It is estimated by some that approximately 20 percent of fertilized eggs fail to develop because of serious developmental anomalies. Less severe aberrations are compatible with shortened fetal survival. There is a natural process of selection in which the greater the structural defect, the less the likelihood of survival.

The causes of congenital malformations are poorly understood at this time. It is believed that approximately 10 percent can be attributed directly to genetic defects, while another 10 percent represent the influence of environmental factors on the developing fetus. The remaining 80 percent may have both genetic and environmental factors involved in their causation. Most of the following material focusses on the 20 percent of malformations whose causes are better understood.

The genetic factors that contribute to congenital malformation have been previously cited in the discussion on genetics. There are other structural anomalies that are suspected but not proven to have genetic origins. Cleft palate and harelip are examples of these defects. Although no well-defined pattern of inheritance has been identified and no demonstrable abnormalities have been discerned in the chromosomes, there is a tendency for these effects to appear in families, suggesting a hereditary genetic origin. Certain environmental influences have been proven to be capable of causing congenital malformations. One would imagine that the fetus would be protected from its environment securely tucked away inside the mother's womb. It has been well documented, however, that radiation, drugs and chemicals, viruses, hormones, and nutrition may reach inside the womb to induce developmental anomalies in the fetus.

Ionizing radiation is a well-documented potential cause of congenital malformations. Pregnant women exposed to radiation have an increased number of fetal deaths as well as an increase in the number of congenital defects in their children. Most of these defects are found above the neck and include microcephaly (small head), skull defects, blindness, and mental retardation.

Although few drugs have been proven to be capable of causing malformation (teratogenic), there are some notable exceptions. Thalidomide, a drug taken as a sedative, was found to cause the formerly rare congenital defect known as phocomelia (seal-flipper arms and legs). Other

Incidence  
of  
congenital  
defects

Radiation  
as cause  
of defects

compounds that cause or may cause malformations include aminopterin and busulfan (both anticancer agents), quinine, and lysergic acid diethylamide (LSD).

Several infectious diseases cause malformations when they occur during pregnancy. Although it is considered a benign childhood disease, German measles (rubella) in the early weeks of pregnancy directly injures the fetus and so leads to certain birth defects in the infant. The nature of these defects is related to the period of pregnancy in which the disease occurs. For instance, cataracts (eye defects) are found in children when the rubella-virus infection occurs in the sixth week of pregnancy. Viral infections in the ninth week of pregnancy result in a strong chance of deafness in the child. Similarly, heart and dental abnormalities are noted in children of mothers affected during the fifth through tenth week of gestation. After the tenth week of pregnancy, rubella infections have little effect on the fetus.

Syphilis, a bacterial venereal disease, during pregnancy is a well-recognized cause of deformities in the offspring. These include thickening of the shins, notching of the teeth, collapse of the bridge of the nose, and eye defects. Since syphilis is an easily treatable disease, such malformations are avoidable.

Neither hormones nor nutritional factors are considered important causal agents in the production of gross structural defects at birth. Diabetes mellitus, a disorder of carbohydrate metabolism caused by a lack of the hormone insulin, is a possible exception. Studies of the offspring of diabetic mothers have revealed a high incidence of stillbirths and neonatal deaths. It has also been noted that the average weight at birth of infants of diabetic mothers is considerably higher than that of normal children. Some investigators claim an increased incidence of congenital defects in the offspring of diabetic mothers, but the validity of these studies is disputed (see also BIRTH DEFECTS AND CONGENITAL DISORDERS).

#### HEREDITY AND ENVIRONMENT

Both genetic and environmental factors appear to play major roles in producing congenital malformations. Other diseases can be spread across a wide spectrum, with predominantly genetic diseases at one extreme of the spectrum and diseases largely environmental at the other. In the genetic part of the spectrum are diseases such as Turner's syndrome; in the environmental part are infectious diseases and chemical poisoning. Lying at some point between these two extremes are the bulk of diseases of man—those with both genetic and environmental causative influences that are significant. Indeed, even at the very extreme ends of the spectrum both factors play some role. The genetic constitution dictates in part the host's response to environmental challenges. Similarly, environmental factors play significant roles in the manifestation of genetically induced disease. Sickle-cell anemia, for example, an inherited disease characterized by abnormal red blood cells and hemoglobin, is seriously exacerbated by low levels of oxygen in the air.

Furthermore, there are many disorders in which there is a familial tendency to develop the disease, but no formal pattern of inheritance has been delineated. Many forms of cancer, high blood pressure, arthritis (inflammation of the joints), and obesity, for example, seem to have a familial tendency. Although the exact roles of environmental and genetic factors are unknown in all these diseases, it is strongly felt that both factors contribute in some part to the disease process.

#### CHEMICAL AND PHYSICAL INJURY

**Chemical injury: poisoning.** A poison is any substance that can cause illness or death when ingested in small quantities. This definition excludes the multitude of substances that can produce harm if ingested in large quantities. Even sugar solutions of high enough concentration can cause damage to cells.

There are several considerations to keep in mind when one discusses poisoning. The first of these, as already suggested, is the degree of toxicity. A substance with a very high toxicity (such as hydrogen cyanide gas) need

only be taken in minute amounts to cause serious harm.

A second consideration is the mechanism by which a poison exerts its harm. Some chemicals act solely on the kidney or liver, while others affect principally the central nervous system. Each poison has a characteristic ability to cause damage at particular sites within the body.

A third factor is the body's ability to eliminate the substance. Some chemicals, rapidly excreted in the urine, must exert their harm rapidly while they remain transiently in the body. Others are poorly eliminated. With these, chronic ingestion of nontoxic amounts leads to a buildup in the body that can eventually reach toxic levels. Lead poisoning is a good example of this phenomenon.

The route of entry is also important. Many substances are harmless when eaten but become deadly if injected into a vein. Similarly, the chemical form of the substance affects its action on the body. Metallic mercury, as found in thermometers, is harmlessly excreted, whereas the chloride salt of the same substance is deadly.

Finally, the condition of the host, the recipient of the poison, is an important consideration. A dose of aspirin harmless to an adult may be poisonous to an infant. Similarly, an elderly person's tolerance of a substance may be much lower than that of a healthy young adult.

There is a wide variety of poisons. As was already noted, almost any substance in sufficient quantity is capable of causing harm. Among the many poisons, a few stand out as being the most commonly encountered in medical practice. Some are of relatively low toxicity, but have importance because of their widespread use. Many physicians consider aspirin (acetylsalicylic acid) the most dangerous poison because of its commonplace use and abuse and because it is the leading cause of poisoning in children. In the following paragraphs three groups of agents will be presented: (1) organic chemicals, (2) inorganic chemicals, and (3) drugs.

**Organic chemicals.** Among the organic chemicals commonly encountered in instances of poisoning are two forms of alcohol, ethyl alcohol (ethanol) and methyl alcohol (methanol). Ethyl alcohol is the form found in most alcoholic beverages. Methyl alcohol, or wood alcohol, is used for a variety of household purposes.

Acute ethyl alcohol poisoning is encountered after ingestion of large quantities over a relatively short time. The alcohol is quickly absorbed from the gastrointestinal tract, and high blood levels can be achieved in a remarkably short time. Ethyl alcohol acts principally as a central-nervous-system depressant and, fortunately, stupor usually results before fatal doses can be reached. The difference in blood levels between intoxication and fatal stupor is very slight, however, and death may result with the ingestion of large quantities of alcohol from depression of the respiratory centre in the brain.

Chronic alcoholism is considered by some as a form of poisoning, but most view it as a sociomedical disease. It may lead to serious liver injury (cirrhosis) over the course of years, but there is debate as to whether it is the alcohol itself that is injurious to the liver or the inadequate food intake of the chronic alcoholic.

Methyl alcohol (methanol) is usually ingested either by accident or with suicidal intent. Once inside the body it is transformed to formic acid, an extremely toxic substance that selects the nerves in the eye as its target. Without treatment, blindness results. Methyl alcohol can also affect the brain tissue itself, causing the brain to swell and leading to death in some instances. Prompt treatment can prevent lasting damage to the brain and the eyes.

Carbon monoxide is a nonirritating, inert gas, without colour, taste, or odour. A poison responsible for a large number of suicidal deaths, it is one of the chemical products of any combustion of organic material. Inhalation of a 1 percent concentration can be fatal within ten to 20 minutes. Once absorbed, carbon monoxide develops a firm union with hemoglobin; thus chronic inhalation of nontoxic concentrations can lead to a cumulative buildup of the substance in the blood. The formation of the compound with hemoglobin prevents the normal carriage of oxygen by the hemoglobin. Thus carbon monoxide acts as an internal asphyxiant by leading to oxy-

Familial  
tendencies  
to disease

Ethyl  
alcohol  
poisoning

gen starvation of tissues. It suffocates the cells of the body and so causes death or serious disease. It should be noted that exposure to even low concentrations can result in the slow accumulation of this poison over hours, days, or weeks, leading very gradually to toxic or fatal levels.

**Inorganic chemicals.** The inorganic chemicals most commonly responsible for poisonings in the United States are cyanide, mercury, arsenic, and lead. It should be remembered that these substances often appear in chemical forms that are quite harmless. In general, it is the soluble salts of the substances that are poisons.

Cyanide poisoning

Cyanide is a dangerous substance in any form. It may occur in the form of hydrocyanic gas or as solid compounds such as potassium cyanide. One of the most lethal poisons known to man, in amounts less than even 0.1 gram it may cause death within minutes. Like carbon monoxide it is an internal asphyxiant, but it differs from carbon monoxide in its site of action. Whereas carbon monoxide prevents the delivery of oxygen to cells, cyanide prevents the utilization of oxygen by cells. Unable to utilize oxygen, the cell is deprived of its energy-generating biochemical reactions, vital to its function and preservation. The result is cell death on the microscopic level and often death of the whole organism.

Mercury in the pure metallic form is rather harmless, but the salt of the same substance, notably mercuric chloride, is a deadly poison. As little as 0.1 gram is enough to cause damage to body tissues and one gram can cause death. This agent causes extensive tissue damage wherever high concentrations of the poison are encountered. When the substance is swallowed, the stomach represents the portal of entry. The mercuric chloride is partially absorbed into the blood, and this portion is excreted through the urine. The remainder affects organs in the digestive tract, principally the stomach, the kidneys, and the colon. Mercuric salts can cause death of cells by precipitating the proteins within the cells, a form of cell injury called coagulative necrosis. The damage to the kidneys leads to kidney failure, abnormally high levels of urea in the blood, and even death. The poison induces ulcerations in the colon and bloody diarrhea. With careful treatment affected persons survive with full recovery. Chronic ingestion of smaller amounts of mercuric salts, as is seen in some industrial settings, can result in disease involving the mouth, skin, and nervous system.

The favourite poison (that is, for homicidal purposes) is arsenic. Both odourless and tasteless compounds of arsenic are found in some rat poisons, plant sprays, paints, and other household preparations. Many of these household staples are ingested accidentally by children. Principally affected by arsenic are the blood vessels and the central nervous system. Indeed, vascular collapse and depression of the central nervous system can be followed by coma and death within hours after ingestion.

Lead salts

The soluble salts of inorganic lead are also strong systemic poisons. They may accumulate within the body over a long period until toxic levels are reached, and cell damage ensues. These salts were at one time commonly found in paints, and lead poisoning was frequently seen in children who chewed on their painted cribs or woodwork. Recent legislation in many countries has outlawed the use of lead-base paints for infants' furniture. Other forms of poisoning are incurred through industrial exposure and ingestion of water from lead pipes. The major effects of lead poisoning are found in the blood-forming organs, the gastrointestinal tract, and the central nervous system. Lead poisoning damages red blood cells and leads to hemolysis (rupturing of red blood cells) with resulting anemia. In the brain, lead accumulation causes the degeneration of nerve cells. This produces such manifestations as mental depression, psychoses, convulsions, and even coma and death. Peripheral nerves are damaged as well, sometimes causing weakness or even paralysis of hands and feet. Within the mouth, a darkish lead line can be seen along the dental margins of the gums. If an early fatality does not occur, the lead is slowly excreted and complete recovery may be anticipated.

**Drugs.** Drugs are another important cause of poisoning. It is a pharmacological principle that for any thera-

peutic gain derived from a drug, a price is paid. There are few drugs used today that have no side effects (*i.e.*, effects unintended when the drug is administered). Although these side effects may be harmless and inconsequential, certain drugs have side effects that are potent. Similarly, a drug may be useful in a certain dose range but harmful when larger doses are taken. Morphine, for example, is an excellent drug for the control of severe pain, but morphine can depress respiration, and too much of it can cause death. The following material is concerned with barbiturates and salicylates, drugs commonly found to cause serious illness from overingestion. In the pill-oriented society of modern developed nations, there is an alarming increase in drug-induced disease and drug-induced death. All drugs are potentially harmful.

Barbiturates are pharmacologically classed as hypnotics, because they are used as sedatives and sleeping pills. Besides their therapeutic use, they are also commonly employed in suicidal attempts, which require far larger amounts than the therapeutic dose. Barbiturates affect the central nervous system almost exclusively. With toxic levels, the vital centres located within the midbrain are depressed; this leads to profound coma, depression of respiration, oxygen starvation of the tissues, and even shock. The identification of barbiturate poisoning relies almost exclusively on finding the substance in the blood or urine, because there is little anatomical change. Treatment is directed toward getting the drug out of the system as quickly as possible, either by inducing copious urinary excretion of the drug or by the use of the artificial kidney—a process called hemodialysis.

Aspirin, or acetylsalicylic acid, is a drug that deserves special mention because it is such a common household item and therefore within the reach of small children. In the United States approximately 27,000,000 pounds of aspirin are consumed yearly, enough to treat about 17,000,000,000 headaches. Approximately ten to 30 grams of aspirin can be fatal in adults, and much smaller amounts can be fatal in children. (A single aspirin tablet of standard size contains approximately one-third gram.) Doses of methyl salicylate (wintergreen oil) as small as three grams have been known to be responsible for infant death. There are many signs and symptoms associated with salicylate poisoning, including headaches, drowsiness, dyspepsia, nausea, vomiting, sweating, and thirst. Salicylate poisoning is an acute medical emergency. Rigorous medical treatment is demanded and use of the artificial kidney is often required.

Aspirin and other salicylates

Heroin is rapidly becoming one of the leading killers among the adolescent population. Not only can overdoses of the drug result in severe respiratory depression and even death, but its injection may bring on such disorders as serum hepatitis—a dangerous form of liver disease—from a contaminated needle and reactions to impurities such as fungi and bacteria. (Heroin and its use and abuse are taken up in a number of other articles; *e.g.*, **NARCOTIC DRUG PROBLEMS.**)

**Physical injury.** Physical injuries include those caused by mechanical trauma, heat and cold, electrical discharges, changes in pressure, and radiation. Mechanical trauma is an injury to any portion of the body from a blow, crush, cut, or penetrating wound. The complications of mechanical trauma are usually related to fracture, hemorrhage, and infection. They do not necessarily have to appear immediately after occurrence of the injury. Slow internal bleeding may remain masked for days and lead to an eventual emergency. Similarly, wound infection and even systemic infection are rarely detectable until many days after the damage. All significant mechanical injuries must therefore be kept under observation for days or even weeks.

**Injuries from cold or heat.** Among physical injuries are injuries caused by cold or heat. Prolonged exposure of tissue to freezing temperatures causes tissue damage known as frostbite. Several factors predispose to frostbite, such as general weakness, lack of adequate clothing, and any type of insufficiency of the peripheral blood vessels. Frostbite tends to occur in the most exposed areas (ears, nose, fingers) and in areas of poor circulation (feet). The

first symptom is usually the sensation of a sharp prickling feeling coming from an area of numb, hard skin. Since the freezing produces local anesthesia, the victim rarely, if ever, suffers severe pain and is often unaware of any harm being done until hours or even days after the exposure. Eventually the affected area becomes swollen, blistered, and, as tissue dies and sloughs off, extremely susceptible to infection. This stage is accompanied by extreme pain (see FROSTBITE).

When the entire body is exposed to low temperatures over a long period, the result can be alarming. At first blood is diverted from the skin to deeper areas of the body, resulting in anoxia (oxygen lack) of the skin and the tissues under the skin, including the walls of the small vessels. This small-blood-vessel damage leads to swelling of the tissues beneath the skin as fluid seeps out of the vessels. When the exposure is prolonged it leads eventually to cooling of the blood itself. Once this has occurred the results are catastrophic. All the vital organs become affected, and death usually ensues.

Burns may be divided into three categories depending on severity. A first-degree burn is the least destructive and affects the most superficial layer of skin, the epidermis. Sunburn is an example of a first-degree burn. The symptoms are pain and some swelling. A second-degree burn is a deeper and hence more severe injury. It is characterized by blistering and often considerable edema (swelling). A third-degree burn is extremely serious; the entire thickness of the skin is destroyed, along with deeper structures such as muscles. Because the nerve endings are destroyed in such burns, the wound is surprisingly painless in the areas of worst involvement.

The outlook in burn injuries is dependent upon the age of the victim and the percent of total body area affected; for instance, a 20-year-old man with third-degree burns over 50 percent of his body has a 50-percent chance of survival, while a 50-year-old person with the same burn has a 20-percent chance.

Loss of fluid and electrolytes and infection associated with loss of skin provide the major causes of burn mortality. Much progress has been made in the treatment of burns with the advent of bacteriocidal creams, better understanding of fluid and electrolyte control, and the improvement of skin grafting techniques (see BURNS).

**Electrical injuries.** The injurious effects of an electrical current passing through the body are determined by its voltage, its amperage, and the resistance of the tissues in the pathway of the current. It must be emphasized that exposure to electricity can only be harmful if there is a contact point of entry and a discharge point through which the current leaves the body. If the body is well insulated against such passage, either at the point of entry or discharge, no current flows and no injury results. The voltage of current refers to its electromotive force, the amperage to its intensity. With high-voltage discharges, such as are encountered when an individual is struck by lightning, the major effect is to disrupt nervous impulses; death is usually caused by interruption of the regulatory impulses of the heart. In low-voltage currents, such as are more likely to be encountered in accidental exposure to house or industrial currents, death is more often due to the stimulation of nerve pathways that freeze muscles and may in this way block respiration. If the electrical shock does not produce immediate death, serious illness may result from the damage incurred by organs in the pathway of the flow of the electricity through the body (see SHOCK, ELECTRICAL).

**Pressure-change injuries.** Physical injuries from pressure change are of two general types: (1) blast injury and (2) the effects of too rapid changes in the atmospheric pressure in the environment. Blast injuries may be transmitted through air or water; their effect depends upon the area of the body exposed to the blast. If it is an air blast, the entire body is subject to the strong wave of compression, which is followed immediately by a wave of lowered pressure. In effect the body is first violently squeezed and then suddenly overexpanded as the pressure waves move beyond the body. The chest or abdomen may suffer injuries from the compression, but it is the

negative pressure following the wave that induces most of the damage, since overexpansion leads to rupture of the lungs and of other internal organs, particularly the intestines. If the blast injury is transmitted through water, the victim is usually floating, and only that part of the body underwater is exposed. An individual floating on the surface of the water may simply be popped out of the water like a cork and totally escape injury.

Disease caused by sudden changes in atmospheric pressure is encountered principally in two situations: in those persons who work below the surface of the earth or underwater, where increased atmospheric pressures are used, and in those who enter high altitudes as in high-altitude flights or in travel by rockets. In the digging of tunnels, the shaft is maintained at a higher than normal atmospheric pressure in an effort to support the outside walls and to prevent seepage of water. The worker adapts to this increased pressure by entering air chambers, where he is slowly pressurized. Similarly, the air pressure within the suits of deep-sea divers is slowly pressurized for the same reasons. In both situations, as the individuals return to normal atmospheric pressures they must slowly be depressurized. If the pressure is reduced too quickly some of the gases that are dissolved in the blood at the higher pressure come out of solution to create small bubbles within the bloodstream. The oxygen in these bubbles is rapidly dissolved, but the nitrogen, which is a significant component of air, is less soluble and persists as bubbles of gas that block small blood vessels. These individuals suffer excruciating pain, principally in the muscles, which causes them to bend over in agony, and this disorder is popularly known as the bends. The same principle applies in those who sally high above the earth's surface. The normal atmospheric pressure of earth progressively diminishes at higher altitudes. If astronauts or those who fly in planes ascend too rapidly bubbles of nitrogen and oxygen likewise appear as they enter rarefied atmospheres. The interior of the plane is pressurized to maintain normal atmospheric levels. If such pressurization were to fail, the victims might suffer the bends. The three cosmonauts in the Russian spaceship Soyuz 11 were said to have died from such a failure, on June 30, 1971, during re-entry into the earth's atmosphere. In usual air flights, however, the altitudes are not high enough to make the bends a serious threat.

**Radiation injury.** Radiation can result in both beneficial and dangerous biological effects. It is one of the effective forms of treatment for certain types of cancer. On the other hand, with the spectre of nuclear warfare ever present, the deleterious effects of radiation exposure are remembered. There are basically two forms of radiation: particulate, comprised of very fast moving particles (alpha and beta particles, neutrons, and deuterons), and electromagnetic radiation in the form of gamma rays and X-rays. From a biological point of view, the most important attribute of radiant energy is its ability to cause ionization—to form positively or negatively charged particles in the substance that it encounters. It is this ionizing effect that appears to cause destruction and even death of cells. The ionization of compounds within the cells theoretically leads to an alteration in the chemical composition of the cells. The damage may affect a wide range of chemical structures from simple inorganic molecules to complex structural proteins and enzymes. Deoxyribonucleic acid (DNA)—the genetic material of the cell—is highly susceptible to ionizing radiation. Cells and tissues may therefore die because of damage to enzymes, because of the inability of the cell to survive with a defective complement of DNA, or as a result of its inability to reproduce viable daughter cells. The cell is most susceptible to irradiation during the process of division.

The severity of radiation injury is dependent upon the penetrability of the radiation, the area of the body exposed to radiation, and the duration of exposure. These variables all add up to the important concept of the total amount of radiant energy absorbed. A quantitative unit of radiation absorbed is called a rad. With total body irradiation, as occurred in the atomic blasts, or in accidents occurring at sites where radioactive material is being

Three  
categories  
of burns

Develop-  
ment of  
the bends

Factors  
affecting  
severity of  
radiation  
injury

handled, large areas are exposed to intense doses of radiation. In these circumstances, the body may receive within seconds enough radiant energy to cause either acute radiation sickness or death. It has been estimated that a dose as small as 500 rads absorbed instantaneously is sufficient to cause acute radiation sickness. This takes the form of nausea, vomiting, loss of appetite, headache, and a general feeling of weakness. Later, serious deficiencies in the blood cells and platelets may become evident as a result of radiation injury to the bone marrow, leading to hemorrhages or increased vulnerability to infections. Total body irradiation of 1,000 rads is almost certain to be fatal. At this level all of the cells of the body are seriously injured and there is total breakdown of normal fluid and electrolyte balance.

When the radiation exposure is confined to only a part of the body and is delivered in divided doses, a frequent practice in the treatment of cancer, the effect of the radiation depends on the vulnerability of the cell types in the body to this form of energy. Some cells, such as those that divide actively, are particularly sensitive to radiation. In this category are the cells of the bone marrow, spleen, lymph nodes, sex glands, and lining of the stomach and intestines. Their vulnerability may be related to the impact of radiant energy on the chromosomal material involved in mitotic division. In contrast, certain cells of the body such as nerve and muscle cells are peculiarly resistant to radiation. Here, too, the fundamental basis may be the fact that these cells never divide in adult life and so never enter a mitotic cycle. It should be pointed out that these general principles underlie the use of radiation in the treatment of cancer. In malignant tumours the cells are actively dividing and so are more sensitive to radiation. The goal of radiation therapy of tumours is to deliver a dosage to the tumours that is sufficient to destroy the cancer cells without injuring too severely the normal cells in the pathway of the radiation. Obviously, when an internal cancer is treated, the skin, underlying fat, muscles, and nearby organs are unavoidably exposed to the radiation. The possibility of delivering effective doses of radiation to the unwanted cancer depends on the ability of the normal cells to withstand the radiation.

Finally, there are probable deleterious effects of radiation in producing congenital malformations, certain leukemias, and possibly some genetic disorders (see RADIATION INJURY).

#### DISEASES OF IMMUNE ORIGIN

The same immune system that protects against infectious disease is also capable of causing disease. These disorders of immunity fall into two broad categories: (1) **hyperreactivity** (increased reactivity) of the immune system to external or environmental antigens and (2) **abnormal reactivity** of the immune system to one's own tissues and cells—called **auto-immunity**.

The immune mechanism involves two quite separate types of response. In the first type an antigen stimulates the production of circulating antibodies that are elaborated by certain cells, called plasma cells, in the lymph nodes and bone marrow. The antibodies, known as immunoglobulins, pass from their sites of origin into the bloodstream and circulate freely, ready to neutralize antigens wherever they are found. Each antigen evokes its own specific antibody and the specificity is exquisitely precise. The antigen to its antibody is as specific as a key to its lock. The antibodies produced by antigens are protein molecules of different sizes. It has been possible to segregate these antibody molecules on the basis of size into classes of immunoglobulins, which have been designated as immunoglobulin A, immunoglobulin G, immunoglobulin M, immunoglobulin E, and, indeed, several other less important classes. The second type of immune response does not yield humoral-circulating antibodies but instead generates lymphocytes (a form of white blood cell) that are reactive against specific antigens. It is not yet understood why certain antigens evoke antibodies while other antigens evoke reactive lymphocytes.

Three pathways have been identified for the production of disease by circulating antibodies and reactive lympho-

cytes: (1) the release of vasoactive substances (substances that affect the blood vessels), (2) the deposit of **antigen-antibody complexes** in tissues, and (3) direct destruction of cells and tissues.

Release of vasoactive substances results from the union of certain forms of immunoglobulins with certain cells in the body. Immunoglobulins of the E class are principally implicated in this pathway. Certain antigens such as plant pollens, dusts, and products found within food evoke in the sensitized individual the formation of immunoglobulin E. When this form of antibody is produced it becomes fixed to one of two types of cells within the body, mast cells or basophilic leukocytes. Mast cells are scattered throughout the supporting tissues of the body. The basophilic leukocytes (white blood cells that stain readily with basic dyes) are found in the circulating blood. Presumably, when an individual first reacts to one of the specific types of antigens, the antibody so formed becomes adherent to these cells. These cells are rich in histamine, one of the major vasoactive substances found in the body. When released, histamine has the ability to dilate small blood vessels and capillaries, causing both redness in the tissue affected and leakage of fluid from the blood into the tissues. When a person is exposed a second time to the same antigen, the antigen combines with the antibody now fixed to these particular cells, and histamine is released. Localized areas of redness and swelling (hives) may occur on the skin. If a more severe reaction occurs, the affected person may have profound circulatory disturbances. Most common food allergies, such as sensitivity to strawberries or egg proteins, are mediated by the release of vasoactive substances.

The second major pathway by which the immune response causes disease is through the formation of antigen-antibody complexes in the circulating blood. The diseases so produced are often referred to as **immune-complex diseases**. The antibody in these instances is not fixed to certain body cells but circulates freely in response to some antigenic challenge. The antigen and antibody in the circulation unite, producing immune complexes. When a particular concentration of antigen and antibody is present in the blood, the antigen-antibody complexes formed are of such a size as to become deposited in blood-vessel walls. Once so deposited the immune complex attracts a substance referred to as complement.

Complement is actually comprised of 11 separable components. Several of these components have the capability of attracting leukocytes. Other components are directly injurious to tissue cell, causing rupture of cell membranes. In diseases mediated by the formation of circulating immune complexes, it is actually the complement that does most of the damage. As the immune complexes become deposited in blood-vessel walls and attract complement, the complement in turn gathers leukocytes about it. Certain of these leukocytes, the polymorphonuclears, release powerful enzymes that damage the blood-vessel wall. The blood vessels may either become filled with blood clot or rupture. This type of **immune-complex disease** is particularly characteristic of immune reactions to antigens contained in certain types of bacteria. Specific strains of streptococci are especially likely to induce immune-complex disease, and, for reasons that are obscure, the immune complexes in streptococcal reactions tend to become deposited in the tiny blood vessels within the kidney and so induce a disease known as **poststreptococcal glomerulonephritis**. The kidney is actually an innocent bystander and is the victim of immune complexes caused by the bacterial infection.

The third pathway by which the immune response causes disease is the direct destruction of cells and tissues by reactive lymphocytes. This pathway is principally involved in the immune reaction against transplanted organs. Each individual's cells have a specific constellation of antigens. These antigens are likely to be proteins and related compounds on the surface of the cell wall. No two individuals have the same precise combination of tissue antigens, with the possible exception of identical twins formed from a single ovum. Even the mother and the father of a child will have tissue antigens distinct

Immune complex diseases

Reactive lymphocytes

Types of immune disorders

from those of their offspring. These tissue antigens, also known as transplantation antigens, are powerful stimuli to the immune response—in this particular setting mediated by reactive lymphocytes. They are responsible for the rejection reaction that follows transplantation of foreign organs into genetically dissimilar recipients; for example, the transplantation of a kidney from a donor to a recipient who is not an identical twin. How these lymphocytes actually cause cell and tissue destruction is somewhat obscure. There is some evidence that the lymphocytes elaborate a variety of factors that cause cell damage. The intensity of the immune response depends to a considerable degree on the extent of the antigenic differences between donor and recipient. This antigenic difference is sometimes referred to as the antigenic barrier, because it constitutes an obstacle to transplantation (see IMMUNITY; ALLERGY AND ANAPHYLACTIC SHOCK).

#### DISEASES OF BIOTIC ORIGIN

**General considerations.** *Types of agents.* Biotic agents include living forms that range in size from the smallest virus, measuring approximately 20 millimicrons in diameter (the finest human hair is about 250 times as thick), to tapeworms that achieve lengths of ten metres (about 33 feet). These agents are commonly grouped as viruses, rickettsia, bacteria, fungi, and parasites. The disease that these organisms cause is only incidental to their struggle for survival. Most of these agents do not require a human host for their life cycles. Many survive readily in soil, water, or lower animal species and so are harmless to man. In fact, some play a vital role in the economy of nature, decomposing organic material and returning it to the soil. They thus contribute to the enrichment of the soil, for example, and so contribute to man's survival. Other living organisms, which prefer or may require the temperature range of warm-blooded animals, may flourish on the skin or in the secretions of fluids of the mouth or intestinal tract but do not invade tissue or cause disease. Thus there is a distinction to be made between infection and disease. All animals are infected with biotic agents. Organisms that do not cause disease are termed nonpathogenic, or commensals. Organisms that invade and cause disease are termed pathogenic. The *Streptococcus viridans* organisms, for example, are found in the throats of over 90 percent of healthy persons. In this area they are not considered pathogenic. The same organism cultured from the bloodstream is highly pathogenic and usually indicates the presence of the disease subacute bacterial endocarditis (chronic bacterial invasion of the lining of the heart). In order for such nonpathogenic agents to achieve pathogenicity, they must obviously overcome the defenses of the host. Most biotic agents require a portal of entry through the intact skin or mucosal linings of the body. They must be present in sufficient number to escape the phagocytes. They must be capable of surviving the inflammatory and immune response. Ultimately, to induce disease, they must have sufficient virulence and invasiveness to cause significant tissue injury.

*Factors that affect invasiveness.* Invasiveness is the capability of penetrating and spreading throughout tissues. Remarkably, little is known of the factors that condition it. In a few instances enzymes produced by biotic agents have been identified that are capable of breaking down the integrity of the supporting tissues of the body, thereby preparing a pathway for the spread of the organism. These enzymes, known as hyaluronidases, are found in certain highly pathogenic forms of streptococci that characteristically cause rapidly spreading infections. Streptococci may also produce streptokinases, substances that dissolve blood clots and further facilitate the spread of the organisms. Only very few bacteria elaborate such enzymes, however, and the general attribute of invasiveness is still poorly understood. There are marked differences in invasiveness to be found among the various types of bacteria. The organism that causes diphtheria (*Corynebacterium diphtheriae*), for example, is capable of invading only the surface cells of the mouth and throat. The disease that it produces results from the elaboration of a powerful

exotoxin (a toxin that is produced by the organism and released into the surrounding tissues) that is absorbed into the bloodstream from the local infection within the throat. This exotoxin evokes the major damage in the heart and the nervous system. The diphtheria bacillus, therefore, is an example of a serious infection in which the organism has low invasiveness. In contrast, the organism that causes syphilis (*Treponema pallidum*) has a high degree of invasiveness. It is one of those rare biotic agents that are capable of penetrating intact skin and mucosal linings of the body. Generally, it is acquired by a normal host during sexual intercourse with an infected individual. It creates a small local lesion, a shallow ulcer, known as a chancre, on the penis or on the external genitalia of the female. From this lesion the organism soon (one to two weeks) penetrates into the bloodstream and disseminates throughout the body. The small local lesion, the chancre, is known as the primary stage of syphilis. The spread throughout the bloodstream is known as the secondary stage of syphilis and is characterized by the appearance of a rash. This phase is followed in months to years by the devastating tertiary stage of syphilis, which may cause serious cardiovascular or central-nervous-system disease.

The invasiveness of viruses undoubtedly is facilitated by their extremely small size, but, because of this size, the exact mechanism is difficult to study. In the case of fungi and parasites, the invasiveness is related to the life cycle of the organism. The formation of tiny spores by fungi and the smaller reproductive forms of the parasites provide vehicles by which infection may be drawn into the lungs or may pass through tiny defects in the skin or mucosal linings of the various openings and tracts of the body.

In general, virulence is the degree of toxicity or the injury-producing potential of a micro-organism. The words virulence and pathogenicity are often used interchangeably. The virulence of bacteria usually relates to their capability of producing a powerful exotoxin or endotoxin. Invasiveness also adds to an organism's virulence by permitting it to spread. But there are additional considerations, poorly understood, that modify the virulence of bacteria. Indeed, specific strains within a single genus may have greatly varying virulence. There are 32 types of pneumococci, for example, all of which may cause pneumonia (inflammation of the lungs). Among these, three types cause more severe disease than do the others. To some extent these differences are related to the powerful toxic polysaccharide capsule of the most virulent strains of this genus. In this particular instance, the polysaccharide is a powerful antigen and therefore imparts virulence to the organism. In many other instances, however, the attribute of virulence is poorly understood.

So far, diseases caused by biotic agents have been considered in terms of the role of the invader. Equally important is the role of the host, the individual who contracts the disease. Any infectious disease is a battle between the invader and the defender. Virulent organisms may be capable of inducing serious illness even in the most robust. The converse is perhaps more important. The weak host is prey to many forms of biotic infection, even those of low virulence and invasiveness. Some of the more important of the many factors that condition the level of resistance to biotic infection in the individual are touched upon in the following paragraphs.

*Factors that affect predisposition.* Age is one of the important influences in the predisposition to biotic disease. The two extremes of life, infancy and old age, are periods of maximal vulnerability. At birth, the infant possesses antibodies of maternal origin that provide some protection for the first months of life. When these are lost there is a period of high vulnerability until the infant develops his own immune responsiveness, about halfway through the first year of life. Later in childhood, when the child has an adequately functioning immune system, he is still somewhat vulnerable because he has not yet had exposure to many organisms and so has many immunologic deficits. Thus such infections as mumps, measles, and whooping cough are known as childhood diseases. The increased

Virulence

Inva-  
siveness

vulnerability of old age to infectious disease may be related to nutritional deficiencies, which are common in the elderly. Poor blood supply because of progressive arteriosclerotic disease (hardening of the arteries) may also play a role. Diseases already present, such as heart failure and cancer, facilitate biotic infections.

The physiologic condition of the host is thought in some way to influence the vulnerability to biotic disease. There is a prevailing opinion, difficult to substantiate by objective data, that the robust, well-conditioned individual is less vulnerable than his more fragile colleague. Perhaps the underlying variables are the state of nutrition, the adequacy of blood supply to the tissues, and the total homeostatic responsiveness of the person in good physical condition.

Role of  
nutrition

Nutrition plays an important and well-documented role in predisposition or resistance to infectious disease. There are abundant observations from both clinical and animal studies that dietary factors such as proteins and vitamins A, D, C, and the B complex are necessary in adequate amounts to maintain a high level of resistance to infections. It has been shown in animals that deficiencies of any of these nutrients increase susceptibility to infection caused by pneumococci, rickettsia, and *Salmonella* organisms. Paradoxically, however, deficiencies of the vitamin B fractions in mice decrease susceptibility to the virus that causes poliomyelitis. It may well be that when this vitamin is not present in sufficient amounts, nerve cells cannot support the growth of the polio virus. Proteins play an important role in protecting against infections by providing an adequate substrate for the synthesis of antibodies. Proteins undoubtedly also play a role in the cell growth necessary for repair and regeneration of injury. Vitamin C is also necessary in the inflammatory process that occurs in infectious disease. War-torn and malnourished populations are frequently decimated by such infections as tuberculosis, bubonic plague, and malaria. Nutrition is then of unchallenged importance.

There is a well-known group of genetic disorders characterized by deficient function of the immune system. Some persons with these disorders are incapable of forming antibodies. Others cannot generate lymphocytes that are involved in the immune response. These immunologically handicapped persons are exceedingly vulnerable to infections; many die in early life because of unresisted biotic disease.

A host of metabolic defects predispose to biotic infections. Diabetes mellitus (a metabolic disease in which inadequate secretion of insulin leads to high blood sugar and a large number of other effects) is associated with vulnerability to infectious diseases. It is not certain that diabetic persons develop more infections, but, in such persons, once an infection begins it tends to become more severe. A number of factors may be responsible for the diabetic's vulnerability. He has a marked predisposition to arteriosclerosis (hardening of the arteries), and such vascular disease reduces the blood supply to many of the tissues and organs of the body and so impairs their defensive capability. Additionally, blood with high levels of sugar may serve as a better growth medium for the bacteria than normal blood. The diabetic is subject to acidosis (*e.g.*, the blood and the body tissues are less alkaline than normal) and nutritional imbalances, and these may also contribute to the predisposition to infection.

Increased levels of adrenal hormones (steroids), whether produced by the glands of a person or given as treatment for some other disease, markedly increase the susceptibility to infections. Tuberculosis often becomes activated or disseminated in such circumstances. The steroids also suppress the inflammatory response.

Drugs as  
factors pre-  
disposing  
to disease

Therapeutic agents, paradoxically, have become important factors in predisposing to disease of biotic origin and indeed in altering the incidence patterns of infectious disease. The drugs that are principally involved include those used to suppress the immune response intentionally, as well as the host of antimicrobial and antibiotic agents now employed in the treatment of infectious disease.

Immunosuppressive drugs are used for the treatment of persons about to receive an organ transplant, to block the immune response. Similarly, these drugs are employed in the treatment of the autoimmune diseases. Whatever the reason, immunosuppressive therapy is a two-edged sword. While it may be vital for the purposes of supporting the transplantation or treating the autoimmune disease (disease involving an immune response to one's own tissues), it renders the patient vulnerable to attack by biotic agents. Indeed, these immunologically crippled persons become susceptible to organisms of extremely low virulence.

Antimicrobial drugs have also been two-edged swords. A patient suffering from a streptococcal disease, for example, may be appropriately treated with penicillin. Certain strains of staphylococci, however, are resistant to penicillin. Although the streptococcal organisms, as well as other commensals, may be eradicated by the antibiotic, the staphylococci begin to proliferate, possibly because the competition with other bacteria for nutrients and food supply has been removed. In this noncompetitive situation they may cause disease. More powerful antibiotics may destroy all bacteria, including staphylococci, but permit the unrestrained proliferation of fungi and other agents of low virulence that are nonetheless resistant to the antibiotic. Thus antibiotics have changed the entire frequency pattern of biotic disease. Organisms that are susceptible to antibiotics have become relatively infrequent causes of disease and rare causes of death. Such infections when recognized can be promptly controlled. But organisms that have proved to be more resistant to antibiotics have become the more common causes of serious clinical infection. For this reason certain forms of drug-resistant bacteria referred to as gram-negative rods (*Escherichia coli*, *Aerobacter aerogenes*, *Pseudomonas aeruginosa*, and strains of *Proteus*) as well as fungi have emerged as the important biotic causes of death.

**Viral diseases.** Of the many existing viruses a few are of great importance as causes of human sickness, being responsible for such diseases as smallpox, poliomyelitis, encephalitis, influenza, yellow fever, measles, mumps, and such minor disorders as the common cold, warts, and cold sores of the lips (herpes simplex). At present, viruses are also highly suspect as possible causes of cancer in man. Indeed, there is a large body of evidence pointing to viruses as causes of cancer in lower animals, but, while there are many hints of similar phenomena in man, the data are insufficient for solid conclusions.

Types of  
viral  
disease

Viruses may survive for some time in the soil, in water, or in milk, but they cannot grow and divide unless they parasitize or invade living cells. These agents are principally made up of nucleic acids (deoxyribonucleic or ribonucleic acid) enclosed within a protein coat. It is the outer coat that provides their antigenic specificity and their ability to penetrate cells, but it is the nucleic acid component that replicates (proliferates) within the cell. How these nucleic acids in the course of their replication cause cell injury is still not entirely clear.

Certain viruses proliferate within the host cells and accumulate in sufficient number to cause rupture of the cells. Others multiply within the cell body and compete with the host for nutrition or vital constituents of the cell's metabolism. Both types of viruses are said to be cytotoxic (cell killing). The virus causing smallpox is such an agent. This disease, fortunately largely eradicated by protective immunization (vaccination) of entire populations, is closely related to chickenpox. It is, however, a far more serious disorder and when it was prevalent caused many deaths. Smallpox is characterized by the appearance of large vesicles (blisters) on the skin, producing a severe generalized skin eruption over the entire surface of the body. Blisters are formed where the cells of the skin have been killed and fluid has accumulated. The virus simultaneously attacks cells in the internal organs, such as the liver, and is often lethal.

Poliomyelitis is another example of a viral disease in which the virus grows within cells and causes their destruction. The polio virus is present in the saliva and

Poliomy-  
elitis

stools of infected individuals. The next host presumably becomes infected by swallowing or inhaling virus-contaminated material such as foods, water, or airborne droplets produced by coughing or sneezing. The virus penetrates the tissues of the mouth and throat and grows in cells there without causing much disability, but, from this vantage point, it is apparently spread through the bloodstream to the brain, where it finds its most desired environment—nerve cells within the brain and spinal cord that innervate muscles. By destroying these nerve cells the virus causes paralysis of muscles. When it affects the muscles required for breathing, it may cause death.

Certain viral agents, particularly those capable of producing tumours in lower animals, flourish within cells and stimulate the cells to active growth. These viruses are referred to as being oncogenic (tumour producing). The number of virus-induced tumours in lower animals is now large. While the only proven virus-induced tumour of man is the skin wart, there is much more evidence relating viruses to some of the tumours of man (see CANCER).

Most viral infections occur in childhood. This age distribution has been explained on immunologic grounds. Viruses usually induce a firm and enduring immunity. On first exposure to a virus, children may or may not contract the disease, depending on their resistance, the size of the infective dose of virus, and many other variables. Those who contract the disease, as well as those who resist the infection, develop a permanent immunity to any further exposure. By either pathway, as children grow older they progressively gather protection against viral infections. Consequently, the incidence of these infections falls in adult and later life. The frequency of common colds is now explained on the grounds that a host of different viral agents all induce similar respiratory infections and, while a single attack confers immunity against the specific causative agent, it provides no protection against the rest.

Viral diseases are resistant to the usual forms of drug therapy now available, such as penicillin and the other antibiotics. This point is made because of a distressing tendency among individuals to take penicillin or another antibiotic for a common cold.

**Rickettsial diseases.** The rickettsial diseases of man are caused by micro-organisms that fall between viruses and bacteria in size. These minute agents are barely visible under the ordinary light microscope. Like viruses, they multiply only within the cells of susceptible hosts. They are found in nature in a variety of ticks and lice, and when transmitted to man by the bite of one of these arthropods usually cause acute febrile (fever-producing) illnesses, most of which are characterized by skin rashes. When these agents invade the cells of man they apparently subvert the metabolism of the host cell to the purpose of the micro-organism and so cause death of the cell.

Epidemic typhus is an acute febrile infection caused by *Rickettsia prowazekii*. The disease is characterized by involvement of many organs, particularly the brain. This agent is found in nature in the human body louse. The louse itself becomes infected by biting a person who has the acute disease. The rickettsia flourish within the intestinal tract of the louse and are transmitted to the new host by the bite of the louse. The louse itself, however, may be carried from man to man by rats or other vermin. Typhus may therefore become epidemic when living conditions deteriorate. It has been estimated that perhaps 25,000,000 cases occurred in Russia during World War I.

**Bacterial diseases.** The diseases produced by bacteria are the most common of infectious biotic disease. They range from trivial skin infections to such devastating disorders as bubonic plague and tuberculosis. Various types of pneumonia; infections of the cerebrospinal fluid (meningitis), the liver, and the kidneys; and the venereal diseases syphilis and gonorrhea are all forms of bacterial infection. Bacteria fall into three large groups, spherical cocci, rod-shaped bacilli, and spiral forms known as spirochetes. Some of the large bacilli are as long as ten

microns, while some of the small cocci and coccobacillary forms are as small as 175 millimicrons.

All bacteria induce disease by one of three methods: (1) the production of a harmful chemical substance that is secreted or excreted by the bacterium (exotoxin), (2) the elaboration of a harmful chemical substance that is liberated only after disintegration of the micro-organism (endotoxin), or (3) the induction of sensitivity within the host to antigenic properties of the bacterial organism. A few brief examples will serve to illustrate these methods of producing disease.

**Exotoxic infection.** Mention has already been made of diphtheria as a disease caused by a powerful exotoxin elaborated by the *Corynebacterium diphtheriae*. An additional dramatic example of an exotoxic disease is botulism, caused by *Clostridium botulinum*. This organism is anaerobic; that is, it can only grow in the absence of air. It is therefore a particularly dangerous contaminant of improperly canned or preserved foods. If the organism has not been destroyed by the methods of sterilization, it will grow under the anaerobic conditions obtained in the canning or preserving and release powerful exotoxins into the canned food. Food poisoning appears, therefore, within hours of the ingestion of these preformed toxins. The organism itself contributes nothing directly to the production of the disease; indeed, as soon as the tin or jar is opened the organism is rendered innocuous, because it cannot grow when exposed to air. The absorbed toxins paralyze nerve endings paralyzing all muscles, and affected persons are unable to speak, swallow, or breathe. Death is usually caused by respiratory-muscle paralysis.

**Endotoxic infection.** An example of an endotoxic infection is typhoid, caused by *Salmonella typhosa*. The infection is almost always acquired by the ingestion of micro-organisms in contaminated food, milk, or water. Once swallowed, the organism creates a local infection within the intestinal tract and then spreads rapidly through the lymphatic system into the blood. The endotoxin is largely concentrated in the cell wall of the bacteria; as bacteria are destroyed by normal body defenses the endotoxin is released to produce the manifestations of a systemic infection. Fever, headache, the development of a skin rash, diarrhea, and muscular weakness are the predominant symptoms. Because the organism is susceptible to antibiotic therapy, deaths are usually infrequent.

Typhoid provides an opportunity to touch upon another bacteriologic phenomenon, the development of a carrier state. About 10 percent of persons who recover from the acute typhoid infection continue to harbour organisms and excrete them in their stools for eight to ten weeks, or more. These carriers constitute reservoirs of infection and may spread the disease to others. When engaged in food-handling occupations, they represent an obvious threat to the public health.

**Sensitization.** Tuberculosis exemplifies a disease resulting from the development of sensitization to the products of an organism. The organism, *Mycobacterium tuberculosis*, is of low virulence, but once the patient is infected with the organism he develops a state of sensitization to certain products formed by the bacteria. It is this adverse immune reaction that is responsible for the death of tissues and for the serious manifestations of the disease. Tuberculosis is usually contracted as a respiratory infection by the inhalation of organisms from an infected individual. Such an individual may have obvious signs of tuberculosis such as cough, fever, and night sweats, or he could be remarkably free of signs and symptoms of the disease and yet be capable of spreading it. If infective particles are coughed up he may contaminate his environment or persons with whom he comes into contact and so spread the disease. The new host inhales the organism. At first these produce only a trivial inflammatory reaction within the lungs, but in the course of a few weeks sensitization occurs to certain of the protein and fatty components of the bacterial cell. Once this sensitivity emerges it induces necrosis (death) of the infected tissues, usually portions of the lung. On first exposure to the organism the individual, usually a child, develops what is called primary tuberculosis. Generally the organisms tend to local-

Carrier  
state

Typhus

Cavitation  
in tubercu-  
losis

ize, at first in the periphery of the lungs. This primary stage may become quiescent or even heal. Weeks to months or even years later, a reactivation or reinfection will cause secondary tuberculosis, in which the organism spreads via the lymphatic channels to localize in the uppermost portions of the lung, known as the apices. It is in the secondary state that the most damage occurs, and the infection may lead to extensive necrosis of regions of the lung, with the formation of large cavities. If the infection spreads into the bloodstream, seeding of any organ or tissues of the body may occur. These disseminated localizations, known as miliary spread, are most often encountered in the brain, spleen, liver, bone marrow, kidneys, and male and female genital tracts. Pulmonary (lung) tuberculosis alone is a serious infection; miliary tuberculosis is even more threatening and is often fatal. Fortunately, when the disease is identified, effective therapy is available for the cure or at least the control of the disease, which was once devastating.

**Fungi and other parasites.** Diseases caused by fungi and parasites are relatively uncommon. Fungal infections, also known as mycotic infections, may affect the skin surfaces or the internal organs of the body. The superficial mycotic infections are generally not serious and include such well-known disorders as athlete's foot (caused by *Tinea pedis*) and ringworm (caused by the agents *Microsporum* and *Trichophyton*). Deep mycotic infections such as histoplasmosis, blastomycosis, coccidioidomycosis, and candidiasis are potentially life threatening.

The other parasites that attack man range from unicellular organisms such as *Entamoeba histolytica* to such multicellular forms as tapeworms and roundworms. Most parasitic infestations are encountered in the less privileged areas of the world, where sanitation is not optimal. Indeed, parasitic infestations constitute major causes of death in regions of Central and South America, Africa, India, and Asia. Parasitic infestations are uncommon in the Northern Hemisphere, but on occasion certain forms such as amebiasis, tapeworms, and trichinosis are encountered even in the industrialized cities of the world. Trichinosis is an excellent example. *Trichina* worms (*Trichinella spiralis*) parasitize pigs, and their larvae are encysted within the muscles of these animals. When pork is inadequately cooked the cysts are not destroyed and so the disease may be contracted. When such pork is eaten the cysts develop into trichina worms in the intestinal tract of man. Here the worms reproduce and spread to the muscles of man. The infestation causes muscle aches and pains, fever, and weakness. When the heart and the muscles of respiration are severely affected, death may result. Trichinosis is still encountered sporadically throughout North America and Europe. In every instance that can be traced, the disease comes from inadequately cooked pork or pork products.

#### ABNORMAL GROWTH OF CELLS

Among the various diseases of man, those resulting from abnormal cell growth are the second most common cause of death. Cancer, for example, a form of abnormal cell growth, accounted for approximately 16 percent of all mortality in the United States in 1969. Only heart disease outranked it. Besides cancer, a malignant tumour, there are benign tumours, which rarely produce serious disease. The two forms of tumours are collectively spoken of in medicine as neoplasms (new growths), and their study is known as oncology. In addition to neoplasms, there are other forms of abnormal cell growth, known as hyperplasias (increased growth of cell), that cause less serious disease. Hyperplasia causes enlargement of tissues and organs, but the abnormal cell growth does not go out of control to produce a tumour.

**Hyperplasia.** Hyperplastic states result from the controlled proliferation of normal cells, in contrast to tumours, in which the growth is uncontrolled and the cells are abnormal. Hyperplasia of the cells of the thyroid gland, for example, causes some enlargement of the gland (known as goitre), but the hyperplastic cells are essentially normal in their appearance and in their manner of mi-

totic division. Because the new cells, like their antecedents, are capable of producing thyroid hormone, the increased number of cells causes excess activity of the thyroid (hyperthyroidism).

Most hyperplasias, wherever they occur, are the result of some stimulatory influence, such as hormonal stimulation or chronic irritation. The increased thickness of the skin that is represented by the ordinary callus or corn on the foot, for example, is due to controlled growth of the cells of the skin in the immediate area of chronic irritation or pressure from ill-fitting shoes. In contrast to the irritation that causes the callus or the corn, the cause of hyperplasia encountered in the thyroid gland is currently thought to be some thyroid-stimulator substance that appears in some individuals for obscure reasons. Hyperplasia of the prostate gland in elderly males is attributable to a relative excess of steroid hormones derived from the adrenal. These adrenal hormones (estrogens) are produced throughout life in both the female and the male. During a man's active reproductive life, the estrogens are more than counterbalanced by the male sex hormones that are produced by the testes. With aging, the testes become functionally less active and the levels of male sex hormones fall. As a consequence, the relative excess of estrogens of adrenal origin causes hyperplasia of the prostate.

It is still not known why hormones and irritation cause cells to grow. Evidence suggests that cell growth, whether normal or hyperplastic, is a fundamental attribute of all cells and is kept under control by mechanisms either within the cell or in the immediate vicinity of the cell. In other words, the normal growth of man from the time of conception is a regulated sequence of control mechanisms. When the controls are turned off, cells immediately begin to proliferate by division. Growth necessary to achieve full adult size is the consequence of release of controls. Hyperplasia is a consequence of the turning down of these controls by hormones or irritation. Cancer results when the controls over certain cells are totally lost.

**Neoplasms.** Cancers are by far the most important form of abnormal cell growth. When cells become cancerous they appear to have escaped from control mechanisms. They grow in a haphazard, disorderly manner and come to have a more or less wild, anarchic appearance. They vary widely in size and shape and no longer resemble the cells from which they arose. Although little is known about the causes of loss of growth controls that permit the development of neoplasms in man, in experimental animals cancers can be induced by a number of agents, including (1) certain chemicals, (2) certain viruses, (3) radiation, and (4) a number of other less well defined influences such as hormones and chronic irritation.

Many chemicals have been shown to be capable of causing cancer in animals. Some of them, known to react with the deoxyribonucleic acid of cells, are suspected of affecting control mechanisms of growth. A few chemicals have been implicated in the production of cancer in man. Workers in rubber industries and dye factories formerly suffered a higher incidence of bladder tumours than normal control populations. It was discovered that some of the solvents used in these industries, the naphthylamines, are capable of causing bladder cancer in animals and were responsible for the increased frequency of these cancers in man. Asbestos fibres such as are used in the manufacture of shingles for houses and brake linings are another hazard to man. When inhaled these fibres may cause certain forms of cancer in the lungs. The mold *Aspergillus flavus*, which grows on peanuts and grains, elaborates a substance that induces liver cancer in animals and is suspected of causing an analogous tumour in man. There is a very high incidence of this form of tumour in the underdeveloped nations of the world, where grains are poorly preserved and where they comprise a large part of the diet.

There is also strong evidence implicating the chemicals in cigarette smoke in the production of lung cancer. The chemicals may act in concert with other influences such as bacterial or viral lung infections.

The cause  
of hyper-  
plasia

Tumours  
and hyper-  
plasias

**Table 3: Major Hormones of Man**

hormone	source	target organ	action
Growth hormone	anterior pituitary	all cells	promotes growth
Thyrotropin	anterior pituitary	thyroid gland	controls secretion of thyroxine
Corticotropin	anterior pituitary	adrenal glands	controls secretion of adrenal hormones
Antidiuretic hormone (ADH)	posterior pituitary	kidney	promotes retention of water
Oxytocin	posterior pituitary	breast and others	promotes lactation
Aldosterone	adrenal gland	kidney	regulates body fluids
Cortisone	adrenal gland	all cells	manifold; plays central role in sugar and fat metabolism
Thyroxine	thyroid gland	all cells	speeds up metabolic machinery
Insulin	pancreas	all cells	facilitates uptake of glucose into cells
Parathormone	parathyroid gland	gastrointestinal tract, bone, kidney	controls serum calcium level
Erythropoietin	kidney	bone marrow	stimulates red-blood-cell production
<b>Testosterone</b>	testis	many tissues	plays role in growth and development of reproductive system in males
<b>Estrogens</b>	ovary	many tissues	in females, similar to testosterone

Mention was made in an earlier section of the possible role of viruses in the induction in man of tumours and, particularly, cancer. It was pointed out that certain viruses cause cells to divide rapidly. How viruses produce this effect is unknown, but it is believed that the DNA and RNA of the virus are incorporated within the genetic apparatus of the cell and in some way modify it so that normal repressor control mechanisms are lost.

The only definitely established viral tumour of man is the common wart, and this is hardly a significant neoplasm. Another tumour of man strongly suspected of having a viral causation is the Burkitt lymphoma, a rare form of cancer most often encountered in South Africa but also occasionally encountered in other areas of the world. When originally recognized in South Africa, it was found in a geographic locale with a high median temperature and a high level of humidity. Moreover, this tumour tended to occur in young children, a distinctly unusual age group to have a high incidence of cancer. All of these observations led to the suspicion that a virus might be the cause. The geographic localization of temperature and humidity raised the possibility that some insect spreads the virus from an infected person to a normal susceptible host. Children might particularly be affected because they had no previous exposure to this agent and would therefore be completely susceptible, or nonimmune. Intensive study of the Burkitt lymphoma has disclosed that it indeed does contain a viral agent and that this virus is capable of transforming cells in tissue culture from normal growth patterns to abnormal cancerous growth patterns. Final proof is lacking, however, because it has not been possible to inoculate this virus into human beings.

Radiant energy is a well-known cause of cancer in animals and man. The pioneer workers in the development of X-rays did not realize the danger involved and so were unduly exposed to this form of energy. Many developed cancers of the skin and arms where they had received excessive exposure. The survivors of the atomic bombs dropped on the Japanese cities of Hiroshima and Nagasaki in 1945 have suffered various forms of cancer, particularly the leukemias, cancers that involve the white blood cells.

It was clear that many influences may induce cancer, but what role these play in the overall problem of cancer in man is still uncertain. The environment contains many potential cancer-producing influences: chemicals, viruses, and radiant energy from the sun; some investigators imply that the occurrence of cancer in the advanced years of life suggests the possibility of the accumulation over decades of enough of these influences to trigger the formation of a malignant tumour.

Cancer may arise in any organ or tissue. Some tumours grow more rapidly and wildly than others, but it is believed that all begin as small aggregations of abnormal

cells that take years to develop into tumorous masses. Indeed, there are good reasons for believing that it may take ten years or more for a cancer to evolve from its early origins to a clinically recognizable disease. Cancers do not explode into being; during the long years of their development they can easily be removed by surgery if discovered. They rarely cause symptoms or illness during this developmental phase, and consequently tests must be sought that can be applied to apparently normal individuals to detect these minute cancers. As cancers grow they invade surrounding tissues. Thus a cancer that begins in the thyroid, for example, may spread into the structures of the neck, such as the trachea (the windpipe), or even more widely. Obviously, when such spread has occurred it is much more difficult, and perhaps impossible, to remove the tumour surgically. And, even more regrettably, most cancers have the ability to seed distant sites, a phenomenon termed metastasis. A cancer of the lung may metastasize to the liver, adrenals, and other tissues in the body. When such distant implants develop, it is evident that surgical removal is impossible, because not all of the implants can be found and removed. The hope, then, is to discover the cancer before it has invaded too widely and before it has metastasized (see CANCER).

#### DISEASES OF METABOLIC-ENDOCRINE ORIGIN

The term metabolism encompasses all the chemical reactions vital to the growth and maintenance of the body: Derangements in metabolism are found in almost every disease condition. Most of these derangements are secondary; *i.e.*, they result from some other basic disorder (infection, kidney disease, or heart disease, for example). A few primary metabolic disorders were mentioned in the discussion of genetic disease. In these, small genetic mutations were shown to lead to derangements in the synthesis of specific proteins. At this point another group of primary metabolic disorders—those associated with hormonal derangements—will be touched upon.

Hormones are rather large organic molecules secreted in small amounts by specific cells in the various endocrine (ductless) glands. These secretions are carried by the blood to distant sites (target organs), where they act to regulate specific chemical reactions. Table 3 summarizes the major hormones in man, their source, target organ, and principal action.

All endocrine disease stems from either an overproduction (hyperfunction) or underproduction (hypofunction) of some hormone-secreting endocrine gland. There are relatively few causes of hormone overproduction. In general it results from hyperplasia, an increase in the number of hormone-secreting cells in a specific endocrine gland. A tumour of an endocrine gland may also cause hypersecretion of a hormone. Although most endocrine neoplasms are benign tumours, the resulting hypersecretion of hormone can have far-reaching effects.

Slow growth of cancers

Viral tumours in man

Cause of endocrine disease

The tiny pituitary gland, for example, tucked into the base of the skull, produces many hormones that have far-ranging effects, mostly controlling the function of the other endocrine glands, such as the adrenals, ovaries, and testes. Acromegaly is a rare endocrine disease caused by excess secretion of pituitary growth hormone in the adult. The disease is characterized by an overgrowth of most of the organs in the body, but especially of bone and connective tissue. A person with the disorder usually has a large head, big, brawny hands, and huge feet. Post-mortem examination reveals the presence of small, benign pituitary tumours in 75 percent of the cases. If the excess growth hormone appears during childhood, it causes exaggerated growth, including extreme height. Another example, a pheochromocytoma, is a small, benign tumour of the adrenal gland having far-reaching effects. These tumours elaborate an excess of catecholamine hormones (norepinephrine and epinephrine), resulting often in severe hypertension (high blood pressure) and subsequent vascular disease.

An example of hormone overproduction because of hyperplasia is hyperthyroidism, the disease produced by an excess of thyroid hormone. It is characterized by a rapid pulse, increased sweating, weight loss, heat intolerance, and frequent disturbances in the heart rhythm. A strange substance called long-acting thyroid stimulator (LATS) is found in the blood of persons with Graves' disease, a variant of hyperthyroidism that is marked by exophthalmos (bulging eyeballs) and diffuse goitre (thyroid-gland enlargement). LATS, which is thought to be responsible for the thyroid hyperplasia, has the same physical properties as an antibody. This suggests that the disease may have an immune origin.

Cause of  
Cushing's  
syndrome

Cushing's syndrome, an exception to the generalization that hypersecretion of hormones is due to either neoplasia or hyperplasia, results from an overproduction of the adrenal steroid hormones (such as cortisol). Persons with this disorder have a characteristic redistribution of fat centring chiefly around the upper part of the back (buffalo hump) and the face (moon faces). They also suffer from impaired carbohydrate metabolism, psychiatric disturbances, and, commonly, high blood pressure. Although the disease is occasionally caused by tumours or by hyperplasia of the adrenals, in most instances it is not. It has been suggested that the disease results either from excessive adrenal-stimulating hormone from the pituitary or from an enzymatic defect that leads to inadequate metabolic breakdown of the steroid hormones, but neither presumed mechanism has thus far withstood the trial of intensive laboratory investigation.

Underproduction of hormone is most often the result of destruction of hormone-secreting cells. This destruction may be caused by infection, infarction (tissue death due to loss of blood supply), or obliteration of endocrine glands by cancer. Underproduction of hormone may also result from failure of the gland to undergo normal fetal development or may be a feature of a hereditary disease (as in diabetes mellitus).

Destruction of endocrine tissue by infection is most often due to tuberculosis. Addison's disease, also known as adrenal insufficiency, was once due almost exclusively to a tuberculous infection of the adrenal glands.

Cretinism, a condition that includes mental retardation and physical stunting, results from the congenital lack of thyroid hormone. The hormone lack is caused by iodine deficiency during the critical growth periods of fetal and neonatal life or, rarely, failure of the thyroid gland to develop at all (thyroid aplasia).

Death of tissue due to inadequate blood supply (infarction) is the most common cause of hypopituitarism and is seen almost exclusively in new mothers (postpartum necrosis of the pituitary). The exact nature of this process is not known, but it is assumed to be related to severe hemorrhages occurring during childbirth.

Treatment of endocrine disease involves either hormone supplementation, in the case of hypofunction, or destruction of endocrine gland tissue, in cases of hyperfunction, by surgery or radiation (see ENDOCRINE SYSTEM DISEASES AND DISORDERS).

## DISEASES OF NUTRITION

Diseases of nutrition include the effects of undernutrition, prevalent in less developed areas but present even in affluent societies, and the effects of nutritional excess.

**Diseases of nutritional excess.** Obesity, perhaps the most important nutritional disease in the United States and in Europe, results, usually, from excessive caloric intake, although emotional, genetic, and endocrine factors may be present.

Obesity predisposes toward several serious disorders, including a state of chronic oxygen deficiency, called the hypoventilation syndrome; high blood pressure; and atherosclerosis, a degenerative condition of the blood vessels that is discussed further below.

Excessive intake of certain vitamins, especially vitamins A and D, can also produce disease. Vitamins A and D are both fat soluble and tend to accumulate to toxic levels in the bodily tissues when taken in excessive quantities. Vitamin C and the B vitamins, soluble in water, are more easily metabolized or excreted and, therefore, rarely accumulate to toxic levels.

**Diseases of nutritional deficiency.** Nutritional deficiencies may take the form of inadequacies of (1) total caloric intake, (2) protein intake, or (3) certain essential nutrients such as the vitamins and, more rarely, specific amino acids (components of proteins) and fatty acids.

Protein-calorie malnutrition is still prevalent in certain areas. It has been estimated that about two-thirds of the world's population has less than enough food to eat. Whereas the average adult in economically developed countries consumes 3,000 or more calories per day, in less developed areas the underprivileged may have less than 1,000 calories of food available per day. Not only is the quantity inadequate but the quality of the food is nutritionally deficient and usually lacks protein. In these deprived areas the malnutrition has its greatest impact on the young; the death rate in children up to the age of five may reach 50 percent, in contrast to a rate of about one per 100,000 in the United States. The deaths from protein-calorie malnutrition result from the failure of the child to thrive, with progressive weight loss and weakness, leading to an infection, usually some form of gastrointestinal bacterial or parasitic disease. In other circumstances adequate calories may be available, but a deficiency of protein induces a disorder known as kwashiorkor. This is seen especially in children who are weaned because of the birth of another child. They are fed on rice water, which may contain enough carbohydrate calories but is lacking in protein calories. Weakness, wasting, liver disease, and bacterial and parasitic infestations follow. Even if these children survive to adulthood they rarely achieve a state of reasonable health.

Vitamin deficiencies, the most important forms of selective malnutrition, may arise in a variety of ways, the most common and the most important being an improper, inadequate diet. When the total caloric intake is inadequate, vitamin deficiencies may also occur, but in these circumstances the more profound lack of calories and proteins masks the lack of vitamins.

Vitamin deficiencies may also be encountered despite a diet that is apparently adequate nutritionally. One source of such a deficiency, called secondary, is interference with absorption of the vitamin. Pernicious anemia is a classic example of this phenomenon. The absence of the substance known as intrinsic factor, normally found in the stomach lining, leads to the inability to absorb and store one of the B vitamins (vitamin B<sub>12</sub>), necessary for the normal formation of red blood cells. The basis of pernicious anemia, then, is a lack of absorption of vitamin B<sub>12</sub>. The absence of certain digestive enzymes, as is found in pancreatic disease, can lead to the inability to digest and absorb fats and the fat-soluble vitamins (A, D, E, and K). Impaired uptake of vitamins may be encountered in gastrointestinal diseases. Some of these diseases reduce the absorptive function of the bowel. Similarly, diseases associated with severe, prolonged vomiting may interfere with adequate absorption.

Avitaminoses (vitamin lack) may be encountered when there are increased losses of vitamins such as occur with

Types of  
nutritional  
deficiency

Secondary  
vitamin  
deficiencies

chronic severe diarrhea or excessive sweating or when there are increased requirements for vitamins during periods of rapid growth, especially during childhood and pregnancy. Fever and the endocrine disorder hyperthyroidism are two additional examples of conditions that require higher than the usual levels of vitamin intake. Unless the diet is adjusted to the increased requirements, deficiencies may develop. Lastly, artificial manipulation of the body and its natural metabolic pathways, as by certain surgical procedures or the administration of various drugs, can lead to avitaminoses. (Diseases involving deficiencies of particular vitamins are discussed in NUTRITIONAL DISEASES AND DISORDERS.)

#### DISEASES OF PSYCHOGENIC ORIGIN

Great numbers of persons are afflicted at some time with diseases of psychogenic origin. It is estimated, for example, that approximately one of every two hospital beds in the United States is occupied by someone who is suffering from mental illness. The large sums of money spent on liquor, tranquillizing drugs, and other anxiety-reducing remedies are further evidence of the widespread prevalence of psychological stress.

One of the major difficulties in assessing mental illness is the establishment of criteria for normal behaviour. Indeed, there are many who feel that everyone is affected at some time with varying degrees of mental illness. These aberrations often appear as minor idiosyncrasies and, as such, rarely pose serious threats to the individual. It is only when such "abnormal" behaviour interferes directly with the ability to adapt and interferes with one's feelings of well-being that it is properly termed mental illness.

Mental disease may be organic—may arise from a physical abnormality—or may be nonorganic. The latter type of disorder is often called functional. For some of the severe psychiatric disorders, such as schizophrenia, an organic basis is postulated, but thus far an exact cause has not been established.

**Organic** psychogenic disease. There is strong evidence that heredity plays an important role in the genesis of mental illness. This is particularly true in the case of schizophrenia, a severe form of mental illness characterized by withdrawal from reality, disturbances in thought processes, and emotional distortion. There are other genetic diseases that demonstrate severe disturbances in the mental processes. Among these are Down's syndrome (mongolism), Huntington's chorea (a disorder characterized by spasmodic movements of the face, arms, and legs, and by gradual loss of the mental faculties), and **phenylketonuria (PKU)**. The latter occurs in infants who lack a specific enzyme needed to break down phenylalanine, one of the amino acids found in proteins. This disorder is believed to be transmitted by a recessive **autosomal** gene (*i.e.*, it is not sex-linked and must be inherited from both parents to be fully manifest) and is associated with severe mental retardation.

Infections, particularly syphilis, are known to be the cause of certain brain disorders. Late stage, or tertiary, syphilis is known to lead slowly to destruction of brain tissue and to be responsible for bizarre psychological manifestations in affected individuals.

Alcohol ingestion over a number of years can cause significant organic brain damage.

Drugs and chemicals are a common source of psychiatric disturbances. Lead poisoning has already been discussed. Steroid hormones, used in the treatment of a variety of disorders, are known to be responsible for unusual psychic changes in a small percentage of users. Lysergic acid diethylamide (LSD) has been reported to precipitate psychiatric distress in predisposed users of the drug.

Dietary factors have been clearly established as involved causally in the development of psychiatric illness. There is a clear association between mental illness and deficiency of pantothenic acid and vitamin B<sub>12</sub>. Furthermore, children raised under starvation conditions are believed to have impaired mental development.

Finally, any serious illness carries with it profound psy-

chological stress, which may be accompanied by symptoms such as denial or depression. The patient's emotional reaction to his illness may make objective appraisal of physical impairment difficult.

**Nonorganic psychogenic diseases.** Just as man the biological organism must defend himself against such physical hazards as bacteria, viruses, and trauma, so man the psychological organism must defend himself against the equally hostile but somewhat different psychic hazards. Here he must deal with the loss of real and fantasied objects, maintain control over biological urges, endure frustration, tolerate injury and disease, and meet demands as a working, interacting member of society. Individuals faced with these stresses may exhibit symptoms of psychiatric illness.

These symptoms include any of a perplexing variety of manifestations. There may be disturbances of thought: compulsions, obsessions, inhibition of thinking, phobias, delusions, or dissociated thinking. Disorders of perception include illusions and hallucinations. Disturbances in human relationships and distortions of self-concept are commonly observed in many psychiatric disorders. Feelings are also often disturbed, anxiety and depression being the most common symptoms. Finally, the most frequent symptoms of psychiatric illness are of a physical nature, pain being the most common. Such symptoms can include virtually every system and may mimic any organic disease. Insomnia, loss of appetite, diarrhea, constipation, nausea, difficulties in swallowing, urinary problems (such as bed-wetting), fainting, seizures, palpitations, weakness, and memory loss are common. Blindness, deafness, mutism, paralysis, and false pregnancy are somewhat more bizarre. Such physical manifestations comprise the group referred to as psychosomatic diseases.

**Classification of mental illness.** Psychological disturbances are usually classified as neuroses, psychoses, and character disorders. There are also categorizations for a whole host of deviant sexual behaviour such as transvestism, voyeurism, sadism, and masochism. These categories are not mutually exclusive and are not distinct entities as understood in organic illness. Rather, they are designations for complex patterns of response to stress. The terms anxiety and depression describe certain affects (feelings) that may be found in any of the aforementioned categories. Anxiety, the feeling of fear in anticipation of an unwanted event, is often useful and may prepare one for a difficult task. When anxiety becomes excessive or inappropriate, however, it can severely hamper one's ability to live in harmony with one's environment. Similarly, depression can entirely disrupt normal existence. Depression can be defined as a feeling of sadness, usually related to unexpressed anger and resulting in feelings of apathy, listlessness, and inability to do work or function in a social setting.

Neurosis and psychosis in their extremes are easily differentiated, but they share many features and can be viewed as a continuum in a spectrum of mental disease. Both the neurotic and the psychotic individual struggle to maintain control of unacceptable impulses related to developmental trauma or conflicts, and yet, both are capable at times of behaviour that is completely normal. What differentiates the neurotic from the psychotic is the psychological mechanisms used to deal with these unacceptable impulses. The neurotic attempts to control his impulses by a variety of mental mechanisms and struggles to maintain interpersonal relations and to adapt to the realities of his external environment. When the neurotic is unsuccessful in keeping sexual, aggressive, or other unacceptable impulses from his consciousness, he is overwhelmed by guilt, shame, and anxiety and experiences himself as ill. The psychotic, on the other hand, distorts or changes his perception of the environment or detaches himself from it to deny or distort the forbidden impulses. He strives to make the environment one in which the forbidden impulses become acceptable to him. The psychotic is less able to maintain socially acceptable behaviour, to carry on interpersonal relationships, or to carry on effective work. In addition, he is usually un-

Symptoms of psychiatric illness

Definition of mental illness

Character disorders

aware of these shortcomings, whereas the neurotic is acutely aware of deficiencies in these areas.

Character disorders, the third broad class of nonorganic psychiatric disease, are characterized by rigidity and inflexibility in dealing with stresses. Whereas the neurotic is capable of living a relatively normal existence and only becomes symptomatic when dealing with a particular stressful situation, the person described as having a character disorder incorporates such neurotic symptoms into his life-style in a permanent way. Thus the neurotic symptoms become indistinguishable from the personality itself. The obsessive-compulsive type, for example, demands strict order in his daily routine. Though such a person may lead a highly useful and productive life, interpersonal relationships often suffer as a result (see PSYCHOSES; PSYCHONEUROSES).

#### DISEASES OF SENESCENCE

The process of aging begins at the time of conception. Throughout life the body undergoes a series of changes that can be considered as manifestations of aging. During the first half of life these changes are generally referred to as maturation; during the last half of life, as progressive senescence. Visual acuity, sensitivity of hearing, and muscular vigour begin to deteriorate after the third decade of life. These changes, although they may begin at different ages and progress at differing rates, are universal among all individuals and must therefore be considered as the normal aging process.

It is extremely difficult to draw a sharp line between the deleterious effects of normal aging and the deleterious effects of diseases of aging. The diseases most commonly manifested in the elderly are disorders of the heart, blood vessels, and joints. The heart disease of the elderly is related to the generalized vascular disease known as arteriosclerosis, which frequently attacks the major coronary arteries of the heart. Arteriosclerosis and arthritis will therefore be briefly touched upon here. More extended discussions may be found in **CARDIOVASCULAR SYSTEM DISEASES AND DISORDERS** and in **JOINT DISEASES AND INJURIES**. These problems and other aspects of aging are also considered in **AGING, HUMAN**.

Arteriosclerosis is not a specific disease. The term is applied to all diseases that cause hardening of the arteries. Several minor processes can induce hardening of the arteries, but the overwhelming preponderance of cases of arteriosclerosis are caused by atherosclerosis. This disorder, which eventually affects all individuals to varying degrees, begins relatively early in life in most persons. There are great variations, however, in the severity of this disease among individuals and among racial, national, and ethnic populations.

Atherosclerosis

Atherosclerosis is characterized by the deposition of fats (cholesterol and other complex lipids) in the linings (intima) of the arteries. These deposits cause bulging plaques referred to as atheromas. As the disease progresses with age, the atheromas enlarge and progressively narrow the arterial channels (lumens). Atheromas have the further distressing potential of becoming solidified by the deposition of calcium salts, and in this manner the blood vessels are converted into rigid pipelike structures. The atheromas may also rupture into the lumen of the vessel and thus induce blood clotting. In this way the artery may become totally obstructed. Atherosclerosis has a predilection for the aorta, the major artery of the body, and the arteries of the heart, brain, and legs. It is atherosclerosis of the arteries of the heart (the coronaries) that is the cause of heart attacks, known technically as myocardial infarction. In most industrialized nations today heart attacks alone cause 20–25 percent of all mortality. When atherosclerosis narrows but does not totally block the coronary arteries, the heart is also injured by lack of adequate blood supply and nutrition and becomes progressively smaller and weaker; even though this disease is not as life threatening as a heart attack, it nonetheless frequently causes heart failure, an inability of the heart to deliver an adequate supply of blood to the tissues. Atherosclerosis of the arteries of the brain is the usual cause of "strokes." When the arteries

to the legs become affected in this way, gangrene may develop.

Regrettably, the exact cause of atherosclerosis has not been determined. There is almost unanimous agreement, however, that the most significant causal factors in the development of this disease are obesity, high blood pressure, and high levels of blood lipids (fats). There is also a widely held suspicion that too much food and excesses of carbohydrates and animal fats (such as are derived from eggs, butter, and meats) contribute to the onset and progression of this disease. Rural peasant populations who live on fish and vegetable oils have less atherosclerosis than the city dwellers of the U.S. and Europe.

Arthritis, probably the second most common and distressing disease among the elderly, is a disease of the joints. It causes considerable pain, discomfort, and lack of mobility and so makes life burdensome. Moreover, arthritic individuals are more subject to other illnesses. Degenerative arthritis (osteoarthritis) is common to all elderly people to a lesser or greater degree.

The ends of the bones that move over each other in the joints of the body are covered by cartilage. This, being more flexible and rubbery than bone, forms a smooth surface, relatively free of friction. In degenerative joint disease these smooth surfaces gradually become rough. The resulting friction between the rough surfaces causes the cartilage to wear away. The bone surfaces then become exposed, and the joint becomes painful and less mobile. As the disease progresses bony spurs form along the ends of the bone, and these may fuse across the joint space and completely immobilize the joint. Osteoarthritis usually begins in the fourth decade of life and slowly progresses with increasing age. Coinciding with these changes in joints are changes involving the bone itself. The bone of elderly persons is known to be less dense and more brittle; it tends, therefore, to fracture more easily. It also heals with greater difficulty.

Degenerative joint disease

There are many subtle changes that occur with the normal aging process. These may include degenerative changes in the brain, leading to impaired mental ability and even senility. As this damage is usually accompanied by atherosclerosis of the arteries of the brain, it is difficult to know how much of the change is the result of impaired blood flow and how much is related to normal aging. Finally, but of no less significance, is the general decline in the body's ability to defend itself against disease. Thus elderly persons are more susceptible to infections, trauma, and a number of other bodily derangements. Simple, uncomplicated pneumonia, which might be easily tolerated by the young, healthy adult, may be fatal for an elderly, weakened person.

#### **IV. Classifications of diseases**

Classifications of diseases become extremely important in the compilation of statistics on causes of illness (morbidity) and causes of death (mortality). It is obviously important to know what kinds of illness and disease are prevalent in an area and how these prevalence rates vary with time. By classifying diseases it became apparent, for example, that the frequency of lung cancer was entering a period of alarming increase in mid-20th century. Once a rare form of cancer, it had become the single most important form of cancer in males. With this knowledge a search was instituted for possible causes of this increased prevalence. It was concluded that the occurrence of lung cancer was closely associated with cigarette smoking. Classification of disease had helped to ferret out an important, possibly causal, relationship.

The most widely used classifications of disease are (1) topographical, by bodily region or system; (2) anatomic, by organ or tissue; (3) physiological, by function or effect; (4) pathological, by the nature of the disease process; (5) etiological (causal); (6) juristic, by speed of advent of death; (7) epidemiological; and (8) statistical. Any single disease may fall within several of these classifications.

In the topographical classification, diseases are subdivided into such categories as gastrointestinal disease, vascular disease, abdominal disease, and chest disease. Various specializations within medicine follow such topo-

Value of disease classification

graphic or systemic divisions, so that there are physicians who are essentially vascular surgeons, for example, or clinicians who are specialized in gastrointestinal disease. Similarly, some physicians have become specialized in chest disease and concentrate principally on diseases of the heart and lungs.

In the anatomic classification, disease is categorized by the specific organ or tissue affected; hence, heart disease, liver disease, and lung disease. Medical specialties such as cardiology are restricted to diseases of a single organ, in this case the heart. Such a classification has its greatest use in identifying the various kinds of disease that affect a particular organ. The heart is a good example to consider. By the segregation of cardiac disease it has been made apparent that heart disease is now the most important cause of death in the United States and in most other industrialized nations. Moreover, it has become further apparent that disease caused by atherosclerosis of the coronary arteries is by far the most important form of heart disease. In making a diagnosis of cardiac disease in an elderly patient, the cardiologist must first determine whether this disease of the coronary arteries is responsible for the heart's failure to function normally.

Physiological classification of disease

The physiologic classification of disease is based on the underlying functional derangement produced by a specific disorder. Included in this classification are such designations as respiratory and metabolic disease. Respiratory diseases are those that interfere with the intake and expulsion of air and the exchange of oxygen for carbon dioxide in the lungs. Metabolic diseases are those in which disturbances of the body's chemical processes are a basic feature. Diabetes and gout are examples.

The pathological classification of disease considers the nature of the disease process. Neoplastic and inflammatory disease are examples. Neoplastic disease includes the whole range of tumours, particularly cancers, and their effect on human beings. Physicians who specialize in neoplastic disease are called oncologists.

The etiologic classification of disease is based on the cause, when known. This classification is particularly important and useful in the consideration of biotic disease. On this basis disease might be classified as staphylococcal or rickettsial or fungal, to cite only a few instances. It is important to know, for example, what kinds of disease staphylococci produce in human beings. It is well-known that they cause skin infections and pneumonia, but it is also important to note how often they cause meningitis, abscesses in the liver, and kidney infections. The venereal diseases syphilis and gonorrhea are further examples of diseases classified by etiology.

The juristic basis of the classification of disease is concerned with the legal circumstances in which death occurs. It is principally involved with sudden death, the cause of which is not clearly evident. Thus, on a juristic basis, some deaths and diseases are classified as medical-legal and fall within the jurisdiction of coroners and medical examiners. A person living alone is found dead in his bed — did he die of natural causes or was he killed? Had the person who dropped dead on the street been given some poison that took a short time to act? Much less dramatic, but perhaps more common, are disease and death caused by exposure of the individual to some unrecognized danger to health in his working or living conditions. Could the illness or disease be attributable to fumes or dusts in a factory? These are examples of the many types of disease and death that fall properly in this classification.

Epidemiological classification

The epidemiological classification of disease deals with the incidence, distribution, and control of disorders in a population. To use the example of typhoid, a disease spread through contaminated food and water, it first becomes important to establish that the disease observed is truly caused by *Salmonella typhosa*, the typhoid organism. Once the diagnosis is established it is obviously important to know the number of cases, whether the cases were scattered over the course of a year or occurred within a short period, and what the geographic distribution is. It is critically important that the precise address and activities of the patients be established. Two widely sepa-

rated locations within a city might be found to have clusters of cases of typhoid all arising virtually simultaneously. It might be found that each of these clusters revolved about a family unit including cousins, nephews, and other friends, suggesting that in some way personal relationships might be important. Further investigation might disclose that all of the infected persons had dined at one time or at short intervals in a specific home. It might further be found that the person who had prepared the meal had recently visited some rural area and had suffered a mild attack of the disease and was now spreading it to family and friends by unknowing contamination of food. This hypothetical case suggests the importance of the etiologic, as well as the epidemiologic, classification of disease.

Epidemiology is one of the important sciences in the study of nutritional and biotic diseases around the world. The United Nations now supports, in part, a World Health Organization, whose chief function is the worldwide investigation of the distribution of disease. In the course of this investigation, many observations have been made that help to explain the cause and provide approaches to the control of many diseases.

The statistical basis of classification of disease employs analysis of the incidence (the numbers of new cases of a specific disease that occur during a certain period) and the prevalence rate (number of cases of a disease in existence at a certain time) of diseases. If, for example, a disease has an incidence rate of 100 cases per year in a given locale, and, on the average, the affected persons live three years with the disease, it is obvious that the prevalence of the disease is 300. Statistical classification is an additional important tool in the study of possible causes of disease. These studies, as well as epidemiologic, nutritional, and pathologic analyses, have made it clear, for example, that diet is an important consideration in the possible causation of atherosclerosis. The statistical analyses drew attention to the role of high levels of fats and carbohydrates in the diet in the possible causation of atherosclerosis. The analyses further drew attention to the fact that certain populations that do not eat large quantities of animal fats and subsist largely on vegetable oils and fish have a much lower incidence of atherosclerosis. Thus statistical surveys are of great importance in the study of human disease.

The state of health, then, is jealously and effectively guarded by a constellation of mechanisms that immediately come into play to correct any deviation from normality. Diseases abound; they emanate from a host of causes. Some are as subtle as an infinitesimal change in the structure of a protein, others are as gross as the massive injuries that follow an automobile accident. But despite all of these threats to health, it must be remembered that the normal longevity in the developed countries of the world has now exceeded the biblical "three score and ten" years through man's increased understanding — and control — of disease.

## Diseases of Animals

Man's concern with diseases that afflict animals dates from his earliest contacts with them and is reflected in

Statistical classification

early views of religion and magic. Diseases of animals remain a concern of man principally because of the economic losses they cause and the possible transmission of the causative agents to humans. The branch of medicine called veterinary medicine deals with the study, prevention, and treatment of diseases not only in domesticated animals but also in wild animals and in animals used in scientific research. The prevention, control, and eradication of diseases of economically important animals are agricultural concerns. Programs for the control of diseases communicable from animals to man, called **zoonoses**, especially those in pets and in wildlife, are closely related to human health. Further, the diseases of animals are of increasing importance, for a primary public-health problem throughout the world is animal-protein deficiency in the diet of humans. Indeed, both the United Nations Food and Agricultural Organization (FAO) and the World Health Organization (WHO) have been attempting to solve the problem of protein deficits in a world whose human population is rapidly expanding.

This article is divided into the following major sections:

- I. General features of animal diseases
  - Historical background
  - Importance
  - Role of ecology
- II. Detection and diagnosis
  - Reactions of tissue to disease
  - Methods of examination
  - Tests as diagnostic aids
- III. Survey of animal diseases
  - Infectious and noninfectious diseases
  - Zoonoses
  - Disease prevention, control, and eradication

## I. General features of animal diseases

### HISTORICAL BACKGROUND

Historical evidence, like that from currently developing nations, indicates that veterinary medicine originally developed in response to the needs of pastoral and agricultural man along with human medicine. It seems likely that a veterinary profession existed throughout a large area of Africa and Asia from at least 2000 BC. Ancient Egyptian literature includes monographs on both animal and human diseases. Evidence of the parallel development of human and veterinary medicine is found in the writings of Hippocrates on medicine and of Aristotle, who described the symptomatology and therapy of the diseases of animals, including man. Early Greek scholars, noting the similarities of medical problems among the many animal species, taught both human and veterinary medicine. In the late 4th century BC, Alexander the Great designed programs involving the study of animals, and medical writings of the Romans show that some of the most important early observations on the natural history of disease were made by men who wrote chiefly about agriculture, particularly the aspect involving domesticated animals.

It is of interest that most of the earliest suggestions of relationships between human health and animal diseases were part of folklore, magic, or religious practice. The Hindu's concern for the well-being of animals, for example, originated in his belief in reincarnation. From the pre-Christian Era to about 1500, the distinctions between the practices of human and veterinary medicine were not clear-cut; this was especially true in the fields of obstetrics and orthopedics, in which animal doctors in rural areas often delivered babies and set human-bone fractures. It was realized, however, that training in one field was inadequate for practicing in the other, and the two fields were separated.

Veterinary literature from the civilizations of Greece and Rome contains reference to "herd factors" in disease; contagion within groups of animals kept together, therefore, was recognized, and both quarantine and slaughter were used to control outbreaks of livestock diseases. Rinderpest (cattle plague) was the most important livestock disease from the 5th century until control methods were developed. Serious outbreaks of the disease prompted the founding of the first veterinary college (*École Nationale Vétérinaire*), in Lyons, France, in 1762.

Many aspects of animal diseases are best understood in terms of population or herd phenomena; for example, herds of livestock, rather than individual animals, are vaccinated against specific diseases, and housing, nutrition, and breeding practices are related to the likelihood of illness in the herd.

The work of Pasteur was of fundamental significance to general medicine and to agriculture. Veterinarians became concerned with foods of animal origin after the discovery of micro-organisms and their identification with diseases in man and other animals. Efforts were directed toward protecting humans from diseases of animal origin, primarily those transmitted through meat or dairy products. Modern principles of food hygiene, first established for the dairy and meat-packing industries in the 19th and early 20th centuries, have been generally applied to other food-related industries. The veterinary profession, especially in Europe, assumed a major role in early food-hygiene programs.

Since World War II, the eradication of animal diseases, rather than their control, has become increasingly important, and conducting basic research, combatting **zoonoses**, and contributing to man's food supply have become indispensable services of veterinary medicine.

### IMPORTANCE

**Economic importance.** About 50 percent of the world's population suffers from chronic malnutrition and hunger. Inadequate diet claims many thousands of lives each day. When the lack of adequate food to meet present needs for an estimated world population of 3,672,000,000 in mid-1970 is coupled with the prediction that the population may increase to 7,000,000,000 by the year 2000, it becomes obvious that animal-food supplies must be increased. One way in which this might be accomplished is by learning to control the diseases that afflict animals throughout the world (see Table 10), especially in the developing nations of Asia and Africa, where the population is expanding most rapidly. Most of the information concerning animal diseases, however, applies to domesticated animals such as pigs, cattle, and sheep, which are relatively unimportant as food sources in these nations. Remarkably little is known of the diseases of the goat, the water buffalo, the camel, the elephant, the yak, the llama, or the alpaca; all are domesticated animals upon which the economies of many developing countries depend. It is in these countries that increased animal production resulting from the development of methods for the control and eradication of diseases affecting these animals is most urgently needed.

Despite the development of various effective methods of disease control, substantial quantities of meat and milk are lost each year throughout the world. The United States Department of Agriculture, for example, has estimated that losses from animal diseases in the United States and other developed countries in 1965 probably amounted to 10 percent of the yearly income from livestock and poultry. It has been estimated that worldwide losses in 1967 as a result of disease included more than 1,000,000,000 each of cattle and sheep; 350,000,000 goats; 100,000,000 buffalo; 11,000,000 camels; 550,000,000 pigs; 119,000,000 horses, mules, and donkeys, and close to 1,000,000,000 fowl. In countries in which animal-disease control is not yet adequately developed, the loss of animal protein from disease is about 30 to 40 percent of the quantity available in underdeveloped areas. In addition, such countries also suffer losses resulting from poor husbandry practices—e.g., the average yield from cattle carcasses in the United States is about 600 pounds (270 kilograms) per animal; that from African cattle is about 325 pounds (150 kilograms).

**Role in human disease.** Animals have long been recognized as agents of human disease. Man has probably been bitten, stung, kicked, and gored by animals for as long as he has been on earth; in addition, early man sometimes became ill or died after eating the flesh of dead animals. In more recent times, man has discovered that many invertebrate animals are capable of transmitting causative agents of disease from man to man or

Role of domesticated animals

from other vertebrates to man. Such animals, which act as hosts, agents, and carriers of disease, are important in causing and perpetuating human illness. Because about three-fourths of the important known zoonoses are associated with domesticated animals, including pets, the term zoonoses was originally defined as a group of diseases that man is able to acquire from domesticated animals. But this definition has been modified to include all human diseases (whether or not they manifest themselves in all hosts as apparent diseases) that are acquired from or transmitted to any other vertebrate animal. Thus, zoonoses are naturally occurring infections and infestations (a term that indicates the presence of invertebrates in or on a host animal) shared by man and other vertebrates. Although the role of domesticated animals in many zoonoses is understood, the role of the numerous species of wild animals with which man is less intimately associated is not well understood. The discovery that diseases such as yellow fever, viral brain infections, plague, and numerous other important diseases involving man or his domesticated animals are fundamentally diseases of wildlife and exist independently of man and his civilization, however, has increased the significance of studying the nature of wildlife diseases. Table 9 contains a partial list of zoonoses, including the causative agents and the animals involved.

Importance of animals in research

**Animals in research: the biomedical model.** Although in modern times the practice of veterinary medicine has been separated from that of human medicine, the observations of the physician and the veterinarian continue to add to the common body of medical knowledge. Of the more than 1,200,000 species of animals thus far identified, only a few have been utilized in research, even though it is likely that, for every known human disease, an identical or similar disease exists in at least one other animal species. Veterinary medicine plays an ever-increasing role in the health of man through the use of animals as biomedical models with similar disease counterparts in man. This use of animals as models is important because research on many genetic and chronic diseases of man cannot be carried out using humans.

It has been estimated that as many as 28,000,000 mice and 250,000 monkeys are utilized each year in research laboratories in the U.S. alone. Animal studies are used in the development of new surgical techniques (e.g., organ transplantations), in the testing of new drugs for safety, and in nutritional research. Animals are especially valuable in research involving chronic degenerative diseases because they can be induced experimentally in them with relative ease. The importance of chronic degenerative diseases, such as cancer and cardiovascular diseases, has increased in parallel with the growing number of communicable diseases that have been brought under control. See Table 1 for a list of animals with diseases similar to those that occur in man.

Examples of animal diseases that are quite similar to commonly occurring human diseases include chronic emphysema in the horse; leukemia in cats and cattle; muscular dystrophies in chickens and mice; atherosclerosis in pigs and pigeons; blood-coagulation disorders and nephritis in dogs; gastric ulcers in swine; vascular aneurysms (permanent and abnormal blood-filled area of a blood vessel) in turkeys; diabetes mellitus in Chinese hamsters; milk allergy and gallstones in rabbits; hepatitis in dogs and horses; hydrocephalus (fluid in the head) and skin allergies in many species; epilepsy (a disease of the central nervous system) in dogs and gerbils; hereditary deafness in many small animals; cataracts in the eyes of dogs and mice; and urinary stones in dogs and cattle.

The study of animals with diseases similar to those that affect man has increased knowledge of the diseases in man; knowledge of nutrition, for example, based largely on the results of animal studies, has improved the health of animals, including man. Animal investigations have been used extensively in the treatment of shock, in open-heart surgery, in organ transplantations, and in the testing of new drugs. Other important contributions to human health undoubtedly will result from new research discoveries involving the study of animal diseases.

## ROLE OF ECOLOGY

Epidemiology, the study of epidemics, is sometimes defined as the medical aspect of ecology, for it is the study of diseases in animal populations. Hence the epidemiologist is concerned with the interactions of organisms and their environments as related to the presence of disease. The multiple-causality concept of disease embraced by epidemiology involves combinations of environmental factors and host factors. In addition to the determination of the specific causative agent of a given disease. Environmental factors include geographical features, climate, and concentration of certain elements in soil and water. Host factors include age, breed, sex, and the physiological state of an animal as well as the general immunity of a herd resulting from previous contact with a disease. Epidemiology, therefore, is concerned with the determination of the individual animals that are affected by a disease, the environmental circumstances under which it may occur, the causative agents, and the ways in which transmission occurs in nature. The epidemiologist, who utilizes many scientific disciplines (e.g., medicine, zoology, mathematics, anthropology), attempts to determine the types of diseases that exist in a specific geographical area and to control them by modifying the environment.

Diseases in animal populations are characterized by certain features. Some outbreaks are termed sporadic diseases because they appear only occasionally in individuals within an animal population. Diseases normally present in an area are referred to as endemic, or enzootic, diseases, and they usually reflect a relatively stable relationship between the causative agent and the animals affected by it. Diseases that occasionally occur at higher than normal rates in animal populations are referred to as epidemic, or epizootic, diseases, and they generally represent an unstable relationship between the causative agent and affected animals.

The effect of diseases on a stable ecological system, which is the result of the dominance of some plants and animals and the subordination or extinction of others, depends on the degree to which the causative agents of diseases and their hosts are part of the system. Epidemic diseases result from an ecological imbalance; endemic diseases often represent a balanced state. Ecological imbalance and, hence, epidemic disease may be either naturally caused or induced by man. A breakdown in sanitation in a city, for example, offers conditions favourable for an increase in the rodent population, with the possibility that diseases such as plague may be introduced into and spread among the human population. In this case, an epidemic would result as much from an alteration in the environment as from the presence of the causative agent *Pasteurella pestis*, since, in relatively balanced ecological systems, the causative agent exists enzootically in the rodents (i.e., they serve as reservoirs for the disease) and seldom involves man. In a similar manner, an increase in the number of epidemics of viral encephalitis, a brain disease, in man has resulted from the ecological imbalance of mosquitoes and wild birds caused by man's exploitation of lowland for farming. Driven from their natural habitat of reeds and rushes, the wild birds, important natural hosts for the virus that causes the disease, are forced to feed near farms; mosquitoes transmit the virus from birds to cattle and man.

## II. Detection and diagnosis

### REACTIONS OF TISSUE TO DISEASE

Disease may be defined as an injurious deviation from a normal physiological state of an organism sufficient to produce overt signs, or symptoms. The deviation may be either an obvious organic change in the tissue comprising an organ or a functional disturbance whose organic changes are not obvious. The severity of the changes that occur in cells and tissues subjected to injurious agents is dependent upon both the sensitivity of the tissue concerned and the nature and time course of the agent. A mildly injurious agent that is present for short periods of time may either have little effect or stimulate cells to increased activity. Strongly injurious agents in prolonged contact with cells cause characteristic changes

Sporadic and endemic diseases

Table 1: A Partial Listing of Biomedical Models in Veterinary Medicine

animal disease (model)	animal affected	human counterpart disease	animal disease (model)	animal affected	human counterpart disease
Cardiovascular system diseases			Muscle diseases (cont.)		
Hereditary lymphedema	<b>dog</b>	<b>Milroy's disease</b>	Polymyopathy	Syrian hamster	muscular dystrophy
Elevated blood pressure	<b>mouse</b>	hypertension	Muscular dysgenesis	mouse	prenatal muscle degeneration
Atherosclerosis	swine	atherosclerosis	Nutritional muscular dystrophy	sheep	muscular dystrophy
Periarteritis nodosa	cattle	periarteritis nodosa	Paralytic myoglobinuria	horse	paroxysmal myoglobinuria
Dissecting aneurysms	turkey	aneurysm	Myoclonia congenita	swine	myotonia congenita
High-altitude disease	cattle	right ventricular hypertrophy	Nervous system diseases		
Endocardial fibroelastosis	<b>dog</b>	endocardial fibroelastosis	Cerebellar hypoplasia	cat	cerebellar hypoplasia
Heart failure	<b>dog</b>	congestive heart failure	<b>Nigropallidal encephalomalacia</b>	horse	Parkinson's disease
Congenital lymphatic edema	dog swine	lymphatic edema	Hydrocephalus	rabbit	hydrocephalus
Endocrine system diseases			Leukoencephalosis	mouse	dystrophy of white matter
Diabetes mellitus	Chinese hamster	diabetes mellitus	Globoid leukodystrophy	<b>dog</b>	<b>globoid leukodystrophy</b>
Antidiuretic-hormone deficiency	mouse	diabetes insipidus	<b>Grand-mal seizures</b>	gerbil	<b>epilepsy</b>
Polyuria	Chinese hamster	diabetes insipidus	Lipodystrophy	<b>dog</b>	familial amaurotic idiocy
Congenital goitre	cattle	goitre	<b>Scotty cramps</b>	<b>dog</b>	neurogenic muscular cramps
Adrenal cortical hypertrophy	<b>dog</b>	hyperadrenocorticism	Milk fever	cattle	hypocalcemia
<b>Snell's dwarf</b>	mouse	thyrotropin deficiency	Trembler mutation	mouse	<b>tremours</b>
<b>Adenohypophyseal aplasia</b>	cattle	adenohypophyseal aplasia	Hereditary ataxia	calf	ataxia
Hyperinsulinism	<b>dog</b>	hyperinsulinism	Congenital myotonia	goat	myotonia
Familial "adiposity"	mouse	obesity	Eye and ear diseases		
Acetonemia	cattle	ketosis	Hereditary deafness	cat	deafness
Early senility	Syrian hamster	aging	Cochlear degeneration	mouse	cochlear degeneration
Gastrointestinal system diseases			Hypoplasia of organ of Corti	<b>dog</b>	<b>hypoplasia of organ of Corti</b>
Esophageal achalasia	<b>dog</b>	achalasia	Hereditary glaucoma	rabbit	glaucoma
Cleft palate	horse	cleft palate	Inherited cataract	cattle	cataract
Gastric ulcer	swine	gastric ulcer	Hereditary iridal heterochromia	cattle	iridal heterochromia
Regional ileitis	swine	regional ileitis	Congenital retinal dysplasia	<b>dog</b>	retinal dysplasia
Granulomatosis colitis	boxer dog	ulcerative colitis	Retinal dystrophy	mouse	pigmented retina
Acute hemorrhagic colitis	rabbit	hemorrhagic colitis	Diabetic microaneurysms	<b>dog</b>	diabetic microaneurysms
Megacolon	mouse	megacolon	Reproductive system diseases		
Pancreatitis	<b>dog</b>	pancreatitis	Toxemia of pregnancy	guinea pig	toxemia of pregnancy
Liver diseases			Prolonged gestation	cattle	prolonged gestation
Viral hepatitis	subhuman primate	viral hepatitis	Uterine cystic hyperplasia	mouse	uterine cystic hyperplasia
Serum hepatitis	horse	transfusion hepatitis	Prostatic hyperplasia	canine	prostatitis
Dubin-Johnson syndrome	sheep	Dubin-Johnson syndrome	Cryptorchidism	swine	cryptorchidism
Congenital photosensitivity	Southdown sheep	Gilbert's syndrome	Respiratory system diseases		
<b>hyperbilirubinemia</b>			Acute pulmonary emphysema	cattle	pulmonary emphysema
<b>Nonhemolytic hyperbilirubinemia</b>	rat	Crigler-Najjar syndrome	Chronic pulmonary emphysema	horse	pulmonary emphysema
Pigmentary liver disease	howler monkey	hepatocellular melanosis	Pulmonary adenomatosis	cattle	adenomatosis
Hepatorenal syndrome	<b>dog</b>	hepatorenal syndrome	Pneumonia	<b>dog</b>	Hecht's pneumonia
Hepatic coma	horse	hepatic coma	Induced lung tumours	mouse	lung tumours
Glycogen-storage syndrome	<b>dog</b>	von Gierke's syndrome	Skeletal system diseases		
<b>Lantana camara</b> poisoning	sheep	kwashiorkor	Osteodystrophy	primate	fibrous osteodystrophy
<b>Pyrrolizidine</b> plant alkaloids	cattle	veno-occlusive disease	Familial osteoporosis	<b>dog</b>	osteogenesis imperfecta
Hemopoietic system diseases			Senile osteoporosis	mouse	senile osteoporosis
Congenital erythrocytic porphyria (recessive)	cattle	congenital erythrocytic porphyria	Achondroplasia	rabbit	dwarfism
Congenital porphyria (dominant)	cat	erythrocytic porphyria	Intervertebral-disk syndrome	<b>dog</b>	disk luxation
Hereditary leukomelanopathy	mink	<b>Chediak-Higashi syndrome</b>	Hip dysplasia	<b>dog</b>	acetabular dysplasia
Pelger-Huet anomaly	cattle	Pelger-Huet anomaly	Clubfoot	mouse	clubfoot
Cyclic neutropenia	<b>dog</b>	cyclic neutropenia	Skin diseases		
Aleutian disease	mink	multiple myeloma	Baldness, male pattern	stumptail macaque	baldness, male pattern
Abnormal lipid in lymphoid tumours	mouse	Niemann-Pick disease	Albinism	mouse	albinism
Viral leukemia	cat	lymphocytic leukemia	Genetic hypotrichosis	cattle	hypotrichosis
Multiple myeloma	<b>dog</b>	multiple myeloma	Hyperkeratosis	cattle	hyperkeratosis
Bialbuminemia	<b>swine</b>	bialbuminemia	Cutis hyperelastica	<b>dog</b>	<b>Ehlers-Danlos disease</b>
Hemophilia (factor VIII)	<b>dog</b>	hemophilia	Seborrheic dermatitis	<b>dog</b>	seborrheic dermatitis
Factor VII deficiency	<b>dog</b>	factor VII deficiency	Impetigo	<b>dog</b>	impetigo
Hemophilia-B-like disease	doa	Christmas disease	<b>Milia</b>	<b>dog</b>	<b>milia</b>
<b>Hertwig's anemia</b>	mouse	macrocytic anemia	Urinary system diseases		
Malaria	penguin	malaria	Diabetes insipidus	mouse	diabetes insipidus
In vitro sickling of erythrocytes	deer	sickle-cell anemia	Cystinuria	blotched genet	cystinuria
Muscle diseases			Chronic interstitial nephritis	<b>dog</b>	uremia
Hereditary muscular dystrophy	chicken	muscular dystrophy	Cystic or absent kidneys	<b>rat</b>	cystic kidneys
			Renal amyloidosis	mouse	renal amyloidosis
			Cloisonne kidneys	goat	renal hemosiderosis

in them by interfering with normal cell processes. Most causative agents of disease fall into the latter category. Causative agents and some of the symptoms of many of the diseases mentioned in this section are found in Tables 2 through 7.

**Characteristics of cell and tissue changes.** Changes in cells and tissues as a result of disease include degenerative and infiltrative changes. Degenerative changes are characterized by the deterioration of cells or a tissue

from a higher to a lower form, especially to a less functionally active form. When chemical changes occur in the tissue, the process is one of degeneration. When the changes involve the accumulation of materials within the cells comprising tissues, the process is called infiltration. Diseases such as pneumonia, metal poisoning, or septicemia (the persistence of disease-causing bacteria in the bloodstream) may cause the mildest type of degeneration—parenchymatous changes, or cloudy swelling

Degeneration and infiltration

Table 2: Selected Infectious and Parasitic Diseases of Animals

animal(s) affected	name(s) of disease	causative organism	nature of disease
Diseases of bacterial origin			
Most mammals, chickens	necrobacillosis, calf diptheria, bovine foot rot, necrotic hepatitis, dermatitis	<i>Sphaerophorus necrophorus</i>	organism invades tissue and causes tissue death (necrosis) after other wounds or infections have occurred; <i>i.e.</i> , disease is known as a secondary infection
Cattle, sheep, horses, chickens, man, many other animals	botulism	toxins produced by <i>Clostridium botulinum</i>	results from eating toxins released in decayed or spoiled foods; toxins cause rapid paralysis of nerves in throat and all muscles, almost always fatal
Swine, cattle, sheep, goats, rabbits, man, dogs, many other animals	listeriosis, circling disease, meningoccephalitis	<i>Listeria monocytogenes</i>	symptoms vary in affected animal; organism may affect the central nervous system (brain, spinal cord) or the membranes surrounding it or cause necrosis of heart muscles, <b>localized</b> tissue death in liver, or a septicemia (persistence of bacteria in the bloodstream)
Swine, cattle, sheep, goats, horses, turkeys, man	erysipelas, diamond-skin disease	<i>Erysipelothrix insidiosa</i>	<b>manifestations include septicemia and pathological di</b> <b>inuties of tissue</b> (lesions) in skin, heart, joints (in swine); arthritis (in sheep, occasionally in cattle, horses, goats); septicemia and death (in turkeys); skin lesions (in man)
Cattle, sheep, goats, horses, mules	anthrax, splenic fever, charbon	<i>Bacillus anthracis</i>	spores (inactive forms) of organisms in soil, transmitted through insect bites or food; manifestations include hemorrhage and edema (accumulation of fluid) in tissues
Swine, cattle, sheep, horses, mules	malignant edema, gas gangrene	<i>Clostridium septicum</i>	spores enter from dirt into injured tissue, cause severe gangrene (rotting of dead tissue), swelling; prognosis (outlook) poor
Swine, cattle, sheep, goats	pyobacillosis	<i>Corynebacterium pyogenes</i>	characterized by multiple abscesses (localized collections of pus) throughout the body; may result in debilitation (including arthritis in swine) and death
Primarily swine, cattle, goats (secondarily in man and other animals)	brucellosis, Bang's disease, contagious abortion; undulant fever. Malta fever (in man)	<i>Brucella abortus</i> , <i>B. melitensis</i> , <i>B. suis</i> .	primarily affects genital organs in both sexes; may cause abortion, sterility. infection of fetus in female, local lesions in various tissues; pasteurization of milk has controlled the disease in man
Swine, cattle, sheep	shipping fever, pasteurellosis, hemorrhagic septicemia	<i>Pasteurella multocida</i> and <i>P. hemolytica</i> ; also in conjunction with viral agents	causes of great economic losses throughout the world; manifestations may include acute to chronic respiratory disease; the various causative organisms vary in virulence (degree of pathogenicity); an acute <b>form</b> ( <i>i.e.</i> , short, severe) affects rabbits
Horses, mules, donkeys (man less susceptible)	glanders, farcy, malleus	<i>Malleomyces mallei</i>	organisms enter animal through digestive tract, travel via blood to lungs, trachea, and skin, and form ulcers; an acute form causes death, a chronic type may persist for years; human infections occur from exposure of broken skin to affected animals
Horses (mules, donkeys less susceptible)	strangles, distemper, infectious adenitis	<i>Streptococcus equi</i>	most common in young, undernourished horses in crowded conditions; manifested by high temperature, nose infections, and abscesses in lymph glands of neck
Horses	purpura hemorrhagica, petechial fever	unknown, but associated with <i>Streptococcus equi</i>	noncontagious, follows acute infections and toxemias; characterized by generalized hemorrhages in tissues and the accumulation of fluid (edema); relapses often occur
Primarily horses	ulcerative lymphangitis or cellulitis	<i>Corynebacterium pseudotuberculosis</i>	chronic disease, develops slowly following the entrance of bacteria through skin; affects <b>hindlegs</b> , sometimes severely
Horses (males most susceptible); sometimes swine, cattle; rarely dogs or cats	tetanus, lockjaw	toxins produced by <i>Clostridium tetani</i>	bacteria enter tissue at time of injury. produce toxins in necrotic tissue; affected animals become stiff; death results from suffocation
Swine	streptococcal infection	<i>Streptococcus</i> species	younger pigs more easily infected; symptoms varied ( <i>e.g.</i> , septicemia, arthritis, uterine inflammation, middle-ear infection, multiple abscesses)
Swine, accidentally in other animals	salmonellosis, enteritis, swine typhoid	<i>Salmonella choleraesuis</i>	may be acute ( <i>i.e.</i> , have a short, severe course) or chronic (persists for a long time); symptoms include loss of weight, sometimes acute septicemia
Swine, cattle	actinobacillosis, botryomycosis, big head	<i>Actinobacillus lignieresii</i>	organism a normal inhabitant of mouth. enters tissues through ulcers or wounds; symptoms include abscesses
Cattle	leptospirosis, hemoglobinuria	<i>Leptospira</i> species	symptoms of acute form include abortion, bloody milk, hemoglobin (blood pigment) in urine, kidney disease, and destruction of red blood cells; a milder form also exists
Cattle	infectious bovine pyelonephritis, infectious cystitis	<i>Corynebacterium renale</i>	usually observed in pregnant cattle in winter; a slowly developing disease that affects kidneys and bladder
Primarily cattle (rarely man, swine, sheep, horses)	tuberculosis, pearly disease	<i>Mycobacterium tuberculosis</i>	a chronic disease characterized by lesions, usually in lungs and lymph nodes, but sometimes in many other organs
Cattle (rarely sheep)	bacillary hemoglobinuria, red water disease	<i>Clostridium hemolyticum</i>	spores eaten with food, develop into active cells, migrate to liver, and produce infarcts (tissue death); usually fatal within 36 hours

**Table 2: Selected Infectious and Parasitic Diseases of Animals** (continued)

animal(s) affected	name(s) of disease	causative organism	nature of disease
Cattle, sheep	pinkeye, infectious keratitis, <b>kerato-conjunctivitis</b>	Moraxella bovis (in cattle). <i>Colesiotea conjunctivae</i> (in sheep)	affects eyes; may result in blindness; a very contagious disease whose spread may be influenced by dust irritation or possibly by viral invasion
Cattle, sheep	<b>Johne's</b> disease, paratuberculosis	<i>Mycobacterium paratuberculosis</i>	a chronic disease; causes diarrhea, progressive weight loss
Cattle, sheep	vibriosis, epizootic abortion	Vibriofetus	a venereal disease ( <i>i.e.</i> , transmitted by sexual contact) in cattle; transmitted in contaminated food and water in sheep; commonly results in infertility or abortion in cattle, abortion in sheep
Cattle, sheep (occasionally swine, goats, deer, horses)	blackleg, black quarter, quarter ill	<i>Clostridium fesceri</i> ( <i>chauvoei</i> )	spores transmitted from soil to animal through wounds or cuts; symptoms include lameness, gangrene of affected tissues (usually in leg muscles); usually fatal
Sheep	enterotoxemia, over-eating disease, pulpy kidney	<i>Clostridium perfringens</i> <b>type D</b>	affected lambs usually fat or feeding on rich clover pasture; usually fatal within a day from acute toxemia (absorption of bacterial toxins)
Primarily sheep	pseudotuberculosis, caseous lymphadenitis	<i>Corynebacterium ovis</i>	organisms transmitted to animal through breaks in the skin; slowly developing abscesses (usually in lungs or lymph nodes) may rupture and spread throughout body
Sheep, goats (occasionally cattle)	black disease, infectious necrotic hepatitis	<i>Clostridium novyi</i>	organisms probably present normally in intestinal tract, associated with fluke (parasitic worm) movements in liver; produce liver damage, toxemia, and death
Diseases of viral origin Mammals	rabies, hydrophobia, <b>lyssa</b> , mad dog, le Rage	rabies virus	transmitted primarily through the bite of a rabid animal; wild animals ( <i>e.g.</i> , skunks, squirrels, bats) a reservoir for infection; disease characterized by central-nervous-system symptoms ( <i>e.g.</i> , rage, excitability; paralysis of jaw with salivation), general paralysis, and death
Mammals (especially cattle)	bovine warts, <b>papillomatosis</b>	papilloma viruses	warts of variable size develop, usually on sides of head and neck of cattle, sometimes on sex organs
Many mammals ( <i>e.g.</i> , swine, cattle, sheep, goats, horses)	pox, variola	pox virus	often an acute highly infectious disease. characterized by formation of papules (small solid elevations), vesicles (small liquid-containing sacs), and pustules (small pus-filled elevations) on the skin
Swine, cattle (also rats, dogs, cats)	pseudorabies. <b>Aujeszky's</b> disease, mad itch	pseudorabies virus	affected animals rub body parts, undergo spasmodic muscle contractions; froth at the mouth; and show nervous irritability; usually fatal
Young pigs	transmissible gastro-enteritis ( <b>TGE</b> )	<b>TGE</b> virus	acute and fatal to pigs less than two to three weeks old; virus attacks absorptive surfaces of small intestine
Swine	hog cholera, swine fever, swine pest	hog-cholera virus	infectious disease; may be acute or chronic; spread by <b>flies</b> , animal contact, garbage, contaminated pastures; symptoms include high fever, severe hemorrhages in skin and organs
Swine	vesicular exanthema ( <b>VE</b> )	<b>VE</b> virus	vesicles form on snout, mouth, abdominal wall; foot lesions occur; highly infectious, spread through animal contact or raw pork scraps in garbage; fatal usually only in <b>young pigs</b>
Swine, ferrets, mice	swine influenza, hog flu	swine-influenzavirus; bacterium; <i>Hemophilus suis</i>	acute contagious disease; virus enters animal through <b>lungworm</b> larvae, acute infection occurs if <i>Hemophilus</i> organisms are in lung; symptoms include fever, pneumonia, bronchitis
Swine, cattle, horses	vesicular stomatitis ( <b>VS</b> ), mouth thrush	vs virus	effects varied; <i>e.g.</i> , high fever, salivation, vesicles in mouth region, lack of appetite (in horses); inflammation of mammary glands, vesicles in mouth region, <b>inflammation</b> of feet (in cattle); snout and mouth lesions, severe feet involvement (in swine)
Cattle	sporadic bovine encephalomyelitis ( <b>SBE</b> ), Buss disease	<b>SBE</b> virus	weakens calves; an infection of brain and membranes of brain and spinal cord; recovery often occurs
Cattle	infectious bovine <b>rhino</b> -tracheitis ( <b>IBR</b> ), red nose, pinkeye, dust pneumonia	<b>IBR</b> virus	acute infection followed by secondary bacterial infections ( <i>Pasteurella multocida</i> , <i>Spherophorus necrophorus</i> ) in lungs, sex organs, eye; nostrils swell, become red
Cattle, buffalo, deer	malignant catarrhal fever ( <b>MCF</b> ), head catarrh, snotsiekte, epitheliosis	<b>MCF</b> virus	numerous symptoms include rapid weight loss, eye lesions, nasal discharge, muscular twitching, convulsions; usually fatal
Cattle, sheep	bluetongue, sore muzzle, catarrhal fever	bluetongue virus	virus transmitted through gnats (small flies); a serious problem in sheep; numerous symptoms; recovery very slow; usually less than 10 percent mortality of a flock
Sheep (also transmissible to cows)	ovine virus abortion ( <b>OVA</b> ), <b>enzootic</b> abortion	<b>OVA</b> virus	causes economic losses through abortion, weak lambs, and poor breeding efficiency

Table 2: Selected Infectious and Parasitic Diseases of Animals (continued)

animal(s) affected	name(s) of disease	causative organism	nature of disease
Sheep, goats, man	contagious ecthyma (cE), sore mouth, <b>doby</b> mouth, orf, pustular dermatitis	CE <b>virus</b>	udder, lips, and nose of sheep affected; secondary bacterial invasion may result in death, but animals usually recover
Horses	equine infectious anemia (EIA), swamp fever, malarial fever	EIA <b>virus</b>	transmitted by mosquitoes, lice, flies, and hypodermic needles; either acute, chronic, or latent (not manifest); varied symptoms include intermittent fever, loss of weight, jaundice, hemorrhages, anemia, and fluid in body cavities
Horses	equine viral arteritis (EVA), infectious arteritis	EVA <b>virus</b>	an acute contagious disease similar to EVR in symptomatology but causes damage to small arteries
Horses, mules, man, laboratory animals	equine encephalomyelitis ( <b>EE</b> ), sleeping sickness, viral encephalitis	EE <b>virus</b>	many viral strains transmitted by an insect (usually mosquitoes or mites or ticks); disease causes inflammation of brain cells; the many symptoms include death; in-apparent infections occur in chickens, pigeons, and pheasants
Horses (also guinea pigs, mice, hamsters)	equine viral rhinopneumonitis ( <b>EVR</b> ), equine virus abortion	EVR <b>virus</b>	disease highly contagious; symptoms include high fever, mild upper-respiratory involvement, and usually abortion with liver damage of fetus in pregnant mares
Diseases of fungal origin Many domestic, laboratory, and wild mammals	histoplasmosis, reticuloendothelial cytomycosis	Histoplasma <i>capsulatum</i>	chronic; may resemble tuberculosis; granulomas ( <b>tumours</b> ) in lungs, liver, and spleen; intestinal involvement in dogs results in diarrhea
Swine, cattle, sheep, horses, fowl, dogs, cats	ringworm, <b>tinea</b> , <b>trichophytosis</b>	Trichophyton and <i>Microsporum</i> species	infectious skin disease caused by invasion of hair follicles; characterized by round crusty lesions, inflammation
Swine, cattle, horses (man secondarily)	actinomycosis, lumpy jaw, wooden tongue	Actinomyces bovis	cattle manifest a <b>bonelike</b> swelling on upper or lower jaw; swine manifest a tumourlike enlargement of udder caused by infections from teeth of suckling pigs
Cattle, horses, cats, dogs, man	cryptococcosis	<i>Cryptococcus neoformans</i>	usually caused by inhalation of contaminated dust; lungs affected primarily; disease may spread to almost any organ
Cattle, sheep, dogs, man	coccidioidomycosis <b>coccidioid</b> granuloma, San Joaquin Valley fever	Coccidioides <i>immitis</i>	in the acute respiratory form, symptoms include cough, with recovery in two weeks; in the more serious chronic form, gradual loss in weight, abscesses, and granulomas in various tissues, including skin, occur
Primarily horses and man	sporotrichosis	Sporotrichum schenckii	occurs first as ulcers on skin, invasion of the lymph glands occurs, may spread throughout circulatory system
Diseases of rickettsial origin Swine	eperythrozoonosis, ictero-anemia, <b>yellow-belly</b>	<i>Eperythrozoon suis</i>	organisms cause red-blood-cell destruction; both acute and mild forms; many animals with a mild form act as carriers
Cattle	<b>anaplasmosis</b> , South African gall sickness	<i>Anaplasma marginale</i>	infectious disease spread either by blood-sucking ticks, mosquitoes, flies, or by mechanical transmission ( <i>e.g.</i> , resulting from dehorning, vaccination); symptoms usually include extreme anemia from destruction of red blood cells; recovered animals are immunological carriers
Diseases of protozoal origin Most animals (including man)	toxoplasmosis	<i>Toxoplasma gondii</i>	transmission not clear but probably occurs by contaminated food or direct contact; symptoms include weakness, respiratory problems, lack of coordination, nodules throughout body, enlarged lymph nodes, and tissue death; treatment difficult
Swine, cattle, sheep, goats	coccidiosis	Eimeria <i>zürnii</i> , E. bovis, and ten other species	causative organisms found in most mature animals; symptoms result in loss of large amounts of blood and dehydration; mortality may be as high as 50 percent
Cattle	<b>trichomoniasis</b>	<i>Trichomonas fetus</i>	transmitted by sexual contact or by artificial insemination, symptoms include abortion, failure to conceive, inflammation of uterus; no symptoms apparent in infected bull that acts as a carrier
Cattle	Texas fever, cattle-tick fever, babesiasis, piroplasmosis, red water	Babesia <i>bigemina</i>	organism, which destroys red blood cells, is transmitted by ticks ( <i>Margaropus</i> species) and mechanical means ( <i>i.e.</i> , surgical instruments, needles); symptoms include high fever, severe anemia, hemoglobin in urine; chronic forms occur; some animals act as carriers
Horses	dourine, equine syphilis, breeding disease	Trypanosoma <i>equiperdum</i>	transmitted by sexual contact or blood-sucking <b>flies</b> ; affects sex organs, causes plaquelike areas on skin, paralysis of muscles, loss of condition
Horses, mules, donkeys	equine piroplasmosis, equine malaria, <b>babesiasis</b>	Babesia caballi, B. <i>equi</i>	acute cases may die quickly; animals with less acute forms have varied symptoms ( <i>e.g.</i> , intermittent fever, jaundice, internal hemorrhages); anemia results from invasion of red blood cells by causative organisms; B. equi more pathogenic than B. caballi

**Table 2: Selected Infectious and Parasitic Diseases of Animals (continued)**

animal(s) affected	name(s) of disease	causative organism	nature of disease
Diseases of nematode (roundworm) origin			
Swine	<b>lungworms</b>	<i>Metastrongylus</i> species	common symptoms include coughing and lung irritation
Swine	kidney worms	<i>Stephanurus dentatus</i>	mature worms live in urinary tract; larvae migrate to liver, produce lesions and weight loss
Swine	intestinal roundworm	<i>Ascaris suum</i>	migrations of organisms through lungs cause hemorrhages and pneumonia, may interfere with bile flow and food absorption
Swine	intestinal threadworm	<i>Strongyloides</i>	migration of large numbers of larvae cause tissue damage
Cattle	stomach worms	<i>Ostertagia</i> and <i>Trichostrongylus</i> species	symptoms include anemia, stunted growth, and diarrhea
Cattle	nodular worm	<i>Oesophagostomum radiatum</i>	nodules form in tissues; poor intestinal absorption caused by larvae (immature forms of organism) and nodules results in diarrhea
Cattle	verminous pneumonia	<i>Dictyocaulus viviparus</i>	ingested infective larvae migrate to lungs, produce toughing, discomfort, and <b>pneumonia</b>
Sheep	lungworms	<i>Dictyocaulus filaria</i> , <i>Muellerius capillaris</i>	symptoms include formation of lung nodules. collapse of portions of lungs
Sheep	hookworms	<i>Bunostomum trigonocephalum</i>	bloodsucking hookworm cause anemia. intermittent diarrhea
Sheep	filarial dermatitis	<i>Elaeophora schneideri</i>	symptoms include skin lesions
Horses	oxyuriasis (pinworm)	<i>Oxyuris equi</i>	<b>worms</b> cause irritation in the area around the anus
Horses	<b>ascariasis</b> (intestinal roundworms)	<i>Parascaris equorum</i>	larval forms cause damage; symptoms include defective intestinal absorption
Horses	strongylosis	<i>Strongylus</i> species	large numbers of worms weaken foals ( <b>new-born</b> horses); migrating larvae may cause formation of clots in blood vessels and lameness
Horses	habronemiasis (summer sores)	<i>Habronema</i> species	habronema larvae may enter skin wounds. causing granulation; eye and stomach inflammations also occur
Diseases of platyhelminth (flatworm) origin			
Sheep	tapeworm	<i>Moniezia expansa</i>	results in poor growth
Sheep	fringed tapeworm	<i>Thysanosoma actinoides</i>	causes digestive disturbances
Horses	tapeworm	<i>Anaplocephala perfoliata</i>	symptoms may include inflammation of gut and ulceration
Diseases of acanthocephalan (spiny-headed-worm) origin			
Swine	spiny-headed worm	<i>Macracanthorhynchus hirudinaceus</i>	nodules form on small intestine; may result in peritonitis (inflammation of lining of internal organs)
Diseases of arthropod origin			
Cattle	scabies (mange)	<i>Chorioptes bovis</i> , <i>Psoroptes equi</i> , <i>Sarcoptes scabiei</i> (mites)	contagious skin diseases
Cattle	<b>grubs</b>	<i>Hypoderma bovis</i> (heel fly)	migrating <b>larvae</b> produce tissue damage, cysts, and hide damage
Cattle	lice	<i>Linognathus vituli</i> , <i>Solenopotes capillatus</i> , <i>Haematopinus quadripertusis</i> (bloodsucking lice). <i>Bovicola bovis</i> (biting louse)	symptoms include dermatitis and anemia
Sheep	screwworm infestations	many fly larvae ( <i>e.g.</i> , <i>Cochliomyia hominivorax</i> , <i>Chrysomya bezziana</i> )	flies lay eggs in open wounds; developing larvae ( <b>screwworms</b> ) burrow into tissue and destroy it
Sheep	psoroptic mange (sheep scab)	<i>Psoroptes communis</i> (mite)	all parts of skin inflamed, particularly those covered with wool

of the cells; the cells **first** affected are the specialized cells of the liver and the kidney. Serious cellular damage may cause the uptake of water by cells (hydropic degeneration), which lose their structural features as they fill with water. The causes for the accumulation in cells of abnormal amounts of fats (fatty infiltration and degeneration) have not yet been established with certainty but probably involve fat metabolism. Poisons such as phosphorus may cause sudden increases in the accumulation of fats in the liver. An abnormal protein material may accumulate in connective-tissue components of small arteries as a result of chronic pneumonia, chronic bacterial infections, and prolonged antitoxin production (in horses); the condition is known as amyloid degeneration and infiltration. Hyaline degeneration, characterized by tissues that become clear and appear glasslike, usually occurs in connective-tissue components of small blood vessels as a result of conditions that may occur in kidney structures (glomeruli) of animals with nephritis or in lymph glands of animals with tuberculosis. Certain

structures (glomeruli) of animals with nephritis or in degeneration.

The condition in which mucus, a secretion of mucous membranes lining the inside surfaces of organs, is produced in excess and accumulates in greater than normal amounts is referred to as mucoid degeneration. Major causes include chronic irritation of mucous membranes and certain mucus-producing tumours. Abnormal amounts of glycogen, the principal storage carbohydrate of animals, may occur in the liver as a result of certain inherited diseases of animals; the condition is known as glycogen infiltration. The abnormal deposition of calcium salts, called hypercalcification, may occur as a result of several diseases involving the blood vessels and the heart, the urinary system, the gallbladder, and the **bone-like** tissue called cartilage. Pigments (coloured molecules) from coal dust or asbestos dust may infiltrate the lungs of certain dogs in two types of lung disease: **anthracosis** and asbestosis. Abnormal amounts of iron-containing coloured molecules (hemosiderin) resulting from the

breakdown of hemoglobin, the gas-carrying protein of red blood cells, are often deposited in the liver and the spleen after diseases that involve excessive breakdown of red blood cells. A black molecule (melanin) occurs abnormally in the livers of certain sheep suffering from Dubin-Johnson syndrome and in certain tumours called melanomas. Uric acid infiltration, which occurs in poultry, is characterized by the deposition of uric acid salts.

Necrosis, the death of cells or tissues, takes place if the blood supply to tissues is restricted; poisons produced by microbes, chemical poisons, and extreme heat or electricity also may cause necrosis. The rotting of the dead tissue is known as gangrene.

Atrophy of animal tissue involves a process of tissue wasting, in which a decrease occurs in the size or number of functional cells; *e.g.*, in inherited muscular dystrophy of chickens. Hypertrophy — an increase in the size of the cells in a tissue or an organ — occurs in heart muscle during diseases involving the heart valves, in certain pneumonia and in some diseases of the endocrine glands. Aplasia is the term used when an entire organ is missing from an animal; hypoplasia indicates arrested or incomplete development of an organ, and hyperplasia an increase in the production of the number of cells; *e.g.*, the persistent callus that forms on the elbows of some dogs. Metaplasia is used to describe the change of one cell type into another; it may occur in chronic irritation of tissues and in certain cancerous tumours.

**Characteristics of inflammatory reactions.** When tissues are injured, they become inflamed. The inflammation may be acute, in which case the inflammatory processes are active, or chronic, in which case the processes occur slowly and new connective tissue is formed. The reaction of inflamed tissues is a combination of defensive and repair mechanisms. Acute inflammation is characterized by redness, heat, swelling, sensitivity, and impaired function. Several types of acute inflammation are known. Mild acute inflammations of mucous membranes resulting in the production of thin watery material (exudate) are called catarrhal inflammations; parenchymatous inflammations occur in organs undergoing degeneration. If the exudate formed in response to an injury is of a serious nature—that is, resembling blood plasma—the process is called serous inflammation. In fibrinous inflammation, a protein (fibrin) forms on membranes, including those in the lungs. In suppurative inflammation, dead tissue is replaced with pus composed of colourless blood cells (leucocytes) and tissue juices.

During the inflammatory reaction, the injured tissue is surrounded by an area of rapidly dividing cells. Specialized cells called macrophages enter the tissue and remove blood and tissue debris. Other cells, called neutrophils, ingest disease-causing bacteria and other foreign material. In chronic inflammations, the connective tissue contains fibroblasts, cells that divide and form new connective, or scar, tissue (see INFLAMMATION).

**Characteristics of circulatory disturbances.** An increase in the rate of blood flow to a body part, referred to as congestion, or hyperemia, occurs during inflammation; a diminished blood flow to tissues is referred to as ischemia, or a local anemia. Examples of hemorrhage, the escape of blood from vessels, include epistaxis, or nosebleeds, in racehorses; hematemesis, or regurgitation of blood, in dogs with uremia; hemoptysis, or blood loss from lungs; hematuria, or blood in urine, of cattle with inflammation of the urinary bladder. Edema, a condition characterized by abnormal accumulations of fluid in tissues, occurs not only in a tissue during inflammation but over the entire body if the concentration of blood-serum proteins, especially albumin, is low. A thrombosis, or a blood clot in a blood vessel, may block or slow circulation of blood to tissues; if blood vessels become blocked, the condition is known as an embolism. The term infarction describes the necrosis that occurs in tissues whose blood supply is blocked by an embolism.

#### METHODS OF EXAMINATION

Before an unhealthy animal is treated, an attempt is made to diagnose the disease. Both clinical findings,

which include symptoms obvious to a nonspecialist and clinical signs appreciated only by a veterinarian, and laboratory tests may be necessary to establish the cause of a disease. A clinical examination should indicate if the animal is in good physical condition, is eating adequately, is bright and alert, and is functioning in an apparently normal way. Many disease processes are either inflammatory or result from tumours. Malignant tumours (*e.g.*, melanomas in horses, squamous cell carcinomas in small animals) rapidly spread and usually cause death. Other diseases cause the circulatory disturbances or the degenerative and infiltrative changes summarized in the preceding section. If a specific diagnosis is not possible, the symptoms of the animal are treated.

A case record of the information pertaining to an animal (or to a herd) suspected of having a disease is begun at the time the animal is taken to a veterinarian and is continued through treatment. It includes a description of the animal (age, species, sex, breed); the owner's report; the animal's history; a description of the preliminary examination; clinical findings resulting from an examination of body systems; results of specific laboratory tests; diagnosis regarding a specific cause for the disease (etiology); outlook (prognosis); treatment; case progress; termination; autopsy, if performed; and utilization of scientific references, if applicable.

The veterinarian must diagnose a disease on the basis of various examinations and tests, since he obviously cannot interrogate the animal. Methods used include inspection—a visual examination of the animal; palpation—the application of firm pressure with the fingers to tissues to determine characteristics such as abnormal shapes and possible tumours, the presence of pain, and tissue consistency; percussion—the application of a short, sharp blow to a tissue to provoke an audible response from body parts directly beneath; auscultation—the act of listening to sounds produced by the body during the performance of functions (*e.g.*, breathing, intestinal movements); smells—the recognition of characteristic odours associated with certain diseases; miscellaneous diagnostic procedures, such as eye examinations, the collection of urine, and heart, esophageal, and stomach studies.

**General inspection.** Deviation of various characteristics from the normal, observation of which constitutes the general inspection of an animal, is a useful aid in diagnosing disease. The general inspection includes examination of appearance; behaviour; body condition; respiratory movements; state of skin, coat, and abdomen; and actions.

The appearance of an animal may be of diagnostic significance; small size in a pig may result from retardation of growth, which is caused by hog-cholera virus (Table 2). Observation of the behaviour of an animal is of value in diagnosing neurological diseases; *e.g.*, muscle spasms occur in lockjaw (tetanus) in dogs, nervousness and convulsions in dogs with distemper (Table 4), dullness in horses with equine viral encephalitis (Table 2), and excitement in animals suffering from lead poisoning. Subtle behavioral changes may not be noticeable. The general condition of the body is of value in diagnosing diseases that cause excessive leanness (emaciation), including certain cancers, or other chronic diseases, such as a deficiency in the output of the adrenal glands or tuberculosis. Defective teeth also may point to malnutrition and result in emaciation.

The respiratory movements of an animal are important diagnostic criteria; breathing is rapid in young animals, in small animals, and in animals whose body temperature is higher than normal. Specific respiratory movements are characteristic of certain diseases—*e.g.*, certain movements in horses with heaves (emphysema) or the abdominal breathing of animals suffering from painful lung diseases. The appearance of the skin and hair may indicate dehydration (excessive loss of water) by lack of pliability and lustre; or the presence of parasites such as lice, mites, or fleas; or the presence of ringworm infections and allergic reactions by the skin changes they cause. The poisoning of sheep by molybdenum in their hay may be diagnosed by the loss of colour in the wool

The animal's appearance

Hemorrhage and edema

**Table 3: Examples of Noninfectious Diseases of Animals**

animal(s) affected	name(s) of disease	nature of disease
Hereditary diseases Pigs, calves, foals	congenital absence of skin ( <b>epitheliogenesis imperfecta</b> )	complete absence of skin over parts of body; fatal a few days after birth
Swine, cattle	congenital porphyria (pink tooth)	causes anemia. wine-coloured urine; results from a biochemical defect in the metabolism of a component (porphyrin) of the iron-containing pigment ( <b>hematin</b> ) of hemoglobin, the oxygen-carrying protein of blood
Cattle	prolonged gestation (prolonged pregnancy)	may cause a three-week to three-month delay in birth of calves, which when born are either large or deformed; a special type in Guernsey and Jersey breeds results in death of calves at birth
Metabolic diseases Cattle (rarely sheep and pigs)	milk fever (parturient paresis)	caused in lactating cattle by loss of calcium into the milk; low levels of calcium in blood cause muscular weakness, circulatory collapse, and loss of consciousness; treatment includes replacing calcium
Cattle, sheep	ketosis (acetonemia in cattle; pregnancy toxemia in sheep)	occurs in lactating cattle following calving and in sheep in terminal stage of pregnancy (both times of increased need for carbohydrates); <b>causes</b> paralysis and death; complex treatment includes replacing carbohydrates
Horses	azoturia (paralytic myoglobinuria)	paralytic disease of unknown cause; occurs during exercise following a period of inactivity; muscles degenerate; results in paralysis, dark-red urine
Functional diseases Cattle, sheep	kidney and bladder calculi ( <b>urolithiasis</b> )	cattle eating range grasses with high silicon content may develop <b>obstructions (solid masses containing silicon and protein)</b> in urinary system; similar effects may occur with diets high in phosphate, in which case the solid mass contains magnesium ammonium-phosphate and protein
Cattle, sheep	bloat (ruminal tympany)	distension (caused by gases) of first two stomachs of cows; conditions preventing eructation (belching) of gases are major causes; occurs primarily when cattle overeat on leguminous pastures (alfalfa and clovers); often fatal
Cattle, horses	pulmonary emphysema (heaves in horses)	acute form occurs in cattle, chronic form in horses; alveoli (small terminal air sacs) in lung rupture, reducing surface area for oxygen transport; causes not yet clear, but disease may follow pneumonia and allergic reactions
Nutritional deficiency diseases Most animals	vitamin A deficiency	caused by dietary insufficiency of vitamin A or substance from which vitamin A is formed (carotene); numerous manifestations in young and adult animals include night blindness
Pigs	iron deficiency	caused by insufficient iron in diet; manifestations include severe anemia and poor growth
Diseases caused by chemical agents Pigs, cattle, horses	bracken-fern poisoning	fern contains thiaminase, which destroys vitamin B <sub>1</sub> (thiamine), thereby producing a vitamin deficiency in horses and swine; in cattle the bone marrow is affected, and deficiency of blood cells and excessive hemorrhages occur
Cattle, sheep, horses	rye-grass staggers	manifestations include either liver degeneration and photosensitization or uncoordination, convulsions, and paralysis; cause not yet established, but fungus on the rye grass plays some role in the liver degeneration
Cattle (occasionally other animals)	sweet-clover poisoning	caused by eating moldy sweet-clover hay, which contains the anti-coagulant compound dicoumarol; manifestations include extensive hemorrhages and severe blood loss after injury
Cattle, sheep	molybdenum poisoning	results if pasture soil contains toxic quantities (three parts per million) of molybdenum, which replaces copper in body; symptoms include diarrhea, loss of hair colour, anemia
Diseases caused by physical agents Cattle	hardware disease (traumatic reticuloperitonitis)	objects such as nails and small pieces of balling wire may be eaten with feed; perforation and inflammation of first stomach (reticulum) may occur; surgery sometimes necessary
Cattle	brisket disease (mountain sickness)	occurs in cattle at high altitudes where levels of atmospheric oxygen are too low to provide oxygen required; manifestations include enlargement of right heart, congestive heart failure

of black sheep. Distension of the abdomen may indicate bloat in cattle or colic in horses.

Abnormal activities may have special diagnostic meaning to the veterinarian. Straining during urination is associated with bladder stones; increased frequency of urination is associated with kidney disease (nephritis), bladder infections, and a disease of the pituitary gland (diabetes insipidus). Excessive salivation and grinding of teeth may be caused by an abnormality in the mouth. Coughing is associated with pneumonia. Some diseases cause postural changes: a horse with tetanus may stand in a stiff manner. An abnormal gait in an animal made to move may furnish evidence as to the cause of a disease, as louping ill in sheep.

**Clinical examination.** Following the general inspection of an animal thought to have contracted a disease, a more thorough clinical examination is necessary, during which various features of the animal are studied. These include the visible mucous membranes (conjunctiva of the eye, nasal mucosa, inside surface of the mouth, and tongue); the eye itself; and such body surfaces as the ears, horns (if present), and limbs. In addition, the pulse rate and the temperature are measured.

The veterinarian examines the visible mucous membranes of the eye, nose, and mouth to determine if jaundice, hemorrhages, or anemia are present. The conjunctiva, or lining of the eye, may exhibit pus in pinkeye infections, have a yellow appearance in jaundice, or exhibit small hemorrhages in certain systemic diseases. Examination of the nose may reveal ulcers and vesicles (small sacs containing liquid), as in foot-and-mouth disease, a viral disease of cattle, or vesicular exanthema, a viral disease of swine. Ulceration of the tongue may be apparent in animals suffering from actinobacillosis, a disease of bacterial origin (see Table 2).

A detailed examination of the eye may show abnormalities of the cornea resulting from such diseases as infectious hepatitis in dogs (Table 4), bovine catarrhal fever, and equine influenza. Cataract, a condition in which the passage of light through the lens of the eye is obstructed, may result from a disorder of carbohydrate metabolism (diabetes mellitus), infections, or a hereditary defect.

An elevated temperature (fever) resulting from the multiplication of disease-causing organisms may be the earliest sign of disease. The increase in temperature

Table 4: Some Common Diseases of Dogs

name(s) of disease	causative agent	nature of disease
Distemper	virus	affects nonvaccinated (nonimmunized) puppies in contact with infected animals; symptoms include loss of appetite, fever; inflammation of the brain is usual cause of death; some dogs may recover, but others have spastic tremors; foxes, wolves, mink, skunks, raccoons, and ferrets also susceptible
Infectious hepatitis (Rubarth's disease)	virus	affects dogs by causing hemorrhages and severe liver damage; affects foxes by causing inflammation of the brain; clinical signs are variable because disease symptoms vary from severe to inapparent ( <i>i.e.</i> , no manifest signs)
Salmon poisoning	rickettsia	occurs after consumption of raw salmon or trout carrying rickettsial-infected flatworm (fluke) larvae ( <i>Nanophyetus salmincola</i> ); affects dogs, foxes, and coyotes primarily in the Pacific northwestern United States; symptoms include high fever, swollen lymph nodes; usually fatal within five days
Prostatitis	varied	inflammation of a gland near the urinary bladder (prostate gland) in male dogs; usually controlled by antibiotic drugs; other prostate-gland disorders may result from tumours (carcinoma, sarcoma) or from abnormal increase in cell multiplication (hyperplasia)
Congenital heart disease	inherited tendency	may occur in 1 percent of all dogs; heart disorders may lead to secondary diseases such as pneumonia, accumulation of fluid in body cavities, laboured breathing, edema; heart failure occurs
Hip dysplasia	apparently inherited tendency	crippling disorder common in many breeds (especially German shepherds); a shallow hip socket (acetabulum) results in an unstable hip joint, particularly during motion of hindleg
Kidney stones (calculi, urolithiasis)	hereditary, functional disturbance	calculi develop in kidney, bladder, and male urethra (tube from bladder to outside of body); surgery usually necessary; inherited types include cystine calculi in certain dachshunds and uric acid calculi in male dalmatians
Hypothyroidism	functional disturbance	thyroid gland may function marginally or be absent; symptoms include awkward, slow movement, coarse, dry coat; treatment includes iodine, thyroid preparations
Dermatitis	varied	common symptoms include skin inflammation and loss of hair; causative agents include nutritional deficiencies, bacterial infections, hypothyroidism, allergies, hormone imbalances, and parasites ( <i>e.g.</i> , fleas, Lice, mites, fly larvae, and ticks)
Strychnine poisoning	chemical compound	accidental ingestion of 0.75 milligram of the poison (found in rat poisons) per kilogram (about $2\frac{1}{4}$ pounds) of body weight may cause death from convulsions and respiratory distress
Glaucoma	hereditary tendency in some breeds	a group of eye diseases in which the retina and optic nerve are damaged; certain breeds have a hereditary tendency for the disease; other breeds develop glaucoma as a result of other eye disorders
Granulomatous colitis	not yet characterized	usually found in boxer dogs; symptoms include bloody diarrhea; severely and chronically affected dogs become emaciated, an infectious agent observed microscopically in the thickened colon has not yet been isolated or characterized
Pancreatitis	unknown	in acute types the gland may be destroyed because of inflammation from unknown causes; an animal that lives may develop diabetes mellitus or be unable to secrete enzymes from pancreas, or both, thus preventing digestion, which increases the appetite and causes progressive weight loss; treatment difficult

activates the body mechanisms necessary to fight off foreign substances. The pulse rate is useful in determining the character of the heartbeat and of the circulatory system.

#### TESTS AS DIAGNOSTIC AIDS

In many cases, the final diagnosis of an animal disease is dependent upon a laboratory test. Some involve measuring the amount of certain chemical constituents of the blood or body fluids, determining the presence of toxins (poisons), or examining the urine and feces. Other tests are designed to identify the causative agents of the disease. The removal and examination of tissue or other material from the body (biopsy) is used to diagnose the nature of abnormalities such as tumours. Specific skin tests are used to confirm the diagnoses of various diseases—*e.g.*, tuberculosis and Johne's disease in cattle and glanders in horses (Table 2).

Confirmation of the presence in the blood of abnormal quantities of certain constituents aids in diagnosing certain diseases. Abnormal levels of protein in the blood are associated with some cancers of the bone, such as multiple myeloma in horses and dogs. Animals with diabetes mellitus have a high level of the carbohydrate glucose and the steroid cholesterol in the blood. The combination of an increase in the blood level of cholesterol and a decrease in the level of iodine bound to protein indicates hypothyroidism (underactive thyroid gland). A low level of calcium in the serum component of blood confirms milk fever in lactating dairy cattle. An increase in the activities of certain enzymes (biological catalysts) in the blood indicates liver damage. An increase in the blood level of the bile constituent bilirubin

is used as a diagnostic test for hemolytic crisis, a disease in which red blood cells are rapidly destroyed by organisms such as *Babesia* species in dogs and in cattle and *Anaplasma* species in cattle.

The examination of the formed elements of blood, including the oxygen-carrying red blood cells (erythrocytes), the white blood cells (neutrophils, eosinophils, basophils, lymphocytes, and monocytes), and the platelets, which function in blood coagulation, is helpful in diagnosing certain diseases. Examination of the blood cells of cattle may reveal abnormal lymphocytic cells characteristic of leukemia. Low numbers of leucocytes indicate the presence of viral diseases, such as hog cholera and infectious hepatitis in dogs. Neutrophil levels increase in chronic bacterial diseases, such as canine pneumonia and uterine infections in female animals. Elevated monocyte levels occur in chronic granulomatous diseases; *e.g.*, histoplasmosis and tuberculosis. Canine parasitism and allergic skin disorders are characterized by elevated eosinophil levels. Prolonged clotting time may be associated with a deficiency of platelets.

Anemia, a disease characterized by a deficiency in red blood cells, has many causes. They include hemorrhages from blood loss after injuries; the destruction of red blood cells by the rickettsia *Haemobartonella felis* in cats; incompatible blood transfusions in dogs; the inadequate production of normal red blood cells, which occurs in iron or cobalt deficiency after exposure to radioactive substances; general malnutrition; and contact with substances that depress the activity of bone marrow.

Poisonings occur commonly in animals. Some species are more sensitive to certain poisons than others. Swine develop mercury poisoning if they eat too much grain

Blood tests

Table 5: Some Common Diseases of Domestic Cats

name(s) of disease	causative agent	nature of disease
Feline distemper (panleukopenia, infectious enteritis)	virus	the most important viral disease of cats; wildcats and raccoons also susceptible; number of white blood cells decreases; fluid losses cause dehydration; treatment includes replacing fluid and preventing bacterial infections; vaccination advisable in kittens
Feline rhinotracheitis (pneumonitis, coryza, and influenza)	viruses (e.g., <i>Miyagawanelia</i> )	any upper-respiratory viral infection with eye and nose involvement; common among cats; seldom causes death; similar to severe head cold in man; treatment includes antibiotic drugs
Feline picornavirus pneumonia	virus	symptoms include watery eyes, nasal inflammation; pneumonia; in severe cases, death is preceded by laboured breathing
Lymphocytic leukemia	virus	cancerous lymphocytic cells enter blood from a malignant tumour (lymphosarcoma); lymph nodes may become enlarged; a progressive anemia, an increase in the level of circulating immature lymphocytes, symptoms may precede death; no curative treatment known thus far
Urinary-bladder infection with stones and obstruction (cystitis)	unknown	urethra is obstructed with crystals of magnesium ammonium phosphate and mucus associated with infection of the urinary bladder (cystitis); death occurs if obstruction not relieved; exact cause of syndrome (set of symptoms) unknown but may be related to diet or to a virus
Ringworm (dermatomycosis)	fungus ( <i>Microsporum canis</i> ; <i>Trichophyton</i> species)	kittens most often affected; disease (a scaly, spreading skin condition) may be transmitted to children: some cats may carry the disease and show no clinical signs
Toxoplasmosis	protozoan ( <i>Toxoplasma gondii</i> )	toxoplasmosis probably occurs frequently in cats; chronic forms affect abdominal organs; organisms may invade nearly any body tissue
Ear mites, ear inflammation (otitis externa)	mite ( <i>Otodectes cynotis</i> )	acquired through contact of kitten with an infected mother; constant scratching of ears eventually causes raw sores and scabs; treatment includes killing the mites and controlling secondary bacterial infections
Osteodystrophy fibrosa (osteogenesis imperfecta)	nutritional deficiencies	once considered congenital in kittens but probably is nutritional, resulting from a calcium deficiency; lameness, first noted at ten to 15 weeks, may lead to paralysis of rear legs, slow growth, bone fractures, and severe pain; treatment includes a diet with adequate calcium
"Fur ball" disease	physical agent	hair balls accumulate in stomach as a result of constant grooming; surgical removal sometimes necessary

that has been treated with mercury compounds to retard spoilage. Dogs may be poisoned by the arsenic found in pesticides or by strychnine, which is found in rat poison. Many plants are **poisonous** to animals if eaten, such as bracken fern, which poisons cattle and horses, and ragwort plant, which contains a substance poisonous to the liver of cattle.

Examination of an animal's urine may reveal evidence of kidney diseases or diseases of the entire urinary system or a generalized systemic disease. The presence of protein in the urine of dogs indicates acute kidney disease (nephritis). Although constituents of bile normally are found in the urine of dogs, the quantity increases in dogs with the presence of infectious hepatitis, a disease of the liver. The presence of abnormal amounts of the simple carbohydrate glucose and of ketone bodies (organic compounds involved in metabolism) in an animal's urine is used to diagnose diabetes mellitus, a disease in which the pancreas cannot form adequate quantities of a substance (insulin) important in regulating carbohydrate metabolism. The urine of horses with **azoturia** (excessive quantities of nitrogen-containing compounds in the urine, Table 3) or muscle breakdown may contain a dark-coloured molecule called myoglobin.

The presence of eggs or parts of worms in the excrement of animals suspected of suffering from intestinal parasites, such as roundworms, tapeworms, or flatworms, aids in diagnosis. Feces that are light in colour, have a rancid odour, contain fat, and are poorly formed may indicate the existence of a chronic disease of the pancreas. Clay-coloured fatty feces suggest obstruction of the bile duct, which conveys bile to the intestine during digestion.

The identification of a disease-causing micro-organism within an animal enables the veterinarian to choose the best drug for therapy. Agglutination tests, which utilize serum samples of animals and micro-organisms suspected of causing a disease, many times confirm the presence of the following bacterial diseases (Table 2): brucellosis in cattle and swine, salmonellosis in swine, leptospirosis in cattle, and actinobacillosis in swine and cattle. Other tests measure the antibodies (specific proteins formed in response to a foreign substance in the body) formed against a disease-causing agent, such as those that cause brucellosis, foot-and-mouth disease, infectious hepatitis in dogs, and fowl pest.

The modern veterinary diagnostic laboratory performs, in addition to the tests mentioned, tests of cells in the

bone marrow; specific-organ-function tests (liver, kidney, pancreas, thyroid, adrenal, and pituitary glands); radioisotope tests, tissue biopsies, and histochemical analyses; and tests concerning blood coagulation and body fluids.

**III. Survey of animal diseases**

INFECTIOUS AND NONINFECTIOUS DISEASES

Disease, the departure from the normal physiological state of an organism, may be either infectious or noninfectious. The term infection implies an interaction between two living organisms, called the host and the parasite. Infection is a type of parasitism, which may be defined as the state of existence of one organism (the parasite) at the expense of another (the host). Agents (e.g., certain viruses, bacteria, fungi, protozoans, worms, and arthropods) capable of producing disease are called pathogens. The term pathogenicity refers to the ability of a parasite to enter a host and produce disease; the degree of pathogenicity—that is, the ability of an organism to cause infection—is known as virulence. The capacity of a virulent organism to cause infection is influenced both by the characteristics of the organism and by the ability of the host to repel the invasion and to prevent injury. A pathogen may be virulent for one host but not for another. Pneumococcal bacteria, for example, have a low virulence for mice and are not found in them in nature; if introduced experimentally into a mouse, however, the bacteria overwhelm its body defenses and cause death.

Many pathogens (e.g., the bacterium that causes anthrax, Table 2) are able to live outside the animal's body until conditions occur that are favourable for entering and infecting it. Pathogens enter the body in various ways—by penetrating the skin or an eye, by being eaten with food, or by being breathed into the lungs. After their entry into a host, pathogens actively multiply and produce disease by interfering with the functions of specific organs or tissues of the host. Table 2 lists some infectious and parasitic diseases of animals and the causative agents.

Before a disease becomes established in a host, the barrier known as immunity must be overcome. Immunity is the ability of a host's body to prevent or to overcome an invasion by a virulent pathogen. Defense against infection is provided by a number of chemical and mechanical barriers, such as the skin, mucous membranes and secretions, and components of the blood and other body fluids. Antibodies, which are proteins formed in response to a specific substance (called an antigen) recog-

Identifica-  
tion of  
causative  
agents

**Table 6: Some Common Diseases of Poultry**

name(s) of disease	causative agent	nature of disease
Coccidiosis	protozoans ( <i>e.g.</i> , <i>Emeria tenella</i> )	affected birds show low egg production, poor growth rates, and high mortality; cecal coccidiosis (the cecum is a pouch in the large intestine), a serious disease caused by <i>tenella</i> ; many protozoa produce intestinal symptoms
Blackhead (histomoniasis)	protozoan ( <i>Histomonas meleagridis</i> )	may kill up to 50 percent of a turkey flock; symptoms include droopy wings and damage to liver and cecum; <i>Heterakis gallinae</i> , a worm in the turkey cecum, probably transmits the protozoan
Psittacosis (ornithosis)	virus ( <i>Bedsonia</i> )	affects parakeets, canaries, parrots, pigeons, and other pet birds; symptoms include lack of appetite, ruffled feathers; can be transmitted to man
Avian lymphomatosis	virus	an infectious disease; manifestations include formation of tumours; three forms occur, depending on location of tumours: visceral (internal organs); neural (nerve); and ocular (eye) lymphomatosis
Pullorum disease	bacterium ( <i>Salmonella pullorum</i> )	affects most species of fowl (chickens); mortality rate high, also reduces egg productivity of mature females; transmitted from egg-producing organs of hen to chick; disease causes hemorrhages throughout body
Digestive diseases in caged birds	functional disturbance	symptoms include slowly emptying, loosely hanging crop (digestive organ); deficiency of grit (particles that aid in digestion) results in poor nutrition; symptoms include obstruction of crop, vomiting, intestinal inflammation, and various liver disorders
Fractured legs in caged birds	physical agent	in canaries, about 70 percent of fractures involve the metatarsus (hind-foot); in budgerigars, 70 percent involve the tibia (hindleg)

nized by the body as foreign, are another important factor in preventing infection. Immunity among animals varies with species, general health, heredity, environment, and previous contact with a specific pathogen (see also IMMUNITY).

As certain bacterial species multiply, they may produce and liberate poisons, called exotoxins, into the tissues; other bacterial pathogens contain toxins, called endotoxins, which produce disease only when liberated at the time of death of the bacterial cell. Some bacteria, such as certain species of *Clostridium* and *Bacillus*, have inactive forms called spores, which may remain viable (*i.e.*, capable of developing into active organisms) for many years; spores are highly resistant to environmental conditions such as heat, cold, and chemical compounds called disinfectants, which are able to kill many active bacteria.

The term infestation indicates that animals, including spiny-headed worms (Acanthocephala), roundworms (Nematoda), flatworms (Platyhelminthes), and arthropods such as lice, fleas, mites, and ticks, are present in or on the body of a host. An infestation is not necessarily parasitic. Table 2 includes various infestations.

Noninfectious diseases are not caused by virulent pathogens and are not communicable from one animal to another (see Table 3). They may be caused by hereditary factors or by the environment in which an animal lives. Many metabolic diseases of animals are caused by an unsuitable alteration, sometimes brought about by man, in an animal's genetic constitution or in its environment. Metabolic diseases usually result from a disturbance in

the normal balance of the physiological mechanisms that maintain stability, or homeostasis. Examples of metabolic diseases include overproduction or underproduction of hormones, which control specific body processes; nutritional deficiencies; poisoning from such agents as insecticides, fungicides, herbicides, fluorine, and poisonous plants; and inherited deficiencies in the ability to synthesize active forms of specific enzymes, which are the proteins that control the rates of chemical reactions in the body.

Excessive inbreeding (*i.e.*, the mating of related animals) among all domesticated animal species has resulted in an increase in the number of metabolic diseases and an increase in the susceptibility of certain animals to infectious diseases.

#### ZOOZOSES

As stated previously, zoonoses are human diseases acquired from or transmitted to any other vertebrate animal. Zoonotic diseases are common in currently developing countries throughout the world and constitute, with starvation, the major threat to human health. More than 150 such diseases are known; some examples are listed in Table 9.

Zoonoses may be separated into four principal types, depending on the mechanisms of transmission and epidemiology. One type includes the direct zoonoses, such as rabies and brucellosis, which are maintained in nature by one vertebrate species. The transmission cycle of the cyclozoonoses, of which tapeworm infections are an example, requires at least two different vertebrate species.

Types of zoonoses

**Table I: Some Common Diseases of Fish**

name(s) of disease	causative agent	nature of disease
Mouth fungus (cotton-wool disease)	bacterium ( <i>Chondrococcus columnaris</i> )	fungus-like disease inaccurately named, since causative agent is a bacterium; a contagious disease; produces swollen lips, loss of appetite, and a "cotton-wool-like" growth on mouth; treatment utilizes antibiotic drugs
Tailrot	bacteria ( <i>Haemophilus</i> and <i>Aeromonas</i> species)	infection may spread from fin and tail to body and cause death; disease may be controlled by surgery or use of drugs
Dropsy (ascites)	possibly associated with a bacterium ( <i>Aeromonas punctata</i> )	characterized by accumulation of liquid in internal organs and tissues, inflammation of intestines, and infection of liver; epidemics can occur; most treatment except the antibiotic chloramphenicol unreliable
Red pest of eels	bacteria ( <i>Vibrio anguillarum</i> ; <i>Aeromonas</i> species)	<i>Vibrio</i> multiplies readily in salty water (1.5 to 3.5 percent) and can cause extensive blood-coloured areas on skin; <i>Aeromonas</i> species produce ulcers in the skin
Fish tuberculosis	bacteria ( <i>Mycobacterium</i> species)	symptoms include loss of appetite, emaciation (leanness), skin defects, blood spots, ulcers, and cysts (on internal organs)
Eye fungus	fungus	infection follows damage to cornea of eye; a typical symptom is a white cotton-wool growth hanging from eye; untreated eye is destroyed within days; untreated fish die
Fish lice	louse ( <i>Argulus</i> species)	bloodsucking parasites on the surfaces of many fish species
Skin flatworms (flukes)	platyhelminth	small parasites; cause skin colour to fade, blood spots, increased respiratory rate, and debilitation
Bursting of the swim bladder	physical agent	occurs if fish in deep water rise to surface too rapidly; fatal
Air embolism	physical agent	occurs if oxygen content of water is higher than normal, as when water temperature is higher than normal; bubbles of nitrogen gas in blood cause the disease

Noninfectious diseases

Table 8: Some Important Diseases of Some Common Laboratory Animals

name or type of disease	causative organism	name or type of disease	causative organism
<b>Mice</b>		<b>Rats (cont.)</b>	
Bacterial diseases		Protozoal diseases	
Mouse pneumonitis	<i>Miyagawanella broncho-pneumoniae</i>	Coccidiosis	<i>Eimeria nieschulzi</i> <i>Hepatozoon muris</i> <i>Toxoplasma gondii</i> <i>Nosema cuniculi</i>
Eperythrozoonosis	<i>Eperythrozoon coccoides</i>	Toxoplasmosis	
Mycoplasma infection	<i>Mycoplasma</i> species	Nosematosis	(encephalitozoonosis)
Pus-producing lesions	<i>Pseudomonas aeruginosa</i>	Helminthic diseases	
Salmonellosis	<i>Salmonella</i>	Mouse tapeworm	<i>Hymenolepis nana</i>
Pseudotuberculosis	<i>Pasteurella pseudotuberculosis</i>	Rat tapeworm	<i>Hymenolepis diminuta</i>
Rat-bite fever	<i>Streptobacillus moniliformis</i>	Cat tapeworm	<i>Taenia taeniaeformis</i>
Fungal disease		Bladder threadworm	<i>Trichosomoides crassicauda</i>
Dermatophytoses (ringworm)	<i>Trichophyton</i> species	Cecal worm	<i>Heterakis spumosa</i>
Viral diseases		Liver threadworm	<i>Capillaria hepatica</i>
Mouse pox (ectromelia)	Ectromelia virus	Arthropod diseases	
Poliomyelitis of mice	Theiler's encephalomyelitis virus	Sucking louse	<i>Polyplax spinulosa</i>
(Theiler's disease)		Ear mite	<i>Notoedres notoedres</i>
EDIM (epizootic diarrhea of infant mice)	EDIM virus	Hair mite	<i>Radfordia ensifera</i>
LIVIM (lethal intestinal virus of infant mice)	LIVIM virus	Guinea pigs	
Protozoal diseases		Bacterial and fungal diseases	
Coccidiosis	<i>Eimeria falciformis</i>	Streptococcal infections	<i>Streptococcus</i> species
Toxoplasmosis	<i>Toxoplasma gondii</i>	(cervical abscesses and lymphadenitis)	
Nosematosis	<i>Nosema cuniculi</i>	Salmonellosis	<i>Salmonella</i> species
(encephalitozoonosis)		Bronchopneumonia	<i>Bordetella bronchiseptica</i>
Helminthic diseases		Respiratory infections	<i>Klebsiella</i> species
Mouse tapeworm	<i>Hymenolepis nana</i>	Dermatophytoses	<i>Trichophyton</i> species
Rat tapeworm	<i>Hymenolepis diminuta</i>	(ringworm, fungus)	
Cat tapeworm	<i>Taenia taeniaeformis</i>	Viral diseases	
Mouse pinworm	<i>Aspicularis tetraptera</i>	Cytomegalic inclusion disease	salivary-gland virus
Pinworm	<i>Syphacia obvelata</i>	Lymphocytic choriomeningitis	LCM virus
Liver threadworm	<i>Capillaria hepatica</i>	Protozoal diseases	
Arthropod diseases		Coccidiosis	<i>Eimeria caviae</i>
Sucking louse	<i>Polyplax serratus</i>	Toxoplasmosis	<i>Toxoplasma gondii</i>
Mite	<i>Psorergates simplex</i>	Hamsters	
<b>Rats</b>		Cytomegalic inclusion disease	salivary-gland virus
Bacterial and fungal diseases		Encephalomyocarditis	picorna virus
Mycoplasma infection		Wet tail (regional ileitis)	virus, bacterium
(associated with chronic pneumonia)	<i>Mycoplasma</i> species	Salmonellosis	<i>Salmonella</i> (bacterium)
Salmonellosis	<i>Salmonella</i> species	Mouse tapeworm	<i>Hymenolepis nana</i> (helminth)
Infectious anemia	<i>Haemobartonella muris</i>	Rabbits	
Pus-forming lesions	<i>Pseudomonas aeruginosa</i> <i>Pasteurella pneumotropica</i> <i>Streptobacillus moniliformis</i> <i>Diplococcus pneumoniae</i>	Pasteurellosis (snuffles)	<i>Pasteurella</i> (bacterium)
Rat-bite fever		Spirochetosis (vent disease)	<i>Spirochaeta</i> (bacterium)
Leptospirosis (Weil's disease)	<i>Leptospira</i> species	Mucoid enteritis	bacterium
Dermatophytoses (ringworm; fungus)	<i>Corynebacterium kutscheri</i> <i>Trichophyton</i>	Myxomatosis	myxoma virus
Viral diseases		Rabbit pox	virus
Pneumonitis	rat virus (Kilham)	Coccidiosis	<i>Eimeria</i> species (protozoan)
Salivary-gland disease	rabula virus	Ear mites	<i>Notoedres notoedres</i>
Hemorrhagic encephalitis	hemorrhagic encephalopathy virus (HER)	Nosematosis	<i>Nosema cuniculi</i>

Both vertebrate and invertebrate animals are required as intermediate hosts in the transmission to man of **metazoonoses**; arboviral and trypanosomal diseases are examples of **metazoonoses**. The cycles of **saprozoonoses** (e.g., histoplasmosis) may require, in addition to vertebrate hosts, specific environmental sites or reservoirs.

Most animals that serve as reservoirs for **zoonoses** are domesticated and wild animals with which man commonly associates. People in occupations such as veterinary medicine and public health, therefore, have a greater exposure to **zoonoses** than do those in occupations less closely concerned with animals.

In addition to the numerous human diseases spread by contact with the parasitic worm helminth and by contact with arthropods (see Table 9), many diseases are transmitted by the bites and the venom of certain animals; poisonous or diseased food animals also transmit diseases. Dog bites may result in serious injury to tissues and also can transmit bacterial infections and rabies, a disease of viral origin. The bite of a diseased rat may transmit any of several diseases to man, including plague, salmonellosis, leptospirosis, and rat-bite fevers. Cat-scratch disease may be transmitted through cat bites, and the deadly herpes B virus can be spread by monkey bites. The bites of venomous snakes and fish account for considerable human discomfort and death. About 200 of the 2,500 known species of snakes are able to cause human disease. One estimate for snakebite deaths throughout the world is 30,000 to 40,000 per year, with the vast ma-

jority occurring in Asia. Poisonous wild animals inadvertently used for food include animals harbouring the anthrax bacillus, as well as those containing the causative agents of salmonellosis, trichinosis, and fish-tapeworm infection. The flesh of various types of fish is toxic to man. Japanese puffers, for example, contain the poisonous chemical compound tetrodotoxin; scombroid fish harbour *Proteus morgani*, which causes gastrointestinal diseases; and mullet and surmullet cause nervous disturbances.

Approaches to the control of **zoonoses** differ according to the type under consideration. Because the majority of direct **zoonoses** and cyclozoonoses and some saprozoonoses are most effectively controlled by techniques involving the animal host, methods used to combat these diseases are almost entirely the responsibility of veterinary medicine. A good example is the elimination of stray dogs, for they are an important factor in the control of **zoonoses** such as rabies, hydatid disease, and visceral larva migrans. In addition, the control of diseases such as brucellosis and tuberculosis in cattle involves a combination of methods—mass immunization, diagnosis, slaughter of infected animals, environmental disinfection, and quarantine. Several supportive measures for the control of disease are useful in some cases. **Air-sanitation** measures are helpful in direct **zoonoses** in which human illness is spread by droplets or dust, and **zoonotic** infections that are spread through a fluid medium, such as water or milk, sometimes can be controlled. Heat, cold,

Control of  
**zoonoses**

Table 9: A Partial List of Zoonoses (continued)

disease	causative organism	animals principally involved	disease	causative organism	animals principally involved
Protozoal diseases			Platyhelminthic diseases (cont.)		
Amebiasis	<i>Entamoeba histolytica</i>	dogs, lower primates	Sparganosis	Pseudophyllidea tape-worms	mice, carnivores including cats, and other vertebrates
Balantidiasis	<i>Balantidium coli</i>	swine			
Coccidiosis	<i>Isospora</i> species	dogs	Taeniasis, cysticercosis, and coenuriasis	<i>Taenia saginata</i> <i>Taenia solium</i> <i>Multiceps multiceps</i>	cattle swine sheep, dogs
Leishmaniasis			Nematode diseases		
Kala Azar	<i>Leishmania donovani</i>	dogs	Ancylostomiasis	<i>Ancylostoma ceylanicum</i> , other species	dogs
Oriental sore	<i>Leishmania tropica</i>	dogs, rodents	Ascariasis	<i>Ascaris suum</i>	swine
American	<i>Leishmania</i> species	dogs, wild mammals	Capillariasis	<i>Capillaria hepatica</i>	rodents
Malaria	<i>Plasmodium knowlesi</i>	monkeys	Dracunculiasis	<i>Dracunculus medinensis</i>	dogs, other carnivores
	<i>Plasmodium simium</i>	monkeys			
	<i>Plasmodium cynomolgi</i>	monkeys	Filariasis	<i>Brugia malayi</i>	primates, other mammals
Pneumocystis infection	<i>Pneumocystis carinii</i>	dogs			
Toxoplasmosis	<i>Toxoplasma gondii</i>	mammals, birds	Larva migrans	<i>Dirofilaria</i> species, occasionally other species	cats, dogs, other mammals
Trypanosomiasis	<i>Trypanosoma cruzi</i>	dogs, small mammals		<i>Ancylostoma braziliense</i> , other species	cats, dogs
	<i>Trypanosoma rangeli</i>			<i>Angiostrongylus cantonensis</i>	rats
	<i>Trypanosoma rhodesiense</i>	antelope, cattle		<i>Anisakis</i> species	fish
Platyhelminthic diseases				<i>Gnathostoma spinigerum</i>	cats, dogs, other vertebrates
Trematode (flake) diseases				<i>Toxocara canis</i> , other ascarid species	dogs, other vertebrates
Amphistomiasis	<i>Gastrodiscoides hominis</i>	swine	Oesophagostomiasis	<i>Oesophagostomum apistomum</i>	primates
Cercarial dermatitis	<i>Schistosoma</i> species	birds, mammals			
Clonorchiasis	<i>Clonorchis sinensis</i>	dogs, cats, swine, wild mammals, fish	Strongyloidiasis	<i>Strongyloides stercoralis</i> , occasionally other species	dogs, primates
Dicrocoeliasis	<i>Dicrocoelium</i> species	ruminants			
Echinostomiasis	<i>Echinostoma ilocanum</i>	cats, dogs, rodents	Ternidens infection	<i>Ternidens deminutus</i>	primates
	<i>Echinostoma</i> species		Trichinosis	<i>Trichinella spiralis</i>	swine, rodents, wild carnivores, marine mammals
Fascioliasis	<i>Fasciola hepatica</i> , F. <i>gigantica</i>	ruminants			
Fasciolopsiasis	<i>Fasciolopsis buski</i>	swine, dogs	Trichostrongylosis	<i>Trichostrongylus colubriformis</i> , occasionally other species	ruminants
Heterophyiasis	<i>Heterophyes heterophyes</i> (and other heterophids)	cats, dogs, fish			
Metagonimiasis	<i>Metagonimus yokogawai</i>	cats, dogs, fish	Arthropod diseases		
Opisthorchiasis	<i>Opisthorchis felineus</i>	cats, dogs	Acariasis	<i>Sarcoptes</i> species	domesticated animals
	<i>Opisthorchis viverrini</i> , other species	wildlife, fish	Tunga infections	<i>Tunga penetrans</i>	domesticated and wild mammals
Paragonimiasis	<i>Paragonimus westermani</i> , other species	cats, dogs, wildlife	Myiasis	<i>Cochliomyia</i> , <i>Cordylobia</i> , <i>Dermatobia</i> , <i>Gastrophilus</i> , <i>Hypoderma</i> , <i>Oestrus</i> , and other genera	mammals
Schistosomiasis	<i>Schistosoma japonicum</i>	wild and domestic mammals			
	<i>S. mansoni</i>	baboons, rodents	Pentastomid infections (including Halzoun)	<i>Linguatula</i> species, <i>Armillifer</i> species, <i>Porocephalus</i> species	dogs, snakes, and other vertebrates
	<i>S. matthei</i> , occasionally other species	cattle, sheep, antelopes			
Cestode (tapeworm) diseases					
Bertiella infection	<i>Bertiella studeri</i>	primates			
Diphyllobothriasis	<i>Diphyllobothrium latum</i>	fish, carnivores			
Dipylidiasis	<i>Dipylidium caninum</i>	dogs, cats			
Echinococcosis	<i>Echinococcus granulosus</i>	dogs, wild carnivores, domestic and wild ungulates			
	<i>E. multilocularis</i>	foxes, dogs, rodents			
Hymenolepiasis	<i>Hymenolepis diminuta</i> , <i>H. nana</i>	rats, mice			
Inermicapsifer infection	<i>Inermicapsifer madagascariensis</i>	rodents

travel

Mass immunization as a preventive technique has the advantage of allowing the resistant animal freedom of movement, unlike environmental control, in which the animal is confined to the controlled area; immunization may, however, provide only short-lived and partial protection. Mass-inoculation techniques against diseases such as Newcastle disease in chickens and distemper in mink and dogs have been successful. Animal diseases have been prevented by methods involving environmental control, including the maintenance of safe water supplies, the hygienic disposal of animal excrement, air sanitation, pest control, and the improvement of animal housing. One specific environmental program, called the portable-calf-pen system, involves routine movement of the pens to avoid a concentration of specific pathogens in them. Other programs involve the utilization of automatic and sanitary watering and feeding equipment and buildings with environmental controls. The use of chemical compounds to prevent illness (chemoprophylaxis) includes a variety of pesticides, which are used to kill insects that transmit diseases, and substances either used internally or applied to the animal's body to prevent the transmission or the development of a disease. An example is the use of sulfonamide drugs in the drinking water of poultry to prevent coccidiosis (see Table 6). Environmental-control methods in the poultry industry have resulted in the most efficient means of poultry production developed thus far.

The early detection of a disease in a population of ani-

mals—a herd of cattle, for example—is particularly useful in controlling certain chronic infectious diseases, such as mastitis, brucellosis, and tuberculosis, as well as certain noninfectious diseases such as bloat. Laboratory tests—the agglutination test in pullorum disease, the tuberculin skin test for tuberculosis, the examination of feces for eggs of specific parasites, the physical and chemical tests performed on milk to diagnose bovine mastitis—are used for the early detection of diseases in an animal population.

Methods of disease control and eradication have been successful in various countries throughout the world. In the United States, for example, the test and slaughter technique, in which simple tests are used to confirm the existence of diseased animals in a population, followed by slaughter of the affected animals, has been of great value in controlling infectious and hereditary diseases, including dourine, a venereal disease in horses, fowl plague, and foot-and-mouth disease in cattle and deer. Bovine tuberculosis has been eliminated from Denmark, Finland, and The Netherlands and reduced to a low level in various other countries, including Great Britain, Japan, the United States, and Canada, by the test and slaughter method. Many infectious diseases have been eradicated from Great Britain—sheep pox, rinderpest, pleuropneumonia, glanders, and rabies. Diseases eliminated from Australia by a combination of methods—control of agents that carry disease, the test and slaughter technique, the use of chemical agents, and more recent-

**Table 10: Animal Diseases Usually Confined to Certain Regions of the World**

name(s) of disease	animal(s) affected	causative organism	distribution	nature of disease
African horse sickness (AHS), equine plague, pestis equorum, perdesiekte	primarily horses, donkeys, mules (occasionally zebras and dogs)	AHS virus	primarily Africa and Middle East; occasionally India, Pakistan	a seasonal disease occurring in late summer; acute form, sometimes fatal within five days, involves excessive fluid in lungs; symptoms of other forms include accumulation of fluid in body cavities
African swine fever (ASF), warthog disease, Montgomery's disease	swine	ASF virus	primarily Kenya and South Africa; occasionally Europe	highly contagious; usually fatal; resembles hog cholera in clinical manifestations (high fever, weakness in hindlegs, and hemorrhages throughout body) but can be distinguished by laboratory tests and isolation of the virus
Contagious pleuropneumonia, lung plague	cattle, buffalo, yaks, sheep, goats	<i>Mycoplasma mycoides</i>	Africa, Australia, Asia, Europe	transmitted by direct animal contact or by contaminated objects; an acute disease producing pneumonia and inflammation of the lung lining; vaccines ineffective because different strains of the organism occur throughout the world
East coast fever, theileriosis, Rhodesian red water or tick fever	cattle, African and Indian water buffalo	protozoan ( <i>Theileria parva</i> )	Central Africa; East Africa	usually fatal; transmitted by three ticks containing pathogen; symptoms include high fever, swelling of lymph glands; not yet prevented effectively by vaccination
Foot-and-mouth disease (FMD), aphthous fever, aftosa	cattle, swine, sheep, goats	FMD virus	worldwide except North America, Central America, New Zealand	symptoms include high fevers, drool from mouth, where vesicles and ulcers form, and lameness; causes great economic losses throughout world; effective vaccines available
Fowl plague, fowl pest	birds, including chickens and turkeys	fowl-plague virus	Europe, Middle and Far East, Argentina, Japan	may cause no apparent symptoms; apparent symptoms include lack of appetite, swollen head, laboured breathing, and hemorrhaging
Heartwater, drunk bull sickness	cattle, sheep, goats	rickettsia ( <i>Cowdria ruminantium</i> )	Africa (southern half); Madagascar	disease has acute and mild forms; symptoms include water in the membrane around heart and in the lung cavity, hemorrhages, and twitching
Louping ill (Li), infectious encephalomyelitis in sheep, trembling ill	primarily sheep (also cattle and man)	Li virus	British Isles, Czechoslovakia, U.S.S.R.	transmitted by bite of sheep tick; characterized by fever, dullness followed by excitement, muscular spasms, leaping gait, convulsions, and death
Nagana, tsetse disease, trypanosomiasis	most domesticated animals	protozoan ( <i>Trypanosoma</i> species)	Africa	may be acute or inapparent; symptoms may include anemia resulting from red-blood-cell destruction; pathogen transmitted by tsetse fly (over 20 species of <i>Glossina</i> ); prevents effective cattle production in nearly all of West Africa
Rift Valley fever (RVF), infectious enzootic hepatitis	cattle, sheep (occasionally man)	RVF virus	Central and South Africa	spread by bloodsucking insects associated with wild animals; symptoms include abdominal pain resulting from liver damage; young animals usually die; mature ones may recover
Rinderpest, cattle plague	cattle, sheep, goats, wild ruminants; yaks, caraboo, gazelles, deer	rinderpest virus	primarily Asia, Africa, Philippines; rarely Europe	rapidly fatal; symptoms include fluid losses (dehydration) from diarrhea caused by massive pathological changes (e.g., hemorrhages, ulcers) in intestinal tract
Surra	primarily in camels and horses; many animals susceptible	protozoan ( <i>Trypanosoma evansi</i> )	primarily Far East (e.g., China), India, Near East (e.g., Iran); North Africa	transmitted by bloodsucking flies and mosquitoes; symptoms include anemia, loss of weight, large swellings in limbs, abdomen, and sex organs
Teschen disease, swine encephalomyelitis, porcine poliomyelitis	swine	Teschen virus	primarily Europe	symptoms include prostration, immobilization, nervous tremors, convulsions, paralysis of legs

ly, biological control—include hog cholera, rinderpest, scrapie, glanders, surra, rabies, and foot-and-mouth disease.

In biological control, enemies of the agents that transmit the disease, enemies of the reservoir host, or a specific parasite are introduced into the environment. If a natural enemy of the tsetse fly could be found, for example, African sleeping sickness in man and trypanosomiasis in cattle could be controlled in West Africa. Successful biological control of the European-rabbit population in Australia has been accomplished through the use of the myxomatosis virus, which is transmitted by mosquitoes and causes the formation of malignant tumours. Although the Brazilian white rabbit is relatively unaffected by the virus, it causes rapid death in the European rabbit. The elimination of the European rabbit in France by the virus was accompanied by a decrease in tick-borne typhus in people, suggesting that the rabbit may be a significant intermediate host for the causative agent, *Rickettsia conorii*. Screwworms, an immature form of the fly *Cochliomyia hominivorax*, have been eradicated in the United States by the release of more than 3,000,000,000 sterilized males.

Disease control and elimination programs require many sophisticated techniques, in addition to diagnosis and the

slaughter of affected animals. They include: the control of insects known to transmit diseases; the cooperation of animal owners with disease-control programs; the development through research of new diagnostic tests for use on large populations; the eradication of animal species from areas in which they are known to transmit disease; sterilization of strains of animals known to carry inheritable metabolic diseases; and effective meat inspection.

## Diseases of Plants

All species of plants, wild and cultivated alike, are subject to disease. Although each species is susceptible to characteristic diseases, these are, in each case, relatively few in number. The occurrence and prevalence of plant diseases vary from season to season, depending on the presence of the pathogen (disease-causing organism), environmental conditions, and the crops and varieties grown. Some plant varieties are particularly subject to outbreaks of diseases; others are more resistant to them.

This article is divided into the following sections:

- I. General features
  - Nature and importance of plant diseases
  - Disease development and spread
  - Diagnosis of plant diseases
- II. Classification and control
  - Noninfectious disease-causing agents
  - Infectious disease-causing agents
  - Principles of disease control

### I. General features

#### NATURE AND IMPORTANCE OF PLANT DISEASES

Some 80,000 diseases of plants have been recorded throughout the world; more than 50,000 occur in the United States, where the average annual loss from plant diseases and attack by nematodes (small roundworms), despite extensive control measures, is estimated at about \$4,000,000,000, or equivalent to the production of over 40,000,000 acres (16,000,000 hectares). This is a loss of about 12 percent, but it is small compared with the total loss that would occur if adequate disease-control measures were unavailable for most crops. In many developing areas of the world, where controls are not used or are unavailable, losses of up to 30 to 50 percent may occur on major crops each year.

Plant diseases are known from times preceding the first writings of mankind. Fossil evidence indicates that plants were affected by disease 250,000,000 years ago. The Bible and other early writings mention diseases, such as rusts, mildews, blights, and blast, that have caused famine and drastic changes in the economy of nations since the dawn of recorded history. Other plant-disease outbreaks with similar far-reaching effects in recent times include potato late blight (*Phytophthora infestans*) in Ireland (1845-60); Sigatoka leaf spot (*Mycosphaerella musicola*) and Panama disease (*Fusarium oxysporum* form species cubense) in Central America (1900-65); powdery and downy mildews (*Uncinula necator* and *Plasmopara viticola*) of grape in France (1851 and 1878); coffee rust (*Hemileia vastatrix*) in Ceylon (starting in the 1870s); *Fusarium* wilts of cotton and flax (*Fusarium oxysporum* form species vasinfectum and *F. oxysporum* form species lini),

southern bacterial wilt of tobacco (*Pseudomonas solanacearum*—early 1900s); black stem rust of wheat (*Puccinia graminis* tritici—1916, 1935, 1953-54); and southern corn-leaf blight (*Helminthosporium maydis*—1970) in the United States.

**Diseases—a normal part of nature.** Plant diseases are a normal part of nature and one of many ecological factors that help keep the hundreds of thousands of living plants and animals in balance with one another. Man has carefully selected and cultivated plants for food, clothing, shelter, fibre, and beauty for thousands of years. Disease is just one of many hazards that must be considered when plants are taken out of their natural environment and grown in pure stands under what are often abnormal conditions.

Many valuable crop and ornamental plants are very susceptible to disease and would have difficulty surviving in nature without man's help. Cultivated plants are often more susceptible to disease than are their wild relatives. This is because large numbers of the same species or variety, having a uniform genetic background, are grown close together, sometimes over many thousands of square miles. A pathogen, or disease-causing organism, may spread rapidly when established under these conditions.

**Definitions of plant disease.** There is no sharp distinction between the healthy and diseased condition (see DISEASE). In general, a plant becomes diseased when it is continuously disturbed by some causal agent that results in an abnormal physiological process. The primary causal factor, which may be a living disease-causing organism (pathogen) or an unfavourable environmental condition, disrupts the plant's normal structure, growth, function, or activities; the result is an interference with one or more essential physiological or biochemical systems. The resulting disease is expressed in characteristic pathological conditions called symptoms. Knowledge of normal growth habits, variety characteristics, and normal variability of plants within a species—as these relate to the conditions under which the plants are growing—is required for recognition of disease.

Injury, in contrast, usually results from a momentary or discontinuous effect, such as lightning, hail, extreme variations in temperature or availability of water, toxic chemicals in the air and soil, or wounding by an insect or rodent.

The study of plant diseases is called plant pathology. Pathology is derived from the two Greek words pathos (suffering, disease) and logos (discourse, study). Plant pathology thus means a study of the diseased plant.

Etiology is the study of the nature, classification, and life histories of the pathogens (e.g., bacteria, fungi, viruses, mycoplasmas, nematodes, and parasitic flowering plants) causing infectious diseases. Many pathogens, especially among the bacteria and fungi, spend part of their life cycles as pathogens and the remainder as saprophytes—organisms that live on dead organic matter.

#### DISEASE DEVELOPMENT AND SPREAD

**Pathogenesis and saprogenesis.** Pathogenesis is the stage of disease in which the pathogen is in intimate association with living host tissue. Three fairly distinct stages are involved: (1) Inoculation—transfer of the pathogen to the infection court, or area in which invasion of the plant occurs. The infection court may be the unbroken plant surface, a variety of wounds, or natural openings—e.g., stomates (microscopic pores in leaf surfaces), hydathodes (stomate-like openings that secrete water), or lenticels (small openings in tree bark). (2) Incubation—the period of time between the arrival of the pathogen in the infection court and the appearance of symptoms. (3) Infection—the appearance of disease symptoms accompanied by the establishment and spread of the pathogen.

Saprogenesis is the part of the pathogen's life cycle when it is not in vital association with living host tissue and either continues to grow in dead host tissue or becomes dormant. During this stage, some fungi produce their sexual fruiting bodies; the apple scab (*Venturia inaequalis*), for example, produces perithecia, flask-shaped spore-

Injury and disease contrasted

Economic impact of plant diseases

producing structures, in fallen apple leaves. Other fungi produce compact resting bodies, such as the sclerotia formed by certain root- and stem-rotting fungi (*Rhizoctonia solani* and *Sclerotinia sclerotiorum*) or the ergot fungus (*Claviceps purpurea*). These resting bodies, which are resistant to extremes in temperature and moisture, enable the pathogen to survive for months or years in soil and plant debris in the absence of a living host.

**Epiphytotics.** When a disease affects large numbers of individual plants, it is called an epidemic (meaning "on or among people"). A more precise term, however, is epiphytotic ("on plants"). In contrast, endemic (enphytotic) diseases occur to some extent in the same area each year and generally cause little concern.

Epiphytotics affect a high percentage of the host plant population, sometimes over a wide area. They may be mild or destructive and local or regional in occurrence. Epiphytotics result from various combinations of factors, including the right combination of climatic conditions. An epiphytotic may occur, for example, when a pathogen is introduced into some area in which it had not previously existed. Examples of this condition include the downy mildews (*Sclerospora* species) and rusts (*Puccinia* species) of corn in Africa during the 1950s; the introduction of the coffee-rust fungus into Brazil in the 1960s, and the entrance of the chestnut blight (*Endothia parasitica*) into the United States shortly after 1900. In addition, when new plant varieties are produced by plant breeders without regard for all epiphytotic diseases that occur in the same area to some extent each year (but which are normally of minor importance), some of these varieties may prove very susceptible to previously unimportant pathogens. Examples of this situation include the development of oat varieties with Victoria parentage, which, although highly resistant to rusts (*Puccinia graminis* avenae and *P. coronata* avenae) and smuts (*Ustilago avenae*, *U. kollerii*), proved very susceptible to *Helminthosporium* blight (*H. victoriae*), formerly a minor disease of grasses. The destructiveness of this disease resulted in a major shift of oat varieties on 50,000,000 acres in the U.S. in the mid-1940s. Maize (corn) with male-sterile cytoplasm (*i.e.*, plants with tassels that do not extrude anthers or pollen), grown on 60,000,000 acres in the U.S., was attacked in 1970 by a virulent new race of the southern corn-leaf blight fungus (*Helminthosporium maydis* race T), resulting in a loss of about 700,000,000 bushels of corn. In 1971 the new *Helminthosporium* race was widely disseminated and was reported from most continents. Finally, epiphytotics may occur when host plants are cultivated in large acreages where previously little or no land was devoted to that crop.

Epiphytotics may occur in cycles. When a plant disease first appears in a new area, it may grow rapidly to epiphytotic proportions. In time, the disease wanes, and, unless the host species has been completely wiped out, the disease subsides to a low level of incidence and becomes enphytotic. This balance may change dramatically by conditions that favour a renewed epiphytotic. Among such conditions are weather (primarily temperature and moisture), which may be very favourable for multiplication, spread, and infection by the pathogen; introduction of a new and more susceptible host; development of a very aggressive race of the pathogen; and changes in cultural practices that create a more favourable environment for the pathogen.

**Environmental factors affecting disease development.** Important environmental factors that may affect development of plant diseases and determine whether they become epiphytotic, include temperature, relative humidity, soil moisture, soil acidity (pH), soil type, and soil fertility.

**Temperature.** Each pathogen has an optimum temperature for growth. In addition, different growth stages of the fungus, such as the production of spores (reproductive units), their germination, and the growth of the mycelium (the filamentous main fungus body), may have slightly different optimum temperatures. Storage temperatures for certain fruits, vegetables, and nursery stock are manipulated to control fungi and bacteria that cause storage decay, provided the temperature does not change

the quality of the products. Little, except limited frost protection, can be done to control air temperature in fields, but greenhouse temperatures can be regulated to check disease development.

Knowledge of optimum temperatures, usually combined with optimum moisture conditions, permits forecasting, with a high degree of accuracy, the development of such diseases as blue mold of tobacco (*Peronospora tabacina*), downy mildews of vine crops (*Pseudoperonospora cubensis*) and lima beans (*Phytophthora phaseoli*), late blight of potato and tomato (*Phytophthora infestans*), leaf spot of sugar beets (*Cercospora beticola*), and leaf rust of wheat (*Puccinia recondita tritici*). Effects of temperature may mask symptoms of certain virus and mycoplasma diseases, however, making them more difficult to detect.

**Relative humidity.** Relative humidity is very critical in fungal spore germination and the development of storage rots. Rhizopus soft rot of sweet potato (*Rhizopus stolonifer*) is an example of a storage disease that does not develop if relative humidity is maintained at 85 to 90 percent, even if the storage temperature is optimum for growth of the pathogen. Under these conditions, the sweet-potato root produces suberized (corky) tissues that wall off the *Rhizopus* fungus.

High humidity favours development of the great majority of leaf and fruit diseases caused by fungi and bacteria. Moisture is generally needed for fungal spore germination, the multiplication and penetration of bacteria, and the initiation of infection. Germination of powdery mildew spores, however, is inhibited by water; germination occurs best at 90 to 95 percent relative humidity. Diseases in greenhouse crops—such as leaf mold of tomato (*Cladosporium fulvum*) and decay of flowers, leaves, stems, and seedlings of flowering plants, caused by *Botrytis* species—are controlled by lowering air humidity or by avoiding spraying plants with water. The combination of heating and circulating greenhouse air usually lowers the humidity enough to prevent these fungi from causing infection.

Low humidity also may be destructive to plants. Leaf scorch, a nonparasitic disease, is common on trees in exposed locations following hot, dry, windy weather when water is lost from leaves faster than it is absorbed by roots. Leaf scorch and sudden flower drop are common indoor plant problems because the humidity in a home, apartment, or office is usually below about 30 percent.

**Soil moisture.** High or low soil moisture may be a limiting factor in the development of certain root-rot diseases. High soil-moisture levels favour development of destructive water mold fungi, such as species of *Aphanomyces*, *Pythium*, and *Phytophthora*. Excessive watering of house plants is a common problem. Overwatering, by decreasing oxygen and raising carbon dioxide levels in the soil, makes roots more susceptible to root-rotting organisms.

Diseases, such as take-all of cereals (*Ophiobolus graminis*); charcoal rot of corn, sorghum, and soybean (*Macrophomina phaseoli*); common scab of potato (*Streptomyces scabies*); and onion white rot (*Sclerotium cepivorum*) are most severe under low soil-moisture levels.

**Soil pH.** Soil pH, a measure of acidity or alkalinity, markedly influences a few diseases, such as common scab of potato and clubroot of crucifers (*Plasmodiophora brassicae*). Growth of the potato-scab organism is suppressed at a pH of 5.2 or slightly below (pH 7 is neutral; numbers below 7 indicate acidity and those above 7 indicate alkalinity). Scab is not normally a problem when the natural soil pH is around 5.2. Some farmers add sulfur to their potato soil to keep the pH around 5.0. Clubroot of crucifers (members of the mustard family), on the other hand, can usually be controlled by thoroughly mixing lime into soil until the pH becomes 7.2 or higher.

**Soil type.** Certain pathogens are favoured by loam soils and others by clay soils. *Phymatotrichum* root rot attacks cotton and some 2,000 other plants in the southwestern United States. This fungus is serious only in black alkaline soils—pH 7.3 or above—that are low in

Disease forecasting

Factors leading to epiphytotics

Controlling acidity of soils

organic matter. Fusarium wilt disease, which attacks a wide range of cultivated plants, causes more damage in lighter and higher (topographically) soils. Nematodes are also most damaging in lighter soils that warm up quickly.

**Soil fertility.** Greenhouse and field experiments have shown that raising or lowering the levels of certain nutrient elements required by plants frequently influences the development of some infectious diseases—for example, fire blight of apples and pears; stalk rots of corn and sorghum; Botrytis blights; Septoria diseases; powdery mildew of wheat; and northern leaf blight of corn. These diseases and many others are more destructive after application of excessive amounts of nitrogen fertilizer. This condition can often be counteracted by adding adequate amounts of potash, a fertilizer containing potassium.

A superabundance of nitrogen may cause deficiency symptoms of potassium, zinc, or other nutrient elements; a lack of or delay in flower and fruit development; and a predisposition to winter injury. If potassium is high, calcium and magnesium deficiencies may occur. Deficiencies or excesses of phosphorus, iron, zinc, manganese, boron, molybdenum, sulfur, copper, and several other elements are known to cause noninfectious diseases.

**Ingredients needed for disease development.** Infectious disease cannot develop if any one of the following three basic ingredients is lacking: (1) the proper environment, the most important environmental factors being the amount and frequency of rains or heavy dews, the relative humidity, and the air and soil temperature; (2) the presence of a virulent pathogen; and (3) a susceptible host. Effective disease control measures are aimed at breaking this environment–pathogen–host triangle. Loss resulting from disease is reduced, for example, if the host can be made more resistant or immune through such techniques as plant breeding. In addition, the environment can be made less favourable for invasion by the pathogen and more favourable for the growth of the host plant. Finally, the pathogen, or disease agent, can be killed or prevented from reaching the host. These basic methods of control can be divided into a number of cultural and chemical practices to help keep disease in check.

#### DIAGNOSIS OF PLANT DISEASES

Rapid and accurate diagnosis of disease is necessary before proper control measures can be suggested. It is the first step in the study of any disease. Diagnosis is largely based on characteristic symptoms expressed by the diseased plant. Identification of the pathogen (by "signs," see Table 2) is also essential to diagnosis.

Three steps involved in diagnosis include careful observation and classification of the facts, evaluation of the facts, and a logical decision as to the cause.

**Variable factors affecting diagnosis.** A skilled diagnostician must know what is normal for an affected plant species; its local air and soil environment; the cultural conditions under which it is growing; and the pathogens described for the area; and the disease-developing potential of the pathogen. Diagnosis is best done in the presence of the growing plant. Disease is suspected when, for example, part or all of a plant starts to die. Disease is also indicated when blossoms, leaves, stems, roots, or other plant parts are abnormal—*i.e.*, misshapen, curled, discoloured, overdeveloped, or underdeveloped. Diseased plants also often fail to respond normally to fertilizing, watering, pruning, insect and mite control, or other recommended practices. Finally, if the plant or variety declines in vigour and productivity after performing well for years, this may be an indication of disease.

Other factors or agencies, however, may produce similar or identical symptoms. Some of these have been described; numerous others that exist must be considered when plants are adversely affected.

For example, an affected plant may not be adapted to the area in which it is growing. It may not be able to withstand the extremes in soil moisture, temperature, wind, light, or humidity of the local situation. Damage to

plants may be caused by insects, mites, rodents, pets, or humans. The soil may be poorly drained, gravelly, or overly sandy; it may be covering buried debris—boards, cement blocks, bricks, and mortar; or it may be too dry or otherwise unfavourable for good plant growth. Problems are also caused by high winds, hail, lightning, blowing sand, a heavy load of snow or ice, flooding, fire, ice-removal chemicals, mechanical injury by garden tools or machinery, and fumes from weed-killing chemicals, trash burners, nearby industrial plants, or car exhaust. The affected plant may have received different treatment from nearby healthy ones—watering, fertilizing, chemical pest control, pruning, or depth of planting are examples. If different species or kinds of plants in the same area have similar symptoms, the chances are that plant disease is not involved. Most infectious diseases are highly specific for individual or closely related plant species and similar symptoms on unrelated plants are usually an indication of some environmental factor rather than a disease-causing organism.

Examination of leaves is usually considered to be the best starting point in diagnosis. Leaves are often the first part to show symptoms and are normally the easiest to examine. Localized spotting or blighting, for example, which may be caused by a wide range of fungi and some bacteria, commonly appears one to two weeks after periods of rainy, cloudy weather. The colour, size, shape, and margins of spots and blights (lesions) are often associated with a particular fungus or bacterium. Many fungi produce "signs" of disease, such as mold growth or fruiting bodies that appear as dark specks in the dead area. Early stages of bacterial infections that develop on leaves or fruits during humid weather often appear as dark and water-soaked spots with a distinct margin and sometimes a halo; a lighter coloured ring around the spot.

Low winter temperatures and late spring or early fall freezes cause blasting (sudden death) of leaf and flower buds or sudden blighting (discoloration and death) of tender foliage.

Insect-injured leaves usually show evidence of feeding, such as holes, discoloration, stippling, blotching, downward curling, or other deformations.

Scorching of leaf margins and between the veins is common following hot, dry, windy weather. Similar symptoms are produced by an excess of water, imbalance of essential plant elements, an excess of soluble salts, changes in the soil water table or soil grade, gas or fume injury, and root injury or disease.

Virus diseases, such as mosaics and yellows, are sometimes confused with injury by a hormone-type weed-killer, unbalanced nutrition, and soil that is excessively alkaline or acid. Nearby plant species are often examined to see if similar symptoms are evident on several different types of plants.

Examination of stems, shoots, branches, and trunk follows a thorough leaf examination. Sunken, swollen, or discoloured areas in the fleshy stem or bark may indicate canker infection by a fungus or bacterium or injury caused by excessively high or low temperatures, hail, tools, equipment, vehicles, or girdling wires.

Fungal mold and fruiting bodies in or on such areas often indicate secondary infection. Accurate identification of signs as belonging to a pathogenic organism or a secondary or saprophytic one is difficult. Tissues directly infected by pathogenic fungi or bacteria normally show a gradual change in colour or consistence. Injuries, in comparison, are usually well defined with an abrupt change from healthy to affected tissue.

Holes and sawdust-like debris are evidence of boring insects that usually invade woody plants in a low state of vigour. Other borer signs include wilting and dieback. These symptoms are also produced by fungi and bacteria that invade water- and food-conducting vascular tissue.

Symptoms of wilt-inducing micro-organisms include dark streaks in sapwood of wilted branches when the wood is cut through at an angle.

Abnormal suckers or water sprouts on trees can indicate careless pruning, extremes in temperature or water supply, structural injury, or disease.

Conditions that produce symptoms similar to disease

The environment–pathogen–host triangle

Diagnosis of stem system

Three causes of galls.

Galls, localized swellings usually affecting only part of a plant, are symptoms of various types of diseases. (Top left) Hedgehog galls on oak leaf are caused by insect damage to vein of leaf. (Right) Cedar apple gall, natural-looking and somewhat attractive, is actually result of fungal infection. (Bottom left) Cane galls on raspberry stems are produced by bacterial infection.

By courtesy of (top left, right) the Morton Arboretum, Lisle, Illinois, (bottom left) Malcolm C. Shurtleff, University of Illinois, Urbana

Galls, which are unsightly overgrowths on stem, branch, or trunk, may indicate crown gall, insect injury, water imbalance between plant and soil, or other factors. Crown gall is infectious and develops as rough, roundish galls at wounds resulting from grafting, pruning, or cultivating.

Wood-decay fungi also enter unprotected wounds resulting in discoloured, water-soaked, spongy, stringy, crumbly, or hard rots of living and dead wood. External evidence of wood decay fungi are clusters of mushrooms (or toadstools) and hoof- or shelf-shaped fungal fruiting structures, called conks, punks, or brackets.

Aboveground symptoms of many root problems look alike. They include stunting of leaf and twig growth, poor foliage colour, gradual or sudden decline in vigour and productivity, shoot wilting and dieback, and even rapid death of the plant. The causes include infectious root and crown rot; nematode, insect or rodent feeding; low temperature or lightning injury; household gas injury; poor soil type or drainage; change in soil grade; or massive removal of roots in digging utility trenches and in street and sidewalk construction.

Abnormal root growth is revealed by comparison with healthy roots. Nematodes, including root knot, produce

small to large galls in roots; sometimes affected roots become discoloured, stubby, excessively branched, and decayed. Bacterial and fungal root rots commonly follow feeding by nematodes, insects, and rodents. Such roots are often discoloured and decayed (water-soaked, mushy, spongy, or firm) and may be covered with mold growth.

Diagnosis of a disease complex, one with two or more causes, is usually difficult and requires separation and identification of the individual causes.

**Symptoms.** The variety of symptoms, the internal and external expressions of disease, that result from any disease form the symptom complex, which, together with the accompanying signs, makes up the syndrome of the disease.

Generalized symptoms may be classified as local or systemic, primary or secondary, and microscopic or macroscopic. Local symptoms are physiological or structural changes within a limited area of host tissue, such as leaf spots, galls, and cankers. Systemic symptoms are those involving the reaction of a greater part or all of the plant, such as wilting, yellowing, and dwarfing. Primary symptoms are the direct result of pathogen activity on invaded tissues (e.g., swollen "clubs" in clubroot of cabbage and "galls" formed by feeding of the root-knot nematode). Secondary symptoms result from the physiological effects of disease on distant tissues and uninvaded organs (e.g., wilting and drooping of cabbage leaves in hot weather resulting from clubroot or root knot). Microscopic disease symptoms are expressions of disease in cell structure or cell arrangement seen under a microscope. Macroscopic symptoms are expressions of disease that can be seen with the unaided eye. Specific macroscopic symptoms are classified under one of four major categories: pre-necrotic, necrotic, hypoplastic, and hyperplastic, or hypertrophic. These categories reflect abnormal effects on host cells, tissues, and organs that can be seen without a hand lens or microscope. See Table 1 for examples of the main disease symptoms that are classified in these four categories.

**Signs.** Besides symptoms, the diagnostician recognizes signs characteristic of specific diseases. Signs are either structures formed by the pathogen or the result of interaction between pathogen and host—e.g., ooze of fire blight bacteria; slime flux from wetwood of elm; odour of tissues affected with bacterial soft rot. See Table 2 for the most frequently encountered signs of pathogen presence and examples of organisms producing them.

## II. Classification and control

Plant diseases are often classified by their physiological effects or symptoms. Many, however, produce practically identical symptoms and signs yet are caused by very different micro-organisms or agents, thus requiring com-

Classification of symptoms

Symptoms of plant diseases.

(Left) Hypoxylon canker, extensive destruction of tissue seen on quaking aspen tree, is a symptom of fungal infection. (Centre) Variation from normal colour is a symptom of disease caused by many different agents, as in this early blight fungal infection of tomato leaf. (Right) Blister spots, shown on apple, are symptomatic of bacterial infection.

Table 1: Plant Disease Symptoms

symptom name	description and causes	examples
Pre-necrotic symptoms	symptom expression that precedes death of cells or their disintegration of tissues	
Water-soaking	a water-soaked, translucent condition of tissues caused by water moving from host cells into intercellular spaces	late-blight lesions on potato and tomato leaves; bacterial soft rot of fleshy vegetables
Wilting	temporary or permanent drooping of leaves, shoots, or entire plants from lack of water	bacterial wilt of cucumber; Fusarium wilt of tomato
Abnormal coloration	yellowing, reddening, bronzing, or purpling in localized areas of leaves where chlorophyll has been destroyed; may be due to a variety of causes the presence of two or more colours in leaves and flowers due to a genetic abnormality is called variegation; viral infection results in "Rower breaking"	cabbage and aster yellows; halo blight of beans; potassium or phosphorus deficiency tulip mosaic
Necrotic symptoms	localized or general death and disintegration of cells and/or tissues	
Blast	sudden blighting or death of young buds, flowers, or young fruit; also, a failure to produce fruit or seeds	<i>Botrytis</i> blight of peony buds; oat blast
Bleeding	flow of sap, often discoloured, from a split crotch, branch stub, or other wound; usually accompanied by an odour of fermentation	bleeding canker of beech, dogwood, and maple
Blight	sudden or total discoloration and killing of large numbers of blossoms, leaves, shoots, limbs, or the entire plant; usually young tissues are attacked; the disease name is often coupled with the name of host and part attacked—blossom blight, twig blight, tip blight	fire blight of pome fruits; Diplodia or <i>Sphaeropsis</i> tip blight of conifers
Canker	a definite, dead, often sunken or swollen and cracked area on a stem, limb, trunk, tuber, or root surrounded by living tissues	anthracnose of sycamore and brambles; Nectria canker of hardwoods; fire blight of pome fruits
Damping-off	decay of seed in soil, rapid death of germinating seedlings before emergence, or when emerged seedlings suddenly wilt, topple over, and die from rot at or near the soil line	pre-emergence damping-off and post-emergence damping-off; both are common in seedbeds
Dieback	progressive browning and death of shoots, branches, and roots starting at the tips	winter injury; wet soil; excess soil nutrients; girdling cankers; stem or root rots; nematodes
Firing	drying and dying of leaves	nitrogen or potassium deficiency in corn; <i>Verticillium</i> wilt of eggplant
Fleck	a small, white to translucent spot or lesion visible through a leaf	ozone injury to many plants; necrotic fleck of lily
Mummification	final stage in certain fruit rots, in which the dried, shrivelled, and wrinkled fruit is called a "mummy"	brown rot of stone fruits; black rot of apple
Net necrosis	an irregular criss-crossing of dark brown to black lines giving a netted appearance	in potato tubers of plants with virus leaf roll
Pitting	small dead areas within fleshy or woody tissues that appear healthy externally; definite sunken grooves or pits are formed	virus stem-pitting in apple and peach trunks; stony pit of pear fruit
Rot	decomposition and putrefaction of cells; later of tissues and organs; the rot may be dry, firm, watery, or mushy and characterized by such names as hard rot, soft rot, dry rot, black rot, and white rot	bacterial soft rot; berry rot; bud rot; bulb rot
Scald	blanching of young fruit, foliage, and shoot tissue; generally superficial	sunscald; apple and pear scald
Scorch	sudden death and "burning" of large, indefinite areas in leaves and fruit	toxicity from pesticides and air pollutants; drought; wind; lack or excess of some nutrient
Shot hole	dead spotting of leaves with diseased tissue dropping out leaving small holes	bacterial spot; <i>Coryneum</i> blight of peach
Spot	a definite, localized, round to regular lesion often with a border of a different colour; characterized as to location (leaf spot, fruit spot) and colour (brown spot, black spot); if numerous or if spots enlarge and merge a large irregular blotch or blight may develop	gray leaf spot of tomato; black spot of rose; tar spot of maple
Staghead	an advanced form of dieback applied to a tree in which large branches in the upper crown are killed	oak wilt on bur oak; dwarf mistletoe on Douglas fir; <i>Armillaria</i> root rot of oak
Streak	narrow, elongated, somewhat superficial necrotic lesions, with irregular margins, on stems or leaf veins	virus streak of pea, raspberry, and tomato; Stewart's wilt of sweet corn
Stripe	narrow, elongated, parallel, necrotic lesions especially in leaf diseases of cereals and grasses	<i>Helminthosporium</i> stripe of barley; <i>Scolecotrichum</i> brown stripe of forage grasses
Hypoplastic	the underdevelopment of plant cells, tissues, or organs	ergot of rye and other grasses
Abortion	halting development of an organ after partial differentiation	strawberry and aster yellows; genetic variegation in corn; iron deficiency of azalea
Chlorosis	yellowing or whitening of normal green tissue due to partial or complete failure of chlorophyll to develop	dahlia stunt or mosaic; curly top of beans; little-leaf disease of pines
Stunting or dwarfing	the underdevelopment of the plant or some of its organs	peach and lily rosette
Rosetting	shortening of internodes of shoots and branches, producing a bunched growth habit	
Hyperplastic or hypertrophic	an overdevelopment or overgrowth of plant cells, tissues, or organs; hyperplastic has come to mean an increase in number of cells; hypertrophic, an increase in cell size	
Abscission or cast	early dropping of leaves, flowers, or small fruits; usually associated with premature formation of an abscission (separation) cell layer	black spot of rose; early blight of tomato; apple scab
Callus	overgrowth of tissues, often at margins of a canker or wound	Nectria canker of hardwoods; stem pitting of peach
Curl	distortion and crinkling of leaves or shoots resulting from unequal cell growth of opposite sides or in certain tissues	tobacco and tomato mosaic; leaf roll of potato; peach leaf curl
Epinasty	downward or outward curling and bending of a leaf or petiole	2,4-D injury to broadleaf plants; Fusarium wilt of tomato
Fasciation, or witches'-broom	a distortion that results in a dense, bushy overgrowth of thin, flattened, and sometimes curved shoots, flowers, fruit, and roots at a common point; usually due to adventitious (abnormally located) development of organs	witches'-broom of hackberry; hairy root of apple; leaf gall or fasciation of geranium (see also <i>Rosetting</i> under Hypoplastic symptoms in this table)
Metamorphosis or transformation	development of more or less normal tissues or organs in an abnormal location	crazy-top of corn and sorghum; formation of aerial potato tubers
Proliferation	continued development of an organ after it would normally stop growing	adventitious shoots in China aster and chrysanthemum from aster yellows mycoplasma
Russetting	usually a brownish, superficial roughening or corking of the epidermis of leaves, fruit, tubers, or other organs; often due to suberization (cork development) of cells following injury	spray or weather injury to apples; sweet potato scurf
Scab	roughened to crustlike, more or less circular, slightly raised or sunken lesions on the surface of leaves, stems, fruit, or tubers	apple, peach, and cucumber scab; common scab of potato
Gall, knot, or tumefaction	formation of local, fleshy to woody outgrowths or swellings; the outgrowth is often composed of unorganized cells	crown gall; black knot of plum; <i>Fusiform</i> gall rust of pine; nematode galls

**Table 2: Signs of Pathogen Presence in Diseased Plants\***

signs	description	examples
Acervulus	a shallow, saucer-shaped fungus structure that bears asexual spores (conidia); it is usually formed below the cuticle or epidermis of leaves, stems, and fruits later rupturing the surface and exposing its spore-bearing surface	anthracnose of muskmelon and tomato; <i>Marssonina</i> leaf spot and twig blight of poplar
Apotheciutn	a disk-, saucer-, or cup-shaped fungus structure that produces sexual spores (ascospores); it is often stalked and fleshy	brown rot of stone fruits; <i>Sclerotinia</i> white mold of fleshy vegetables
Cleistothecium	a speck-sized, black fruiting body completely enclosing sexual spores	many powdery mildew fungi
Conidiophores	asexual fungus structures of various colours that bear conidia and appear powdery, velvety, or downy en masse; often cover lesions on leaf, stem, or fruit	<i>Botrytis</i> blight or gray mold of many flowers, <i>Penicillium</i> mold of citrus fruit; downy mildew of grape
Conk or punk	fruiting bodies (sporophores) of wood-rotting fungi that produce tremendous numbers of spores (up to 100 billion per day); conks are usually large and woody and are found on tree stumps, branches, or trunks	<i>Fomes</i> and <i>Polyporus</i> wood rots of hardwoods and conifers
Mushroom (toadstool)	fleshy, umbrella-shaped fruiting bodies of wood-decay fungi	<i>Armillaria</i> and <i>Clitocybe</i> root rots
Mycelium	the vegetative body of a fungus, which is composed of a mass of branched filaments (hyphae) often interwoven into a feltlike or woolly mass	<i>Rhizopus</i> soft rot of sweet potato and leak of strawberry; <i>Sclerotinia</i> white mold of beans
Nematode cysts	round to lemon-shaped, speck-sized bodies, white to brown in colour, are diagnostic for cyst nematodes; they are often evident on the root surface	sugar beet, soybean, and clover cyst nematodes
Odours	many pathogens or the process of host colonization give off characteristic odours	bacterial soft rot; stinking smut or bunt of wheat; slime flux of elm
Ooze or exudate	droplets of bacteria or fungus spores, usually mixed with host-cell decomposition products, found on surfaces of lesions	ooze from fire blight; scab on cucumber fruit; cut stem of cucumber affected with bacterial wilt
Perithecium	speck-sized fungus fruiting body that produces large numbers of sexual spores; perithecia are dark coloured, round to flask-shaped, usually partially buried in diseased tissue; they resemble pycnidia	apple and pear scab; <i>Gibberella</i> stalk and ear rot of corn
Powdery mildew	white, powdery to mealy, superficial growths of mycelia and conidiophores on surfaces of leaves, stems, flowers, and fruit	powdery mildew diseases of bluegrass, phlox, zinnia, and rose (see also <i>Cleistothecium</i> , this table)
Pycnidium	speck-sized fungus fruiting body that produces large numbers of asexual spores (conidia); pycnidia are dark coloured, round to flask-shaped, usually partially buried in diseased tissue; they resemble perithecia	<i>Septoria</i> leaf spots, <i>Diplodia</i> stalk rot of corn
Rhizomorph	cordlike or rootlike strands, composed of a bundle of closely intertwined hyphae, by which certain fungi make their way through soil and over or under bark of woody plants	<i>Armillaria</i> and <i>Clitocybe</i> root rots; <i>Sclerotium rolfsii</i> stem rot of peanuts
Sclerotium	brown to black, compact, hard resting bodies of certain fungi with a rindlike covering; their size varies from a fly speck to a large sweet potato depending on the fungus forming it	ergot of rye; onion white rot; <i>Verticillium albo-atrum</i>
Seeds	dodder seed is a sign of this parasitic flowering plant when found in clover or alfalfa seed	dodder ( <i>Cuscuta</i> , about 170 species)
Sorus (pustule)	a compact mass of spores, or a cluster of sporangia (spore bearing structures), produced in or on the host by fungi causing such diseases as white rust, smut, and true rust; before rupturing, the sorus is normally covered by host epidermis	white rust of crucifers; corn and bluegrass smuts; black stem rust of cereals
Spores	microscopic, usually single- or few-celled reproductive bodies of fungi corresponding in function to seeds of higher plants; spores vary greatly in size, shape, and colour; they are asexually produced, or result from sexual processes; asexual spores may be formed directly from vegetative hyphae but are often produced in special fruiting structures, (e.g., acervulus, coremium, pycnidium, and sporodochium)	
Sporodochium	a cushion-shaped stroma covered with conidiophores bearing asexual spores; found scattered in leaf, stem, and fruit lesions	<i>Cercospora</i> leaf spot of celery and sugar beet; brown rot of stone fruits; <i>Fusarium</i> blight of bluegrass
Stroma	a crustlike or cushion-like mass of fungus hyphae often intermingled with host tissue on or in which spores are produced—usually in reproductive bodies	tar spot of maple and sycamore
Synnema or coremium	a tight cluster of erect conidiophores forming an elongated column on which asexual spores are borne	Dutch elm disease; oak wilt; black rot of sweet potato

\*The structures listed are formed by the pathogen.

## Use of the host index

pletely different control methods. Classification according to symptoms is also inadequate because a causal agent may induce several different symptoms, even on the same plant organ, which often intergrade. Classification also may be according to the species of plant affected. Host indices (lists of diseases known to occur on certain hosts in regions, countries, or continents) are valuable in diagnosis. When an apparently new disease is found on a known host, a check into the index for the specific host often leads to identification of the causal agent. It is also possible to classify diseases according to the essential process or function that is adversely affected. The best and most widely used classification of plant diseases is based on the causal agent, such as a noninfectious agent, virus, mycoplasma, bacterium, fungus, nematode, or parasitic flowering plant.

Agents or factors inducing disease in plants may be divided into two broad groups: noninfectious (also called abiotic, physiogenic, or nontransmissible) and infectious (biotic or transmissible).

### NONINFECTIOUS DISEASE-CAUSING AGENTS

Plants in poor health because of some factor in the environment probably outnumber plants attacked by patho-

gens. Noninfectious diseases, which sometimes arise very suddenly, are caused by the excess, deficiency, nonavailability, or improper balance of light, air circulation, relative humidity, water, or essential soil elements; unfavourable soil moisture-oxygen relations; extremes in soil acidity or alkalinity; high or low temperatures; pesticide injury, other poisonous chemicals in air or soil; soil-grade changes; girdling of roots; mechanical and electrical agents; and soil compaction. In addition, unfavourable preharvest and storage conditions for fruits, vegetables, and nursery stock often result in losses. The effects of noninfectious diseases can often be seen on a variety of plant species growing in a given locality or environment. Many diseases and injuries caused by noninfectious agents result in heavy loss but are difficult to check or eliminate because they often reflect ecological factors beyond man's control. Symptoms may appear several weeks or months after an environmental disturbance.

Injuries from accidents, poisons, or adverse environmental disturbances often result in injured tissues that weaken a plant, enabling bacteria, fungi, or viruses to enter and add further damage. The cause may be obvious (lightning or hail); often it is obscure. Symptoms alone are often unreliable in identifying the causal factor.

Low-  
tempera-  
ture injury

**Adverse environment.** High temperatures may scald corn, cotton, and bean leaves and may induce formation of cankers at the soil surface of tender flax, cotton, and peanut plants. Frost injury is relatively common, but temperatures just above freezing may also cause damage, such as net necrosis in potato tubers and "silvering" of corn leaves. Isolated, thin-barked trees growing in northern climates, subjected to frequent thawing by day and freezing by night, may develop dead bark cankers or vertical frost cracks on the south or southwest sides of the trunk. Alternate freezing and thawing, heaving, low air moisture, and smothering due to an ice-sheet cover are damaging to alfalfa, clovers, strawberries, and grass on golf greens. Legume (members of the pea family) crowns commonly split under these conditions and are invaded by decay-forming fungi.

The drought and dry winds that often accompany high temperatures cause stunting, wilting, blasting, marginal scorching of leaves, and dieback of shoots. Similar symptoms are caused by a change in soil grade; an altered water-table level; a compacted and shallow soil; paved surface over tree roots; temporary flooding or a water-logged (oxygen-deficient) soil; girdling tree roots; salt spray near the ocean; and an injured or diseased root system. Injured plants are often very susceptible to air and soil pathogens and secondary invaders.

Blossom-end rot of tomato and pepper is prevalent when soil moisture and temperature levels fluctuate widely and calcium is low.

Poor aeration may cause blackheart in stored potatoes. Accumulation of certain gases from respiration of apples in storage may produce apple scald and other disorders.

A deficiency, excess, or imbalance of essential elements in soil often results in symptoms that vary depending on stage of plant growth, soil moisture, and other factors. Symptoms include stunting of plants; scorching or malformation of leaves; abnormal coloration; premature leaf, bud, and flower drop; delayed maturity or failure of flower and fruit buds to develop; and dieback of shoots. Nutrient deficiency or excess symptoms are rare if temperature and soil moisture is adequate, the soil contains an ample and balanced supply of available mineral elements, and soil reaction is favourable. A pH of 5.5 to 7 is best for most crop, garden, and house plants.

An excess of water-soluble salts is a common problem with house plants. Salt concentrations may build up as a whitish crust on soil and container surfaces of potted plants following normal evaporation of water over a period of time. Symptoms include leaf scorching, bronzing, yellowing and stunting, wilting, plus root and shoot dieback. Damage from soluble salts is also common in arid regions and in regions in which ice-control chemicals are applied in large amounts.

Several nonparasitic diseases (*e.g.*, oat blast, weakneck of sorghum, straighthead of rice, and crazy-top of cotton) are caused by combinations of environmental factors—*e.g.*, high temperatures, moisture stress and/or poor irrigation practices, imbalance of mineral nutrients, and reduced light.

Environmental disturbances alter the normal physiology of the plant, activity of pathogens, and host–pathogen interactions.

**Toxic chemicals.** Many complex chemicals are routinely applied to plants alone or in combination to prevent attack by insects, mites, and pathogens; to kill weeds; or to control growth. Serious damage may result when fertilizers, herbicides, fumigants, growth regulators, anti-desiccants, insecticides, miticides, fungicides, nematocides, and surfactants (substances with enhanced wetting, dispersing, or cleansing properties, such as detergents) are applied at excessive rates or under hot, cold, or slow-drying conditions.

Some 200,000,000 tons of air pollutants are released over the U.S. each year; other industrialized and densely populated countries have similar problems. In fact, plant injury is increasing all over the world near urban centres, refuse dumps, major highway systems, factories, and power plants. The major plant-toxic pollutants are sulfur dioxide, fluorine, ozone, and peroxyacetyl nitrate.

Sulfur dioxide results largely from the burning of large amounts of soft coal and high-sulfur oil. It is toxic to a wide range of plants at concentrations as low as 0.25 parts per million (ppm) of air (*i.e.*, on a volume basis, a part per million represents one volume of pure gaseous toxic substance mixed in 1,000,000 volumes of air) for eight to 24 hours. Gaseous and particulate fluorides are more toxic to sensitive plants than is sulfur dioxide because they are accumulated by leaves. They are also toxic to animals that feed on such foliage. Fluorine injury is common near metal-ore smelters, refineries, and industries making fertilizers, ceramics, aluminum, glass, and bricks.

Ozone and peroxyacetyl nitrate injury (also called oxidant injury) have become more prevalent in and near cities with heavy traffic problems. Exhaust gases from internal combustion engines contain large amounts of hydrocarbons (substances containing principally carbon and hydrogen molecules—gasoline, for example). Smaller amounts of unconsumed hydrocarbons are formed by combustion of fossil fuels (coal, oil, natural gas) and refuse burning. Ozone, peroxyacetyl nitrate, and other oxidizing chemicals (smog) are formed when sunlight reacts with nitrogen oxides and hydrocarbons. This pollutant complex is damaging to susceptible plants many miles from its source. Ozone and peroxyacetyl nitrate are capable of causing injury if present at levels of 0.01 to 0.05 parts per million for several hours.

**Physical injury.** Lightning, hail, high winds, ice and snow loads, machinery, insect and animal feeding, and various cultural practices may seriously injure plants or plant products. With the exception of lightning, which may cause death of trees and succulent crop plants in limited areas, such injury does not usually kill plants. Wounds are created, however, through which pathogens may enter.

#### INFECTIOUS DISEASE-CAUSING AGENTS

Some parasitic micro-organisms secure their nutrition from living plants. If these organisms cause injury or disease, they are called pathogens. An obligate parasite requires living tissue as a food source; a facultative parasite may grow on living or nonliving material.

**Viruses.** Plant viruses are extremely small infectious agents that pass through fine filters and are visible only with the electron microscope. Viruses may occur naturally as complexes or strains differing in mode of transmission, virulence, host plants attacked, symptoms produced, and physical and chemical characteristics (see VIRUS). One plant species may be susceptible to 20 to 40 different viruses.

Plant viruses cause many major diseases of important food crops such as potato, tomato, wheat, oats, rice, corn, peach, orange, sugar beet, sugarcane, and palms. Virus diseases are generally most serious in plants that are vegetatively propagated (*i.e.*, grown from cuttings, cut divisions, sprouts, etc., rather than from seeds; examples include potato, sweet potato, carnation, chrysanthemum, dahlia, geranium, gladiolus, lilies, orchids, tree and cane or bush fruits, and strawberries).

Virus-induced disease symptoms. Viruses induce a wide range of plant symptoms. Rarely they may kill the host in a short time (*e.g.*, spotted wilt and curly top of tomato). More commonly, they cause reduced yield and lower quality of product. Virus symptoms fall into four groups: (1) change in colour—yellowing, green and yellow mottling, and vein clearing; (2) malformations—distortion of leaves and flowers, rosetting, proliferation and witches'-brooms, and little or no leaf development between the veins; (3) necrosis—leaf spots, ring spots, streaks, wilting or drooping, and internal death, especially of phloem (food-conducting) tissue; and (4) stunting or dwarfing of leaves, stems, or entire plants.

Virus-infected plants are often more susceptible to root rots, stem or stalk rots, seedling blights, and possibly other types of diseases.

Some plants may carry one or more viruses and show no symptoms; thus, they are latent carriers and a source of infection for other plants. Symptoms of certain virus-

#### Non-pathogenic injuries.

(Left) Sumac damaged by sulfur dioxide. (Top centre) Lettuce leaf damaged by peroxyacetyl nitrate, or PAN. infected plants, such as geraniums, may be masked at high temperatures. Virus symptoms reappear when the weather cools.

For convenience, virus diseases are often grouped together generally by symptoms, regardless of true virus relationships. Viruses can also be grouped into strains, each differing greatly in virulence (ability to cause disease) and other properties. For example, two virus strains, chemically distinct, may produce indistinguishable symptoms in one orchid plant but strikingly different symptoms in another. Diseases caused by unrelated viruses may resemble one another more closely than diseases caused by strains of the same virus. Certain variegated plants, such as *Abutilon* and Rembrandt tulips, owe their horticultural uniqueness and desirability to being inherently virus infected.

**Virus transmission.** Some viruses are quite infectious and spread easily from diseased plants by contact. With the exception of tobacco-mosaic virus, however, relatively few viruses are spread extensively in the field by contact between diseased and healthy leaves.

All viruses that spread within their host tissues (systemically) can be transmitted by grafting branches or buds from diseased plants on healthy plants. Natural grafting and transmission are possible by root grafts and with dodder (*Cuscuta* species). Vegetative propagation often spreads plant viruses. Fifty to 60 viruses are transmitted in seed, and a few seed-borne viruses, such as sour-cherry yellows, are carried in pollen and transmitted by insects.

Most disease-causing viruses are carried and transmitted naturally by insects and mites, which are called vectors of the virus. The principal virus-carrying insects are about 200 species of aphids, which transmit mostly mosaic viruses, and over 100 species of leafhoppers, which carry yellows-type viruses. Whiteflies, thrips, mealybugs, plant hoppers, grasshoppers, scales, and a few beetles also serve as vectors for certain viruses. Some viruses may persist for weeks or months and even duplicate themselves in their insect vectors; others are carried for less than an hour. Slugs, snails, birds, rabbits, and dogs also transmit a few viruses, but this is not common.

A small number of plant viruses are soil borne. Viruses causing grape fanleaf, tobacco rattle, tobacco and tomato ring spots, as well as several strawberry viruses, are spread by nematodes feeding externally (*i.e.*, ectoparasitic) on plant roots. A few soil-borne viruses may be spread by the swimming spores of primitive, soil-inhabit-

ing pathogenic fungi, such as those causing big vein of lettuce, soil-borne wheat mosaic, and tobacco necrosis.

Viruses often overwinter in biennial and perennial (plants that overwinter by means of roots and produce seed in their second year or during several years, respectively) crops and weeds, in plant debris, and in insect vectors. Plants, once infected, normally remain so for life. Most, if not all, plant viruses can persist in a number of different host plants.

**Control of virus diseases.** After a plant is infected with a virus, little can be done to restore its health. Control is accomplished by several methods, such as growing resistant species and varieties of plants or obtaining virus-free seed, cuttings, or plants as a result of indexing and certification programs. Indexing is a procedure to determine the presence or absence of viruses not readily transmitted mechanically. Material from a "test" plant is grafted to an "indicator" plant that develops characteristic symptoms if affected by the virus disease in question. In addition, more drastic measures are sometimes followed, including destroying (roguing) infected crop and weed host plants and enforcing state and national quarantines or embargoes. Further control measures include controlling insect vectors by spraying plants with contact insecticides or fumigating soil to kill insects, nematodes, and other possible vectors. Growing valuable plants under fine cheesecloth or wire screening that excludes insect vectors is also done. Separation of new from virus-infected plantings of the same or closely related species is sometimes effective, and the simple practice of not propagating from plants suspected or known to harbour a virus also reduces loss.

Infected peach, apple, and rose budwood stock and carnations have been grown for weeks or months at temperatures around 37° to 38° C (99° to 100° F) to free new growth from viruses. Soaking some woody plant parts or virus-infected sugarcane shoots in hot water at about 50° C (120° F) for short periods is also effective. Both dry- and wet-heat treatments are based on the sensitivity of certain viruses to high temperatures. Rapidly growing dahlia and chrysanthemum sprouts outgrow viruses so that stem tips can be used to propagate healthy plants. With certain carnations, chrysanthemums, and potatoes, a few cells from the growing tip have been grown under sterile conditions in tissue culture; from these, whole plants have been developed free from viruses.

Temperature treatments for virus control

**Examples of virus-caused diseases.** Among the viruses affecting plants, tobacco mosaic virus (TMV) is best known and has great economic importance. Besides affecting many members of the nightshade family (Solanaceae), which includes tobacco, tomato, potato, pepper, eggplant, and petunia, TMV infects more than 70 species of plants in 14 other families. Symptoms characteristically appear as dark-green leaf blotches, irregularly elevated and scattered. The remainder of the leaf becomes more and more pale green and sometimes yellow. The name mosaic derives from these small irregular blotches of different shades of green and yellow.

TMV, unlike most viruses, is resistant to high temperatures (up to 90° C, or 190° F), alcohol, and various germicides; it has been established that TMV retains infectivity in dried tobacco leaves for more than 50 years.

The virus disease curly top caused almost complete abandonment of the sugar-beet industry in parts of the world from 1916 to 1932, when it was controlled by the development of resistant varieties. Intermittently, it still causes severe damage to tomatoes, beans, and other crops. The virus affects a wide range of cultivated and weed hosts in over 70 different plant genera. Young susceptible beet plants turn yellow and usually die quickly when infected by the virus. Symptoms on older sugar beets include a stunting or dwarfing of plants and a thickening, curling, and yellowing of affected leaves; cross sections of roots show dark necrotic areas in the phloem, or food-conducting vascular tissue, of the plant. The virus survives between crops in weed hosts and in the beet leafhopper, the main carrier. Distribution of curly top in sugar-beet fields reflects migration patterns of the beet leafhopper as influenced by the prevalence of other hosts in the vicinity, direction of prevailing winds,

and temperature. Judicious use of herbicides, early planting, controlled grazing, and other management practices help reduce the magnitude of the spring leafhopper migration from weedy to cultivated areas, which may sometimes be many miles apart. The key to maintaining high production in sugar beets, however, has been the use of resistant varieties.

Spotted wilt, transmitted by onion and flower thrips, has become widespread and now is responsible for losses to tomato, potato, lettuce, pea, other vegetables, and ornamentals in many parts of the world. Control measures involve sanitation and weed control, spraying to control the thrips vector, and obtaining virus-free plants.

Virus diseases of citrus are a major concern wherever these crops are grown; for example, between 1936 and 1946, tristeza (quick decline) caused the loss of 7,000,000 orange trees in the State of São Paulo, Brazil. Tristeza has attacked or now threatens many millions of trees in various tropical and subtropical areas. The principal controls for citrus virus diseases include costly programs of roguing (destroying) infected trees plus the development of virus-free rootstocks and topworking (grafting) them with budwood from trees known to be free of virus diseases, such as tristeza, exocortis, psorosis, xyloporosis, stubborn disease, tatterleaf, and vein enation.

The worldwide increase in destructiveness of virus diseases and in the number of known plant viruses largely results from the expansion of agricultural enterprises and increased movement of plants and plant products in recent years and from the introduction of single-crop planting in large regions.

**Mycoplasmas.** Since 1968, around 60 of the "yellows" or "witches-broom-type" diseases previously thought to be virus in origin have been shown to be caused by tiny, unicellular organisms known as mycoplasmas. These are the simplest and smallest known organisms capable of growing on laboratory culture media.

Plant mycoplasmas are characteristically delimited by a distinct double membrane that is flexible. Being soft and plastic, they assume a great variety of sizes and shapes. When viewed in the electron microscope, mycoplasmas are seen to vary from small, round bodies to branched, wormlike forms smaller than bacteria but within the range of large virus particles.

Antibiotic drugs and several sulfa drugs used to treat one type of pneumonia in man caused by a mycoplasma are effective in combatting aster yellows and other diseases caused by mycoplasmas. Plants showing severe symptoms, when treated with an effective antibiotic, produce new, healthy appearing foliage. If test plants are no longer given drugs, symptoms may reappear in several weeks.

Aster yellows infects about 300 species of crop and weed plants in 48 families. The disease is common and destructive in most of the world where air temperatures do not persist much above 32° C (90° F). High temperatures inactivate the mycoplasma in plants and in the leafhopper vectors. Aster yellows can cause serious losses on China aster, daisies, chrysanthemum, lettuce, endive, escarole, carrot, parsnip, celery, parsley, and New Zealand spinach. Diseased asters are stiff, upright, and stunted with numerous yellowish secondary shoots. Flowers are green (virescent) and distorted, dwarfed or lacking. Seventeen species of leafhoppers, depending on the area and strain of the mycoplasma, serve as transmitting agents.

The mycoplasma multiplies both in the leafhopper and in the host plant. Nine to 16 days must elapse after the leafhopper feeds on a diseased plant before it can infect a healthy plant. Transmission does not occur through insect eggs or aster seeds. Control is against leafhopper vectors and involves frequent spraying or dusting with contact insecticides; prompt destruction of infected plants and overwintering weeds that may harbour leafhopper eggs; and growth of asters and other plants commercially under cheesecloth or fine wire screening to exclude insects. Antibiotic sprays or dips appear promising for providing mycoplasma-free cuttings, grafting materials, and seed.

Control of citrus virus

Control of leafhopper transmitted mycoplasmas

**Bacteria.** Most of the 4,000 described species of bacteria are harmless or even beneficial to man. Over 100 species are known to cause human and animal diseases; however, the almost 200 species that cause plant disease infect over 150 different genera of higher plants in more than 50 families. Bacterial diseases can be grouped into three categories: wilting, necrosis, and overgrowth, or hypertrophy. Wilting results from invasion of the vascular system of the plant by bacteria; examples include bacterial wilts of sweet corn, alfalfa, tobacco, tomato, and cucurbits (squash, pumpkins, cucumbers); and black rot of crucifers. Necrosis is a condition in which plant cells are killed, forming leaf spots, stem blights or cankers, and soft rots; examples are delphinium black spot, fire blight of pome fruits, bacterial blights of beans and peas, and soft rot of iris. Examples of overgrowth, or hypertrophy, include crown gall of many plants, cane gall of brambles, hairy root of apple, and olive knot.

Most bacterial pathogens produce one major symptom; others manifest a range or combination of symptoms. In general, it is difficult to determine the species designation of a bacterium, but it is not particularly difficult to tell that a plant is affected by a bacterial pathogen.

All true bacteria (order Eubacteriales) that cause plant disease are one-celled, rod-shaped organisms that do not form spores. Only five genera of true bacteria cause plant disease. About one half of the species are in the genus *Pseudomonas*. Another important genus, *Xanthomonas*, is characterized by the water-insoluble yellow pigment it forms when grown in the laboratory. In contrast to animal and human pathogens, those that infect plants are usually favoured by a nearly neutral (pH 6.5 to 7.5) medium and low temperatures (20° to 30° C, or 68° to 86° F).

**Infection processes.** Bacterial pathogens enter plants through wounds, principally produced by adverse weather conditions, man, tools and machinery, insects, and nematodes; or natural openings such as stomates (pores in leaves), lenticels (pores in bark), hydathodes (structures that discharge water from leaf interiors to the surface), nectar-producing glands, and leaf scars.

Most foliage invaders are spread from plant to plant by wind-blown rain or dust. Man disseminates bacteria through cultivation, grafting, pruning, and transporting diseased plant material. Animals, including insects and mites, are other common transmission agents. Some bacteria, such as the causal agent of Stewart's, or bacterial, wilt of corn (*Erwinia stewarti*), are not only spread by a flea beetle but also survive over winter in this insect.

When conditions are unfavourable for growth and multiplication, bacteria remain dormant on or inside plant tissue. A few, such as the crown gall bacterium, may survive for months or years in the soil.

Bacterial diseases are influenced greatly by temperature and moisture. Often, a difference of only a few degrees in temperature determines whether a bacterial disease will develop. Moisture as a water film on plant surfaces is often essential for entry.

Most pathogenic bacteria of plants are quickly killed by exposure to high temperatures (e.g., ten minutes at 52° C [126° F]), very dry conditions, and strong sunlight. Many pathogenic bacteria in soil are eaten by protozoans, lysed (destroyed) by phages, or killed by extracellular toxic products of other soil-inhabiting organisms.

**Control of bacterial diseases.** In general, the diseases caused by bacteria are relatively difficult to control. This is partly attributable to the speed of invasion since bacteria enter natural openings or wounds directly. Direct introduction also enables them to escape the toxic effects of chemical protectants. Losses from bacterial diseases are reduced by the use of pathogen-free seed grown in arid regions. Examples of diseases controlled by this method include bacterial blights of beans and peas, black rot of crucifers, and bacterial spot and canker of tomato. Seed treatment with hot water at about 50° C (120° F) is also effective for crucifers, cucurbits, carrot, eggplant, pepper, and tomato. Bactericidal seed compounds control some bacterial diseases, such as angular leaf spot of cotton, gladiolus scab, and soft rot of ornamentals. Rota-

tion with nonhost crops reduces losses caused by wilt of alfalfa, blights of beans and peas, black rot of crucifers, crown gall, and bacterial spot and canker of tomato. Eradication and exclusion of host plants has been useful against citrus canker, angular leaf spot of cotton, fire blight, and crown gall. Resistant varieties of crop plants have been developed to reduce losses from wilts of alfalfa, corn, and tobacco; angular leaf spot of cotton and tobacco; and bacterial pustule of soybeans, among others. Protective insecticidal sprays help control bacterial diseases, such as wilts of sweet corn and cucurbits and soft rot of iris. Protective bactericidal sprays, paints, or drenches containing copper or antibiotics are used against bacterial blights of beans and celery, fire blight, crown gall, blackleg of delphinium, and filbert and walnut blights. Finally, sanitary measures—i.e., clean plow down of crop refuse, destruction of volunteer plants and weeds, sterilization of pruning and grafting tools—as well as refraining from cultivating when foliage is wet, overhead watering and spraying of indoor plants, and late cutting or grazing of alfalfa and other crops, are useful in reducing the incidence of bacterial diseases.

**Fire blight.** The first plant disease proved to be caused by a bacterium was fire blight of apple, pear, quince, hawthorn, *Pyracantha*, and related plants. Fire blight, caused by *Erwinia amylovora*, has destroyed all high-quality pear orchards in parts of the United States. The bacteria invade flower nectaries and leaves, spread to young fruits, and pass rapidly down susceptible shoots in the phloem, darkening and killing the tissue. Extensive, slightly sunken cankers, with a definite margin, form, and during warm, moist weather, bacterial ooze (exudate) appears on the surface. The bacteria overwinter at the edges of cankers on the branches or the trunk. Plant parts and other trees become infected when rains splash the bacteria-laden exudate that appears at the edges of cankers.

Careful removal of diseased parts and weekly application of antibiotic sprays during the blossom and post-bloom period greatly reduce disease severity. Resistance to fire blight is available in species of *Pyracantha*, *Cotoneaster*, and *Crataegus* (hawthorn) as well as in varieties of crabapples, apples, and pears.

**Crown gall.** Perhaps the best known bacterial plant disease is crown gall, which derives its name from the rounded, rough growth that appears at the stem base or root crown. The disease occurs widely over the world. The causative bacterium, *Agrobacterium tumefaciens*, which is distributed with nursery stock, has a wide host range, affecting plants in more than 40 families, including peach, apple, pecan, grape, fig, raspberry, rose, willow, euonymus, and sugar beet.

The bacteria enter only through wounds, and grow between cells that are then stimulated to increase in size and number. Bacteria may be washed from the gall surface into the soil or transported by chewing insects. The disease has been controlled by nursery inspection, disinfection of parts used for vegetative propagation, and planting in well-drained soil free of root-chewing insects.

**Southern bacterial wilt.** One of the most important bacterial diseases is the wilt caused by *Pseudomonas solanacearum*, which attacks tobacco, potato, tomato, eggplant, beans, bananas, peanut, and numerous other vegetables and ornamentals. The disease occurs in warm temperate, subtropical, and tropical areas throughout the world.

Typical external symptoms include stunting, yellowing, and wilting. The vascular tissue usually becomes dark brown. The bacteria may live in fallow (plowed but unplanted) soil for six years or more and then usually enter roots through wounds and spread upward in water-conducting tissue. There the bacteria multiply, forming an extracellular slime and other products that eventually prevent water movement to the leaves and cause wilting.

Insects are usually not involved in plant-to-plant spread, with the exception of banana, in which case insects may introduce the bacteria into the flower parts. Spread into new areas occurs by infected transplants, potato tubers, or by cultural practices—such as irrigation and use of

tools and machinery coated by soil containing the organism. Development of disease is favoured by high soil moisture levels and high temperatures (optimum about 30–32° C, or 86–90° F).

Bacterial wilt of tobacco and peanut has been controlled by development of resistant varieties. High-quality varieties of tomato, potato, and banana with adequate wilt resistance are not yet available. Normal crop rotations, soil treatments, and other practices have not provided adequate control on most crops.

**Fungi.** Of the 100,000 described species of fungi, approximately 20,000 produce disease in plants. These include 4,600 rusts, 700 smuts, and 1,000 powdery and downy mildews—a total of 6,300 obligate parasites.

Fungi cause the great majority of infectious plant diseases (about 75 percent). They include all white and true rusts, smuts, needle casts, leaf curls, mildews, sooty molds, and atrachnoses; most leaf, fruit, and flower spots; cankers; blights; scabs; root, stem, fruit, and wood rots; wilts; leaf, shoot, and bud galls; and many others. All economically important plants apparently are attacked by one or more fungi; often ten to 50 or more different fungi may cause disease on one plant species.

Fungal hyphae (filaments of the main growing body of a fungus) may penetrate a plant by growing into a wound, by passing through a natural opening, or by forcing their way directly through a plant's protective epidermis. Fungi, like bacteria, are more prevalent and damaging in damp areas or wet seasons than in dry ones. Moisture is usually essential for their rapid spread, penetration, and infection. Fungi overwinter in soil, plant refuse, living plants, seeds, storage organs, and sometimes insects.

Descriptions of the various fungus groups and their activity appear elsewhere (see MYCOTA). The examples below represent major types of diseases incited by fungi.

**Late blight.** The causal fungus of late blight (*Phytophthora infestans*) occurs in cool, moist regions wherever potatoes are grown. A devastating epiphytotic of this disease on potatoes began in Europe in 1845 and brought about the Irish famine that caused starvation, death, and mass migration of the population. In a population of 8,000,000, about 1,000,000 (about 12.5 percent) died of starvation and 1,500,000 (almost 19 percent) emigrated, mostly to the United States, as refugees from the destructive blight. This fungus thus had a tremendous influence on the economic, political, and cultural development in Europe and the U.S. During World War I, late blight damage to the potato crop in Germany may have helped end the war.

Symptoms of late blight may appear on any part of the potato plant, including potatoes in storage. Water-soaked, dark green to black or purplish lesions with pale green margins appear first on the lower leaves. The lesions often rapidly increase in size. A downy white mildew (composed of sporangiophores and sporangia—spore-producing structures) is usually present near the lesion margins on the underside of leaves. Tubers may also be infected in field or storage. A brown or rusty, sometimes purplish skin discoloration appears, and a reddish-brown dry rot may extend into the tuber for five to ten millimetres. Later, a slimy, foul-smelling rot may destroy the tuber. Progress of late blight through a potato field is

rapid in cool, moist weather. Hot, dry weather checks the spread of the disease.

The infective cycle begins with the planting of infected tubers, in which the fungus overwinters. Infection may also result from diseased cull (waste) piles or volunteer field plants. Spores from these sources infect nearby plants and spread rapidly in successive cycles of increasing intensity so long as cool, moist weather prevails. External symptoms appear on the potatoes five days or less from the time of infection; the *Phytophthora* fungus quickly forms mildew again on the undersides of leaves.

Controls include the frequent and thorough application of protectant sprays, use of certified seed potatoes, destruction of potato dump and cull piles, delay of digging until two weeks after tops die or are purposely killed, and growing of resistant varieties.

Blight-forecasting services have been started in several countries; they are based on weekly graphs prepared by plotting the cumulative rainfall, periods of time leaf surfaces are wet, and mean temperatures. The forecasting of weather favourable and unfavourable for a blight epiphytotic has saved potato farmers time and money by eliminating unneeded sprays.

**Chestnut blight.** Native American chestnuts have been practically eliminated from their natural range by a fungus (*Endothia parasitica*), accidentally imported from the Orient, where blight occurs as a minor disease on native chestnuts. When blight was first observed in New York in 1904, its seriousness was not realized. By 1908, however, chestnut blight had killed thousands of trees in areas around New York, and the fungus had spread many miles in all directions. By 1925, the disease had eliminated chestnuts in Illinois; four years later, it reached the Pacific Northwest. Costly efforts failed to bring the epiphytotic under control, and it continued to spread, killing millions of trees and finally eliminating this valuable native hardwood species as a major forest component in eastern North America.

Young infections on two- to six-year-old chestnut shoots appear as yellowish to reddish-brown patches against the olive green of healthy bark. The lesions spread until the twig or limb is girdled and killed by slightly sunken or swollen and cracked cankers. After one to several years, large trees assume a staghead appearance; blight quickly spreads down into the trunk, killing the entire top of the tree. Roots and old stumps have a surprising capacity for sending up sprouts, which often escape the disease for several years. During moist weather, spores (conidia), embedded in a mucilaginous matrix are extruded from reddish reproductive structures (pycnidia) in back crevices, forming long, irregularly twisted, yellow to buff coloured tendrils or spore horns.

The extruded conidia are spread short distances by splashing rain and wind or insects and over long distances by migratory birds. Presumably, birds carry spores on their feet to healthy trees, sometimes many miles away. The number of spores produced is enormous. An average spore horn contains over 100,000,000 spores. In addition to conidia in spore horns, a second sexual stage is produced—vast numbers of ascospores are discharged from flask-shaped fruiting bodies (perithecia) and are carried many miles by wind currents.

Although no control measures were available to save the native American chestnuts, Chinese and Japanese species show good to excellent resistance. Crosses between American and Asiatic chestnuts have produced varieties with excellent nuts; timber quality of these trees, however, usually is closely linked with susceptibility to blight.

**Dutch elm disease.** A serious new disease of elms was described in 1921 in The Netherlands, thus the name Dutch elm disease. The causal fungus (*Ceratocystis ulmi*) is believed to have moved to Europe from Asia during World War I. Following description of the disease, reports of its occurrence soon came from many regions in Europe and Asia. The fungus was apparently introduced into the United States in 1930 on elm burl logs imported for furniture veneer. Overland spread from original introduction points occurred by road and rail traffic and especially by movement of elm bark beetles (European: *Scolytus multistriatus*; American: *Hylurgopinus rufipes*—both are carriers). These beetles may fly up to several miles in search of breeding sites in weakened or dead elm wood. Dutch elm disease has killed millions of elms in the eastern two-thirds of the U.S. and Canada, and the disease has continued to spread westward and southward.

Leaves on diseased elm twigs suddenly and progressively wilt, turn dull green to yellow or brown, curl, and usually drop off. Progress of the disease is rapid in young, rapidly growing trees, which may die in one to two months. Older or more slowly growing elms sometimes die slowly over several years, the upper dead branches appearing stagheaded. A cut across an infected branch shows a brown to almost black arc or ring where tyloses (growths or plugs that fill the interiors of vessel cells) and brownish gum have accumulated in water-conducting vessels. Symptoms are easily confused with other elm wilts caused by species of *Verticillium* or *Dothiorella*. Growth in the laboratory of the causal fungus is thus necessary for positive diagnosis.

The fungus spreads rapidly, especially in the spring, through the large xylem vessels. European and American elm bark beetles tunnel into dying or dead elm branches and trunks where the females lay eggs under the bark. Conidia of the fungus develop in great abundance on coremia (fruiting structures) in the beetles' galleries. When the adult beetles emerge from the galleries, sticky spores are carried on their bodies. Spores are deposited

in vascular tissue of nearby healthy elms when the beetles feed in the crotches of young twigs or leaf axils (the angles between leafstalks and twigs). Healthy elms also become infected by natural-root grafts within 50 feet (15 metres) of diseased trees.

Smoothleaf elm (*Ulmus carpinifolia*) seedlings have shown resistance in The Netherlands. Some species, such as Chinese elm (*U. parvifolia*) and Siberian elm (*U. pumila*), as well as hybrids between American and Asiatic elms, are resistant. The best control measures include the removal and destruction of beetle breeding sites and all dead and weakened elm wood and the use of a dormant spray with a suitable insecticide which prevents the beetles from feeding in small elm twig crotches. Disease spread by root grafts can be stopped by a fumigant.

**Black stem rust of wheat.** One of the oldest and still important diseases is black stem rust, which is caused by the fungus *Puccinia graminis*. All cereals and many grasses are infected by one of the six varieties of this rust. The discussion below is limited to wheat. Black stem rust occurs essentially wherever wheat is grown. In 1935 this rust destroyed almost 60 percent of the total hard red spring-wheat crop in Minnesota and the Dakotas. In 1953 and 1954 outbreaks of black stem rust in the same area reduced yields as much as 80 percent on durum wheats and 30 percent on spring wheats. Losses were measured in tens of millions of bushels.

During its complex life cycle, *Puccinia graminis* produces five different kinds of spores, three on wheat and two on barberry. The uredial, or red-rust, stage occurs on wheat culms (stems), leaves, and glumes (bracts enclosing flowers) as elongated, reddish-brown pustules (uredia), each containing up to 350,000 rust-coloured spores (uredospores). Developing pustules rupture the epidermis (skin) of the plant, giving it a ragged, powdery appearance. Uredospores, blown to other wheat plants, germinate and initiate infections. The cycle is repeated at intervals of seven to 14 days as long as there is susceptible living wheat and warm, moist weather prevails. Symptoms vary from scattered yellow flecks to numerous large pustules, depending on resistance of the wheat variety and weather conditions.

When the wheat ripens, the rust-coloured pustules gradually turn black as another spore type, the blackish teliospore, develops (hence the name black stem rust). The thick-walled, two-celled teliospores survive the winter, germinating in the spring to form special spores, called sporidia, or basidiospores. Basidiospores cannot infect wheat; they affect only the common barberry, in which the fungus develops yellow-orange spots on the upper leaf surface that contain pycnia—spore-producing structures. The dark, flask-shaped pycnia exude a sticky liquid containing pycniospores. Following cross-fertilization, which is aided by insects, the fungus develops an orange cluster of tubular cups (aecia) on the lower leaf surface. In these cups are formed aeciospores, which can infect wheat but not barberry. When wind-borne aeciospores infect wheat, the red-rust stage develops again. Wind may carry uredospores many hundreds of miles, even across continents.

Control of  
Dutch elm  
disease

Eradication of barberry

The fungus overwinters in the red-rust stage in warm climates. In the spring, waves of uredospores blow northward where they start new infections on wheat—bypassing the barberry.

Since 1918, intensive efforts to eradicate the susceptible common barberry (*Berberis vulgaris*) have continued in North America. Many millions of bushes, each capable of producing several billion spores each spring, have been removed by hand or killed by chemicals. The Japanese barberry (*B. thunbergii*), a common ornamental shrub, is fortunately immune to black stem rust.

The rust fungus and the wheat plant are highly variable. Through distinctive rust symptoms produced on 12 differential wheat varieties, over 325 physiological races of black stem rust have been described. Only about 12 races are important in any year. Certain wheat varieties are highly resistant or immune to some races but susceptible to others. No wheat is highly resistant to all races.

Eradication of rust-spreading barberries is important for two reasons. First, new rust races are produced on barberry from hybridization or cross-fertilization of existing races; second, rust spreads from barberry to nearby wheat two or three weeks before uredospores are normally wind-borne from the south. With an early start, rust can severely damage young grain plants.

Wheat-breeding programs emphasize the development of varieties resistant to regionally important races of black stem rust, other rusts, smuts, root rots, other diseases, insects, and various characters that add to the quality and yield of grain. To keep ahead of the variability of the fungi, wheat breeding must be a continuing process.

Blister rust disease of white pines, caused by *Cronartium ribicola*, has a comparable cycle to black stem rust, but with gooseberries and currants (*Ribes* species) as the alternate hosts. In this case, the white pines carry the fungus spore stages equivalent to those found in the barberry of the wheat rust disease; and the stages infecting the *Ribes* alternate host are like those found in the wheat plants.

Wood rots. Certain higher fungi actively decompose and stain forest timber. Losses from dead trees and effects of decay on growth may approach 45 percent of the timber losses from all causes. Such fungi may decay lumber and wood products already in use, making expensive replacements necessary.

**Nematodes.** Nematodes parasitic on plants are active, slender, unsegmented roundworms (also called nemas, or eelworms). The great majority cannot be seen with the unaided eye because they are tiny and translucent. Practically all adult forms fall within the range of 0.25 to two millimetres (0.01 to 0.08 inch) in length. About 1,200 species cause disease in plants. Probably every form of plant and animal life is fed upon by at least one species of nematode. They usually live in soil and attack small roots, but some species inhabit and feed in bulbs, buds, stems, leaves, or flowers (see *ASCHELMINTHES*).

Mode of nematode attack. Nematodes parasitic on plants obtain food by sucking juices from them. Feeding is accomplished by a hollow, needlelike mouthpart called a spear or stylet. The nematode pushes the stylet into plant cells and injects a liquid containing enzymes (biological catalysts), which digest plant cell contents. The liquefied contents are then sucked back into the nematode's digestive tract through the stylet. Nematode feeding lowers natural resistance, reduces vigour and yield of plants, and affords easy entrance for wilt-producing or root-rot-producing fungi or bacteria and other nematodes. Nematode-infested plants are weak and often appear to suffer from drought, excessive soil moisture, sunburn or frost, a mineral deficiency or imbalance, insect injury to roots or stem, or disease.

Common symptoms of nematode injury include stunting, loss of green colour and yellowing; dieback of twigs and shoots; slow general decline; wilting on hot, bright days; and lack of response to water and fertilizer. Feeder root systems are reduced; they may be stubby or excessively branched, often discoloured, and decayed. Winter-kill of orchard trees, raspberries, strawberries, ornamen-

tals, and other perennials is commonly associated with nematode infestations.

Root injury develops partly from the nematodes feeding on cells and partly from toxic salivary excretions of the parasite. Tissues often respond by producing either an enlargement (hypertrophy) or degeneration of cells; sometimes both occur.

Many nematodes are native and attack cultivated plants when their natural hosts are removed. Others have been introduced with seedling plants, bulbs, tubers, and particularly in soil balled around roots of infested nursery stock.

Nematodes may live part of the time free in soil around roots or in fallow gardens and fields. They tunnel inside plant tissues (endoparasites) or feed externally from the surface (ectoparasites) and may enter a plant through wounds, natural openings, or by penetrating roots and pushing in between cells. All nematodes parasitic on plants require living plant tissues for reproduction. Nematodes are attracted to host roots by sensing either the heat given off by roots or the chemicals secreted by roots.

Most species require 20 to 60 days to complete a generation from egg through four larval stages to adult and back to egg. Some nematodes have only one generation a year but still produce several hundred offspring.

Soil populations and developmental rate of nematodes are affected by the length of the growing season; temperature; availability of water and nutrients; and moisture, type, texture, and structure of soil. Also important are populations of nematode-parasitic bacteria, viruses, some 50 different nematode-trapping fungi, protozoans, mites, flatworms, or other pests, and other nematodes. Toxic chemicals in the soil or secreted by plant roots; crop rotations and past cropping history; species, variety, age and nutrition of growing plants; and other factors are additional conditions that affect nematode populations.

Certain species live strictly in light, sandy soils; some built up high populations in muck soils; and a few seem to thrive in heavy soils. High populations and greater crop damage are much more common in light sandy soils than in heavy clay soils.

Many plant-infecting nematodes become inactive at temperatures between 5° and 15° C (41° and 59° F) and 30° and 40° C (86° and 104° F). The optimum for most is 20° to 30° C (68° to 86° F), but this varies greatly with the species, stage of development, activity, growth of the host, and other factors.

Nematodes may be found in plant tissues in large numbers. A large *Narcissus* bulb may contain 250,000, an infested root system of a peppermint or tomato plant 100,000, and one gram of young strawberry roots 3,500 at the height of the growing season.

After a plant-infecting nematode has been accidentally introduced into a garden or field, several years pass before the population builds up sufficiently (*i.e.*, up to several billion or more active nematodes per acre) to cause conspicuous symptoms in a large number of plants. This is because nematodes move very slowly through soil—rarely more than 30 inches (75 centimetres) a year. Nematodes are easily spread, however, by moving infested soil, plant parts, or contaminated objects—*e.g.*, tools and machinery, bags and other containers, running water, wind, clothing, shoes, animals, and birds, and infested planting stock.

Nematode diseases. Root-knot nematodes (*Meloidogyne* species) are well known because of conspicuous "knots," or gall-like swellings, they induce on roots. Over 2,000 kinds of higher plants are subject to their attack. Losses are often heavy, especially in warm regions with long growing seasons. Certain species, however, such as the northern root-knot nematode (*M. hapla*), are found where soil may freeze to depths of three feet. Vegetables, cotton, strawberries, and orchard trees are commonly attacked. Garden plants and ornamentals frequently become infested through nursery stock.

Root-lesion nematodes (*Pratylenchus* species), cosmopolitan in distribution, are endoparasites that cause severe losses to hundreds of different crop and ornamental plants by penetrating roots and making their way through

Numbers of nematodes in diseased plants

Symptoms of nematode injury

the tissues, breaking down the cells as they feed. They deposit eggs from which new colonies develop. After a root begins to decline in vigour, they move into the soil in search of healthy roots. Lesions form in the root as fungi and bacteria enter damaged tissues, and root rot often occurs. Annual crops may succumb early in the season, but perennials and orchard trees may not decline (show reduced vigour and growth) for several years.

The golden nematode of potatoes (*Heterodera rostochiensis*) is a menace of the European potato industry. Great efforts have been made to control it. The speck-sized golden cysts that dot infested plant roots are the remains of female bodies. Each cyst may contain up to 500 eggs, which hatch in the soil over a period of up to 17 years. A chemical given off by potato and tomato roots stimulates hatching of the eggs.

A related, cyst-forming species, the sugar-beet nematode (*H. schachtii*), is a pest that has restricted acreage of sugar beets in Europe, Asia, and America.

The citrus nematode (*Tylenchulus semipenetrans*) occurs wherever citrus is grown, exacting a heavy toll in fruit quality and production. Typical symptoms are a slow decline, yellowing and dying of leaves, and dieback of twigs and branches in many groves 15 years or older. Infested nursery stock has widely distributed the nematode. The burrowing nematode (*Radopholus similis*) is a serious endoparasite in tropical and subtropical areas, where it attacks citrus (causing spreading decline), banana, avocado, tomato, black pepper, abaca, and over 200 important crops, trees, and ornamentals, causing severe losses.

Many important ectoparasites feed on plant roots—dagger nematodes (*Xiphinema*), stubby-root nematodes (*Trichodorus*), spiral nematodes (*Rotylenchus* and *Helicotylenchus*), sting nematodes (*Belonolaimus*), and pin nematodes (*Paratylenchus*). Leaf, or foliar, nematodes (*Aphelenchoides* species) and bulb and stem nematodes (*Ditylenchus dipsaci*) cause severe losses in vegetable and ornamental bulb crops, clovers, alfalfa, strawberry, sweet potato, orchids, chrysanthemums, begonias, and ferns.

Control measures. Control measures for nematodes often include rotation with nonhost plants, growing of

resistant varieties and species, use of certified, nematode-free nursery stock, and use of soil fumigants (nematicides) as preplant or postplant treatments. Steam or dry heat is applied to soil in confined areas, such as greenhouse benches and ground beds. Exposure to moist heat, such as steam or hot water, at 50°C (120°F) for 30 minutes, is sufficient to kill most nematodes and nematode eggs. Shorter periods are needed at higher temperatures. Hot water soak treatments have been developed for freeing a wide range of seeds, bulbs, corms, and tubers, as well as potted or dormant plants, of nematodes. State and federal quarantines prohibiting movement of infested soil, plants, or plant parts, machinery, and other likely carriers also exist. Cultural practices to promote vigorous plant growth (*i.e.*, watering during droughts, proper application of fertilizers, clean cultivation, fall and summer fallowing, use of heavy organic mulches or cover crops, and plowing out roots of susceptible plants after harvest) are useful for specific nematodes. Asparagus, marigolds (*Tagetes* species), and *Crotalaria* species are toxic to many plant-infecting nematodes. They contain a number of chemical substances that are receiving attention as possible means of biological control in reducing soil nematode populations.

**Parasitic seed plants.** A number of flowering plants are important as parasites of other plants. Among the more important ones are mistletoe, dodder, and witchweed.

**Mistletoe.** Mistletoes are semiparasitic seed plants that feed on trees and obtain water and mineral salts by sending rootlike structures (haustoria) into vascular tissue of the inner bark (see SANTALALES). There are three important types: American (*Phorodendron* species), European (*Viscum album*), and dwarf (*Arceuthobium* species). All produce sticky seeds spread by birds. American mistletoe, restricted to the Americas, is best known for its ornamental and sentimental uses at Christmas time. The leafy, bushy evergreen masses, up to three feet or more in diameter, appear on tree branches. They are most conspicuous after deciduous leaves have fallen. The European mistletoe is similar in habit and appearance to its American relative. Tree branches infected by mistletoes may become stunted or even die.

**Dwarf mistletoe.** Dwarf mistletoe is common on and very destructive to conifers in forests. Seedlings and young trees may be stunted, deformed, or killed. Conspicuous witches'-brooms form in the crown or spindle-shaped swellings (later cankers) in limbs and trunk. Canker and wood-rotting fungi often enter through mistletoe wounds. Dwarf mistletoes often escape detection because the scaly-leaved plants may be less than one inch (2.5 centimetres) long; they do range to 12 or 18 inches (30 to 45 centimetres), however. Dwarf mistletoes occur scattered along conifer limbs and small branches. After the mistletoe has grown internally for about a year, the branch may start to form a witches'-broom. Four to five years elapse before the yellow to brown to olive-green shoots form fruits. The sticky seeds are shot with explosive force from the fruit for horizontal distances ranging from 15 (five metres) to more than 60 feet (18 metres); this is one of the most remarkable methods for seed discharge among plants. Once seeds adhere to a branch, they germinate on young bark and penetrate into the host tree's vascular system. Control for mistletoes in individual trees involves removal of infected branches a foot or more beyond any evidence of the parasite before the fruits ripen.

**Dodder.** The 170 species of dodder (*Cuscuta*) are widely distributed and called such names as strangleweed, devil's-hair, pull down, hell-bind, love vine, and gold-thread. The leafless, yellow-orange, threadlike stems twine around a number of field and garden host plants. By extending to nearby plants, it may draw them together and downward until a tangled yellowish-orange patch is formed. The infested area is usually less than three metres across the first year; it spreads more rapidly in succeeding years. Dodder is widely distributed as a contaminant with field seed; hence the losses in clover, alfalfa, and flax fields. Dodder is controlled by planting

certified, properly cleaned seed, and by mowing patches of dodder in the field well before the seeds form. The dried patches are sprinkled with fuel oil and burned. Careful application of selective herbicides or a soil fumigant, and sowing heavily infested areas with resistant plants (e.g., garden beans, soybean, corn, cowpea, pea, grasses, or small grains) are also control methods.

**Witchweed.** Witchweed, a small parasitic weed (*Striga asiatica*), is widely distributed in Asia and south Africa. It has been known in the coastal sandy soils of North and South Carolina since the mid 1950s but through intensive efforts is slowly being eradicated. Witchweed parasitizes the roots of many hosts, including maize (corn), sorghum, sugarcane, rice, small grains, and more than 50 species in the grass and sedge families. A serious infestation may cause corn plants to be severely stunted, wilt, and turn yellow or brown thus reducing the acre yield. *Striga* plants rarely grow over eight to ten inches (20 to 25 centimetres) tall with small, red, yellowish-red, yellow, or white flowers. One plant may produce 500,000 tiny brown seeds that can remain alive in soil for years until stimulated to germinate by a secretion from a nearby host root. Witchweed robs the host of water and food, causing it to grow more slowly than normal and often to die before maturing. Control is difficult; useful measures include application of selective herbicides before seeds are produced; rotation with a resistant crop and keeping it free of weed grasses that may serve as hosts; and prevention of seed set by growing trap crops and then destroying them with herbicides.

Control of  
witchweed

#### PRINCIPLES OF DISEASE CONTROL

Successful disease control is a broad, highly technical, and rapidly developing scientific field based on accurate diagnosis; thorough knowledge of the causal agent and the disease cycle; host-pathogen interactions in relation to environmental factors; and cost. Disease control starts with the best variety, seed, or planting stock available and continues through the growing season in garden or field. Relatively few diseases are controlled by one method; the majority require several approaches. These often need to be integrated into a broad program of biological or cultural and chemical methods to control as many different pests—including diseases, insects, mites, rodents, and weeds—on a given crop as possible (see PEST CONTROL; WEED CONTROL).

Most control measures are directed against inoculum of the pathogen or disease agent and involve the principles of exclusion and avoidance, eradication, protection, host resistance and selection, and therapy.

**Exclusion and avoidance.** The principle of exclusion and avoidance is to keep the pathogen away from the growing host plant. This practice commonly excludes pathogens by disinfection of plants, seeds, or other parts, using chemicals or heat. Inspection and certification of seed and other planting stock help insure freedom from disease. For gardeners this involves sorting bulbs or corms before planting and refusing to buy obviously diseased plants. Federal and state plant quarantines, or embargoes, have been established to prevent introduction of potentially destructive pathogens into areas currently free of the disease. More than 150 countries now have established quarantine regulations.

**Eradication.** Eradication is concerned with elimination of the disease agent after it has become established in the area of the growing host or has penetrated the host. Such measures include crop rotation, destruction of the diseased plants or alternate host plants, pruning, disinfection, and heat treatments.

Crop rotation with nonsusceptible crops "starves out" bacteria and fungi with a restricted host range. Some pathogens can survive only as long as the host residue persists, usually no more than a year or two. Many pathogens, however, are relatively unaffected by rotation because they become established as saprophytes or soil inhabitants (e.g., *Fusarium* and *Pythium* species; *Rhizoctonia solani*; and the potato scab actinomycete, *Streptomyces scabies*) or their propagative structures remain dormant but viable for many years (e.g., cysts of cyst

nematodes, sporangia of the cabbage clubroot fungus, and onion smut spores).

Burning, deep plowing of plant debris, and fall spraying are used against such diseases as leaf blights of tomato, Dutch elm disease, and apple scab. Destruction of weed hosts also helps control such virus diseases as cucumber mosaic and curly top. Destruction of alternate hosts is used against black stem rust of cereals and white pine blister rust. Destruction of diseased plants helps control Dutch elm disease, oak wilt, and peach virus diseases—mosaic, phony peach, and rosette. Elimination of citrus canker in the southeastern United States has been one of the few successful eradication programs in history. Infected trees were sprayed with oil and burned.

Pruning and excision of a diseased portion of the plant, followed by a protective wound dressing, have aided in reducing inoculum sources for canker and wood-rot diseases of shade trees and fire blight of pome fruits. Disinfection of contaminated tools, as well as packing and shipping containers, controls a wide range of diseases. Direct application of dry or wet heat is used to obtain seeds, bulbs, other propagative materials, and even entire plants free of viruses, nematodes, and other pathogens.

**Protection.** The principle of protection involves placing a protective barrier between the pathogen and the susceptible part of the host. This can be accomplished by regulation of the environment, cultural and handling practices, control of insect carriers, and application of chemical toxicants (poisons).

**Regulation of the environment.** Selection of outdoor growing areas where weather is unfavourable for disease is a method of controlling disease by regulating the environment. Control of virus diseases of potato, for example, can be accomplished by growing the seed crop in northern regions where low temperatures are unfavourable for the aphid carriers. Another environmental factor that can be brought under control is the storage and in-transit environment. A variety of post-harvest diseases of potatoes, sweet potatoes, onions, cabbage, apples, pears, and other crops are controlled in storage and shipment by keeping humidity and temperature low and by reducing the quantity of ethylene and other natural gases in storage houses.

**Cultural practices.** Selection of the best time and depth of seeding and planting is an effective cultural practice that reduces disease impact. Shallow planting of potatoes may help to prevent *Rhizoctonia* canker. Early fall seeding of winter wheat may be unfavourable for seedling infection by wheat-bunt teliospores. Cool-temperature crops can be grown in soils infested with root-knot nematode and harvested before soil temperatures become favourable for nematode activity. Adjustment of soil moisture is another cultural practice of widespread usefulness. For example, seed decay, damping-off, and other seedling diseases are favoured by excessively wet soils. The presence of drain tiles in poorly drained fields and the use of ridges or beds for plants are often beneficial. Adjustment of soil pH also leads to control of some diseases. Common potato scab can be controlled by adjusting the pH to 5.2 or below; other acid-tolerant plants then must be used in crop rotation, however.

**Regulation of fertility level and nutrient balance.** Potash and nitrogen, and the balance between the two, may affect the incidence of certain bacterial, fungal, and viral diseases of corn, cotton, tobacco, and sugar beet. A number of microelements (i.e., nutrient elements required by plants in minute quantities), including boron, iron, zinc, manganese, magnesium, copper, sulfur, and molybdenum, may cause noninfectious diseases of many crop and ornamental plants. Adjusting the soil pH, adding chelated (bound or enclosed in large organic molecules) or soluble salts to the soil, or spraying the foliage with these or similar salts is a corrective measure.

**Handling practices.** Late blight on potato tubers can be controlled by delaying harvest until the foliage has been killed by frost, chemicals, or mechanical beaters. Avoidance of bruises and cuts while digging, grading, and packing potatoes, sweet potatoes, and bulb crops also reduces disease incidence.

Burning  
and  
destruction

Tempera-  
ture,  
moisture,  
and soil  
reaction

**Control of insect vectors.** There are many examples in which losses by virus and mycoplasma diseases can be reduced by controlling aphids, leafhoppers, thrips, and other carriers of these agents.

**Toxicants.** The term toxicants includes chemicals that inhibit or kill bacteria (bactericides), fungi (fungicides), and nematodes (nematicides). Toxicants can be applied to seed, foliage, fruit, or soil and prevent infection by placing a toxic barrier between plant and inoculum. Germinating fungus spores are very sensitive to fungitoxics (see PEST CONTROL).

Seed treatments are used to protect many kinds of seeds, bulbs, corms, and tubers. These are routinely treated with chemicals to eradicate pathogenic bacteria, fungi, and nematodes and to protect the seed against decay and damping-off organisms (mainly fungi) in the soil. Major materials used in eradicated seed treatments are hot water, formaldehyde, benomyl, and DMOC (5,6-dihydro-2-methyl-1,4-oxathiin-3-carboxanilide). Benomyl and DMOC are also protectants. Some protective seed treatments include thiram, captan, chloranil, maneb, HCB (hexachlorobenzene), and Dexon (*para*-dimethylamino-benzenediazosodium sulfonate). Products used for systemic (internal) treatments are taken up by seeds or seedlings and distributed within the plants. The better materials are DMOC, benomyl, TBZ (2-[4-thiazolyl]-benzimidazole), and chloroneb.

Chemicals  
used in soil  
treatments

Soil treatments are designed to kill soil-inhabiting nematodes, fungi, and bacteria. Such soil-treatment types as steam, methyl bromide, chloropicrin, MIT (methyl isothiocyanate), DMTT (3,5-dimethyltetrahydro-1,3,5,2H-thiadiazine-2-thione), SMDC (sodium *N*-methylthiocarbamate dihydrate), D-D (a mixture of 1,3-dichloropropane and 1,2-dichloropropane), EDB (ethylene dibromide), and formaldehyde are used after the crop is harvested or before planting. Some fungitoxics (*i.e.*, PCNB [pentachloronitrobenzene], captan, chlorothalonil, folpet, thiram, zineb, ziram, chloroneb, Dexon, ferbam, TBZ, and benomyl) can be sprayed on young seedlings in the seedbed or mixed with soil at planting time.

Foliage and fruit treatments include a wide range of organic chemicals that are used for spraying and dusting a diversity of field, plantation, fruit, and vegetable crops as well as ornamentals—*e.g.*, captan, zineb, maneb, chlorothalonil, dodine, ferbam, folpet, thiram, benomyl, fixed coppers, and sulfur compounds. Antibiotics, such as streptomycin and cycloheximide (Acti-dione), have been developed for use on plants. Most of these organic materials have relatively little toxicity to plants, animals, or humans and are rapidly degraded on plants and in soil. Without these materials to control fungal diseases, production on a commercial scale of such crops as bananas, potatoes, tomatoes, grapes, stone fruits, apples, and pears would be impossible.

Many toxicants are combined by the grower or are sold as multipurpose sprays and dusts so that one application acts against insects, mites, and plant pathogens.

**Host resistance and selection.** Ideal control is normally provided by plant varieties with good genetic resistance to most common diseases. Resistant or immune varieties are critically important for low-value crops in which other controls are unavailable or their expense makes them impractical. Much has been accomplished in developing disease-resistant varieties of field crops, vegetables, fruits, turf grasses, and ornamentals. Although great flexibility and potential for genetic change exist in most economically important plants, pathogens are also flexible. Sometimes, a new plant variety is developed that is highly susceptible to a previously unimportant pathogen.

**Variable resistance.** The characters associated with resistance or susceptibility are subject to several types of variation. These include nongenetic variations, which result from a variation in ecological conditions, and genetic variations. Genetic variations are new gene combinations resulting from normal sexual reproduction.

**Obtaining disease resistant plants.** Several means of obtaining disease-resistant plants are commonly employed alone or in combination. These include introduc-

tion from an outside source, selection, and induced variation. All three may be used at different stages in a continuous process; for example, varieties free from injurious insects or plant diseases may be introduced for comparison with local varieties. The more promising lines or strains are then selected for further propagation, and they are further improved by promoting as much variation as possible through hybridization or special treatment. Finally, selection of the plants showing greatest promise takes place. Developing disease-resistant plants is a continuing process.

Special treatments for inducing gene changes include the application of mutation-inducing chemicals and irradiation with ultraviolet light and X-rays. These treatments commonly induce deleterious genetic changes, but, occasionally, beneficial ones may also occur.

Methods used in breeding plants for disease resistance are similar to those used in breeding for other characters except that two organisms are involved—the host plant and the pathogen. Thus, it is necessary to know as much as possible about the nature of inheritance of the resistant characters in the host plant and the existence of physiological races or strains of the pathogen.

**Therapy.** Therapeutic measures are much less used in plant pathology than in human or animal medicine. Recent advances in the development of systemic fungitoxics and fruit indicate that revolutionary changes in disease control lie ahead. These new chemicals may restrict spread and development of pathogens by direct or indirect toxic effects or increase the ability of the host to resist infection.

## BIBLIOGRAPHY

**General works:** COMMONWEALTH MYCOLOGICAL INSTITUTE, *Plant Pathologist's Pocket-Book* (1968), a compilation of useful information on the diagnosis, isolation, and culture of various types of plant pathogens; G.L. CAREFOOT and E.R. SPROTT, *Famine on the Wind: Man's Battle Against Plant Disease* (1967), a popular account, vividly told, of how some plant diseases have profoundly influenced the history of many countries of the world; J.L. FORSBERG, "Diseases of Ornamental Plants," *University of Illinois, College of Agriculture, Spec. Publ. No. 3* (1963), a well-illustrated popular book for home owners, professional and amateur gardeners, and commercial florists; N.W. FRAZIER (ed.), *Virus Diseases of Small Fruits and Grapevines* (1970), an important handbook on virus and viruslike diseases of non-tree fruits; K.F. BAKER and W.C. SNYDER (eds.), *Ecology of Soil-Borne Plant Pathogens* (1965), an important collection of 41 review articles on plant pathogens in soil and their biological control; C.S. HOLTON *et al.* (eds.), *Plant Pathology: Problems and Progress, 1908–1958* (1959); J.G. HORSFALL and A.E. DIMOND (eds.), *Plant Pathology: An Advanced Treatise*, 3 vol. (1959–60), an important work that presents an integrated synthesis of the parts of plant pathology; E.C. LARGE, *The Advance of the Fungi* (1940), a popular account of how plant disease epidemics have affected man's economic and political history; P.P. PRORONE, *Tree Maintenance*, 3rd ed. (1959), a popular and practical book written for arborists, city foresters, park superintendents, nurserymen, and the average tree owner that covers all phases of shade and ornamental tree maintenance; M.C. SHURTLEFF, *How to Control Plant Diseases in Home and Garden*, 2nd ed. (1966), a profusely illustrated, popular, encyclopaedia-type book covering more than 5,200 diseases of over 3,200 cultivated plants; UNITED STATES DEPARTMENT OF AGRICULTURE, "Plant Diseases," *Yearbook of Agriculture, 1953* (1953), a series of popular articles written primarily for farmers and home gardeners covering practical discussions on the causes and controls of plant diseases; CYNTHIA WESTCOTT, *Plant Disease Handbook*, 3rd ed. (1971), an excellent reference book for professional and amateur gardeners on over 2,000 diseases of plants grown in gardens, under glass, or in the home within the continental United States.

**College-level texts:** G.N. AGRIOS, *Plant Pathology* (1969), general considerations of disease, parasitism and pathogenicity, and the biochemistry of host-parasite relationships; F.C. BAWDEN, *Plant Viruses and Virus Diseases*, 4th ed. (1964); A.F. BIRD, *The Structure of Nematodes* (1971); W. CARTER, *Insects in Relation to Plant Disease* (1962); C. CHUPP and A.F. SHERF, *Vegetable Diseases and Their Control* (1960), an exhaustive treatment with numerous fine illustrations; H.B. COUCH, *Diseases of Turfgrasses* (1962); E. EVANS, *Plant Diseases and Their Chemical Control* (1968), a summary of basic concepts, principles, and modern methods of chemical

disease control; S.D. GARRETT, *Pathogenic Root-Infecting Fungi* (1970); R.N. GOODMAN, Z. KIRALY, and M. ZAITLIN, *The Biochemistry and Physiology of Infectious Plant Disease* (1967), a discussion of key biochemical and physiological processes that occur in the healthy plant and how these processes are disturbed; G.H. HEPTING, *Diseases of Forest and Shade Trees of the United States* (1971); W.R. JENKINS and D.P. TAYLOR, *Plant Nematology* (1967), covers plant-parasitic nematodes; K. MARAMOROSCH (ed.), *Viruses, Vectors, and Vegetation* (1969), review articles on the many fascinating interactions between viruses, their numerous carriers, and host plants; T.R. PEACE, *Pathology of Trees and Shrubs* (1962), covers all important infectious and noninfectious diseases of temperate forest and ornamental trees and shrubs; P.P. PIRONE, *Diseases and Pests of Ornamental Plants*, 4th ed. (1970), reference for professional and amateur gardeners that covers the diseases, pests, and other troubles that affect nearly 500 genera of trees, shrubs, flowers, vines, houseplants, and turf-grasses; K.M. SMITH, *Plant Viruses*, 4th ed. (1968), discussion of the properties and diseases caused by each plant-infecting virus and its important strains; C. STAPP, *Pflanzenpathogene Bakterien* (1958; Eng. trans., *Bacterial Plant Pathogens*, 1961), text stressing description and classification, symptoms, host-parasite relations, geographical distribution and control of bacterial plant pathogens in temperate countries; R.B. STREETS, *The Diagnosis of Plant Diseases* (1969), useful field and laboratory manual emphasizing the most practical methods for rapid identification of plant diseases and the pathogens or agents that cause them; G.A. STROEBEL and D.E. MATHRE, *Outlines of Plant Pathology* (1970); J.C. WALKER, *Plant Pathology*, 3rd ed. (1969); B.E.J. WHEELER, *An Introduction to Plant Diseases* (1969); R.K.S. WOOD, *Physiological Plant Pathology* (1967), a description of the factors affecting infection, how bacteria and fungi enter higher plants and cause them to be diseased, and the properties of plants that make them resistant to disease; B.M. ZUCKERMAN, W.F. MAI, and R.A. ROHDE (eds.), *Plant Parasitic Nematodes*, 2 vol. (1971).

## Disney, Walt

The American motion-picture and television producer Walt Disney pioneered the art of animated cartoon films; he created such universally beloved cartoon characters as Mickey Mouse and Donald Duck and cinematically adapted such storybook favourites as Snow White and the Seven Dwarfs as full-length cartoon motion pictures. He also designed and promoted a world-famous amusement park, Disneyland, in California. A second Disneyland (Walt Disney World) opened in Florida after his death. His imagination and energy, his whimsical humour, and his gift for being attuned to the vagaries of popular taste inspired him to develop well-loved amusements for "children of all ages" throughout the world. His achievement as a creator of entertainment for an almost unlimited public and as a highly ingenious merchandiser of his wares may be compared to that of a successful industrialist. Yet, in spite of his tremendous success, he remained in fact a rather homespun individual, a lover of gadgets who made no pretensions to a knowledge of art and, in the early years of his work, would hardly have dreamed of emerging a tycoon.

*Early life.* Walter Elias Disney was born in Chicago on December 5, 1901, the fourth son of Elias Disney, a peripatetic carpenter, farmer, and building contractor, and his wife, Flora Call, who had been a public school teacher. When Walt was little more than an infant, the family moved to a farm near Marcelline, Missouri, a typical small Midwestern town, which is said to have furnished the inspiration and model for the Main Street U.S.A. of Disneyland. Here Walt began his schooling and first showed a taste and aptitude for drawing and painting with crayons and watercolours.

His restless father soon abandoned his efforts at farming and moved the family to Kansas City, Missouri, where he bought a morning newspaper route and compelled his young sons to assist him in delivering papers to home subscribers in rain or shine. Walt later said that many of the habits and compulsions of his adult life stemmed from the disciplines and discomforts of helping his father with the paper route. In Kansas City, the young Walt began to study cartooning with a correspondence school and later took classes at the Kansas City Art Institute and School of Design.

EB Inc.

In 1917 the Disneys moved back to Chicago, and Walt entered McKinley High, where he took photographs, made drawings for the school paper, and studied cartooning on the side, for he was hopeful of eventually achieving a job as a newspaper cartoonist. But his progress was interrupted by World War I, in which he participated as a truck driver for the American Red Cross in France and Germany.

Returning to Kansas City in 1919, he found occasional employment as a draftsman and inker in commercial art studios, where he met Ub Iwerks, a young artist who was to prove perhaps the most fortunate associate of his career after his brother Roy, who was his partner and the strongest counsellor throughout life.

*First animated cartoons.* Dissatisfied with their progress, Disney and Iwerks started a small studio of their own and acquired a second-hand motion-picture camera with which they made one- and two-minute animated advertising films shown on local movie-theatre programs, much as commercials are shown on television today. They also did a series of animated cartoon sketches called "Laugh-O-Grams" and a series of seven-minute animated fairy tales, which they called "Alice in Cartoonland." A New York film distributor cheated the young producers, and, destitute and disheartened, Disney left for Los Angeles to join his brother Roy.

With Roy as business manager, Disney resumed the "Alice" series, persuading Iwerks to join him and assist with the drawing of the cartoons. They invented a character called Oswald the Rabbit, contracted for distribution of the films at \$1,500 each, and propitiously launched their small enterprise. Just before the transition to sound in motion pictures in 1927, Disney and Iwerks experimented with a new character—a cheerful, energetic, and mischievous mouse called Mickey. They planned two shorts, called *Plane Crazy* and *Gallop'n' Gaucho*, that were to introduce Mickey Mouse when *The Jazz Singer*, a motion picture with the popular singer Al Jolson, brought the novelty of sound to the movies. Fully recognizing the possibilities for sound in animated-cartoon films, Disney quickly produced a third Mickey Mouse cartoon equipped with voices and music, entitled *Steamboat Willie*, casting the other two soundless cartoon films aside. When it appeared in 1928, *Steamboat Willie* was a sensation.

The following year Disney started a new series called "Silly Symphonies" with a picture entitled *The Skeleton Dance*, in which a skeleton rose from the graveyard and did a grotesque, clattering dance to the music of Saint-Saëns's *Danse macabre*. Original and briskly syncopated, the film launched the series most successfully, but with costs mounting because of the more complicated drawing and technical work, Disney's operation was continually in peril.

The growing popularity of Mickey Mouse and his girl friend, Minnie, however, attested to the public's taste for

Street  
U.S.A.

the fantasy of little creatures with the speech, skills, and personality traits of human beings. (Disney himself provided the voice for Mickey.) This popularity led to the invention of other animal characters for the "Silly Symphonies." Donald Duck and the dogs Pluto and Goofy were introduced in 1931 and 1932, and in 1933 Disney produced a short, *The Three Little Pigs*, which arrived in the midst of the Great Depression and took the country by storm. Its treatment of the fairy tale of the little pig who works hard and builds his house of brick against the huffing and puffing of a threatening wolf suited the need for fortitude in the face of economic disaster; and its song "Who's Afraid of the Big Bad Wolf" was a happy taunting of adversity. It was in this period of economic hard times in the early 1930s that Disney fully endeared himself and his cartoons to audiences all over the world, and his operation began making money in spite of the Depression.

Through successive additions and advances in the animated-cartoon field, Disney continued to progress all through the 1930s. He had now gathered a staff of creative young people, who were headed by Iwerks. Colour was introduced in the "Silly Symphony" film, *Flowers and Trees* (1932), while other animal characters came and went in films such as *The Grasshopper and the Ants* (1934) and *The Tortoise and the Hare* (1935). Roy franchised tie-in sales with the cartoons of Mickey Mouse and Donald Duck—watches, dolls, shirts, and tops—and reaped more wealth for the company.

Walt Disney was never one to rest or stand still. He had long thought of producing feature-length animated films in addition to the shorts. In 1935 he began work on a version of the classic fairy tale that he called *Snow White and the Seven Dwarfs*, a project that required great organization and coordination of the creative and technical talents in his studio. Disney possessed a unique taste and capacity for such a task. While he actively engaged in all phases of creation in his films, he functioned chiefly as coordinator and final decision maker rather than as designer and artist. *Snow White* was widely acclaimed by critics and audiences alike as an amusing and sentimental romance. By animating substantially human figures in the characters of Snow White, the Prince, and the Wicked Queen and by forming caricatures of human figures in the seven dwarfs, Disney departed from the scope and techniques of the shorts and thus made a momentous transition in the nature of his type of film. While he continued for a while to do short films presenting the anthropomorphic characters of his little animals, he was henceforth to develop a wide variety of full-length entertainment films.

*Snow White* was followed three years later by other feature-length classics for children, *Pinocchio* (1940) and *Dumbo* (1941), the story of an elephant that could fly; and then Disney produced another totally unusual and exciting film—his multisegmented and stylized *Fantasia* (1940), in which cartoon figures and colour patterns were made to move to the music of Stravinsky, Paul Dukas, Tchaikovsky, and others.

But music critics and other intellectuals began to question Disney's taste and artistic talents in his more ambitious projects. They challenged him as a commercial opportunist and a mixer of artistic metaphors, an accusation that did not greatly disturb him, though Disney had by now acquired some of the smugness and intractability that many individuals do who achieve sudden success. In 1940 Disney moved his company into a new studio in Burbank, California, abandoning the old plant it had occupied in the early days of growth. The following year his staff went on strike. Although he and Roy held out against the artists, it was a blow to the image of Disney as a generous-hearted, amiable befriender of his own people.

**Major film production.** During World War II, the Disney studio did a great deal of work for the military and the federal government in the course of which it perfected the methods of combined live action and cartoon. After the war, Disney made many films with these hybrid techniques: *The Reluctant Dragon* (1941), *Saludos*

*Amigos* (1942), *The Three Caballeros* (1944), *Make Mine Music* (1946), and *Song of the South* (1946).

The Disney studios were now established as a big business enterprise, and they began to produce a variety of entertainment films. One immensely popular series, called "True-Life Adventures," featured actual motion pictures of nature, but they were usually so trickily edited that, rather than being true-to-life documentaries, they betrayed the Disney tendency to fantasize. Among these were *Seal Island* (1948), *Beaver Valley* (1950), and *The Living Desert* (1953). They also turned to production of live-action fictional feature films; and more full-length animation romances, such as *Cinderella* (1950), *Alice in Wonderland* (1951), and *Peter Pan* (1953) and a flow of low-budget, live-action films, including *The Parent Trap* and *The Absent-Minded Professor* in 1961.

The Disney studio was among the first to foresee the potentialities of television as a popular entertainment medium and to produce films directly for it. The *Zorro* and *Davy Crockett* series were fantastically popular with children and led to further profits for the company through tie-in sales of coonskin hats, powder horns, and Zorro capes. *Walt Disney's Wonderful World of Colour* became a continuing television fixture. But the climax of his career as a theatrical film producer came with his release of *Mary Poppins* in 1964. This adaptation of the popular children's story by Pamela L. Travers won worldwide acclaim and popularity.

**Disneyland.** Meanwhile, back in the early 1950s, Disney had initiated plans for a huge amusement park to be built near Los Angeles. When Disneyland opened in 1955, much of Disney's disposition toward nostalgic sentiment and fantasy was evident in its design and construction. It soon became a mecca for tourists from all over the world. A second Disney park in Florida was under construction at the time of his death, on December 15, 1966.

**Reputation.** In his later years, critical estimations of Disney and his works changed considerably, and his taste, as well as his political conservatism, were criticized by some. Social scientists and educators challenged the violence, cruelty, and sadism they found in many of his films, as well as the aesthetic vulgarities, and Disneyland was often referred to as "an amusement supermarket." But Disney himself, who in his last years contributed heavily with his family to the establishment of the California Institute of the Arts (called Cal-Art) in Valencia, California, was never visibly fazed by critics. "I've never called this art," he once commented with respect to all his activities. "It's show business, and I'm a showman."

#### MAJOR WORKS

**FILM SHORTS:** Included are 121 Mickey Mouse, 77 Silly Symphony, 126 Donald Duck, 51 Goofy, 48 Pluto, and 3 Figaro. The following in this category are all Academy Award winners: *Flowers and Trees* (1932); *The Three Little Pigs* (1933); *The Tortoise and the Hare* and *Three Orphan Kittens* (both 1935); *The Country Cousin* (1936); *The Old Mill* (1937); *Ferdinand the Bull* (1938); *The Ugly Duckling* (1939); *Lend a Paw* (1941); and *Der Fuehrer's Face* (1942).

**FEATURE FILMS:** *Snow White and the Seven Dwarfs* (1937); *Pinocchio* and *Fantasia* (both 1940); *The Reluctant Dragon* (1941); *Bambi* and *Saludos Amigos* (both 1942); *Victory Through Air Power* (1943); *The Three Caballeros* (1944); *Make Mine Music* and *Song of the South* (both 1946); *Fun and Fancy Free* (1947); *Melody Time* (1948); *So Dear to My Heart* and *The Adventures of Zehabod and Mr. Toad* (both 1949); *Cinderella* and *Treasure Island* (both 1950); *Alice in Wonderland* (1951); *The Story of Robin Hood and His Merrie Men* (1952); *Peter Pan, The Sword and the Rose*, and *Rob Roy: The Highland Rogue* (all 1953); *Stormy, the Thoroughbred with an Inferiority Complex* and *20,000 Leagues Under the Sea* (both 1954); *Davy Crockett, King of the Wild Frontier*, *Lady and the Tramp*, and *The Littlest Outlaw* (all 1955); *Westward Ho! The Wagons*, *The Great Locomotive Chase*, and *Davy Crockett and the River Pirates* (all 1956); *Johnny Tremain* and *Old Yeller* (both 1957); *The Light in the Forest* and *The Sign of Zorro* (both 1958); *Darby O'Gill and the Little People*, *The Shaggy Dog*, *Sleeping Beauty*, *The Third Man on the Mountain*, *Zorro the Avenger*, and *The Peter Tchaikovsky Story* (all 1959); *Toby Tyler or Ten Weeks with a Circus*, *Kidnapped*, *Pollyanna*, *The Hound That Thought He Was a Raccoon*, *Ten Who Dared* *Swiss*

First  
feature-  
length

Films for  
television

*Family Robinson*, and *One Hundred and One Dalmatians* (all 1960); *The Absent-Minded Professor*, *Greyfriars Bobby*, *The Parent Trap*, and *Babes in Toyland* (all 1961); *Moon Pilot*, *The Prince and the Pauper*, *Bon Voyage!*, *Big Red*, and *In Search of the Castaways* (all 1962); *Son of Flubber*, *Savage Sam*, *The Miracle of the White Stallions*, *Yellowstone Cubs*, *Sunimer Magic*, *The Incredible Journey*, *The Three Lives of Thomasina*, and *Sword in the Stone* (all 1963); *The Misadventures of Merlin Jones*, *The Waltz King*, *The Moon-Spinners*, *Mary Poppins*, and *Emil and the Detectives* (all 1964); *Those Calloways*, *The Legend of Young Dick Turpin*, *The Monkey's Uncle*, and *That Dam Cat* (all 1965); *Jungle Book* (1966).

**BIBLIOGRAPHY.** RICHARD SCHICKEL, *The Disney Version* (1968), is the sole objective and definitive biography. DIANE DISNEY MILLER (with PETE MARTIN), *The Story of Walt Disney* (1957), is an affectionate daughter's reminiscences. R.D. FEILD, *The Art of Walt Disney* (1942), provides excellent technical analysis of stories and animation styles in the films up to the time of its publication; and JOHN HALAS and ROGER MANVELL, *Design in Motion* (1962), includes a well-informed discussion of Disney's work in a brief but commendable survey of film animation. DEEMS TAYLOR, *Walt Disney's Fantasia* (1940), is a pleasant and informative participant's account of the making and the contents of that film, with many colour illustrations.

(B.Cr.)

## Disraeli, Benjamin

British statesman and novelist, twice prime minister, who provided the Conservative Party with a twofold policy of democracy and imperialism as well as an efficient organization, Benjamin Disraeli, later earl of Beaconsfield, was one of the most extraordinary figures ever to reach the summit of British politics. That a man of Jewish origin, loaded with debts, and widely regarded as a combination of flashy litterateur and opportunist adventurer should have become leader of the Tory (Conservative) Party may well be evidence of the unexpected fluidity of the Victorian social structure, but it is also evidence of a determination, a courage, and a parliamentary genius seldom surpassed in British history. If the "myth" of popular Toryism by which he interpreted past history can be easily destroyed, this does not alter the fact that he made it a reality in his own day. More than almost any other contemporary statesman he discerned intuitively what the newly enfranchised masses wanted both at home and abroad. His policy of social reform, his vision of the British Empire as a great confederation of self-governing states tied to the mother country by an imperial tariff, and his determination to stand up for what he deemed to be Great Britain's vital interests might well have ensured a long lease of power for the Conservative Party, had his health been stronger and his energy greater. The sincerity of his beliefs and the extent to which he was influenced by opportunism and love of power rather than high principle must always remain a matter of argument. He was an enigma to his contemporaries, and he remains one even today.

**Early life.** Disraeli was born in London on December 21, 1804, of Italian-Jewish descent, the eldest son and second child of Isaac D'Israeli and Maria Basevi. His grandfather Benjamin D'Israeli had emigrated to England from Cento, near Ferrara in Italy, in 1748 and, after a moderately successful business career, had become a member of the London Stock Exchange. His second wife, Disraeli's grandmother, was descended from the great Portuguese Jewish family of Vila Real. The most important event in Disraeli's boyhood was Isaac D'Israeli's quarrel in 1813 with the Sephardic synagogue of Bevis Marks, which led him in 1817 to decide to have his children baptized as Christians. Since, before 1858, Jews (by religion) were excluded from Parliament, it can safely be asserted that but for this curious accident Disraeli's subsequent political career could never have taken the form it did.

Disraeli was educated at small private schools. At the age of 17 he was articled to a firm of solicitors but longed to make his mark on the world in a more sensational manner than was open to a mere lawyer's clerk. His first efforts were disastrous.

In the autumn of 1824 he began to engage in reckless speculation in South American mining shares. The bubble burst a year later, and Disraeli was subsequently burdened with a debt that was to encumber him until he was well past middle age. Before this calamity he had persuaded his father's friend, the great publisher John Murray, to launch a daily newspaper, the *Representative*, which proved a complete failure. Disraeli was unable to pay his promised share of the capital, and the resulting recriminations involved him in quarrels with Murray and various other people of importance in the Tory literary-political world. As if this were not enough for a young man of barely 21, he then produced an anonymous novel, *Vivian Grey*, in which he lampooned Murray and related the whole story of the *Representative* under the thinnest of disguises. The author's identity was soon discovered, and the critics did not spare him.

the University of Texas at Austin

Disraeli, albumen print by W. & D. Downey.

The strain of all these events induced in Disraeli something that would now be called a nervous breakdown. He did little of interest during the next four years apart from writing another equally extravagant novel, *The Young Duke*, and in 1830 he set off on 16 months of travel in the Mediterranean and the Middle East. Disraeli's experience of the colour and glamour of the East not only produced the Oriental descriptions with which his novels abound but also affected his attitude toward foreign affairs, and it is by no means fanciful to see in those experiences the origin of his policy toward India, Egypt, and Turkey in the 1870s.

On his return to England he at once plunged into London social and literary life. His dandified dress, his conceit and affectation, his exotic good looks made him a striking though not always popular figure wherever he went. He soon found himself beset with invitations to fashionable parties and met most of the celebrities of the day. During the next few years he published a number of books; the only one of any literary value was *Contarini Fleming*, which also has considerable autobiographical interest.

**Political beginnings and marriage.** Disraeli by 1831 had made up his mind to enter politics, and since his family was then settled at Bradenham, near Wycombe in Buckinghamshire, it was natural that he should seek a seat in that locality. As an independent radical, he fought and lost High Wycombe twice in 1832 and once in 1835. He then realized that he must attach himself to one of the great political parties, and, since his radicalism had many features not inconsistent with a somewhat eccentric interpretation of Toryism, he gravitated toward the Tory-Conservative Party and in 1835 unsuccessfully fought Taunton as the official Conservative candidate. Disraeli's extravagant behaviour, load of debts, and open liaison

Levantine  
tour

Parliamentary debut

with Henrietta, wife of Sir Francis Sykes (and the original of his novel *Henrietta Temple*), combined to give him a dubious reputation at this time. Finally at the election of 1837 he was returned to Parliament as Conservative member for Maidstone in Kent. His maiden speech in the House of Commons (December 7, 1837) was a failure. A combination of elaborate metaphors, affected mannerisms, and foppish dress resulted in his being howled down. But he was not silenced. The last words of his speech, shouted high above the clamour, were both defiant and prophetic: "I will sit down now, but the time will come when you will hear me."

Disraeli was never a man to ignore the lessons of experience, and before long he became a speaker who commanded attention. His social position was consolidated by his marriage in 1839 to Mrs. Wyndham Lewis (*nee* Mary Anne Evans). She was 12 years older than Disraeli and highly eccentric, but she had a life interest in a London house and in a fortune that produced some £4,000 a year and was deeply devoted to her second husband. It would be absurd to deny that Disraeli's motives in proposing were principally material, but there is no reason to doubt the truth of her own half-jesting remark: "Dizzy married me for my money but if he had the chance again he would marry me for love."

Breach with Peel. The Conservative leader, Sir Robert Peel, anxious to cultivate talent in his party, seems to have encouraged Disraeli, but when in 1841 the Conservatives won the election Disraeli was not given office. Much mortified at the rebuff, he began to assume an ever more critical attitude toward Peel and the type of Conservatism that he represented.

Disraeli's pen had not been idle during the past ten years. He had written a number of novels, of which *Venetia*, a fictional account of the lives of Lord Byron and Percy Bysshe Shelley, remains very readable and *Henrietta Temple* is one of the most attractive of all his romances. During these years, too, he wrote a series of political works, including *Vindication of the English Constitution* and *The Letters of Runnymede*, a series of pseudonymous letters, satirizing the characters of the principal Whig (the future Liberal) ministers. In the 1840s Disraeli's Toryism took on a new colour with the emergence of a group of youthful Tories (of which George Smythe, later Lord Strangford, and Lord John Manners, later duke of Rutland, were the most important members) who were nicknamed Young England and who looked to Disraeli for their inspiration. In 1844 he wrote *Coningsby; or, The New Generation*, the novel that immortalizes their attitudes and aspirations, and the hero is a portrait of Smythe. Young England was hostile to the cool pragmatic humdrum middle class conservatism of Peel. It was romantic, aristocratic, nostalgic, and escapist, looking to a nonexistent golden past in which the people and the nobility were united in a generous alliance supporting an enlightened throne and a conscientious church. A year later (1845) Disraeli published *Sybil; or, The Two Nations*, in which the causes and nature of Chartism, the working class political movement, were vividly analyzed and depicted.

The Young England group

In the autumn of 1845 the combination of the Irish famine and the arguments of Richard Cobden decided Peel to repeal the protective duties on foreign imported grain known as the Corn Laws. Here was an issue on which Disraeli, now in more or less open revolt against Peel, could rally not merely the romantic scions of noble houses but the great mass of country squires who formed the backbone of the Conservative Party. Acting ostensibly as lieutenant to Lord George Bentinck, who nominally led the rebels, Disraeli in a series of brilliant speeches consolidated the opposition to Peel. But his invective greatly embittered politics and created lasting resentment among the supporters of his former chief. Disraeli and the protectionists could not stop the repeal of the Corn Laws because the bill was backed by the Whigs, but they were able to put Peel in a minority on another issue, forcing him to resign (June 1846).

Conservative leader in the House of Commons. The Corn Laws crisis was a turning point in Disraeli's career.

The loyalty of nearly all the Conservative former ministers to Peel and the death of Bentinck in 1848 gave Disraeli an indisputable claim to the leadership of the opposition in the House of Commons—a claim that even Lord Stanley, who led the Conservative Party as a whole, could hardly contest. Disraeli devoted the next few years to endeavouring to extricate his party from what he by then recognized to be "the hopeless cause of protection." The policy was sensible enough, but it inspired mistrust among his followers, as did Disraeli's pride in and insistence upon his Jewish ancestry. The party could not, however, dispense with his talents, whatever it thought of his character. Besides, with his election to Parliament as member for the county of Buckinghamshire in 1847 and his purchase of Hughenden Manor, near High Wycombe, in 1848, his social and political position was fortified. His finances, however, despite his father's death (1848) and his wife's income, remained shaky in the extreme.

The Whig government fell in 1852 and the Earl of Derby (as Lord Stanley had become since his father's death in 1851) formed a short-lived minority government. Disraeli was chancellor of the exchequer despite his protest that he knew nothing of finance. His budget in fact brought the government down (December 1852), but Disraeli can hardly be blamed for this. The free-trade majority in the house was determined to defeat measures that relieved agriculture, even though the method chosen did not involve protection; and yet Disraeli could not escape bringing forward some such proposals if he was to placate his own followers. For the next six years the Tories were in opposition. In 1858, however, Derby once again formed a minority government with Disraeli as chancellor of the exchequer. Disraeli with his notions of popular Toryism had for some time felt that there was no reason to leave parliamentary reform as a Whig monopoly. Accordingly he introduced a moderate reform bill in 1859. But its provisions seemed too obviously designed to help his own party, and the majority of the house combined to defeat them and turn out the government. Again the Tories were out of office for six years.

Chancellor of the exchequer

In 1865 the Whig-Liberal leader Lord Russell brought forward a measure of parliamentary reform. Moderate though this was, it aroused the strong opposition of the Tories and, more seriously, a revolt within his own party. Russell was defeated, and Derby formed his third minority government with Disraeli again chancellor of the exchequer. Disraeli's opposition to the Liberal bill had been based on opportunism rather than principle. Although the initiative for a new Conservative reform bill came from Queen Victoria and Lord Derby, Disraeli plunged into the battle with an enthusiasm combined with a mastery of parliamentary tactics unsurpassed by any other statesman of the day. He believed strongly that the measure should be a sweeping one, subject to certain safeguards, and he was determined that the bill should be carried by a Conservative government. But with the Liberals in a majority in the House of Commons, Disraeli was obliged to accept their amendments, and in the end nearly all the safeguards intended to protect Conservative interests vanished. The resulting measure doubled the existing electorate and was undoubtedly far more democratic than most Conservatives had envisaged. It was indeed "a leap in the dark," as Derby described it; but Disraeli could fairly claim that the measure had gone far toward "realizing the dream of my life and re-establishing Toryism on a national foundation."

The "top of the greasy pole." In February 1868 Derby retired from politics and Disraeli became prime minister. "Yes," he said in reply to a friend's congratulations, "I have climbed to the top of the greasy pole." It was in a sense a "caretaker" premiership, for everyone awaited the general election that was due to be held as soon as the new electoral register was completed, and the autumn election, as expected, was won by the Liberals. Disraeli set a precedent by resigning without waiting for Parliament to meet.

"Care-taker" premiership

The whole face of politics had changed in the three years since the death of Lord Palmerston, the great Whig prime minister, who had dominated political life in his last years. From a chaotic collection of ill-defined shifting groups influenced as much by personalities as politics, there emerged two great parties with intelligible coherent policies. Their respective leaders, Disraeli and W.E. Gladstone, seemed singularly well chosen to polarize the confused forces that had hitherto animated British politics. For 12 years they fought a deadly duel. Each detested the other, and history records scarcely a flicker, on either side, of those generous emotions toward the political enemy that have so often softened the seeming acerbity of parliamentary life.

For the moment Disraeli deemed it wise to play a comparatively peaceful role, gradually creating for the Conservative party a new image that would in the course of time, he hoped, persuade the new electorate. His seeming apathy, however, disturbed his supporters; and misgivings were increased by the publication of *Lothair*, described by G.E. Buckle, Disraeli's biographer, as "a gaudy romance of the peerage, so written as to make it almost impossible to say how much was ironical or satirical, and how much soberly intended." To many grave persons it must have seemed an undignified production for a former prime minister.

From 1872 onward, however, Disraeli took charge of his party with a firm hand. On three broad issues he sharply differentiated Conservative from Liberal policy. In a speech in April 1872 he defended the monarchy, the House of Lords, and the church against the radical threat that he claimed to discern in Gladstone's policy. Three months later he asserted for the first time the Conservative belief in consolidating the empire, with special emphasis on India. And in the same speech he dwelled on the importance of social reform: his old "condition of the people" question, which he had earlier analyzed so vividly in *Sybil*. During these years of opposition, yet a fourth distinctive Conservative policy began to emerge: the belief in a strong foreign policy, especially toward Russia, and in the greatness of Britain.

In December 1872 Disraeli suffered a personal bereavement none the less poignant for having been long expected. His wife died of cancer after many months of illness. Her oddities never disturbed Disraeli, while her affection, her management of domestic affairs, and her deep devotion to him had rendered his life happy as it had never been before. There were more material losses too. He no longer had her house in London, and her fortune, which was entailed, passed to her cousins. Disraeli was now 68 and his health was not good. It is a testimony to his indomitable will that he determined to continue the political battle despite the personal distress and confusion into which he was thrown. The society of women remained essential for him. From this period dates his romantic friendship with the sisters, Lady Bradford and Lady Chesterfield, to whom he poured out the secrets of politics and the affections of his heart in a profuse and fascinating series of letters that only ceased with his death.

At this juncture public affairs at last began to move in his favour. Gladstone's ministry was defeated in the House of Commons in 1873. Gladstone promptly resigned, but Disraeli shrewdly refused to take office on the ground that he could not dissolve Parliament for some months owing to the amount of uncompleted business and that a minority government could only damage his party's prospects. Gladstone reluctantly returned to office, but less than a year later himself decided on a sudden dissolution. Disraeli had not neglected the vital problems of party organization and machinery so necessary in the new era of mass democracy. The result was a triumphant conservative electoral victory.

**Second administration, 1874–80.** It was Disraeli's tragedy that power came to him too late. He had never possessed the vitality and the iron constitution of statesmen such as Gladstone, and he aged rapidly during his second premiership. Certainly he achieved much, but he could have done far more, even a few years earlier. He

formed a strong cabinet and was further fortified by his friendship with the Queen, who was politically conservative and had already acquired a considerable dislike for Gladstone. Disraeli treated her as a human being, whereas Gladstone treated her as a political institution. In doing so he indulged in a degree of flattery to which the word Oriental has been legitimately applied.

Embarking on a program of social reform that touched the real interests of the masses more effectively than most of Gladstone's measures, Disraeli was at last able to show that Tory democracy was not a mere phase. The Artizans' and Labourers' Dwellings Improvement Act was the first measure to make effective slum clearance possible. The Public Health Act of 1875 codified the complicated law on that subject and translated into reality Disraeli's own half-joking witticism in a speech of 1872: "Sanitas sanitatum, omnia sanitas" (an alliterative misquotation of *vanitas vanitatum, omnia vanitas*, "vanity of vanities, all is vanity," taken from the Book of Ecclesiastes). Equally important were an enlightened series of factory acts preventing the exploitation of labour and two trades union acts that clarified the doubtful legal position of those bodies.

Important though Disraeli's domestic program was, it took second place in the public eye to his imperial and foreign policy. His first great success was the affair of the Suez Canal shares. The extravagant and spendthrift ruler of Egypt, the khedive Ismā'il Pasha, owned slightly less than half the Suez Canal Company's shares and was anxious to sell them. This fact was communicated by a patriotic journalist to the Foreign Office, which regarded a purchase as absurd. Disraeli, however, at the end of November 1875 boldly bought them for the government, the money being put up by his friends the Rothschilds until Parliament could confirm the bargain. Financially it was an excellent bargain, and in terms of imperial prestige it seemed a notable triumph.

Disraeli's next effort, early in 1876, was to bring in a bill conferring on Queen Victoria the title empress of India. The measure passed, but there was a good deal of opposition; Disraeli himself would gladly have postponed it, but the Queen insisted. For some time his health had been poor, and it became clear to him in the summer of 1876 that the strain of leading the House of Commons was too much. Accordingly in August he accepted a peerage, taking the title earl of Beaconsfield.

From 1876 to 1878 his life was dominated by a major issue of foreign policy. The conflict between Russia and Turkey that had lain dormant since the end of the Crimean War in 1856 was abruptly reopened by the revolt of the Christian subjects of the Ottoman Empire against intolerable misrule. Russia declared war on Turkey in April 1877, and its troops reached the gates of Constantinople early the next year. Their victories renewed British fear for the safety of the route to India. Disraeli, knowing that the Russian forces were exhausted, rightly assumed that the threat of British intervention would be enough. As a result of his actions, Russia was obliged to submit the highly pan-Slavist Treaty of San Stefano, which it had forced upon Turkey, to a European congress. Beaconsfield attended the Congress of Berlin in the summer of 1878 and made a great impression, obtaining nearly all the concessions he wanted. He was able to return in triumph to London, declaring that he had brought back "peace with honour."

This was the climax of his career. The Queen offered him a dukedom, which he refused, and the Order of the Garter, which he accepted. His prestige was at its height. Thereafter his fortunes waned. The aggressive policy of Lord Lytton, the viceroy of India, brought disaster in Afghanistan, and in South Africa an unwary British force was slaughtered by the Zulus. Agricultural distress combined with an industrial slump to bring the government into disfavour. At the general election of 1880 the Conservatives sustained a heavy defeat. Beaconsfield courageously agreed to retain the party leadership and despite this burden found time to finish *Endymion*, a mellow political novel in which he surveyed his own early career through the rose-coloured spectacles of

Friendship  
with Queen  
Victoria

Bereave-  
ment

"Peace  
with  
honour"

romantic nostalgia. His health was, however, failing rapidly, and he died at his London home on April 19, 1881. A few days after his burial in the family vault at Hughenden, Queen Victoria came in person to lay a wreath upon the coffin of her favourite minister.

#### MAJOR WORKS

NOVELS (MAINLY POLITICAL): *Vivian Grey*, 5 vol. (1826–27); *The Young Duke*, 3 vol. (1831); *Contarini Fleming*, 4 vol. (1832); *Henrietta Temple*, 3 vol. (1837); *Venetia*, 3 vol. (1837); *Coningsby; or, The New Generation*, 3 vol. (1844); *Sybil; or, The Two Nations*, 3 vol. (1845); *Tancred; or, The New Crusade*, 3 vol. (1847); *Lothair*, 3 vol. (1870); *Endymion*, 3 vol. (1880).

POLITICAL WRITINGS AND SATIRE: *Vindicta of the English Constitution* (1835); *The Letters of Runnymede* (1836); *The Spirit of Whiggism* (1836); *Lord George Bentinck: A Political Biography* (1852).

MISCELLANEOUS POEMS: *The Revolutionary Epick* (1834); *The Tragedy of Count Alarcos* (1839).

**BIBLIOGRAPHY.** *Novels and Tales by the Earl of Beaconsfield*, Hughenden edition, 11 vol. (1881); *Lord Beaconsfield's Letters*, 1830–1852, ed. by R. DISRAELI (1887, reprinted 1928); *Letters from Benjamin Disraeli to Frances Anne, Marchioness of Londonderry, 1837–1861*, ed. by the MARCHIONESS OF LONDONDERRY (1938); *The Letters of Disraeli to Lady Bradford and Lady Chesterfield*, ed. by the MARQUIS OF ZETLAND, 2 vol. (1929); *Selected Speeches of . . . the Earl of Beaconsfield*, ed. by T.E. KEBBEL, 2 vol. (1882). The official biography is W.F. MONYPENNY and G.E. BUCKLE, *The Life of Benjamin Disraeli, Earl of Beaconsfield*, 6 vol. (1910–20; rev. ed., 2 vol., 1929, reprinted 1968). See also ANDRE MAUROIS, *La Vie de Disraeli* (1927; Eng. trans., rev. ed. 1947); ROBERT BLAKE, *Disraeli* (1966) and *Disraeli and Gladstone* (1970); and RICHARD A. LEVINE, *Benjamin Disraeli* (1968), a study of the novels, particularly *Coningsby*, *Sybil*, and *Tancred*. A popular biography is HESKETH PEARSON, *Dizzy* (1951). For his early life, see B.R. JERMAN, *The Young Disraeli* (1960). The best short life is HAROLD BEILEY, *Disraeli* (1936).

(B.)

## Distilled Liquor

Distilled liquors are all alcoholic beverages in which the concentration of ethyl alcohol (the intoxicating agent) has been increased above that of the original fermented mixture. The production of distilled liquor is based upon fermentation, the natural process of decomposition of excess vegetative materials. Fermentation occurs in nature whenever the two necessary ingredients, carbohydrate-bearing vegetation and yeast, are available. Yeast, a vegetative micro-organism living and multiplying in media containing carbohydrates and particularly in simple sugars, has been found throughout the world, including frozen areas and deserts.

The principle of alcoholic distillation is based upon the different boiling points of alcohol (78.5° C, or 173.3° F) and water (100° C, or 212° F). If an alcohol-containing liquid is heated to a temperature above 78.5° C but below 100° C, the alcohol will vaporize and separate from the original liquid and can be gathered and recondensed into a liquid of much greater alcoholic strength.

**History.** Because the two ingredients necessary to alcoholic fermentation are widely spread and always appear together, civilizations in almost every part of the world early developed some form of alcoholic beverage. By 800 BC the Chinese were distilling a beverage from rice beer, and in the East Indies arrack was distilled from sugarcane and rice. The Arabs developed a distillation method which they used to produce a distilled beverage from wine. Greek philosophers reported a crude distillation method, and the Romans apparently produced distilled beverages, but no reference to these has been found in their writings before AD 1000. Production of distilled liquors was reported in Britain before the Roman conquest, but it is likely that the metal containers and metal-working techniques brought by the Romans greatly accelerated the development of distillation operations. Spain, France, and the rest of western Europe may have produced distilled liquors at an earlier date, but production apparently gained impetus in the 8th century, after contact with the Arabs.

The first distilled liquors were made from natural sugar-based materials, the two most important of which were

grapes—producing brandy—and honey—the raw material of distilled mead. The earliest use of starchy grains in distilled-liquor production is not known, but their use was flourishing by the late Middle Ages and, by the middle of the 17th century, was of sufficient importance to attract widespread government control. The idea of rectification, or distilling in such a way as to divide the fermented mixture into various liquid fractions, first appeared in France at the beginning of the 16th century (this important process is described in detail below). By the early 19th century large-scale continuous stills, basically identical with those used in industry today, were operating in France and England. As production methods improved, the distilled-liquor industry became a source of government revenue, often with rigid controls on both production and sale.

Table 1 shows the origin of some distilled liquors.

**Table 1: Origins of Various Distilled Liquors**

	date	raw material	fermented liquor	distillate
China	—	rice and millet	tchou	sautchoo
Ceylon and India	800 BC	rice and molasses or palm sap	toddy	arrack
Asiatic	—	cow's milk	kefir	arika
Tatary	—	mare's milk	koumiss	skhou
Caucasia	—	rice	sake	sochu
Japan	—	honey	mead	mead
Britain	AD 500			distilled
Italy	1000	grapes	wine	brandy
Ireland	1100	oats and barley malt	beer	usquebaugh
Spain	1200	grapes	wine	aqua vini
France	1300	grapes	wine	cognac
Scotland	1500	malted barley	beer	aqua vitae, whiskey

#### DISTILLED LIQUOR PRODUCTION

**Raw materials.** In general, the raw material for a distilled liquor is a natural sugar—such as those found in honey, ripe fruit, sugarcane, beetroot, and milk—or a substance of an amylaceous (starchy) nature that may be easily converted into a sugar. This change is simply effected, for some of the active agent is already present in cereals containing the necessary starch or is easily developed in them; when it is absent, as in potato starch, a suitable malted cereal can be added.

The active agents that break down starches into sugars and sugars into alcohol are known as enzymes; these active proteins are catalysts, and even small amounts will cause a fundamental change in large quantities of the material being processed. Enzymes are easily poisoned by certain substances, such as hydrocyanic acid, mercury salts, and Formalin; are sensitive to temperature variations (being rendered inactive in certain conditions); and are specific in action in that each is effective for certain classes of substance only. They convert complex insoluble material into simpler assimilable substances: amylase, for instance, will reduce starch to dextrin and then to the sugar maltose; maltase will reduce maltose to the simpler sugar dextrose; and zymase will ferment the dextrose to alcohol and carbon dioxide. All these changes take place in aqueous solution.

**Sugary materials.** Grapes, cultivated in most of the subtropic and warm temperate zones of the world, are the major fruit employed as the raw material of distilled liquor, and the final product of their fermentation is brandy. Other natural fruits, such as apples and peaches, are used to a lesser extent, and many fruits are limited to local importance. Grapes made into wine for use in brandy production require only simple crushing and pressing. Apples and citrus fruits are put through crushers, and the fermentable juices are either pressed out for fermentation, as in apples, or the entire mass is fermented.

Sugary vegetables include sugarcane, sugar beets, and *Agave tequilana* (a type of cactus). Sugarcane and its products, including cane juices, molasses, and sugar, are the most important of the vegetable group. Grown

Enzyme activity

throughout the tropics and semitropics, sugarcane is used in making rum and an alcohol derived from rum. Sugarcane juice can be pressed from the cane for use as the base raw material for fermentation, or the juice may be concentrated for sugar production, with the molasses residue from the sugar crystallization used as a base for fermentation. This process is also applied to sugar beets.

**Starchy materials.** For many centuries, it was only feasible to employ local grain crops for liquor production, and, in this way, the basic characteristics of the local distilled beverage was established. Improved transportation has removed this restriction, and today economic considerations frequently determine grain selection, with the principal grain used being the one available at the lowest price per unit of fermentable materials.

Cereal grains used for liquor production

Corn (maize) is the most important cereal grain employed; principal producing countries include the United States, Argentina, Brazil, Mexico, South Africa, Thailand, and France. Rye grain, though less efficient in fermentation than corn, is used extensively in whiskey production, primarily for the flavour characteristics it imparts to the final product. It is particularly employed in Canada and the United States, accounting for as much as 25 percent of total grains used. Rice, a widely grown cereal, has limited use in distilled liquor production outside of eastern and southeastern Asia from India to Japan. Barley grain, probably the first cereal employed for distillation in large quantities, was formerly a major crop throughout Britain, Scotland, Ireland, and western Europe. Wheat, because of its high cost, is used only where corn is in short supply and is then limited to production of grain alcohol for blending or in production of liqueurs. Potatoes have been used in distilled-liquor production primarily in central Europe; in the tropics, certain starchy roots are also employed.

Preparation for fermentation, similar for all grains, involves grinding and mashing. In grinding, the grains are reduced to a coarse meal in various types of mills to allow thorough wetting of their starch cells. In mashing, the starch cells of the grain, enclosed in their own protective coatings, are broken to allow wetting and liquefaction of the entire starch mass. Mashing usually begins with the grain most difficult to treat. When corn is used, the ground meal is wetted at temperatures approximately 150° F (66° C), and the temperature is then raised to boiling or sometimes higher while under pressure. Temperature is reduced when the starch cells are broken. The grain ranking second in cell resistance (usually rye) is added next. Temperature is again reduced before ground malt meal, either in dry form or as a water slurry (insoluble mixture), is added. The time and temperature for each operation varies according to the grain used and the final distillates desired. The completed mashing process produces a mixture in which the starches have been converted to fermentable sugars, suitable for utilization by the yeast (see below). The sugars, principally dextrose and maltose, vary in concentration among producers but, generally, are sufficiently concentrated to make a final product ranging from 7 to 9 percent alcohol. Other starchy substances, such as potatoes, are usually crushed and heated, exploding the starch cells; the liquefied starch obtained is converted to fermentable sugar by the action of amylase enzymes.

Use of malt

**Malt.** Malt, a major raw material in distilled-liquor production, consists of grain, softened by steeping in water and allowed to germinate; it can be produced from any cereal grain. As the grain germinates for the production of a new plant, changes take place within the kernel. Embryo development begins, and enzymes within the kernel initiate the process of making carbohydrate, protein, and other constituents into a soluble substance available to the embryo. Although many enzymes affect this process, the most important for distilled-liquor production are the amylases, enzymes converting the high-molecular-weight carbohydrates into simple soluble form for utilization by the embryo. This process also allows the embryo to develop a root structure capable of taking needed nutrients from the soil. The fermenting industry employs the same process, under controlled conditions,

to produce malt. In malting, grain is thoroughly soaked in water, then allowed to germinate until the embryo has partially developed. At this stage the enzymes, particularly amylases, have increased beyond the amounts necessary for conversion of the starch within the individual grain. After partial germination, the grain is dried at low temperatures. The resulting malt contains sufficient enzymes to convert approximately ten times its weight in other unmalted grains (see also BREWING).

Barley is the grain most commonly used to produce malt for the distilled-liquor industry. Of the two amylases—alpha and beta—developed during the malting process, the alpha is the most important for conversion of other grains. In addition to converting starches from other carbohydrates to sugars, barley malt contains soluble proteins (amino acids), contributing flavour to the distillate secured from fermentation and distillation of grain-malt mixtures.

Fungal amylase, less important to distilled-liquor production, is derived from mold growth. Although producing high concentrations of amylases, this type of enzyme conversion is used primarily in alcohol production and not for the distilled liquors, which derive their flavour from grain mixtures.

**Yeast and yeast culture.** As mentioned above, yeasts are found throughout the world; more than 8,000 strains of this vegetative micro-organism have been classified. Approximately nine or ten pure strains, with their subclassifications, are used for fermentation of grain mash; these all belong to the type *Saccharomyces cerevisiae*. Each strain has its own characteristics, imparting its special properties to the distillate derived from its fermentation. A limited number of yeasts, all in the classification *Saccharomyces ellipsoideus*, are used in the fermentation of wines, from which brandy is distilled. Strains used in the fermentation of grain mash are also used in fermentation for rum and beer production.

In grain-based products, yeast cells are grown in grain mixtures. The preparation of a cooked mash of rye and barley malt is most common. The mash is sterilized, then inoculated with lactic acid bacteria to increase acidity. When the desired acidity is reached, the mixture is again sterilized and a pure yeast culture is added. The yeast has been grown under controlled conditions until it reached the optimum point for mixing with the grain mash. In liquid fermentation, as from fruits and sugarcane, the yeast is generally grown in a mixture similar to the one it will be used to ferment; for example, a yeast culture to be used for molasses fermentation is usually grown in molasses.

**Fermentation.** In the fermentation process, simple sugars, including dextrose and maltose, are converted to ethyl alcohol by the action of yeast enzymes. Several intermediate compounds are formed during this complex chemical process before the final ethyl alcohol is obtained (see ALCOHOLS, PHENOLS, AND ETHERS: *Alcohols*).

Yeast functions best in a slightly acid medium, and the prepared grain mash, fruit juice, molasses, or other mixture must be checked for adequate acidity (pH value). If acidity is insufficient, acid or acid-bearing material is added to achieve the necessary adjustment. The previously prepared yeast is then added, and final dilution of the mixture is made. The final concentration of sugars is adjusted so that the yeast fermentation will produce a finished fermented mixture containing between 7 and 9 percent alcohol.

Commercial fermentation is carried on in large vats. Although open vats may be used, closed vats are preferred for sanitary purposes and are easier to equip for temperature control. The time required for completion of fermentation is mainly dependent upon the temperature of the fermenting mash. Normal yeast is most effective in breaking down all of the fermentable sugars at temperatures ranging from 75° to 85° F (24° to 29° C), and, in this range, completion of fermentation requires from 48 to 96 hours. Fermentation at lower temperatures requires longer periods. The mash is ready for distillation upon completion of fermentation and, if allowed to continue past this period, will be adversely affected by

Equipment for fermentation

bacterial action beginning conversion of the ethyl alcohol to acids, reducing the alcoholic content and influencing the flavour and aroma of the finished product.

**Distillation.** As mentioned above, the difference in the boiling points of alcohol and water is utilized in distillation to separate these liquids from each other. Basic distillation apparatus consists of three parts: the still or retort, for heating the liquid; the condenser, for cooling the vapours; and the receiver, for collecting the distillate.

**Equipment.** Early distillation methods were crude, and satisfactory equipment for large-scale commercial use was not developed until after the year 1000. The first crude pot still was based upon primitive methods. The simple pot still is a large enclosed vessel, heated either by direct firing on the bottom or by steam coils within the vessel, with a cylindrical bulb at its top leading to a partially cooled vapour line. The bulb and vapour line separate entrained liquid particles from the vapour on its way to the final condenser. The usual pot-still operation involves a series of two or three pot stills. The vapour from the first is condensed: any vapour falling below a predetermined alcoholic content is fed into a second still; and condensed vapour from the second still falling below the required alcoholic content is fed to the third. The condensed vapours of the desired alcoholic content from all three stills are comingled in a single receiving container.

The pot still, used primarily in Scotland and Ireland for whiskey production and in France for brandies, has had only brief use in distilled-liquor production elsewhere and is gradually becoming obsolete. Even in countries in which the pot still has long been used, it has been replaced by continuous distillation for the major portion of alcoholic-liquor production, and its current use is limited to production of flavouring whiskies and other flavouring ingredients.

The continuous still, coming into use in the early 19th

The pot still

any overflow caught by the plate below, the liquid level on each plate is maintained. Use of a sufficient number of plates assures that the concentration of alcohol in the vapour leaving the top of the still will be appropriate for the desired product and that the liquid leaving the bottom of the still has been stripped of any alcohol.

Many distillation operations combine column and pot stills. The condensed distillate from the column still is fed to the doubler, a kind of pot still heated by closed steam coils, and redistilled.

**The rectification process.** Rectification is the process of purifying alcohol by repeatedly or fractionally distilling it. It was mentioned above that a fermentation mixture primarily contains water and ethyl alcohol and that distillation involves increasing the percentage of ethyl alcohol in the mixture. Water vaporizes very easily, however, and, unless care is taken, the distillate of a fermentation mixture will contain unacceptably large quantities of water. Hence, the column through which the vaporized fermentation mixture passes is provided with baffles onto which the water vapour condenses, while the alcohol vapour passes through. In this way, the distillate obtained will have a high alcohol content. The fermentation mixture furthermore contains small quantities of complex constituents known as congeners or congeners that give each distilled liquor its individual character. These congeners, described below in greater detail, have lower boiling points than water and thus also pass through the distillation column into the distillate. Discovery of this process of rectification permitted production of distilled liquors as they are known today; it is used widely in other industries.

**Maturation and storage.** The products obtained directly from the distillation of fermented materials are usually undesirable for human consumption and require further processing or maturation. The maturation process involves a series of chemical reactions producing changes in the original distillate that improve the aroma and taste of the final product. Some changes result from reactions of compounds after long exposure to each other within the distillate itself; others result from oxidation of some of the compounds because of the presence of small quantities of oxygen taken from the air; still other changes result from the presence of extracts from the wood of the barrel, either as direct flavouring ingredients or produced by chemical reaction between the barrel extracts and some of the ingredients in the distillate. Generally, a longer maturation period is required when the concentration of heavy compounds is high, and distillates produced at very high proof (alcohol content; see below) require a much shorter maturation period than those produced at lower proofs. Maturation systems vary according to the type of alcoholic liquor.

The maturation of whiskies falls into two categories, according to the type of container employed. Sometimes in Canada, and by law in the United States, charred new white-oak containers are used for maturation of products to be called straight bourbon or straight rye whiskey. These containers, holding approximately 50 gallons or about 200 litres, are usually stored in dry warehouses, often having controlled temperature and humidity. During maturation, wood extracts, caramelized wood, and other ingredients are extracted from the container; maturation also results from contact of oxygen from the outside air with the ingredients in the alcoholic mixture. White oak is one of the few woods holding liquids while allowing the process of breathing through the pores of the wood. This breathing process is caused by temperature changes of the liquid in the barrel. Temperature increases cause pressure to develop within the barrel, forcing some of the liquid into the barrel staves; temperature reduction decreases internal pressure, bringing part of this liquid back into the main body of liquid along with a small amount of air. The more frequently this breathing process occurs, the more rapidly maturing progresses. Modern warehouses are often mechanically equipped to allow control of the heating and cooling cycle.

Outside the United States, reused cooperage is common. Since used containers have already yielded their initial

Continuous still for preparing distilled liquors.

century, consists of a tall cylindrical column filled with perforated plates (see illustration). These plates serve as a series of small pot stills, one on top of the other. Live steam, used as the heat source, is fed to the bottom of the still, and the liquid to be distilled is fed near the top. Steam pressure holds the liquid on the plates, and, with

The breathing process

oak extracts, the resulting product is low in extracted flavouring ingredients, which is desirable in some beverages. This maturation method, typified by Scotch and Irish whiskies, can be carried on in casks holding up to 132 gallons or about 500 litres. These casks have usually had previous use for storage or maturation of other whiskies or wines and may be reused for many maturation cycles. Maturation in dry warehousing increases alcoholic content of the liquid in the container, but the more common practice for Scotch and Irish whiskies of maturation in high humidity warehouses reduces alcoholic concentration.

The maturation procedure for brandies is similar to that of some whiskies, but the brandies are usually matured in fairly large casks or oak containers. Most brandies are matured for three to five years, but some remain for as long as 20 to 40 years or even longer.

Rum is usually matured in reused oak containers; high concentrations of oak extracts are not considered desirable. Normal maturation time is two to three years, but rum, generally a blended product, may contain a percentage of older rums.

In distilled liquors, the term age refers to the actual duration of storage, while maturity expresses the degree to which the chemical changes described above have taken place. Most governments specify storage time for various products. The United States requires a two-year storage period for most whiskies but has no requirement for any pure alcohol or neutral spirits (close to 100 percent alcohol) added to such whiskies in the production of blended whiskey. Canada requires storage of two years for all distilled liquors; Scotland and England require a three-year storage; while Ireland requires five years for all products classified as whiskey but has no requirements for vodka and gin.

**Packaging.** Distilled liquors react upon exposure to most substances, extracting materials from the container which tend to destroy the liquor aroma and flavour. For this reason, glass, being nonreactive, has been the universal container for packaging alcoholic liquors. Packaging economics require containers that are standardized in size and shape and that lend themselves to automatic processes. In the early 1970s suitable plastics became available and were approved by food and health departments in many countries. Containers made from such plastics, however, were not economical for use.

Early hand methods of filling, labelling, corking, and other operations have been replaced by highly mechanized bottling lines, with bottles cleaned, filled, capped, sealed, labelled, and placed in a shipping container at a rate as high as 240 bottles per minute. This progress became possible with the development of high-strength glass, plastic caps with inert liners, and high-speed machines. Even specialized packaging, long a hand operation, has been replaced by standardization of containers, allowing production on automatic lines.

#### COMPOSITION OF DISTILLED LIQUOR

Though the major components of distilled liquors are ethyl alcohol ( $C_2H_5OH$ ) and water, a simple combination of these two substances does not produce an attractive beverage. The minor constituents or congeners mentioned above, including higher alcohols, aldehydes, ethers, esters, volatile acids, furfural (a liquid aldehyde of penetrating odour, usually made from plant materials), and other organic compounds influence the character, aroma, and flavour of the beverage out of all proportion to their quantities. As they are too great or too small, they invest the liquor with fuller or feebler flavour than may be desired.

**Proof systems.** Mixtures of alcohol and water (such as are found in distilled liquor) have values intermediate between those of the pure components of some of their physical characteristics—such as viscosity, heat of vaporization, specific heat, thermal expansion, vapour pressure, electrical conductivity, boiling point, refractive index, and specific gravity. Although the variations may not be strictly proportional to the amount of alcohol present, they are nevertheless generally progressive for certain

ranges; this fact has provided some convenient physical means of determining spirit strength, and it is common practice to derive such information from specific gravity (the ratio of the density of one substance to the density of another substance when both are weighed in air). Provided that the liquid is free of or has been freed by distillation from saccharine and other matter that would interfere, the specific gravity is determined by immersing in it a hydrometer, which may be graduated (1) in terms of specific gravity; (2) with arbitrary scales (United Kingdom, Soviet Union); (3) in percentages by volume of alcohol (Belgium, France, Italy, Norway, Sweden); (4) in percentages by weight of alcohol (Germany); (5) in percentages by volume of proof spirit (United States), as described below; and (6) with a scale based upon fractions of the volume of the instrument (The Netherlands). In all cases, these instruments are calibrated at standard temperatures; when the liquid to be tested is cooler or warmer (as it usually is), reference is made to tables to ascertain the true value for the spirit at the standard temperature.

Spirit strength may be designated in several ways—percentage by weight, weight per gallon, gallons per hundredweight, or percentage by volume, all these having reference to absolute (*i.e.*, pure) alcohol and water. But there are other standards in common use; *e.g.*, United States proof spirit, which is 50 per cent by volume of alcohol and water, and British proof spirit, which is of such a strength that at 51° F (11° C) its weight is  $\frac{17}{13}$  of an equal volume of water. Thus in the United States, each degree of proof represents 0.5 percent of alcohol, so that a liquor having 50 percent alcohol is termed 100 proof. British proof is based on a specific concentration of alcohol, a 50 percent alcoholic content being equivalent to 114.12 United States proof. In the United States proof system, distilled liquors are expressed in direct proof figures; in the British system, distilled liquors are expressed as being over or under 114.12 proof. The metric Gay-Lussac system simply states the percentage by volume of alcohol in a distilled liquor.

**Classification of distilled liquors.** Chemical characteristics of distilled liquors vary widely, and a detailed chemical analysis cannot be spelled out for any one type or group. Most distilled liquors, especially those produced from natural fermentations, contain a large number of chemical compounds. Table 2 lists the most widely dis-

Determining specific gravity

Mechanized packaging

**Table 2: Distilled Liquor Analyses**  
(grams per 100 litres)

	bourbon		Canadian	Scotch	Irish	blend	brandy
	bottled in bond	straight					
Percentage of alcohol by volume	50.0	43.0	40.0	43.0	43.0	43.0	40.0
Total acids	79.2	67.2	26.4	12.0	16.8	67.2	33.6

The  
division  
of the  
social  
product

## Distribution, Theory of

The theory of distribution deals with the way in which a society's product is distributed among the members of that society. It involves three distinguishable sets of questions. First, how is the national income distributed among persons? How many persons earn less than \$2,000, how many between \$2,000 and \$4,000, how many between \$4,000 and \$6,000, and so on? Are there regularities in these statistics? Is it possible to generalize about them? This is the problem of personal distribution. Second, what determines the prices of the factors of production? What are the influences governing the wage rate for a specific kind of labour? Why is the general wage level of a country not lower or higher than it is? What determines the rate of interest? What determines profits and rents? These questions have to do with functional distribution. Third, how is the national income distributed proportionally among the factors of production? What determines the share of labour in the national income, the share of capital, the share of land? This is the problem of distributive shares. Although the three sets of problems are obviously interrelated, they should not be confused with one another. The theoretical approaches to each of them involve quite different considerations.

### ASPECTS OF DISTRIBUTION

**Personal distribution.** Personal distribution is primarily a matter of statistics and the conclusions that can be drawn from them. When incomes are charted according to the number of people in each size category, the resulting frequency distribution is rather startling. Generally the top 10 percent of income receivers get between 25 and 35 percent of the national income, while the lowest 20 percent of the income receivers get about 5 percent of the national income. The inequality seems to be greatest in poor countries and diminishes somewhat in the course of economic development.

There are various explanations of the inequality. Some authorities point to the natural inequality of human beings (differences in intelligence and ability), others to the effects of social institutions (including education); some emphasize economic factors such as scarcity; others invoke political concepts such as power, exploitation, or the structure of society.

**Distributive shares.** For a long time economists were pessimistic as to the possibilities of any substantial improvement in the lot of those at the bottom of the income distribution. They generally held that the scarcity of productive land and the tendency of population to increase faster than the means of subsistence imposed limits on distributive justice. David Ricardo, in *On the Principles of Political Economy and Taxation* (1817), held that the landlords would receive an increasing part of the national income while capitalists would get less and less and that this shift in distribution would lead to economic stagnation. Karl Marx prophesied that the workers would be increasingly exploited and made miserable and these conditions would lead to the downfall of capitalism. Neither prediction materialized. Thus in the Western world the share of rents has dwindled to a few percent of the national income, while the share of labour has gradually increased. For some time, economists believed that the share of labour was more or less constant, but investigations show that economic development is accompanied by an increasing share of labour. Though the statistics are complicated by technical problems, it is safe to say that in the U.S., the share of wages rose from more than half the national income at the beginning of the century to more than 70 percent in the 1970s.

Contemporary approaches to this aspect of income distribution vary. Some are highly abstract and are closely related to the study of the whole, the modern macroeconomics of saving and investment. These will not be dealt with here. A simple common-sense approach employs an equation that starts by writing labour's share as the quotient of the total wage bill and the national income, labour's share =  $\frac{\text{total wage bill}}{\text{national income}}$ , and then writes the

wage bill as the product of the wage level and the amount of labour (wage bill = wage level  $\times$  amount of labour); next the national income is written as the product of the national output and the price level (national income = national output  $\times$  price level); the result is that the share of labour equals the quotient of the average real wage rate and labour productivity, share of labour =  $\frac{\text{average real wage rate}}{\text{labour productivity}}$ , the latter being the quotient of

the national output and the amount of labour: labour productivity =  $\frac{\text{national output}}{\text{amount of labour}}$ . If these two variables

move parallel, the share of labour is constant. If the real wage rate increases faster than labour productivity, the share of labour goes up. Similar reasoning applies to the shares of capital and land. This simple arithmetic is useful for an understanding of what happens in the real world, but for a profounder analysis one must turn to the theory of functional distribution.

**Functional distribution.** The theory of functional distribution, which attempts to explain the prices of land, labour, and capital, is a standard subject in economics. It sees the demand for land, labour, and capital as derived demand, stemming from the demand for final goods. Behind this lies the idea that a businessman demands inputs of land, labour, and capital because he needs them in the production of goods that he sells. The theory of distribution is thus related to the theory of production (*q.v.*), one of the well-developed subjects of economics. The reasoning that synthesizes production and distribution theory is called neoclassical theory, and it will be the main subject of this article.

### THE NEOCLASSICAL THEORY OF DISTRIBUTION

The basic idea in neoclassical distribution theory is that incomes are earned in the production of goods and services and that the value of the productive factor reflects its contribution to the total product. Though this fundamental truth was already recognized at the beginning of the 19th century (by the French economist J.B. Say, for instance), its development was impeded by the difficulty of separating the contributions of the various inputs. To a degree they are all necessary for the final result: without labour there will be no product at all, and without capital total output will be minimal. This difficulty was solved by J.B. Clark (*c.* 1900) with his theory of marginal products. The marginal product of an input, say labour, is defined as the extra output that results from adding one unit of the input to the existing combination of productive factors. Clark pointed out that in an optimum situation the wage rate would equal the marginal product of labour, while the rate of interest would equal the marginal product of capital. The mechanism tending to produce this optimum begins with the profit-maximizing businessman, who will hire more labour when the wage rate is less than the marginal product of additional workers and who will employ more capital when the rate of interest is lower than the marginal product of capital. In this view, the value of the final output is separated (imputed) by the marginal products, which can also be interpreted as the productive contributions of the various inputs. The prices of the factors of production are determined by supply and demand, while the demand for a factor is derived from the demand of the final good it helps to produce. The word derived has a special significance since in mathematics the term refers to the curvature of a function, and indeed the marginal product is the (partial) derivative of the production function (see below).

One of the great advantages of the neoclassical, or marginalist, theory of distribution is that it treats wages, interest, and land rents in the same way, unlike the older theories that gave diverging explanations. (Profits, however, do not fit so smoothly into the neoclassical system.) A second advantage of the neoclassical theory is its integration with the theory of production. A third advantage lies in its elegance: the neoclassical theory of distributive shares lends itself to a relatively simple mathematical statement.

The  
theory of  
marginal  
productivity

An illustration of the mathematics is as follows. Suppose that the production function (the relation between all hypothetical combinations of land, labour, and capital on the one hand and total output on the other) is given as  $Q = f(L, K)$  in which  $Q$  stands for total output,  $L$  for the amount of labour employed, and  $K$  for the stock of capital goods. Land is subsumed under capital, to keep things as simple as possible. According to the marginal productivity theory, the wage rate is equal to the partial derivative of the production function, or  $\partial Q / \partial L$ . The total wage bill is  $(\partial Q / \partial L) \cdot L$ . The distributive share of wages equals  $(L/Q) \cdot (\partial Q / \partial L)$ . In the same way the share of capital equals  $(K/Q) \cdot (\partial Q / \partial K)$ . Thus the distribution of the national income among labour and capital is fully determined by three sets of data: the amount of capital, the amount of labour, and the production function. On closer inspection the magnitude  $(L/Q) \cdot (\partial Q / \partial L)$ , which can also be written  $(\partial Q / Q) / (\partial L / L)$ , reflects the percentage increase in production resulting from the addition of 1 percent to the amount of labour employed. This magnitude is called the elasticity of production with respect to labour. In the same way the share of capital equals the elasticity of production with respect to capital. Distributive shares are, in this view, uniquely determined by technical data. If an additional 1 percent of labour adds 0.75 percent to total output, labour's share will be 75 percent of the national income. This proposition is very challenging, if only because it looks upon income distribution as independent of trade union action, labour legislation, collective bargaining, and the social system in general. Obviously such a theory cannot explain all of the real economic world. Yet its logical structure is admirable. What remains to be seen is the degree to which it can be used as an instrument for understanding the real economic world.

#### SPECIAL PROBLEMS

**Returns to scale.** Neoclassical theory assumes that the total product  $Q$  is exactly exhausted when the factors of production have received their marginal products; this is written symbolically as  $Q = (\partial Q / \partial L) \cdot L + (\partial Q / \partial K) \cdot K$ . This relationship is only true if the production function satisfies the condition that when  $L$  and  $K$  are multiplied by a given constant then  $Q$  will increase correspondingly. In economics this is known as constant returns to scale. If an increase in the scale of production were to increase overall productivity, there would be too little product to remunerate all factors according to their marginal productivities; likewise, under diminishing returns to scale, the product would be more than enough to remunerate all factors according to their marginal productivities.

Research has indicated that for countries as a whole the assumption of constant returns to scale is not unrealistic. For particular industries, however, it does not hold; in some cases increasing returns can be expected, and in others decreasing returns. This situation means that the neoclassical theory furnishes at best only a rough explanation of reality.

One difficulty in assessing the realism of the neoclassical theory lies in the definition and measurement of labour, capital, and land, more specifically in the problem of assessing differences in quality. In macroeconomic reasoning one usually deals with the labour force as a whole, irrespective of the skills of the workers, and to do so leaves enormous statistical discrepancies. The ideal solution is to take every kind and quality of labour as a separate productive factor, and likewise with capital. When the historical development of production is analyzed it must be concluded that by far the greater part of the growth in output is attributable not to the growth of labour and capital as such but to improvements in their quality. The stock of capital goods is now often seen as consisting, like wine, of vintages, each with its own productivity. The fact that a good deal of production growth stems from improvements in the quality of the productive inputs leads to considerable flexibility in the distribution of the national income. It also helps to explain the existence of profits.

**Substitution problems.** Another difficulty arises from the fact that marginal productivity assumes that the factors of production can be added to each other in small quantities. If one must choose between adding one big machine or none at all to production, the concept of the marginal product becomes unworkable. This "lumpiness" creates an indeterminacy in the distribution of income. From the viewpoint of the individual firm, this objection to neoclassical theory is more serious than from the macroeconomic viewpoint since in terms of the national economy almost all additions to labour and capital are very small. A related problem is that of substitution among factors. The production function implies that land, labour, and capital can be combined in varying proportions, that every conceivable input mix is possible. But in some cases the input mix is fixed (e.g., one operator at one machine), and in that situation the neoclassical theory breaks down completely because the marginal product for every factor is zero. These cases of fixed proportions are scarce, however, and from a macroeconomic viewpoint it is safe to say that a flexible input mix is the rule.

This is not to say that substitution between labour and capital is so flexible in the national economy that it can be assumed that a 1 percent increase in the wage rate will reduce employment by a corresponding 1 percent. That would follow from the neoclassical theory described above. It is not impossible, but it requires a very special form of the production function known as the Cobb-Douglas function. The pioneering research of Paul H. Douglas and Charles W. Cobb in the 1930s seemed to confirm the rough equality between production elasticities and distributive shares, but that conclusion was later questioned; in particular the assumption of easy substitution of labour and capital seems unrealistic in the light of research by Robert M. Solow and others. These investigators employ a production function in which labour and capital can replace each other but not as readily as in the Cobb-Douglas function, a change that has two very important consequences. First, the effect of a wage increase on the share of labour is not completely offset by changes in the input mix, so that an increase in wage rates does not lead to a proportionate reduction in total employment; and second, the factor of production that grows fastest will see its share in the national income diminished. The latter discovery, made by J.R. Hicks (1932), is extremely significant. It explains why the remuneration of capital (interest, not profits) has shrunk from 20 percent or more a century ago to less than 10 percent of the national income in modern times. In a society where more and more capital is employed in production, a continually smaller proportion of the income goes to the owners of capital. The share of labour has gone up; the share of land has gone down dramatically; the share of capital has gradually declined; and the share of profits has remained about the same. This picture of the historical development of income distribution fits roughly into the frame of neoclassical theory, although one must also make allowance for the short-run effects of inflation and the long-run effects of technological progress.

#### RETURNS TO THE FACTORS OF PRODUCTION

The demand side of the markets for productive factors is explained in large degree by the theory of marginal productivity, but the supply side requires a separate explanation, which differs for land, labour, and capital.

**Rent.** The supply of land is unique in being rather inelastic; that is, an increase in rent does not necessarily increase the amount of available land. Landowners as a group receive what is left over after the other factors of production are paid. In this sense, rent is a residual, and a good deal of the history of the theory of distribution is concerned with the issue whether rent should be regarded as part of the cost of production or not (as in Ricardo's famous dictum that the price of corn is not high because of the rent of land but that land has a rent because the price of corn is high). But inelasticity of supply is not characteristic only of land; special kinds of labour and the size of the total labour force also tend to be unresponsive to

Applica-  
tion of the  
theory to  
reality

The  
analysis of  
earnings

variations in wages. The Ricardian issue, moreover, was important in the context of an agrarian society; it lacks significance now, when land has so many different uses.

Wages. In analyzing the earnings of labour, it is necessary to take account of the imperfections of the labour market and the actions of trade unions. Imperfections in the market make for a certain amount of indeterminacy in which considerations of fairness, equity, and tradition play a part. These affect the structure of wages—*i.e.*, the relationships between wages for various kinds of labour and various skills. Therefore one cannot say that the income difference between a carpenter and a physician, or between a bank clerk and a truck driver, is completely determined by marginal productivity, although it is true that in the long run the wage structure is influenced by supply and demand.

The role of the trade unions has been a subject of much debate. The naive view that unions can raise wages by their efforts irrespective of market forces is, of course, incorrect. In any particular industry, exaggerated wage claims may lead to a loss of employment; this is generally recognized by union leaders. The opposite view, that trade unions cannot influence wages at all (unless they alter the basic relationship between supply and demand for labour), is held by a number of economists with respect to the real wage level of the economy as a whole. They agree that unions may push up the money wage level, especially in a tight labour market, but argue that this will lead to higher prices and so the real wage rate for the economy as a whole will not be increased accordingly. These economists also point out that high wages tend to encourage substitution of capital for labour (the cornerstone of neoclassical theory). These factors do indeed operate to check the power of trade unions, although the extreme position that the unions have no power at all against the iron laws of the market system is untenable. It is safe to say that basic economic forces do far more to determine labour's share than do the policies of the unions. The main function of the unions lies rather in modifying the wage structure; they are able to raise the bargaining power of weak groups of workers and prevent them from lagging behind the others.

Interest and profit. The earnings of capital are determined by various factors. Capital stems from two sources: from saving (by households, financial institutions, and businesses) and from the creation of money by the banks. The creation of money depresses the rate of interest below what may be called its natural rate. At this lower rate, businessmen will invest more, the capital stock will increase, and the marginal productivity of capital will decline. Although this chain of reactions has drawn the attention of monetary theorists, its impact on income distribution is probably not very important, at least not in the long run. There are also other factors, such as government borrowing, that may affect the distribution of income; it is difficult to say in what direction. The basic and predominant determinant is marginal productivity: the continuous accumulation of capital depresses the rate of interest.

One type of earning that is not explained by the neoclassical theory of distribution is profit, a circumstance that is especially awkward because profits form a substantial part of national income (20–25 percent); they are an important incentive to production and risk taking as well as being an important source of funds for investment. The reason for the failure to explain profit lies in the essentially static character of the neoclassical theory and in its preoccupation with perfect competition. Under such assumptions, profit tends to disappear. In the real world, which is not static and where competition does not conform to the theoretical assumptions, profit may be explained by five causes. One is uncertainty. An essential characteristic of business enterprise is that not all future developments can be foreseen or insured against. Frank H. Knight (1921) introduced the distinction between risk, which can be insured for and thus treated as a regular cost of production, and uncertainty, which cannot. In a free enterprise economy, the willingness to cope with the uninsurable has to be remunerated, and thus it is a factor

of production. A second way of accounting for profits is to explain them as a premium for introducing new technology or for producing more efficiently than one's competitors. This dynamic element in profits was stressed by Joseph Schumpeter (1911). In this view, prices are determined by the level of costs in the least progressive firms; the firm that introduces a new product or a new method will benefit from lower costs than its competitors. A third source of profits is monopoly and related forms of market power, whether deliberate as with cartels and other restrictive practices or arising from the industrial structure itself. Some economists have developed theories in which the main influence determining distributive shares is the relative "degree of monopoly" exerted by various factors of production, but this seems a bit one-sided. A fourth source of profits is sudden shifts in demand for a given product—so-called windfall profits, which may be accompanied by losses elsewhere. Finally, there are profits arising from general increases in total demand caused by a certain kind of inflationary process when costs, especially wages, lag behind rising prices. Such is not always the case in modern inflations.

#### DYNAMIC INFLUENCES ON DISTRIBUTION

**Pri** Neoclassical theory throws light upon the long-run changes in distribution of income. It fails to take account of the short-run impact of business fluctuations, of inflation and deflation, of rapidly rising prices. This failure is an omission, though it is true that distributive shares do not fluctuate as much as employment, prices, and the state of business generally. This lagging in the behaviour of shares can be understood by remembering that they are determined by the quotient of the real remuneration of the factor and its productivity; both variables move, according to marginal productivity theory, in the same direction. Yet inflation and deflation do have a certain impact upon distribution: if purchasing power shrinks, profits are the first income category to suffer; next come wages, particularly through the effects of unemployment. In a depression, the recipients of fixed-money incomes (such as interest and pensions) gain from lower prices. In an inflation the opposite happens.

The traditional inflationary sequence was that as prices rose, profits would increase, with wages lagging behind; this would tend to diminish the share of labour in the national income. Experience since World War II, however, has been different; in many countries wage levels tended to run ahead in the inflationary spiral and profits lagged behind, although most entrepreneurs eventually succeeded in shifting the burden of wage inflation onto the consumers. The result of the postwar inflation was a slight acceleration of the increase in the share of labour, while the shares of capital and land decreased faster than they would have in the absence of inflation. Profits as a whole held their own. The struggle among the various participants in the economic process no doubt added fuel to the inflationary fires.

Technology. Another dynamic influence is technological progress. The concept of the production function assumes a constant technology. But in reality the growth of production is much less the consequence of increased quantities of labour and capital than of improvements in their quality. This element in increased production is distributed in a way not fully explained by neoclassical theory. Part of the change in distribution that is caused by technological progress can be analyzed as resulting from changes in the elasticities of production. If  $\frac{K}{Q} \cdot \frac{\partial Q}{\partial K}$  goes

up, technological change is said to be "capital-using," and the share of capital will increase. This is what, in fact, may have happened; the change in technology has offset, though it has not neutralized, the decline in the share of capital caused by the employment of a higher amount of capital per worker. But another part of the fruits of technological progress is garnered by profit receivers, probably quite a substantial part. Businessmen who are quick innovators make high profits; in a rapidly changing society, profits tend to be high, a circumstance that is fortunate because profits are the mainspring of economic

**How**  
incomes  
are  
affected by  
changing  
conditions

change. The high rate of growth experienced by the post-World War I Western world stemmed from this profit-innovation-profit nexus.

#### PERSONAL INCOME AND NEOCLASSICAL THEORY

The neoclassical theory outlined above endeavours to explain the prices of **productive** factors and the distributive shares received by them. It does not come to grips with a third category of distribution, that of personal income, which is **much** more affected by institutional arrangements and by characteristics of the social structure. Profits in particular may be shared in various ways: they may accrue to stockholders, to workers, to management, or to the government or they may be retained in the corporation. What happens depends on dividend policy, tax policy, and the existence of profit-sharing arrangements with workers. Neoclassical theory has little to say on these matters or on the fact that in present-day capitalist society the managers of big business are virtually in a position to fix their own personal incomes. Managers have so much power vis-à-vis the stockholders and their total share of profits is so relatively little that their ability to pay themselves high salaries is limited only by the conventions of the business world. These high incomes cannot be explained by the categories of the neoclassical theory, and they do not constitute an argument against the theory. They may well argue for changes in society's institutions, but that is a matter on which the neoclassical theory of distribution does not pontificate. A great deal of change could occur in the legal and social order without any disturbance to the theory.

**BIBLIOGRAPHY.** JOHN BATES CLARK, *Distribution of Wealth* (1899), the classic work on marginal productivity theory whereby distribution is viewed as a harmonious process in which the factors of production receive as income what they contribute to the product; PAUL H. DOUGLAS, *The Theory of Wages* (1934), marginalist theory based on statistical research that sets forth the famous Cobb-Douglas function; JOHN R. HICKS, *The Theory of Wages*, 2nd ed. (1964), a sophisticated treatment of marginal productivity theory; NICHOLAS KALDOR, "Alternative Theories of Distribution," in *Essays on Value and Distribution* (1960), a discussion of various theories from Ricardo to Keynes; FRANK H. KNIGHT, *Risk, Uncertainty and Profit* (1921, reprinted 1971), an analysis of profits viewed as a result of imperfect foresight and as a remuneration for risk-bearing; KARL MARX, *Capital: A Critique of Political Economy*, vol. 1 (1867, many reprints), the process of distribution seen as pure conflict; DAVID RICARDO, *Principles of Political Economy and Taxation* (1817, reprinted 1933), the classical subsistence theory of wages; JOSEPH SCHUMPETER, *Theory of Economic Development* (1912), an analysis of economic development as a result of the innovations of entrepreneurs motivated by profit; K.J. ARROW *et al.*, "Capital-Labor Substitution and Economic Efficiency," *Review of Economics and Statistics*, 43:225-250 (1961), an econometric study explaining the falling share of capital in the national income by the elasticity of substitution.

(J.P.)

### Distribution of Organisms

The way in which animals and plants are distributed has long held the attention, and exercised the imagination, of naturalists. Quite apart from the intrinsic scholarly interest in the distribution of organisms, however, are aspects of direct benefit to man. The fact that certain organisms are found within **definite** limits of environmental conditions can be of considerable value to man. A farmer, for example, who wants to know whether an area is suitable for growing a certain crop, can be aided by knowledge of the naturally occurring plants of that area, as indicators of soil and moisture conditions. (Ironically, it is often the weedy plants, usually considered the enemy of the farmer, that give him precisely the information he wishes to know.)

The subject of distribution embraces the individual organism as a unit of study as well as the highest taxonomic unit. As far as scale is concerned, the range is equally great, from a drop of water to the largest ocean. Not surprisingly, the study of distribution encompasses several overlapping disciplines. Ecology is concerned with the numbers and distribution of organisms on a local

scale, and biogeography is concerned with distribution on a regional or even world-wide scale. Other disciplines contribute much to the study of distribution and are in turn helped by it. The two most prominent of these are systematics and the study of evolution. Systematics, the study of the relationships between organisms, in the widest sense embraces classifying and naming organisms, information essential to biology in general and to the study of distribution in particular. Systematists, in turn, use distribution information in reaching decisions on the relationships between organisms. The study of evolution has benefitted considerably from distribution information, as the most well-known pioneers in the field, Charles Darwin and Alfred Russel Wallace, freely acknowledged. In return, a knowledge of the processes of natural selection has made large contributions to the understanding of the reasons for changes in distribution with time.

#### PATTERNS AND PROCESSES OF DISTRIBUTION

It is convenient to distinguish two closely related modes of distribution that are, in fact, inseparable in nature: (1) the local arrangement—on a small scale—of members of a population to ensure their survival by maximizing the use of the environment, often in accordance with the time of day, week, month, or year; (2) the large-scale geographical spread—on a regional, or even global scale—of a species over a long span of time. Obviously, the distribution of organisms on a local scale eventually affects the geographical arrangement of the species.

**Local distribution.** Just as the body of an organism has a structure, so does a population of organisms. The structure that results from the distributions of organisms is termed a pattern. Patterns may be characterized either by the forces that produced them (physical, social, or other) or, as in this article, by the ability of the organisms themselves to adjust their distribution.

**Spatial and temporal arrangements.** In a homogeneous environment—one that varies little from place to place—all parts of the environment may be occupied or visited by organisms. The activities of protozoans may be distributed throughout a small pool of water, and all available space on a rock in the intertidal zone of a shore may be covered by mussels or barnacles. In a heterogeneous environment, the total volume occupied or visited by a population may contain parts that are not exploited. In the pelagic, or open water, realm of an ocean, minute plantlike organisms may occur patchily, and the animals that feed upon them may be distributed in the same manner. These extremes of distribution are difficult to characterize because of the problems of measurement and representation in three dimensions. If the third dimension is not occupied, or unimportant enough to ignore, then distribution in a single plane, such as a flat piece of ground, is easy to characterize.

There are three patterns of internal distribution (or dispersion) of a population in a single plane (Figure 1). Organisms are distributed at random when individuals are free to choose a place to settle. But individuals often influence each other. When they attract each other, an aggregation, or clump, tends to form; when they repel each other, an overdispersion, or uniform spacing of the individuals, results. In the soil or in the leaf litter of a forest floor, almost all arthropod species are distributed in a clumped or aggregated fashion, with only a few species randomly distributed. Territorial animals, such as birds, and some plants, such as certain cacti, repel each other at a certain distance and thereby assume a uniform pattern of distribution.

The importance of scale is illustrated in Figure 1. It shows that on a small scale, members of a population are uniformly distributed, but on a large scale they are aggregated in clumps. This happens, for example, when many flocks of birds occur in a large area but retain their discreteness. A certain minimum distance is maintained between individuals in each flock by mutual avoidance, yielding uniform spacing within the flock. But the flocks themselves may be randomly distributed or

The three patterns of dispersion

Significance of distribution

clumped (for further information on population dispersion see POPULATION, BIOLOGICAL).

For many species, distribution is a function of time. The members of a population make regular movements, so that their distribution is different from one hour to the next; one day, week, or month to the next. Short-term shifts in distribution are best exemplified by plankton, small, often microscopic, organisms that float in the surface waters of lakes and seas. They move vertically in response to daily changes in light intensity, so that they are at greatest depth at midday and are at the surface or close to it, at dawn and dusk.

More striking, perhaps, are the regular annual movements of some animals, which bring them to one region at the time of breeding and to another region in the non-reproductive season. Such movements are known as migrations (see MIGRATION, ANIMAL).

**Environmental influences.** Organisms cannot exist outside a certain range of environmental conditions. There is an upper temperature limit to the activities of protoplasm, beyond which proteins are denatured, and a lower limit, which for many organisms corresponds with the temperature at which water freezes. Many organisms, however, are capable of existing, at least for a short time, under inclement conditions. They can survive long enough to move out of the area (by migrating) or to become physiologically inactive and, thus, protected against adverse conditions (by hibernating, estivating, or encysting). Some "cold-blooded" animals have the ability to adjust or acclimate physiologically by altering their metabolic activities in such a way as to operate best under the prevailing temperatures. Physiological adjustments of this sort are possible only when the environmental conditions change relatively slowly and by a relatively small amount.

Within this framework, many processes operate in the establishment of a pattern of distribution of a species on a local scale. Perhaps the easiest to envisage is a distribution determined largely by the characteristics of reproduction. In many plants, and some lower animals,

the reproductive products (seeds, spores, etc.) remain close to the parents because their dispersal capabilities are poorly developed, thus creating an aggregated distribution. In contrast are the intertidal organisms, many of which, although themselves fixed firmly to the substrate, shed their reproductive products into the water at high tide. The larvae develop in the pelagic realm of the sea and are carried to shore at the time they are metamorphosing to the adult stage.

The distribution pattern of adults that results from this combination of dispersal and settlement is determined by two kinds of processes, which are termed vectorial and stochastic. The vectorial process refers to directional dispersal caused by environmental motion, as in wind and water currents. The stochastic process refers to essentially random forces whose operation does not allow a prediction to be made as to where organisms will be carried and will settle.

As was mentioned earlier, the pattern of distribution may be determined also by the influence of one organism upon another. The social process that gives rise to the pattern is one of signalling. The messages are either "come here," leading to aggregation, or "go away," leading to uniform spacing. Alternatively, these two patterns, as well as a random one, may be produced by each organism responding individually to environmental features such as nutrients, which are themselves distributed in random, clumped, or uniform fashion.

**Interactions with other organisms.** Finally, the distribution of organisms of a species may be determined by interactive processes with other species. Heavy grazing by animals in a certain area often leads to a sparseness of plant species in the grazed area. Similarly, competitor species may influence each other, the one causing the other to be either rare or absent in one part of a local area. Throughout Europe, North Africa, and some of the Canary Islands, for example, the chaffinch (*Fringilla coelebs*) occurs in both deciduous and coniferous forests, but on two of the Canary Islands, Tenerife and Gran Canaria, it occurs only in deciduous forests, a closely related species, the blue chaffinch (*Fringilla teydea*), occupying the coniferous areas. The distribution of the chaffinch on Tenerife and Gran Canaria appears to be influenced, in a restrictive way, by the blue chaffinch, with which it could compete for space and food. This type of influence, while not easy to recognize, is probably exercised commonly between species that live in the same habitat as well.

Differences in the way in which the three basic patterns of distribution—random, clumped, or uniformly spaced—are set up have been emphasized, but a single mechanism could be responsible for any one. Consider plants, for example. If the spatial pattern of germinating seeds is random, if they thrive only in space not occupied by other root systems, and if they grow to a size that depends upon the space available, then the resulting distribution will depend solely upon the density, or numbers of seeds. Going from low to medium to high density, the distribution changes from clumped to random to uniformly spaced. Thus, the factors that govern the abundance of a species within a local area indirectly determine the distribution of the species in that area. It is possible that the factors that govern the abundance of a species also limit the distribution of that species. The processes leading to the establishment of a distribution range (area or volume), as opposed to the pattern of distribution within that range, are discussed in the next section.

**Large-scale distribution.** More is known about distribution on large scale than on a local scale. The reasons are partly practical and partly historical; it is easier to collect a few isolated specimens of plants or animals over a wide area than to study in detail their distribution in a clearly circumscribed area such as a field or a grove. In the past taxonomists and students of evolution have spent much energy trying to determine the extent of geographical variation in morphological characters of organisms, for which purpose collected specimens are sufficient.

Directional versus random forces

**The shape and extent of spread.** Most species occupy areas of irregular shape. The irregularities are often determined by obvious environmental features. The irregular pattern of distribution in North America of the pika (*Ochotona princeps*), a small rabbitlike animal, for example, corresponds with the irregular pattern of distribution of its habitat—rock slides and talus slopes at high altitude in the Rocky Mountains. When the distribution of certain habitat features is essentially linear, so too is the distribution of the species; the emergent vegetation at the edge of a lake and the intertidal mollusks in a narrow band along a rocky seacoast are cases in point.

### Continuous versus discontinuous distribution

Viewed on a local scale, the distribution of organisms may be continuous, or without interruption, but when viewed on an intermediate regional scale, the distribution may be discontinuous, or spotty, because of unsuitable habitat intervening between areas of suitable habitat. Viewed on a large scale, a continental or worldwide scale, the distribution may appear continuous once again, as the narrow bands of unsuitable habitat that produce the discontinuities slip out of focus. But discontinuities on a worldwide scale are evident for some species. King crabs (family Limulidae) are found on the Atlantic coast of North America from the state of Maine to Mexico.

These crabs are not found on the west coast of that continent, however, but on Asian coasts, from India to Japan, thousands of miles away. Another example is provided by beetles of the genus *Catops*, which are distributed around the North Temperate Zone in four widely separated areas (Figure 2).

Adapted from Jeannel, *La Genèse des faunes terrestres* (1942); Presses Universitaires de France, Paris

Figure 2: Discontinuous distribution of three beetles of the genus *Catops* in the North Temperate Zone.

Few species—of which man is one—have a worldwide distribution. Of those that do, several are associated closely with man and have achieved their present distribution as a result of this relationship. Nevertheless, there are cosmopolitan species that have achieved worldwide distribution by their own efforts. Such are the short-eared owl (*Asio flammeus*) and the osprey (*Pandion haliaetus*), two birds, both predators, conspicuous on all continents excluding Antarctica.

It is much more common to find species with restricted distributions. Aside from the numerous species confined to single, small islands, are continental species found in extremely small areas on large landmasses. The dusky seaside sparrow (*Ammospiza nigrescens*), for example,

occurs only in the salt marshes around Merritt Island, Florida, and on the adjacent peninsula.

Another form of restriction is indicated by the distribution of *Catops* beetles (Figure 2): restriction to a climatic zone, in this case the North Temperate Zone. The booby (*Sula leucogaster*), a seabird, has a pantropical distribution, breeding only—but extensively—within the tropical zones.

Two closely related species of the marine wormlike *Priapul* are restricted to the polar regions, one in the Arctic, the other in the Antarctic. In all these instances, and in variations upon these patterns, the restriction is the result of the inability of the organisms to exist beyond a range of environmental conditions. This is contrasted with restriction caused by the inability of organisms to travel over barriers, which has led to regional differentiation of faunas and floras. (This phenomenon is considered in more detail in the article BIOGEOGRAPHIC REGIONS.)

**The factors limiting spread.** Although more is known about the gross distribution of species than about their distribution within local areas, little has been established with certainty concerning the determination of the limits of an area occupied. In some cases the reasons for limitation of geographic range are obvious: the distribution of terrestrial organisms stops at the edge of sea, lake, or river; freshwater organisms occupy the length of a river, but extend no further than its estuary. But within the major environments the reasons for the observed distributions are not always so easy to discern.

At the outer edge of a distribution range the continued existence of organisms depends upon either reproduction or immigration from more central regions. The requirements of the individual for existence and reproduction must be met. One obvious way in which the distribution is limited is by insufficiency of the supply, or rate of supply, of these requirements. Any number of environmental factors, acting singly or in combination, can act in this limiting way.

### Limiting factors

The northernmost limit of distribution of the frog *Rana sylvatica*, in North America, is almost certainly set by a combination of temperature and time. Complete development of the tadpole stage in one summer is the rule. At their northern limit, these frogs have just enough time in the short Arctic summer, at the prevailing low temperatures, to complete development. Temperature has also been implicated as a factor in limiting the southern distribution of introduced pheasants (*Phasianus* species) in North America. If the environmental temperature is high before incubation of the eggs, the eggs will not hatch. The southern limit to the distribution of the pheasant in North America corresponds approximately with those spring temperatures that are critically high.

In Scandinavia, the distribution of a carabid beetle, *Bembidion aeneum*, corresponds well with the distribution of soil that was lightly salted when the land was covered by the sea about 9,000 years ago. The beetle appears to depend upon the salt, either directly or, perhaps more likely, indirectly, through plants or other animals that require the salt and that themselves serve as food for the beetle.

In general, gross climatic and soil conditions determine the distribution of plants, singly and as assemblages; animals, being dependent upon plants for energy, follow the plant distribution. There are some highly specialized associations between plants and animals, as between some pollinators and the plants they pollinate; the edges of the distributions of the two interdependent species coincide.

Many animal species, however, are not so much limited in distribution by a single plant species as by an assemblage of plant species, such as those constituting a savannah or a tidal marsh, for example.

Factors limiting the distribution of a species are more easy to recognize when they are discrete rather than graded, as is temperature. The lizard *Uta stansburiana*, for example, which occurs in the deserts of southwestern North America, breeds only in the abandoned nests

of the pack rat (*Neotoma micropus*); the number of such nests thus sets an upper limit to the number and the distribution of breeding pairs of lizards.

The Australian ecologists H.G. Andrewartha and L.C. Birch have suggested that the factor or factors that limit the abundance of an animal species within its distribution range also limit the range itself. Exceptions to this are easy to find, particularly where the limit of distribution is set, at least in part, by a physical barrier, such as a mountain range. Nevertheless, the statement is likely to be widely true, especially for arthropods, and it is easy to appreciate when the species fluctuates in numbers markedly from one year to the next. A fine example is provided by the cutworm moth (*Porosagrotis orthogonia*), a pest species in North America, whose larvae feed on the roots of wheat. In Montana, for instance, in years of great abundance the species occurs throughout most of the state, but in years of scarcity it is either rare or absent from some parts.

Not only are distributional limits at one point set by an interaction of factors, but different boundaries are set by different factors. The saguaro cactus (*Cereus giganteus*) occurs in the Sonoran Desert of the United States and Mexico, but is not found either at the highest or lowest altitude within its area of distribution. The upper limit appears to be set by low winter temperatures, and the lower limit is set by a variety of factors, most important among which seems to be the fineness of the soil; this in turn probably affects the plants in a complex way through its properties of stability and of retention of nutrients and water.

One species can prevent the spread of another by virtue of competitive superiority in the range that it occupies, thereby setting the limit to the distribution of the other species. The distribution of two species of pocket gophers in western North America is representative. *Thomomys talpoides* occurs in northern states and *Thomomys bottae* in southern ones. An outline of their distributions shows that there is little overlap and that their boundaries are often complementary (Figure 3). No conspicuous envi-

#### THE NATURE OF DISPERSAL

The requirements of an organism are a place to live, food, and, for sexually-reproducing organisms, a mate. The requirement of space is not easily met in a densely populated area. Animals, of course, possess the ability to seek out unoccupied space, but for plants there is a strong element of chance in the finding of suitable space. In both, however, the dispersal characteristics of the organisms are of fundamental significance and, as such, are strongly under the influence of natural selection. These characteristics partly determine whether a species is widely or narrowly distributed, and whether it can establish itself in isolated areas. Dispersal characteristics also influence the evolutionary process. Since the evolution of two populations from a single ancestral population usually requires spatial isolation, the dispersal frequency of members of the populations determines whether the degree of isolation is sufficient for evolution to take place.

Mechanisms of dispersal can be considered under two headings, active and passive. The seeds of some plants are actively dispersed by mechanical means, as when a seed pod dries out, splits open, and sends a shower of seeds to the ground in the vicinity of the parent plant. Generally, however, plants rely on passive means of dispersing, whereas both passive and active means are used widely by animals.

Active dispersal. The conditions under which active dispersal occurs are not uniform throughout the life of organisms. Dispersal usually occurs at the time of reproduction, when the individual seeks a mate or, in the case of many vertebrates, seeks a place in which it can attract a potential mate. The first patch of suitable terrain or water is chosen by the dispersing individual, and this may be close to the place where it was born. If all the space in the vicinity of home is already occupied by other individuals, however, then that individual will be forced to disperse more widely, to increase its chances of securing a mate and food. It is these far-dispersing individuals that are likely to significantly alter the distribution range of the species. The rule is almost certainly that most of these individuals perish as they encounter unsuitable conditions beyond the limit of distribution of the species. Still, some reach suitable pockets of habitat beyond and somewhat isolated from the original distribution range, and occasionally these give rise to new populations.

The most spectacular of dispersal movements, however, are the so-called irruptions of birds. These movements are not the result of a search for a place to breed, but are induced by a combination of poor food supply and possibly other adverse environmental conditions coupled with unusually high density at the end of the breeding season. An example of such an irruption is observed in Britain, which is beyond the breeding range of Pallas's sandgrouse (*Syrhaptes paradoxus*), but which has been visited irregularly by sizable numbers of this species. As far as vertebrates are concerned, it seems that all individuals in a population have an approximately equal ability to disperse. Whether they do disperse, and how far, is dependent upon density in relation to the required resources of food and water, and the availability of mates.

Somewhat distinctive dispersal abilities are exhibited by members of many insect populations. Perhaps the best known examples are found among locusts, ants, and termites. In central and east Africa the locust *Schistocerca gregaria* occasionally swarms and consumes all green plant material in its path. The species actually occurs in two forms of quite different behaviour. The bright green form is solitary and sluggish, while the darker form, the one observed in the plagues, is highly mobile and gregarious. If the young produced by the green form are raised at high density with frequent physical contact between individuals, they develop into adults of the dark form and not the green form. This phenomenon, known as phase polymorphism, is admirably suited to the species. As the population increases and depletes its food supply, a developmental and behavioral mechanism comes into play, resulting in the production of individuals that are predisposed to dispersing.

The caste polymorphism of ants and termites serves a

The role of natural selection

Polymorphism: forms to fit the need for dispersal

ronmental feature coincides with the highly distinctive boundaries, so it appears that the species have set them themselves by interacting.

similar function. In these highly social insects, in which different members of the society are structurally and behaviourally specialized to perform different tasks, dispersal to new areas and the founding of new colonies is the task of the winged forms.

A third form of polymorphism exhibited by insects is life-history polymorphism as exhibited among butterflies, dragonflies, and wasps. In all of these insects the wingless larvae are the feeding phase and disperse little, whereas the adults are the dispersal phase and feed little. In fact, the adults of some insects, such as mayflies, do not feed at all, but disperse, mate, lay eggs, and die.

There are exceptions to the statement that larval insects disperse little, which introduces a fourth kind of polymorphism, termed behavioural polymorphism. In a population of the larch budmoth (*Zeiraphera griseana*) in Switzerland, there are at least two types of larva that differ in structure and behaviour. One is intolerant to crowding; it disperses readily and is usually the first to appear on the principal food plant, larch trees. The other is tolerant to crowding and disperses little. The proportion of these two types in the population varies from time to time in accordance with the overall density. A balance of advantages and disadvantages allows the two forms to persist together without one replacing the other.

As indicated by the above example, natural selection does not always favour the individuals that disperse the most. If the chances of dispersing and finding a new, suitable, and unexploited environment are very low, selection will act against the strong dispersers. Such seems to be the case in highly restricted and well-isolated environments such as oceanic islands and mountain tops. In these environments the number of flightless birds and insects is striking, and is much greater than in continental regions. Charles Darwin pointed out that the possession of large wings and well-developed powers of flight could be a disadvantage to animals on oceanic islands, particularly small ones, because an occasional strong wind might carry an already airborne animal away from the island and out to sea. The zoogeographer P.J. Darlington has emphasized that wings are also used in flight from predators, but predators are scarce or absent on these islands, so the need for dispersal powers within the island environment is not as great as within continental environments.

**Passive dispersal.** Organisms are dispersed passively by three principal agents: wind, water, and other organisms.

**Dispersal by wind and by water.** The capability of wind to transport organisms is well known, but the extent and the scale of such transportation is only now becoming clear. Microscopic organisms, such as viruses and protozoa, are readily carried by the wind, but even some of the smaller vertebrate animals such as frogs can be carried along on strong winds. Spiders, mites, and insects have been collected on airplane flights across the Pacific Ocean at distances up to 3,000 kilometres (1,900 miles) from land. Because of the method of capture, specimens are dead, so there is no means of distinguishing whether they were or were not living when they were collected. Nevertheless, in view of these remarkable results, it is no longer surprising that even the most isolated islands have an extensive insect fauna. There are, for example, close to 4,000 insect species native to the geographically rather remote Hawaiian Islands. It has been suggested that these species evolved from 250 ancestral types that could have been windborne from continents.

In a similar way, winds carry insects from lowland regions to mountain tops, where they may be deposited in the snow. Those incapable of existing in this climatically rigorous environment (probably almost all) are eaten by the native arthropod fauna. In fact, the native arthropods may be dependent upon this wind-drifted food, just as some stream-dwelling insects are dependent for food upon the organic matter drifting down from upper levels of the stream.

A study of the spotted alfalfa aphid (*Therioaphis maculata*) in California indicates that an amazingly large number of organisms are passively transported by wind. Mil-

lions of these winged aphids alone float passively with the current in the spring months.

Structural adaptations facilitating dispersal by wind are strongly developed in some groups of spiders. Gossamer, the silk secreted by the spider, is blown by the wind, and the spider, attached to it, is carried along, assisted sometimes by rising air currents.

Water currents carry organisms in the same manner as wind. In the aquatic environment, however, the terrestrial organisms must stay afloat, avoid becoming saturated with water, and maintain their internal salt balance. Some outstanding examples of long distance passive dispersal by ocean currents are known. Marine invertebrates are carried from West Africa to South and Central America on the main equatorial current of the Atlantic. Some water in this current comes from the Niger and Congo rivers, so it is possible for estuarine and freshwater animals to be transported to another continent by this means as well.

The distribution of several species of terrestrial animals is evidence that long distance dispersal has been achieved by major ocean currents. One dramatic example is the distribution of a flightless staphylinid beetle, *Micralymma marinum*, believed to have been carried passively from the Western hemisphere to the Eastern by means of the Gulf Stream.

The odds are considerable against terrestrial organisms surviving the ordeal of a prolonged journey in the surface waters of the sea. Some vertebrates may actively participate in the travel by swimming, thereby increasing their chances of survival. Others may cling to floating debris or natural rafts of land or ice. Pieces of river banks or fringing swamp vegetation and soil break off and are carried out to sea, particularly when flood conditions prevail, and with the rafts go the animals that were stranded on them. Pack ice, breaking loose, can similarly function as a raft for polar animals, such as polar bears, foxes, etc. A remarkable floating island was observed in the Atlantic off the coast of North America in 1892. It was estimated to be 100 feet square, with trees 30 feet high, and to have drifted at least 1,000 miles. Whether it reached land and its plant and animal passengers were able to colonize the new land is not known, but this example at least demonstrates the feasibility of distribution of organisms on rafts.

The distinction between airborne and waterborne means of dispersal is easy to make, but the two are not alternatives, because many organisms that start a journey on air complete it by water. Insects cross the Baltic Sea from Estonia to Finland, originally participating in mass flights, but reaching the other side in the water, many of them alive.

**Dispersal by other organisms.** The third means of dispersal—by other organisms—may be regular, in the case of a host transporting a parasite, or irregular, as in the chance attachment of one organism to another. For parasites, finding a host is a major problem, and an efficient means of dispersal from one host to another or to the environment in which another can be found, is essential. Consequently, parasites have developed remarkable specializations to the life history characteristics of the host that enable the parasite to disperse at the most favourable time. Dispersal is often assisted by the use of an additional species as a transporting agent, or carrier, from one host to another. A case in point is the myxoma virus, which parasitizes rabbits and uses mosquitoes as carriers. When aided by wind, an individual mosquito can carry the virus as far as 40 miles before infecting a rabbit; by this process of transporting and infecting, the mosquito population can disperse the virus rapidly over a large area.

Many organisms are distributed by attachment to mobile organisms. Small invertebrates such as snails and flatworms, for example, are accidentally transported on the legs of migrating birds. Undigested food items, such as the seeds of some plants, can be widely dispersed by their consumers in excrement deposited far from the source. There are numerous cases of mutualistic associations between animals and plants in which the plants are

Adaptations for dispersal

dispersed. One example is provided by flightless weevils of the genus *Gymnopholus*, which carry fungi, lichens, algae, or liverworts in depressions on their back. From this association the plants gain a place to grow and a vehicle of dispersal. Plant dispersal is also carried out by mites that live for part of the time in the plant association growing in the weevil's back. The advantage gained by the weevils is that of camouflage; to a predator they appear to be part of the vegetation-covered tree bark on which they occur (see also BIOTIC INTERACTIONS).

Introduc-  
tions by  
man

Probably the most effective agent of dispersal is man, by virtue of his numbers, widespread distribution, long-distance travel and shipping, and the objects he uses. It is not surprising to find, for example, that ports of entry are the centres of distribution of some arthropod groups newly introduced to a continent. The arthropods, other small animals, and plant seeds are transported in boats with cargo. It used to be the custom for vessels to take on soil as ballast in England and unload it in Newfoundland, which resulted in the introduction to Newfoundland of a number of soil organisms not previously found there. These examples might be termed adventitious transport through the agency of man. By contrast, there are also numerous instances of deliberate introduction of "exotic" species of plants and animals to new areas. In many cases, the newly introduced species perishes or simply does not spread from the point of introduction, as has happened with the skylark (*Alauda arvensis*), introduced from Britain to southern Vancouver Island, Canada. In other instances, the introduced species has exploited the new environment and spread rapidly. It took only 50 years for the rabbit *Oryctolagus cuniculus*, exported from Britain, to spread the length and breadth of Australia from a single farm, even in the face of efforts to prevent the spread.

The dispersal of plants depends largely on their exploitation of animals as carriers. Their structural specializations to being carried and dispersed exhibit great variety. These include a variety of hooks, barbs, bristles, and sticky secretions to aid attachment to animals, fleshy palatable fruit for consumption by animals (but enzyme-resistant seed walls), very small seeds light in weight but large in area to facilitate wind dispersal, and resistance to saltwater to facilitate dispersal by ocean currents.

The means of transport determine the type of environment to which the plant part (seed, fruit, spore, etc.) will be carried. In a study of flowering plants on various islands and island groups, it has been found that different types of island situations receive dispersing plant species by different means. Atolls, for example, receive most of their plant colonists by oceanic drift. Plants have colonized high islands most frequently by bird transport. Adherence of bristly seeds to the feathers of migratory birds is responsible for the extensive plant populations of dry volcanic islands. Air transport, whether aided by birds or not, is most effective for carrying plants to islands near the mainland.

Reduction  
in  
dispersal  
powers

Both plants and animals exhibit a loss or reduction of dispersal powers on islands. Examples include an increase in fruit size without concomitant increase in appendages such as hooks that serve in dissemination, a diminution or actual loss of those appendages, and an alteration of the mechanism of the release of fruits. These evolutionary shifts prevent the loss of reproductive products to unsuitable neighbouring environments in which they may not survive. There also tends to be a corresponding reduction in the number of seeds or fruits produced. And, in the case of increases in fruit size, there is the additional advantage of a greater volume of stored food, of particular help to seedlings growing under shady forest conditions. There are probably other less conspicuous changes in the dispersal abilities of plants, affecting such attributes as resistance to seawater, resistance to the digestive enzymes of animals, and the length of viability of seeds.

#### COLONIZATION OF NEW AREAS

From what has been said about the dispersal powers of organisms, it is a wonder that all taxonomic groups are

not found everywhere. They are not, for two principal reasons. Different groups have different dispersal abilities, and environments have a limited capacity for supporting organisms, in terms of both number of individuals and number of species.

**Effects of dispersal abilities.** The probability that an organism will colonize successfully a new area is lessened by the distance it must travel and increased by the suitability of the new area. The most rapidly successful colonizing species are those with well-developed dispersal powers and a wide tolerance for environmental conditions. Plants referred to as weeds have these properties, and in addition they have the ability to exploit recently disturbed terrain. As a community of plants and animals undergoes a natural successional change toward greater complexity and stability, these pioneer organisms are replaced by organisms inferior in dispersal abilities but superior in competitive abilities. Such pioneer species, both plants and animals, tend to be found in ecologically marginal and geographically peripheral regions, from which position they are well suited to disperse to new areas. Many of them have other advanced biological properties that relate to their role of ecological opportunism, including the ability to reproduce without fertilization.

The future of initial colonists is partly determined by the ability of other competing species to reach the new area. The barrier to be crossed in reaching the new area—be it mountain, sea, river, or climatic zone—is not to be considered an insuperable one; it simply presents an obstacle that reduces the probability of transgression by some organism. There may be what has been termed a filter route across the barrier; that is, a route suitable for only some members of a fauna or flora, those with the most well-developed dispersal powers (Figure 4). An is-

Figure 4: Barriers and possible filters for animal dispersal.

land twenty miles from the mainland can be colonized by birds flying across the water barrier, a route suitable only for the more dispersive members of the mainland bird life. Alternatively, the barrier may be almost impenetrable. For some organisms, the Sahara must be such a formidable barrier. The route across it is a "sweepstakes route"—to use the term coined by the American paleontologist George Gaylord Simpson—for the probability of any organism crossing the barrier is very low indeed, and yet some do cross it. Chance plays the major role in determining which ones get across, and when.

The most strongly isolated environments may be so difficult to reach that the initial colonists have the opportunity to undergo evolutionary changes, unaffected by immigration of members of the same species or members

Chance in  
dispersal

of different species. In both plants and animals, these changes involve the relinquishing of their opportunistic characteristics.

**Effects of the new environment.** On the other hand, an organism arriving in a new area may have little chance of establishing itself, either because the habitat is unsuitable or because numerous other species already occupy the area. There appears to be a maximum number of species that can be supported in a given area (or volume) of environment. Size of the environment itself is one determinant of this maximum; the larger the area, the larger the number of species (and individuals) present. Climatic and related physico-chemical factors are other determinants; these are responsible for the gradual change in species from the equator to the poles. This variation in species number with latitude is well illustrated for the mammals. It is equally well illustrated by mollusks, snakes, birds, ants, or corals. In contrast, variation in species number with longitude is less pronounced and less predictable. The number of species at any point along the latitudinal gradient is more or less the maximum possible, given present-day physico-chemical conditions and the total number of species in the world today. In other words, most areas are saturated with species; if a new species arrives in an area, it can establish itself usually only by displacing a resident species.

The process by which an area becomes saturated with species can be expressed in a simple model (Figure 5).

Adapted from R.H. MacArthur and E.O. Wilson, *The Theory of Island Biogeography* "Monographs in Population Biology," vol. 1 (1967); Princeton University Press

Figure 5: Model of species equilibrium on a single island (see text)

Immigration and successful establishment of new species depends on the number of species already present. The rate of establishment of new species declines and the rate of extinction of older species rises until a point is reached when these two processes are equal, and no further change in number of species takes place; the area is then saturated. There are interesting variations of this model that allow assessment of the importance of size of area and degree of isolation upon the two processes and upon the equilibrium number of species. Large size and weak isolation, for instance, are conditions conducive to a large equilibrium number (many species), and small size and large isolation yield a small equilibrium number (fewer species).

If the environment changes, however, the equilibrium number is subject to change. The shifting of average temperature over a long period of time in water, for example, may enable more species to exist at a given position in that body of water. In the terrestrial environment, the geographical distribution of climate has changed frequently in the past, which has caused a change in the distributions of organisms.

#### CHANGES IN DISTRIBUTION WITH TIME

Interpretation of past biological events will always remain a challenge because the necessary information will never be complete. The determination of past distribu-

tions of organisms, and changes in them, is biological detective work with generally few clues at hand. It is first of all dependent upon fossils that can be identified and located as to place and time of occurrence. Attention is focussed less on individual species than on large groups (such as a family or order) or an ecological assemblage (such as a community or population). It is, secondly, based upon the principle that biological and ecological processes operating today are the same as those that operated in the past.

**Centres of evolutionary origin.** A survey of many groups of organisms shows a common pattern. It is characterized by evolution and proliferation (adaptive radiation) into a diversity of types adapted to performing a variety of ecological roles. The adaptive radiation of marsupial mammals in Australia from a primitive insectivore is a good example. The evolutionary processes are accompanied by expansion of distribution ranges and a geographical radiation. There follows recession or contraction of distribution ranges, of the group as a whole or of individual species, as new groups arise and partly supplant their predecessors. Superimposed upon this pattern are large-scale shifts in distribution, without necessarily any expansion or contraction, as environmental conditions change; for instance, there was a steady southward shift of northern vegetation zones during much of the Tertiary Period (7,000,000 to 65,000,000 years ago), evidently caused by a cooling of northern climates. The distribution of organisms in the past can be viewed as an ever-changing kaleidoscope, the result of movements, countermovements, spreadings, competitions, extinctions, and replacements of a diversity of plants and animals over the whole of the diverse surface of the world.

An examination of the distribution of fossil material and the distribution of present-day organisms suggests that there were regular aspects to the kaleidoscope. It has been recognized, for example, that there were major centres of origin and evolution of terrestrial vertebrates, although the identification of these centres has not met with unanimous approval because the fossil evidence by itself is not convincing. Some biologists have suggested that the North Temperate Zone was the centre of origin because its variable climate continually presented challenges to vertebrates, to which the vertebrates responded evolutionarily by diversifying. Others have argued instead for the tropics as a centre of origin and evolution, in view of the greater number and variety of species in the tropics than in either temperate zone today. Furthermore, North Temperate forms are not usually peculiar to the north, but are representatives of groups also present, often more abundantly, in the tropics; among birds, the hawks, owls, and finches may be cited as among these forms. Finally, many groups present in the tropics are absent in the north.

There are other reasons for considering the tropics to be an evolutionary centre, and here historical clues play a large part. It seems reasonable to expect that (1) the region in which the largest number of species and genera existed in the past is where the majority of them originated, (2) the region of greatest degree of differentiation might be the place of origin of a group, and, finally, (3) the region of largest area would have been occupied longest. The fossil evidence interpreted in the light of these three statements points strongly to the Old World tropics as the main origin of terrestrial vertebrates.

**The subsequent spread of organisms.** *Environmental influences.* Major shifts in the distribution of whole faunal and floral assemblages can usually be correlated with inferred environmental change. At different times in the history of the earth there have been different patterns of climate and, more particularly, the average temperature has been higher or lower than at present. Climatic changes have had profound effects upon animal and plant distribution, both directly and indirectly. In colder periods, for example, the earth was covered with more ice and less water, and the sea level was sufficiently depressed that landmasses, now separated by a water barrier, were connected.

The tropics as the evolutionary centre

The best known of these climatic changes is the most recent Ice Age, comprising several glacial (cold) and interglacial (warm) periods. The sea level was as much as 120 metres (390 feet) lower than at present during glacial periods, and as much as 50 metres (165 feet) higher than at present during interglacial periods. These fluctuations affected organisms most profoundly in polar and temperate regions, least in the tropics.

At the start of the Tertiary (Paleocene Epoch), there were great differences between the faunas and floras of North America and Eurasia. There then occurred an interchange of faunas, and the geological and fossil evidence suggests that the interchange occurred across a land bridge in what is now the Bering Sea. Initially, the interchange involved large parts of the continental faunas and many major groups, most noticeably among the mammals. Subsequently, exchanges were increasingly selective and tended to involve smaller fractions of faunas, progressively less distinctive types of animals, lower taxonomic categories only, and ecological types less novel in the invaded regions. This has been interpreted to mean that the land bridge was increasingly difficult to cross, perhaps the result of an increasingly effective climatic barrier; additionally, each continent may have become increasingly saturated with the major types of animals, making it progressively more difficult for a potential colonist to establish itself. This whole process, extending down through the Tertiary Period and up to the recent Ice Age (Pleistocene Epoch), was evidently interrupted three or more times by submergence and subsequent elevation of the land bridge.

One of the species of mammals taking advantage of the land bridge across the Bering Sea, it is thought, was man himself. By late Pleistocene times man had become a dominant species throughout the Old World through the evolution and development of ecological versatility. In several waves of dispersal, man entered North America, probably at the last continental glaciation. Dispersal and changing (mainly expanding) distribution have continued to be characteristic of the species.

In contrast to the events in the far north, North and South America were separated during most of the Tertiary Period. They were connected by land possibly at the beginning, and then again late in the Pliocene Epoch. The effect of this Pliocene connection upon the distribution of organisms can be illustrated with mammals, of which many fossils are available. Before the connection was made, North America had about 27 families of terrestrial mammals, and South America had 29 families. Only one or two families were common to both continents. After the connection, the number of families in common rose to a maximum of 22. IncurSIONS, withdrawals, and extinctions led to North America possessing 23 families and South America, as before, 29. North America benefitted by the arrival of opossums, three families of ground sloth, two stocks of armadillos, and many others. South America benefitted by the arrival of several species or genera of cats (including saber-toothed tigers), horses, camels, elephants, tapirs, and rabbits. Most have survived to the present day, although tapirs, camels, elephants, horses, and sabre-toothed tigers have since disappeared from North America, and South America has lost a portion of its rich fauna also.

The recurring expansion and contraction of distribution ranges have produced some patterns exhibited by contemporary organisms that at first sight seem inexplicable. Continuous distributions are not difficult to understand, but what past events led to the highly discontinuous or disrupted distributions evident today, such as the distribution of king crabs in North America and southeast Asia? Migration from one area to another is possible but unlikely, it is more likely that the distribution was once more widespread and either continuous or moderately discontinuous, and that a shrinking of distribution range has occurred. The distribution of fossils indicates that king crabs were widespread and abundant in the Paleozoic Era, and that a restriction of range occurred in the Mesozoic, possibly as a result of competition with newly evolved marine invertebrates.

Other species were profoundly affected by climatic disturbances, such as the recent Ice Age, surviving partly in relatively small areas of suitable habitat, or refuges, and partly in larger areas farther away, to which they dispersed when the climatic change rendered the previously occupied area unsuitable. The evidence for this consists of numerous instances of much differentiated forms isolated from the main range of the group. These are referred to as relicts. Examples are Arctic plants found isolated on mountain tops in north and middle Europe.

Even before Darwin's time, their occurrence was explained as due to survival in refugia, areas untouched by glaciers but once surrounded by them.

Certain groups of coastal plants still may be confined to their glacial refugia because they are not evolutionarily versatile enough to break out from them; their variability became restricted during the past glaciation when new variants would have been at a disadvantage during the harsh conditions. In contrast, there are some species, termed disharmonious relicts, which occur in unusual and isolated habitats where they are thought to have survived because of broad ecological tolerance in the past.

Relict patterns of distribution are found on islands as well. These are in irregular and unpredictable patterns interpreted as having been formed by partial extinction of an old fauna or flora formerly common to all the islands. They are most pronounced on oceanic islands. An example is the distribution of frogs on islands in the Indian Ocean. The pattern is replete with discontinuities and mixed relationships, which indicates that the fauna is partly a relict one, and that existing geographical relationships are partly the result of extinction and survival rather than of direct dispersal. The relict pattern of distribution contrasts with an immigrant pattern, characteristic of continental islands, in which the number of species in a taxonomic group decreases in more or less orderly fashion with distance from the continent, although modified by island area.

**Geological influences.** Much has been said about the distribution of terrestrial organisms, as if the organisms have moved and the land has stood still. But, in fact, there is a growing body of evidence to indicate that the land also has moved, and that the continents have not always been in their present positions. If this is true, the distributions of organisms, in relation to the Earth's axis, have undergone even more change than has been referred to so far.

The theory of continental drift (*q.v.*) proposed by the geologist A.L. Wegener holds that the continents were once connected, but that they split apart before or during Early Mesozoic times (150,000,000 to 225,000,000 years ago) and gradually drifted apart. Often maligned, the theory is currently in favour as a result of new evidence, and mechanisms of continental drift have been proposed in detail. Some of the geological evidence is based on the shapes of continents. The outline of West Africa, for example, is complementary to that of eastern South America. If the two continents are fitted together like a jigsaw puzzle, the Paleozoic and Early Mesozoic rocks of the two continents in the vicinity of their (present) coasts show remarkable correspondence. The paleontological evidence is that the flora and fauna of the two continents showed a great degree of resemblance in those early times, and this resemblance may have diminished progressively thereafter. The fossil evidence is equivocal, however, and the similarity of geological strata on the separate continents has been attributed alternatively to similarity of climate (on separate continents) in times past, so the theory is far from being universally accepted. If continental drift was a reality, however, it must be viewed as a major contributor to changes in the distribution of organisms in time.

**Human influence.** It is appropriate to conclude with a few remarks about man. The agricultural, industrial, and commercial activities of man have had an enormous impact upon the distribution of organisms. In the last 10,000 years man has replaced the climate as the most

Man's  
impact  
on dis-  
tribution

The  
dispersal  
of man

Contem-  
porary  
patterns  
of dis-  
tribution

important agent of change. Even in the Pleistocene Epoch man may have been an important agent of change, for it has been suggested that large-scale extinctions of mammals at that time were not the result of climatic change but of "overkill" at the hands of man.

Some organisms are more widely distributed now as a result of man's activities, many more are more restricted, and a sizable number have disappeared altogether. Since 1600, almost 100 species of birds and 40 species of mammals are known to have become extinct, and it is probable that man exercised an important, if not decisive, influence in these extinctions. Moreover, many species are now on the verge of extinction, again largely because of man's activities.

Man's influence upon the distribution of organisms has been, and continues to be, needlessly destructive. Admittedly, some destruction is probably inevitable, since species like man, with novel ecological features, spread and cause a reduction in numbers of other species. But this process leads to a state of dynamic equilibrium, to something approaching stability. Unfortunately, modern man shows no sign of approaching an equilibrial relationship with his environment in the immediate future.

**BIBLIOGRAPHY.** Local distribution is considered in detail in H.G. ANDREWARTHA and L.C. BIRCH, *The Distribution and Abundance of Animals* (1954); and V.C. WYNEEDWARDS, *Animal Dispersion in Relation to Social Behaviour* (1962). Large-scale distribution is dealt with in S.P. EKMAN, *Tiergeographie des meeres* (1953; Eng. trans., *Zoogeography of the Sea*, 2nd ed., 1967); P.J. DARLINGTON, JR., *Zoogeography: The Geographical Distribution of Animals* (1957); P. DAN-SEREAU, *Biogeography: An Ecological Perspective* (1957); R.H. MACARTHUR, *Geographical Ecology: Patterns in the Distribution of Species* (1972); L.F. DE BEAUFORT, *Zoogeography of the Land and Inland Waters* (1951); L.C.M. CROIZAT, *Panbiogeography*, 3 vol. (1958); W.B. GEORGE, *Animal Geography* (1962); R. ## Divination

Divination, the alleged art or science of foretelling the future by various natural, psychological, and other techniques, is a phenomenon found in all civilizations in all times and areas. It is known especially in the modern Western world in the form of horoscopic astrology.

### NATURE AND SIGNIFICANCE

In the context of ancient Latin language and belief, divination was concerned with discovering the will of the gods. Today, however, scholars no longer restrict the word to that earlier root meaning. Divinatory practices and the beliefs undergirding them are greater in scope than the ancient methods of discerning the will of the gods and the fatalistic view of the human condition that inspired so much of early Mediterranean religious thought. In some societies, in fact, divination is a practice to which many persons frequently resort, but never in terms of discovering the will of the gods. The idea of a godly providence controlling human affairs, in such societies, is unusual, although humbler spirits are often thought to intervene in troublesome ways.

Divination is universally concerned with practical problems, private or public, and seeks information upon which practical decisions can be made; but the source of such information is not conceived as mundane, and the technique of getting it is necessarily fanciful. The mantic (divinatory) arts are many, and a broad understanding can only emerge from a survey of actual practices in various cultural settings. A short definition, however, may be offered as a preliminary guide: divination is the effort to

gain information of a mundane sort by means conceived to transcend the mundane.

Though the act of divination is attended by respect and the attitude of the participants in the divinatory act may be religious, the subject matter of divination (like that of magic) is **ephemeral**—e.g., a trouble case, an illness, a worrisome portent, an object lost. Divination is a consultative institution, and the matter posed to a diviner may range from a query about a few lost coins to high questions of state. The casual or solemn nature of the matter is normally matched by that of the diviner in terms of attitude, technique, and style. Where the diviner is a private practitioner, the quality of the procedure may be linked to the fee. This can become a matter for bargaining or implicit contention, so that worldly motives are patent. In contrast to the pecuniary motive of some diviners, the ancient Etruscans in Italy and the Maya in Mexico viewed the calling of diviner-priest as sacred, and his concern was for the very destiny of his people. Divination has many rationales, and it is difficult to describe the diviner as a distinctive social type. He may be a shaman (private curer employing psychic techniques), a priest, a peddler of sorcery medicines, or a holy man who speaks almost with the voice of prophecy. To appreciate the significance of the diviner's art in any culture or era, one must know the culture or era's fundamental beliefs about man and the world. In Christian times Europe has moved from a horror of necromancy (conceived not as consultation with a ghost but as a literal "raising of the dead") to an amused tolerance (among the educated) of spiritualism as a sort of parlour game. To assert that European beliefs about God and man have remained the same throughout the Christian Era would be to ignore the broad impact of natural science and secularization in the modern era. On the other hand, to suppose that divination has been doomed by science and secularism would be to ignore the abiding popularity of horoscopic astrology (divination by means of relating the movement of stars, planets, the Sun, and the Moon to a person's birth date) and recurrent fashions for other mantic disciplines—and perhaps to misjudge the security of "modern" beliefs.

### THE STRUCTURE OF DIVINATION

The extent to which a practice such as divination should be called a corollary of the beliefs entailed and the extent to which the opposite might be true (i.e., the beliefs deriving from the practice as an after-the-fact explanation) is difficult to ascertain. Among the great cultures, the Chinese tradition has given the broadest scope to divination; yet there is no single Sinic religious cosmology, or theory on the ordering of the world, comparable to those of the Maya, Sanskrit (Hindu), or Judeo-Christian traditions, from which the variety of popular practice can be seen to derive. Sometimes, as with the flourishing business of astrology in Christian countries since the Renaissance, the metaphysical (transcendent) presuppositions of mantic practice may have been de-emphasized in order to minimize conflict with official religious and scientific doctrines. Generally, however, it may be said that the philosophical underpinnings of divination need not be deep or well worked out, but, where they are, they will afford clues to fundamental beliefs about man and about visible or invisible nature. Some traditions of divination—such as astrology, geomancy (divination by means of figures or lines), or the Chinese divinatory disciplines—are so old and firmly established that it is virtually impossible to discover their original contexts. Over the centuries such practices have survived many changes and they have become—as they have passed over numerous local and cultural boundaries—timeless answers to the constant questions of the human condition.

Established long ago in the hieratic (priestly) discipline of primitive theocracies, such a tradition still bears the marks of the specialists who worked out its systematic techniques and its cogent symbolic structures. Since the practice is now observed only as a folk or plebeian tradition, however, it would be rash to suppose that the true philosophical tradition undergirding divination survives.

Importance of world views and philosophical undergirding~for divination

Concerns of divination

Only in the case of the I Ching, the Chinese Book of Changes, have scholarly commentaries accumulated over the millennia in a context of considerable intellectual continuity. Systematic studies of geomancy are recent, and the literature of astrology is as perishable as it is massive. Babylonian astrology, from which later forms are derived, arose in an agrarian Mesopotamian civilization concerned with the vicissitudes of nature and the affairs of state. The mercantile, seafaring, and individualistic Greeks absorbed the mantic system of the collectivistic, floodplain civilization of Mesopotamia, elaborated on it by adding the horoscopic discipline, and transmitted it, through Hellenistic (3rd century BC–3rd century AD), Egyptian, and Islāmic science, to Europe. In the course of this transformation, the dual influence of world view upon the structure of divination may be seen: a most varied band of priests, scholars, and innovators have made their contributions to the system; yet there also is a clear correspondence between the general character of a culture and the uses it finds for divination. That is, the world view or views implicit in the divination system itself may reflect the historical rather than the current context of use. It requires only practical understanding to consult a ouija board or use a forked stick to decide where to drill for water. Hence, men of very different beliefs may adopt the same practices, and a full correspondence between practice and belief can only be expected where both have developed in the same cultural context. Where much of the popularity of the mantic art derives from its "exotic" flavour, its symbolism may be little understood. By its very nature, however, divination tends to develop as a discipline, becoming the tradition of an organized body of specialists. This is because the means to which the diviner must resort are conceived as setting him apart. That is the case even among such peoples as the Azande of the Nile-Congo Divide in Africa, where the resort to divination is frequent, and the most common techniques utilized are recognized to be within the competence of ordinary men. There, on a sensitive or contentious issue, an extraordinary credibility is desired, and the ultimate reliability of an oracle reflects the political standing of its owner—the king's oracle, for example, is viewed as the final authority, and the royal court is scrupulously organized to guard this vessel of power (divinatory and other) from contamination. Few societies are as enthusiastically given to divination as the Azande, who routinely employ it to explore their thoughts and who will not consider any important undertakings without oracular confirmation in advance. Among the Azande, the ordinary man could be considered a divinatory specialist. Elsewhere, men are content to reserve divination for special crises, and consultation must be with a recognized expert in order to distinguish an authentic answer from a spurious one. The diviner builds up his credibility through a dramatization of his role, the use of impressive paraphernalia, striking behaviour, or a combination of special accoutrements used for effect and an unusual rhetoric or rapport.

**Types of divination.** As schools of dramatic art range from those relying on explicit technique to those teaching intuitive identification with a role, mantic skills range from the mechanical to the inspirational but most often combine both skills in a unique, dramatically coherent format. The comparative study of divinatory practices is at least as old as the 1st-century-BC Roman orator and politician Cicero's treatise *De divinatione* (Concerning Divination), and the convenient distinction there drawn between inductive and intuitive forms designates the range. An intermediate class, interpretive divination, allows a less rigid classification, since many divinatory disciplines do not rely strongly either upon inductive rigour or upon trance and possession.

Inductive divination presupposes a determinative procedure, apparently free from mundane control, yielding unambiguous decisions or predictions. The reading of the "eight characters" of a Chinese boy and girl before proceeding to arrange a marriage—the year, month, day, and hour of birth of the two persons to be betrothed—illustrates this class of procedures. The "characters" are all

predetermined by the accidents of birth date and hour; and it is supposed that all proper diviners would come to the same conclusions about them.

Interpretive divination requires the combination of correct procedure with the special gift of insight that sets a diviner apart from his fellows. The contemporary Maya diviner of Guatemala, seeking to diagnose an illness, will carefully pass a number of eggs over the patient's body in order to draw into them an essence of the affliction. The intact contents are then collected in water, and the diviner withdraws into a darkened corner to bend over the receptacle and read the signs of the eggs. His recitation then explains the origin and nature of the disease, according to his reading.

Intuitive divination presupposes extraordinary gifts of insight or ability to communicate with beings in an extra-mundane sphere. The "Shaking Tent" rite of the Algonkian Indians of Canada illustrates the use of uncanny phenomena to lend credence to a mediumistic performance. The diviner, bound and cloaked, is no sooner placed in his barrel-like tent than the tent begins to shake with astonishing vigour and to fill the air with monstrous noises; and this continues with great effect until, all of a sudden, the communicating spirit makes his presence known from within the tent and undertakes to answer questions. The virtuoso performance illustrates the difficulty of explaining the phenomena of spirit possession as products of deliberate instruction. Evidently, such skills must be actively sought by the neophyte, and they answer to deep tendencies in his personality.

The cosmological and psychological conditioning that affects divinatory practices within a cultural tradition will influence in a similar fashion all of its religious practices. The Greeks tended to the intuitive or "oracular" style, and the Etruscans, in contrast, elaborated upon the more systematic but less versatile inductive practice of Mesopotamia—developing an authoritative state religion in which the positions were monopolized by the ruling class. Greek divination was eccentric in that sanctuaries were located apart from the centres of political power; the Etruscan system, on the other hand, was concentric, focussed at the summit itself. Rome eclectically incorporated both Greek and Etruscan elements, the ecstatic cult and the expert "reading" of livers—i.e., haruspimancy. Rome, however, never allowed divination to become the central preoccupation of society as it had been for Etruria, nor did it become an autonomous force in society as it had been for the Greeks. In this, Rome represented a balance that is more congenial to modern Western thought. Throughout the ancient Mediterranean world, the notable exception being Egypt, divination was tied to expiation and sacrifice: fate was perceived as dire but not quite implacable, and the function of divination was to foresee calamity in order to forestall it. In trans-Saharan Africa, religion centres about expiation and sacrifice, and divination is a pivotal institution, but the Mediterranean notion of fate is not developed. Instead, the trouble of a person is attributed to witchcraft, sorcery, or ancestral vexation—all of which are believed to be arbitrary and morally undeserved. Divination is employed to discover the source of trouble in order to remove it, whether by sacrifice, countersorcery, or accusation and ordeal. The mind is turned to past events or hidden motives of the present time, however, and not to the future—that would be to borrow trouble.

**The function of divination.** The function of divination needs to be understood in its motivational context. It is not enough to say that information won from the diviner serves to allay uncertainty, locate blame, or overcome man's impotence before misfortune. Divination is motivated to the extent that information, whether spurious or true, will please a client. Unless one assumes that the information is usually not misleading or palpably false, one should expect that clients would be displeased and skeptical. A careful assessment of the kinds of information that divinatory systems are required to yield is thus in order. The two main kinds are general information about the future and specific information about the past as it bears upon the future.

Cosmological and psychological conditioning

Inductive, intuitive, and interpretive forms of divination

The first kind of information is yielded by horoscopic divination. It is usually so general that it cannot be properly tested, for it bears the stamp of destiny. If such information were specific enough, the prediction could interfere with its own fulfillment, acting as a warning or breeding overconfidence. The other kind of information demanded from diviners is specific enough to be tested and often is; but testing a particular diviner's competence is seldom conceived to put the institution to test. It is common in trans-Saharan societies for a troubled client to consult a series of diviners until he finds one who is convincing. Again, many systems of divination have a double check built into them: the question is posed first in the positive and then in the negative, and the oracle must (obviously without manipulation) answer consistently. The chances are actually even that any oracle will fail to do so, yet the credibility of such oracles seems not to be lost. Technically, this means that untenable or invalid information can be obtained by a client without disconfirming his belief in the source. Early students of divinatory practice concluded that clients must be gullible, superstitious, illogical, or even "prelogical"; *i.e.*, culturally immature. Ethnographic studies do not confirm this, suggesting rather that what a client seeks from the diviner is information upon which he can confidently act. He is seeking, in so doing, public credibility for his own course of action. Consistent with this motive, he should set aside any finding that he thinks would lead him into doubtful action and continue his consultations until they suggest a course that he can take with confidence. The diviner's findings are judged pragmatically.

Men seek out a diviner when they are unsure how to behave—when there is illness, drought, or death and the fear of death; when there is suspicion of malevolence, secret thieving, or breach of faith; when dreams or other symptoms are disturbing or the signs of the time seem bad. Divination universally serves the purpose of circumscription, of marking out and delimiting the area of concern: the nature of the crisis is defined, the source of anxiety is named. Concern becomes allegation, bafflement decision. The diviner may function as a stage manager, speeding up the action, rejecting false moves in advance, or indicating the secret fear or the hidden motive. Finally, when the client is content to act upon the diviner's information—such as accusing a thief or sanctioning his wife for adultery—his course of action is self-explanatory. Where divinatory practice is a recognized resource, a man who ignores it is considered arbitrary, and one who heeds it needs no further justification. In this sense, the ultimate function of divination is the legitimization of problematic decisions.

#### VARIETIES OF DIVINATION

Because dramatic effect is important, divination takes many forms and employs a wealth of devices. In a general way, it may be said that inductive divination employs nonhuman phenomena, either artificial or natural, as signs that can be unambiguously read. The prime condition is that the signs appear to be genuine, not manipulated. Interpretive divination commonly combines the use of nonhuman phenomena with human action, employing devices so complex, subtle, or fluid that the special gifts of the diviner seem required if the meaning is to be known. It is here that divination takes its most characteristically dramatic forms. Intuitive divination usually places little reliance upon artificial trappings, except for dramatic effect. The performance exhibits and may crucially test deep human qualities: the impressive performer may want gifts like those that in a different context would have made him an effective actor, writer, or political leader. Where the diviner can produce voices other than his own, the impression is that the gods or spirits are speaking.

**Inductive divination.** To speculate that inductive divination from natural phenomena must be very old—*i.e.*, that it arose from early man's intimate acquaintance with nature—is tempting. In fact, however, evidence of an awareness of nature as a system among preliterate peoples is spotty, and this is particularly true in respect to

astral observation. Divination from the skies—involving such phenomena as configurations of the stars, planets, the Sun, and the Moon—is concerned pre-eminently with the future but presupposes a concern with cycles of time and history. Quite distinctive attitudes were taken toward the celestial clock by the ancient Maya astronomers and those of Mesopotamia; and distinct but related forms of astrology were developed in the Western, Indian, and Chinese civilizations. But the foundation of astrology in scientific astronomy is quite apparent, and the two "sciences" were inseparable in the West until early modern times.

Associated with the observation of the heavens is the reading of signs in the weather and the movement of birds. The interpretation of lightning as a decipherable message from the gods—not simply as an outburst of divine anger—was brought to the level of a pseudoscience by the Etruscans. Winds and clouds, being suited to less exact observation, invited interpretive rather than inductive divination. Weather phenomena were also conceived to be in a special status relative to man, in that rain, drought, and natural disasters are forces that man seeks not simply to read but to control. Nonetheless, Hindu Scripture discusses the art of interpreting "castles in the air"—celestial cities seen in towering clouds.

Augury, the art of interpreting omens, is the attempt to discover divine will in phenomena of animate nature. In Mesopotamia, augury was associated with sacrifice and perhaps developed from it. As the priests watched the rising smoke to divine the answer to a ritual query, they observed the movement of birds as auspicious or inauspicious. As a further augury the viscera of the sacrificial victim were examined, and particularly the liver, which (rather than the heart) was conceived as the vital centre. The discipline of augury diagrammed cosmic space with the sacrificial altar at the centre, and each sector was assigned a definite meaning. Every event in the heavens could thus be charted and pondered. In parallel fashion, haruspicy, the meticulous examination of the liver, was developed by mapping that organ in the manner of a microcosm and reading it as one may read the palm.

Inductive divination from nature is associated with the reading of artificially contrived events, such as the movement of sacrificial smoke, the fall of an arrow shot upward, or the cast of dice or lots. A much-used natural-artificial technique consists in the braising of bone or shell to produce a system of signs. Scapulimancy—divination from a fire-cracked shoulder blade—was widespread in North America and Eurasia. The related but more elaborate Chinese technique of tortoiseshell divination was inspired by the idea of equating the carapace (back) and ventral (lower) shell with their view of a rounded sky over flat earth. Only the "earth" was inscribed and heated to produce signs. In general, however, artificial systems of signs are likely to be manipulatory, as they will be used in an artful way by the professional diviner—and in such cases interpretive techniques have to be taken into account.

**Interpretive divination.** Interpretive divination involves, in the main, the reading of portents, omens, or prodigies. To the scientifically minded person who views the world as subject to an ordering of matter and events, accidents are meaningless. Yet, the accidental does occur within an ordered world and thus is subject to various kinds of interpretation. Manipulated accident is the essential dramatic element of interpretive divination, but the less active forms depend upon projection, **introjection**, and free association—thus being associated, to some degree, with intuitive techniques.

Pyromancy, divination by fire, may be highly dramatic in a society dependent on fire for light and safety at night. In some trans-Saharan societies the diviner may test an accusation at a seance around the fire, which will suddenly explode upon the "guilty" one. Elsewhere, objects may be overtly cast into the fire and signs read in the reaction. Hydromancy, divination by water, is usually less dramatic, ranging from the reading of reflections in a shallow surface, like the crystal gazer, to construing the movements of floating objects, as in the reading of tea leaves.

A range of related **mantic** practices may be grouped under the terms **cleromancy**, **divination by lots**, and **geomancy**, which may involve the casting of objects upon a map or a figure drawn on the ground. Cleromantic practices in trans-Saharan Africa may rely on the supposed magical—or indeed horrifying—qualities of objects in the diviner's bag or basket. When they are thrown, the proximity of one piece to another—for example, a dried bit of intestine from a murdered child and a man-eating animal's tooth—may be regarded as having meaning; or the **position** of a particular piece at the centre or apart from the others may be picked out. Often, the diviner must first prove his ability by discovering the client's problem, through a line of patter accompanying the throws—suggesting this, questioning that, leaping from one matter to another until the reactions of the client betray his interest. Here the diviner may be said to introject ideas and attitudes, while the lots act for the diviner and client alike as a projective device, the meaning of which is only half-formed in the objective pattern cast. A far

more elaborate practice is the **geomancy** of West Africa, in which elegant equipment is combined with impressive erudition to produce a seance in which lots are used to select verses, wherein the client is expected to find his answers. The nature of the lots employed, the number lore on which the selection of verses is based, and the verses themselves are entirely distinct from their counterparts in the Chinese yarrow (an herb with finely dissected leaves) tradition embodied in the *I Ching*, but the general equivalence of the two elaborations is noteworthy. The parallel has perhaps been obscured by the use of “geomancy” in China to signify only a specialized art by which propitious locations are selected.

Sometimes a diviner can be said to interpret signs so characteristic of his client that the practice falls between interpretive and intuitive arts. Somatomancy, body divination, is clearly interpretive in most forms, whether in China or the West, though the system of signs employed comprises private attributes of the client's physique. Examples are phrenology, employing features of the head that are normally unnoticed; and the reading of moles, where the body is treated as a microcosm bearing astrological signs. But oneiromancy, dream interpretation, employs explicitly psychic phenomena; and here the diviner may be said to assist the intuition of meaning by his client as often as he can be said to introject. The Ojibwa and Bella Coola Indians of North America were characteristically preoccupied with the meanings of their dreams.

**Intuitive divination.** The prototype of the intuitive diviner is perhaps the occasional shaman or curer who uses trance states—which are achieved idiopathically (*i.e.*, arising from the self spontaneously) or induced by drugs or by autokinetic (self-energized) techniques, such as hand trembling among the Navajo, a large North American Indian tribe. As a mantic art, trance is associated with oracular utterance and spirit possession. An impressive performance will be taken to represent the actual voice of a god or spirit, addressing the client directly; and divination in this mode is known from diverse religious traditions, including Christianity. The idea that the gods may be importuned to speak to a matter of temporal human concern is, most likely, very ancient. In early Egypt incubation was practiced—*i.e.*, sleeping in the temple in the hope of being inspired by the resident god. The idea behind Maya maiden sacrifice was the same: a number of maidens were cast into the sacred cenote or deep well, and those who survived after some hours were brought back to recite the messages received during their ordeals—a virtual enactment of the journey into the underworld. As oracular utterance comes to be regularly desired, special techniques or contraptions are developed for making the god's image show assent or denial or for amplifying the sound of an unseen priest's voice. In nomadic societies today, however, the diviner still may achieve his authority by passing into trance before his fellows, trembling and speaking “as if possessed”—that is, as if his own spirit had ceased to inhabit his body and had been replaced by another.

Related to possession is the conviction that malevolent persons are essentially unlike innocent folk, though not in outward appearance. When a test is devised for discovering malevolence, commonly conceived as witchcraft or as a nonhuman force dissembling itself in human form, the test takes the form of an ordeal. This may be a demonstration of immunity from harm—since the presence of blessed qualities is viewed as inconsistent with malevolence; among the many types of ordeals are walking on coals and retrieving an object from boiling liquid. The ordeal may also be mortal: in the ordeal by water, a witch was expected to float and so not be spared burning, but an innocent person would be accepted by the water and drown. In trans-Saharan poison ordeals the innocent person is expected to survive, but the malevolent one, it is believed, will be struck dead by the poison.

Intuitive divination may also be a wholly private affair. A Roman who heard a warning from the gods in a bit of innocent conversation was projecting his fears, as was the Aztec dismayed by an animal's howl. The North American Indian who sought a private vision through isolation,

self-mutilation, and fasting would preserve the memory of that vision through youth and later life, turning to it as his unique guardian spirit.

Divination today. The immense popularity of horoscopic astrology in the urban West during the latter half of the 20th century illustrates the almost exclusive concern with individual fortune-telling that characterizes divination in a mobile and competitive mass society. Chiromancy, Tarot (fortune-telling) cards, and crystal gazing represent respectively body divination, sortilege (divination by lots), and trancelike performance in styles suitable for what might be called the casual encounter with the idea of fate. Necromancy, in the modern spiritualist form, is suitable for a more serious and sustained effort to establish contact with extramundane beings. But astrology, of the various popular forms, is best suited to mass distribution as printed matter, since it is based on a well-articulated body of lore, touches matters of high destiny as well as individual fortune, and "personalizes" its introjective advice without the necessity of interviewing the client. On the other hand, the more esoteric mantic arts have the appeal of discipline—an individual may enter into the lore deeply until it becomes a part of his own world view and affects his attitude toward life and himself. Such involvement is demonstrated on the part of those individuals who study the *I Ching* for divinatory purposes.

**BIBLIOGRAPHY.** The scope of divination, historically and ethnographically, is well represented in a recent work by specialists in many fields, *La Divination*, 2 vol., ed. by ANDRÉ CAQUOT and MARCEL LEBOVICI (1968). For a briefer introduction the reader may wish to consult the pertinent section in W.A. LESSA and EVON Z. VOGT (eds.), *Reader in Comparative Religion*, 2nd ed. (1965). The classic treatment of modern times is A. BOUCHE-LECLERCQ, *Histoire de la divination dans l'antiquité*, 4 vol. (1879–82). Recent studies of Mesopotamian, classical Mediterranean, and Chinese systems of divination are: J. NOUGAYROL (ed.), *La Divination en Mésopotamie ancienne et dans les régions voisines* (1966); R. FLACELIERE, *Devins et oracles grecs* (1961; Eng. trans., *Greek Oracles*, 1965); G. DUMEZIL, *La Religion romaine archaïque* (1966; Eng. trans., *Archaic Roman Religion*, 2 vol., 1970); WILLIAM A. LESSA, *Chinese Body Divination* (1968); C.K. YANG, *Religion in Chinese Society* (1961); and HELMUT WILHELM, *Die Wandlung: Acht Essays zum I-Ching* (1958; Eng. trans., *Change: Eight Lectures on the I Ching*, 1960).

Three ethnographic studies of African divination are significant: HENRY CALLAWAY, *The Religious System of the Amazulu* (1870); E.E. EVANS-PRITCHARD, *Witchcraft, Oracles, and Magic Among the Azande* (1937); VICTOR W. TURNER, *Ndembu Divination* (1961). Detailed studies of West African geomancy are WILLIAM BASCOM, *Ifa Divination* (1969), and BERNARD MAUPOIL, *La Géomancie à l'ancienne côte des esclaves* (1943). Another ethnographic study is EVON Z. VOGT and RAY HYMAN, *Water Witching, U.S.A.* (1959).

## Djakarta

Djakarta (Jakarta, formerly Batavia) is the capital of the Republic of Indonesia and the largest and most consistently growing city in that country. Coextensive with the metropolitan district of Djakarta Raya, it has an area of 223 square miles (578 square kilometres) and lies at the mouth of the Tji (river) Liwung (Chiliwong) on the northwestern coast of Java. Its population in 1971 was 4,576,009.

In 1966 the city was declared to be a special capital region (Daerah Khusus Ibukota, or DKI), thus gaining a status approximately equivalent to that of a state or province. The city has long been a major trade and financial centre; it has also become an important industrial city and an important centre for education.

**History.** The first settlements were established at the mouth of the Tji Liwung, perhaps as early as the 5th century. Its official history, however, starts in 1527, when the Sultan of Bantam defeated the Portuguese there and called the place Djajakerta, meaning Glorious Fortress.

The Dutch, under the leadership of Jan Pieterszoon Coen, captured and razed the city in 1619, after which he established the capital of the Dutch East Indies—a walled township named Batavia—on the site.

The colonial history of the city can be divided into three

major periods. First was that of the Dutch East India Company, when most of the activities of the city centred around the fortress and the company warehouses. At that time the city somewhat resembled a typical Dutch town, complete with canals. The second period began in the early 1800s, when the city was extended to include higher and more healthful areas to the south, which would later become the seat of the new colonial government. A brief interval of British control during the Napoleonic Wars, ending in 1815, interrupted the second period. During the third period, which lasted from about the 1920s to 1941, the city became a truly modern tropical city.

The colonial era ended with the entry of Japan into World War II, when Indonesia was occupied by Japanese forces. After the war the city was briefly occupied by the Allies and then was returned to the Dutch. When Indonesia gained full independence on December 27, 1949, the city was renamed Djakarta and proclaimed the national capital.

The present city. Djakarta lies on a low, flat alluvial plain, with extensive swampy areas; it is easily flooded during the rainy seasons. The parts of the city further inland are slightly higher. As most of the soil is of old volcanic origin, the area is quite fertile.

**Climate and environment.** Djakarta is a tropical, humid city, with temperatures ranging between the extremes of 75° and 93° F (24° and 34° C) and a humidity of between 75 and 85 percent. The average mean temperatures are 79° F (26° C) in January and 82° F (28° C) in October. The annual rainfall is more than 67 inches. Temperatures are often modified by sea winds.

The draining of swamps for building purposes has increased the probability of floods. With an excess of water in the soil, Djakarta experiences a shortage of clean drinking water, for which there is a high demand. Air pollution has not yet become a problem.

**City plan and traditional neighbourhoods.** Although the Dutch were the first to attempt to plan the city, the contemporary city layout is probably more British than Dutch in character, as can be seen from such large squares as the Medan Merdeka (Freedom Field) and Lapangan Banteng (Place of the Gaur [large wild ox]). The Oriental style, or "indische" style, as the Dutch call it, is, however, not only apparent in the city's way of life but also in the types of houses, the wide, tree-lined streets, and the spacious gardens and house lots. In Kebajoran, a satellite town built since World War II on the southwest side of the city, the houses and garden lots are much smaller than in the older colonial districts.

Djakarta has always been a city of new settlers who assimilated local ways and became Djakartans themselves. Some traditional neighbourhoods can, however, be identified. The Kota (Fort), or Old City, for example, sometimes also called the downtown section, is the central business district and also the financial capital of Indonesia. It houses a significant part of the Chinese population. The area of the Kemajoran (Progress) and Senen sections, originally on the eastern fringe of the city, is now almost central in its location and increasingly is becoming the major retail area of the city.

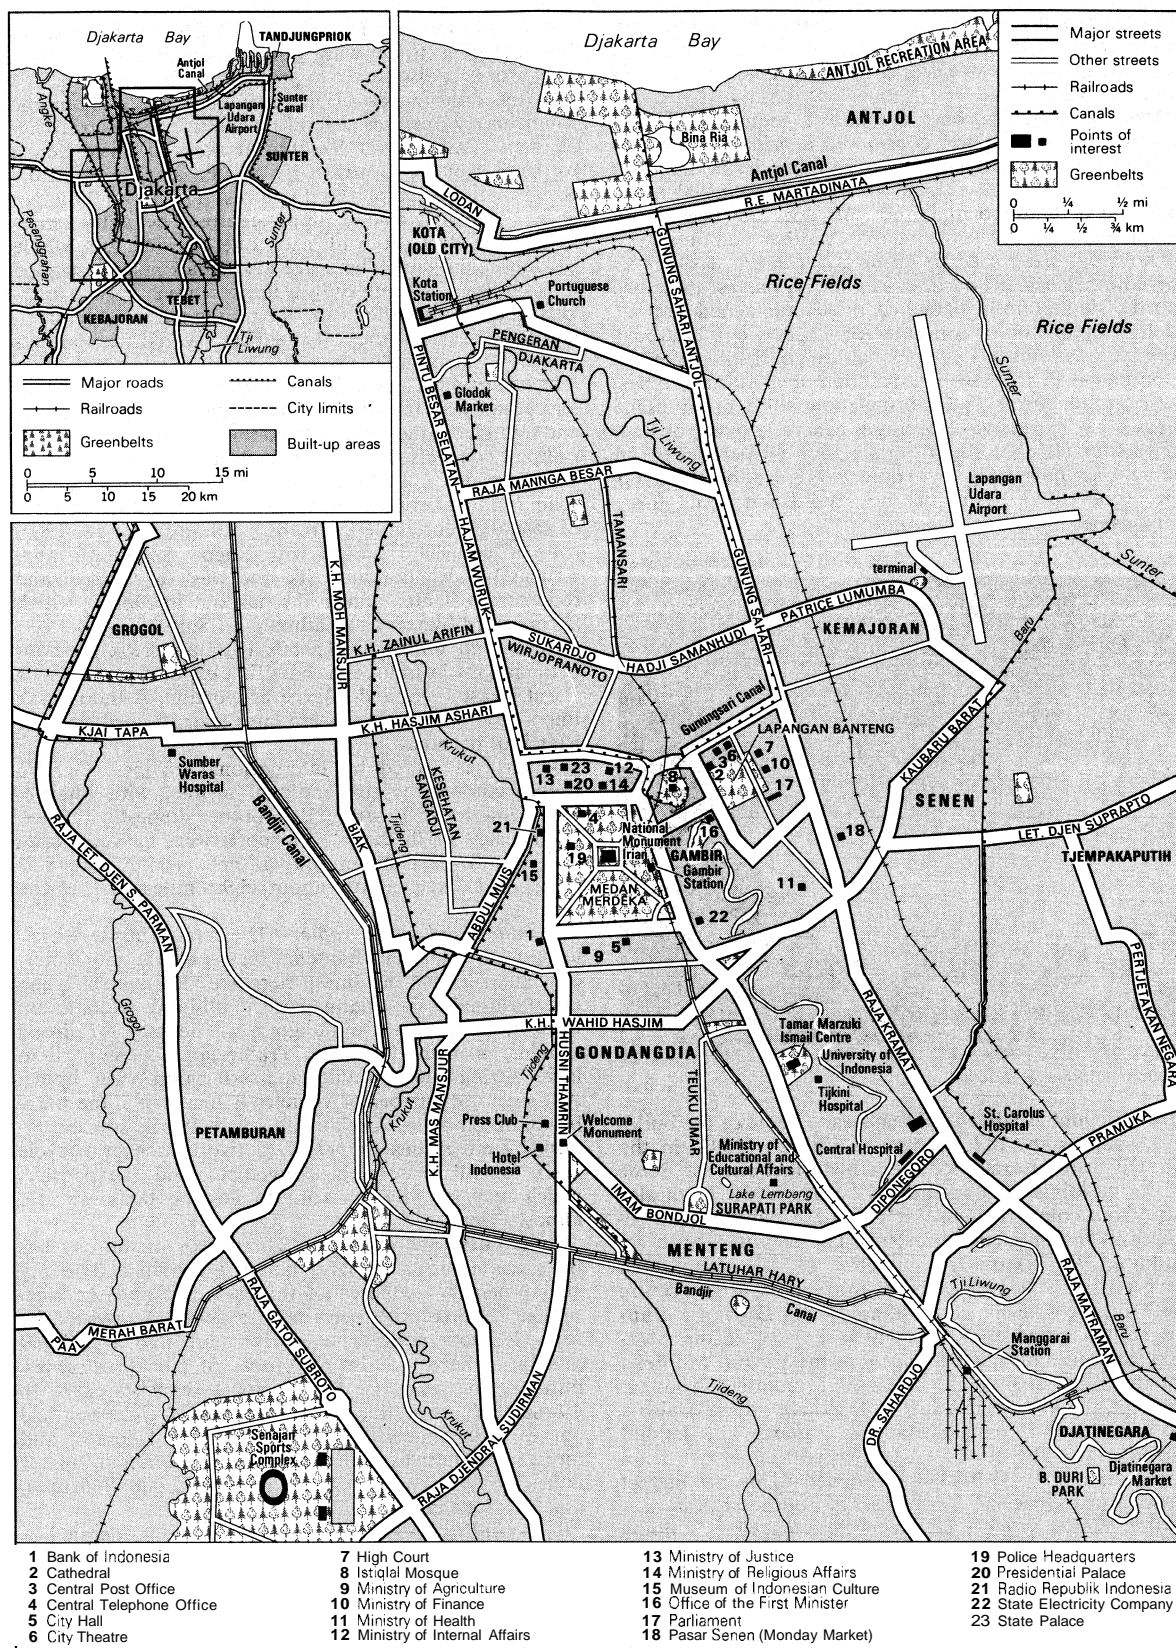

The Djatinegara (Real Country) section, originally a Sundanese settlement but later incorporated as a separate town, after which it became a Dutch army camp, has now merged with the rest of Djakarta and includes many new settlers. The Menteng and Gondangdia section is a fashionable residential section near the central part of the city. To the west, the Tanahabang Petamburan section is, like the Kemajoran and Djatinegara sections, densely developed. Tandjungpriok is the community attached to the harbour.

**Demography.** *Population and population growth.* The population of Djakarta at the 1971 census was 4,576,009. Pronounced growth had occurred only since 1940. According to the 1930 census, the city's population was 530,000; the estimate for 1940 was still only 540,000, but by 1950 it had risen to 1,400,000, and at the 1961 census it was 2,900,000; the 1965 estimate was 3,800,000. About half of this extraordinary rate of increase (about

The  
colonial  
era

A city of  
new  
settlers

Diakarta and (inset) its metropolitan area.

4 percent annually) is attributed to immigration. Although government regulations close the city to unemployed new settlers, better economic conditions inevitably attract new people. In addition, much of the population is young and fertile, resulting in a very high natural increase potential. In the near future, therefore, the same rate of increase is expected to continue. Meanwhile, most urban services are operating at capacity.

*Composition and employment.* Analysis of the immigrant stream shows that after the West Javanese, the largest groups are the Central and East Javanese; a sizable number also are from Sumatra. Other population groups—Arabs, Indians, Europeans, and Americans—are minor.

Among the working force the largest group is engaged in commerce, trade, banking, or related occupations;

the next group works in service industries (including government); and in the third largest group are industrial and transportation workers (including a large group of *betjak* drivers).

**Housing.** Because of the relatively equable climate, housing, as such, is not considered a primary problem. The most common type of house in the city is the *kampung* ("village") house; most are built of materials such as wood or bamboo mats, but this does not necessarily mean that they are substandard. Another common type of housing, often used to house government workers, is the colonial urban house, or *rumah gedongan*; these are mostly single-family detached or semidetached houses, each standing on a separate lot. Apartment buildings constitute a newer category; although they are more economical in the use of land than single-family types, their architectural and construction costs often make them fairly expensive. Housing is generally overcrowded. It is estimated that slightly more than 60 percent of all households have only one room; there are, on the average, about five persons per household and about three persons per room.

H. Armstrong Roberts

Presidential Palace, Djakarta.

**Historic and architectural features.** Some of the buildings, such as the old Portuguese Church (1695) in the Old City, are of architectural or historical interest. Some of the buildings around the city square in the Kota also date from colonial times, including the old city hall, restored as the municipal museum. The National Archives building was originally the palace (1708) of a Dutch governor general, van Riebeeck. In the present city centre the Ministry of Finance building, facing Lapangan Banteng Square, and the Presidential Palace, facing Merdeka Square, both date from the same period. Merdeka Square is the site of the National Monument Irian (at 360 feet, the highest building in Djakarta); there is also a monument on Lapangan Banteng Square. The Istiqlal Mosque, near the northwest corner, still under construction in the early 1970s, was designed to be the largest mosque in Indonesia, if not in all of Southeast Asia.

After World War II Djakarta experienced a building boom. The Hotel Indonesia (the city's first high-rise building) and the Senayan Sports Complex were built for the Asian Games in 1962. Most high-rise buildings stand along Husni Thamrin Road.

**Economic life.** Economically, Djakarta can be identified first as the national capital and a central place of control for the national economy, then as an administrative centre in its own right, and, finally, as a significant industrial hub. In addition, its location as a port makes it an important centre for trade.

The cost of living in the city in the early 1970s tended to rise. Land was very expensive, and rents were high, so that industrial development and the construction of housing usually was undertaken on the outskirts, while commerce and banking remained concentrated in the city

centre. The Indonesian Chamber of Commerce is active in promoting trade with other countries; the annual Djakarta Fair also serves to promote trade.

To meet the needs of the local city population, the municipality operates several markets. The Central City Markets (Pasar Kota), like the markets of Pasar Senen to the east of the Central City and Pasar Glodok in the Kota area, are major retail centres. The Pasar Djatinegara is primarily a food supply centre. The district markets are fairly large, with each one catering to a whole section of the city. There are also small neighbourhood markets, each serving only a limited area. Special markets include one selling fish, one selling automobile parts, and the Pasar Rumpit "fly market." Djakarta also has about 90 general markets.

**Transportation.** *Roads and railways.* Major road arteries lead west from the centre of the Old City and east and south from the centre in Gambir. To the east, a major railroad connects the city with all of the island of Java. There is also a highway, primarily a regional supply road, running between Djakarta and the productive areas of east and central Java. To the south, a major road and railroad connect Djakarta with Bogor, Sukabumi, and, ultimately, also Bandung. To the west, a railroad and road run to Banten and to the harbour in Merak, which is connected by ferry to Lampung in Sumatra.

*Sea and air links.* Djakarta's Tanjungpriok Harbour is the largest in Indonesia, handling exports from Jawa Barat (West Java) and a large proportion of Indonesia's import trade; many goods are later transshipped to other islands or harbours.

Djakarta is served by international airlines, Garuda Indonesian Airway (the national airline, with international and domestic service), and other domestic airlines. In the early 1970s the city's airports were at Kemajoran and Halim Perdanakusuma; a new jet airport was planned at Tjengkareng, about eight miles east of the city.

**Terminals and urban traffic.** The central bus terminal, located on Lapangan Banteng, serves all the city, inter-city, and regional bus lines; there are also five suburban bus terminals—in Djatinegara (Tjililitan), Kebajoran, Grogol, Kota, and Tanjungpriok. The major railroad terminal is in the Old City. Traffic jams occur particularly during the morning and afternoon rush hours. Although the number of vehicles is increasing, the number of automobiles is relatively small. Public transportation, by either bus or *betjak* (a two-passenger tricycle taxi), is still reasonably convenient and inexpensive, which may be why the automobile-type taxis are still almost absent.

**Government and services.** The mayor of the city has the same status as the governor of a province. The city government is composed of the executive and the electorate. The executive consists of a governor assisted by four vice governors, an executive staff, and a regional secretary; there are also a number of city directorates, bureaus, and agencies. The electorate consists of 35 to 40 members, including representatives of eight political parties, four representatives of the armed forces, and nine representatives of the so-called functional groups. It is headed by a council of five members, one chairman, and five vice chairmen.

**Public utilities.** Public utilities are usually operated or owned by the Indonesian government. The State Electricity Company and the subsidiary State Gas Company both supply Djakarta. Postal and cable services and telephone services are supplied by state companies working under the aegis of the Ministry of Communications. Djakarta's electricity comes from several sources; these include the thermal plant in Antjol, close to Tanjungpriok Harbour, smaller diesel plants in various parts of the city, and the Djatiluhur hydroelectricity project located close to Purwakarta, about 70 miles east of Djakarta.

The city government is responsible for the water supply; as already mentioned, there is a shortage of drinking water. The city water is obtained in part from freshwater springs in the Bogor area, but most of the supply

City-operated markets

The *betjak*, or tricycle taxi

Buildings from colonial times

comes from the Pedjompongan water treatment plant. Water is required mainly for domestic purposes but is also needed for industry and to supply shipping. The removal of garbage and the provision of other sanitation services are also the responsibility of the municipality.

**Health and safety.** There are three major hospitals—one operated directly by the Ministry of Health, one by the Roman Catholic Church, and one by a Protestant mission. Three municipal hospitals each serve a separate area of the city—the Sumber Waras Hospital in west Djakarta, the Fatmawati Hospital in Kebajoran (south Djakarta), and the Persahabatan (Friends) Hospital in east Djakarta. Altogether Djakarta has almost 40 general or special hospitals, with a capacity of about 2,000 beds in the early 1970s. In addition, there are more than 400 general clinics or polyclinics scattered throughout the city. A quarantine hospital is in operation in Tandjungpriok. The city also operates a hospital and rehabilitation centre for the mentally ill and socially deprived, and there are almost 50 family-planning clinics.

There are 18 fire-brigade posts, nine of which are in the central area. Djakarta has a low crime rate. The city police are more concerned with maintaining general order and regulating traffic than with combating organized crime.

**Education.** To meet the needs for primary education, many new elementary schools and secondary schools were built in the late 1960s; a number of old school buildings were also renovated. Altogether, there were about 270 kindergartens, 1,200 elementary schools, 230 *madrasah* ("religious schools"), 300 secondary schools, and 120 high schools. There were also about 550 vocational and special schools and more than 100 universities, academies, and institutes for higher learning. The largest and best known university is the Universitas Indonesia; its most important departments are the school of medicine, the school of law, and the school of economics.

**Cultural life, recreation, and mass media.** Among other cultural activities, the Tamar Marzuki Ismail Centre has facilities for traditional or classical art performances as well as theatres for presenting modern plays and concerts; the centre also has a planetarium. Traditional performances include *wayang* dance and drama, gamelan music, and *wayang* puppet shows. Traditional performances representing the culture of other parts of Indonesia are included in the programs presented at the annual Djakarta Fair.

Extensive public recreation areas include the Bina Ria seaside recreation area and the Ragunan zoo, close to Pasarmingu. Playgrounds include, among others, the Taman Ria complex at the Djakarta Fair. Public recreation facilities include a bowling centre, a greyhound racecourse, and a horse racecourse.

There are about 25 major newspapers in the city. Of these the *Berita Yudha*, *Kompas*, *Indonesia Raya*, *Merdeka*, *Pedoman*, and *Sinar Harapan* have the largest circulation. There are two English-language newspapers, the *Indonesian Observer* and the *Djakarta Times*. *Indonesia* is a newspaper printed in Chinese. There are three national news agencies; numerous foreign and international news agencies and reporters are also based in Djakarta. There are about five general weekly magazines.

In addition to the Radio Republik Indonesia, the national radio system, some private radio companies also broadcast programs from Djakarta. The national television (TVRI) operates from the city and has a network covering most of the island of Java. Since the opening of the earth-satellite station in Djatiluhur, the Indonesian television network can be connected with programs in European or other Asian countries.

**BIBLIOGRAPHY.** On the history of Djakarta, see F. DE HAAN, *Uit Oud-Batavia* (1898); and DJAKARTA, KOTAPRADJA, *Sedjarah pemerintahan kota Djakarta* (1958). A contemporary description is given in the guidebook, *Djakarta*, issued by the PETUNDJUK DCI (1969). Census and population information may be found in BIRO PUSAT STATISTIK, *Sensus penduduk 1961 D.C. I. Djakarta Raya* (1963); and in H.J. HEEREN (ed.), *The Urbanisation of Djakarta* (1955). See also *Djakarta: Its Rehabilitation and Development* (n.d.), issued

by the Badan Perentjana Pembangunan (Development Planning Body) of the City Government; and PAULINE D. MILONE, *Urban Areas in Indonesia* (1966).

(W.J.W.)

## Dnepr River

The Dnepr (conventional English spelling Dnieper, Ukrainian Dnipro, Belorussian Dnepro, the Borysthenes of ancient Greek authors) is the second river in length and basin area in the European part of the U.S.S.R. and the third longest in Europe, after the Volga and Danube. It is 1,400 miles (2,200 kilometres) long and drains an area of about 195,000 square miles (504,000 square kilometres).

The Dnepr rises at an altitude of 721 feet in a small peat bog on the southern slope of the Valdai Hills, 46 miles northwest of Vyazma, and flows into the Dnepr Estuary of the Black Sea. For the first 300 miles, it passes through the Smolensk (Smolenskaya) *oblast* of the Russian Soviet Federated Socialist Republic (R.S.F.S.R.), first to the south and then from Dorogobuzh to the west; near Orsha it turns south once more and for the next 370 miles flows through the Belorussian Soviet Socialist Republic. Next, it flows through Ukrainian territory: south to Kiev, southeast from Kiev to Dnepropetrovsk, and then south-southwest to the Black Sea.

The Dnepr watershed includes the Volyno-Podolsk Upland (Volino-Podolskaya Vozvyshennost), the Valdai Hills, the Belorussian Ridge (Belorusskaya Gryada), the Central Russian Upland, and the Priazovsk Upland (Priazovskaya Vozvyshennost). The centre of the basin consists of broad lowlands. Within the forest area, and to some extent within the forest-steppe area, the basin is covered with morainic and fluvio-glacial deposits; on the steppe, it is covered with loess. In some places, where the basin borders upon the basins of the Western Bug and the Western Dvina, there is a flat swampy area. This facilitated the cutting of connecting water routes from the Dnepr to neighbouring rivers even in ancient times. At the end of the 18th century and the beginning of the 19th, the Dnepr was connected to the Baltic Sea by several canals; the Dnepr-Bug Canal (Dneprovsko-Bugsky Kanal) running by way of the Pripyat, the Western Bug, and the Vistula; the Oginsky Canal by way of the Pripyat and the Neman; and the Berezina water system by way of the Berezina and the Western Dvina. These canals later became obsolete.

**The natural environment.** The Dnepr is customarily divided into three parts: the Upper Dnepr as far as Kiev, the Middle Dnepr from Kiev to Zaporozhye, and the Lower Dnepr from Zaporozhye to the mouth. The basin of the Upper Dnepr is mainly within a forest area where peat-podzolic soils predominate (replaced in the southern portion of the upper course by podzolized, gray forest soils). The Upper Dnepr is characterized by excessive moisture and great swampiness. The river network is well developed here, for this is where 80 percent of the basin's annual runoff forms and the longest, most water bearing tributaries (the Berezina, Sozh, Pripyat, Teterev, and Desna) flow. The basin of the Middle Dnepr is in a forest-steppe area with black earth. There are forests in the watersheds and along the river valleys. The river network is thinner here, and the rivers contain comparatively little water. The principal tributaries of the Middle Dnepr are the Ross, Sula, Psyol, Vorskla, and Samara. The Lower Dnepr basin lies within the Black Sea Lowland, in the black-soil steppe area, which has now been completely plowed up. The grassy steppe vegetation has been preserved only in the national forests and in old ravines and gullies. Near the Black Sea there is wormwood-fescue vegetation of the semi-arid type in chestnut-brown soil mixed with saline solonetz and solonchak soils. The Lower Dnepr passes through a region of insufficient moisture, where irrigation and flooding are employed. The river network here consists for the most part of dry river beds (ravines) that fill up with water in the spring and after torrential rains. The largest tributary is the Ingulets.

The climate of the Dnepr Basin is, on the whole, moder-

The Dnepr watershed

Hospitals and clinics

Climates  
of the  
river's  
course

ately warm, milder, and damper than that of more eastern regions of the R.S.F.S.R. located at the same latitude. The continental nature of the climate increases from northwest to southeast. The mean annual air temperature in the upper part of the basin is 41° F (5° C); in the middle (near Kiev), 45° F (7° C); and in the lower reaches of the Dnepr, 50° F (10° C). Winters in the northeast of the basin are long and of steady intensity, the mean temperature in January being 16° F (−9° C); whereas in the south they are shorter and milder with frequent thaws, the mean temperature in January being 27° F (−3° C). The amount of precipitation decreases from north to south. On the slopes of the Valdai Hills and the Minsk Heights (Minskaya Vozvyshehnost), annual precipitation is about 30–32 inches, while in the Lower Dnepr region it is about 18 inches. The mean annual precipitation for the Upper Dnepr Basin (above Kiev) is about 28 inches, with about 27 inches for the entire basin, with 60–70 percent falling in the form of rain during the summer and fall.

From its source to Dorogobuzh, the Dnepr is a small river flowing past low wooded and, in some places, swampy banks. Downstream the banks rise, and the width of the depression before Orsha varies for the most part from two to six miles, narrowing to 0.3 mile in places. Its bed, from 130 to 400 feet wide, is sinuous but steady, with numerous sandbanks. Above Orsha the Dnepr crosses a layer of Devonian limestone, forming the so-called Kobelyaki Rapids (Kobelyakskiy Porogi), which hamper navigation into the lower waters. From Orsha to Shklov, the Dnepr flows between raised, sometimes steep banks overgrown with woods; then the left bank drops, while the right remains high as far as the Sozh Basin. The depression is wide, reaching six to nine miles in places. The river bed from Orsha to Mogilyov is comparatively steady; below Mogilyov, the Dnepr splits into branches, producing many islands and sandbanks. The width of the river from Orsha to the mouth of the Sozh is 260–1,300 feet, and from the mouth of the Sozh to the mouth of the Pripyat it is 1,600–2,000 feet. The tidal vegetation of the Upper Dnepr consists mainly of rather broad tidal meadows, thickets of willows and alders, and old lowland marshes.

Marked asymmetry of the depression is characteristic of the Middle Dnepr. The steep, high right bank (up to 130–260 feet) forms the escarpment of the Volyno-Podolsk Plateau, which stretches along the whole middle course of the river. The low and sloping left bank is formed by broad, ancient terraces. Single hills, reaching over 300 feet in height, sometimes rise on the low-lying left bank—for example, Pivikha Hill near Gradizhsk. On the southern portion of the Middle Dnepr, the river cuts through the Ukrainian crystalline massif and flows for 56 miles in a narrow, almost unterraced valley bounded by high rocky banks. The famous Dnepr Rapids, which for centuries prevented continuous navigation, were once located here. The rapids were flooded by the backwaters of the Dnepr hydroelectric power station dam, which raised the level of the river by 121 feet.

Below Zaporozhye, the Dnepr again passes into a very wide valley with a high right bank (130 feet near Nikol, 260 feet near Kherson). The slopes of the river here are very slight. Before the development of the Kakhovka Reservoir (Kakhovskoye Vodokhranilishche), the waters of which overflowed a vast territory, the Dnepr split into a multitude of streams; flat swampy islands, overgrown with tidal vegetation and reeds, lay among the channels. Today, much of this is hidden under the waters of the Kakhovka "sea."

Below Kherson, the Dnepr forms a delta whose numerous streams flow into the Dnepr Estuary. Some have been deepened for navigational purposes.

The water conditions of the Dnepr have been rather thoroughly studied. The data on the river's annual runoff go back to 1818, while the maximum discharges, computed from the old high-water marks, go back more than 250 years. More than 300 hydrometric stations and posts operate in the Dnepr Basin. The Dnepr is among those rivers that have a spring high and a summer and winter

low, with increased runoff in the fall. The principal source is the water entering the upper part of the basin as a result of the spring snowmelt. During the spring, from March to May, about 60 percent of the annual runoff passes through. The period of stable ice on open water in the Upper Dnepr sets in at the beginning of December, and in the Lower Dnepr at the end of December. Thaw starts at the beginning of April in the upper course, and in early March in the lower course. The mean annual runoff of the river is 13 cubic miles. In individual years, the variations in the runoffs can be quite considerable. The water of the Dnepr is low in minerals and soft. In a year the river carries an average of 8,600,000 tons of dissolved matter to the sea.

The Dnepr has rather diverse aquatic flora and fauna. In its upper course the plankton consists mainly of diatom and protococcal algae, rotifers, and *Bosmina*. Blue-green algae come from the mouth of the Pripyat. In its lower course, the amount of plankton decreases sharply under the influence of the reservoirs. Up to 66 species of fish live in the Dnepr. The following are of commercial importance: pike, roach, chub, ide, rudd, rapfen, tench, barbel, alburnum, golden shiner, goldfish, carp, catfish, burbot, pike perch, perch, and ruff. In the spring, the Lower Dnepr is enriched with migratory and semimigratory fish (sturgeon, herring, roach, and others). The reservoirs have been artificially stocked with fish of commercial importance, including whitefish, pike perch, golden shiner, and carp.

**The human imprint.** The Dnepr Basin has been populated since ancient times. It was of central importance in the history of the peoples of eastern Europe, particularly in the founding of the ancient Kievan state. Along this waterway a system of river routes developed in the 4th to 6th centuries, a "route from the Varangians to the Greeks," connecting the Black Sea with the Baltic and linking the Slavs with both the Mediterranean and the Baltic peoples. Most of the Dnepr (677 miles) passes through territory of the Ukrainian Soviet Socialist Republic, and the river is for the Ukrainians the same kind of national symbol that the Volga is for the Russians.

The first historical information about the Dnepr is recorded by the Greek historian Herodotus (5th century BC); the river is also mentioned later by the ancient writers Strabo and Pliny the Younger. It was first depicted on a map drawn by the Byzantine geographer Ptolemy in the 2nd century AD. Instrument surveys of the Dnepr were begun at the beginning of the 18th century.

Under the Soviets, in line with the general plan for development of the water economy, a great deal of work has been done on the reconstruction of the Dnepr and the comprehensive use of its water resources. As early as 1932, in accordance with the country's electrification plan, as formulated by the State Commission for the Electrification of Russia (Goelro), the first hydroelectric power station was built at Zaporozhye in the region of the rapids. It was the largest power station in Europe, with a capacity of 560 megawatts, until the construction of the Volga power stations. Completely destroyed by the Germans during World War II, it was rebuilt in 1947 and its capacity was raised to 650 megawatts. By the early 1970s the following hydroelectric power stations and reservoirs had been built on the Dnepr: Kiev (1967), Kanev (construction being completed), Kremenchug (1961), Dneprodzerzhinsk (1964), Zaporozhye (1932, 1947), and Kakhovka (1955). The total capacity of the five stations in operation is more than 2,000,000 kilowatts, with an electrical power output of 8,000,000,000 kilowatt-hours per year. As a result of their construction, many problems have been solved: a continuous deep-water route from the mouth of the Pripyat to the Black Sea has been created; the water-supply problem of the Donbass and Krivoy Rog industrial regions has been solved; and irrigation of arid lands in the southern Ukraine and the Crimea has been made possible.

Regular navigation on the Dnepr extends as far as Orsha, and, when the water is high, to Dorogobuzh. On the Upper Dnepr the required depths are maintained by straightening and by dredging work. Below the Pripyat,

Flora and  
fauna

River  
develop-  
ment

The lower  
river

navigable locks make the passage of modern vessels possible. The principal cargoes are coal, ore, mineral building materials, lumber, and grain. The chief ports are Dorogobuzh, Smolensk, Orsha, Mogilyov, Rechitsa, Loyev, Kiev, Cherkassy, Kremenchug, Dnepropetrovsk, Zaporozhye, Nikopol, Kakhovka, and Kherson.

The Krivoy Rog region is supplied with water from the Kakhovka Reservoir by means of the Dnepr-Krivoy Rog Canal. The North Crimea Canal, which was completed in 1975, originates in the reservoir; the canal, 250 miles long, is designed for irrigation of the steppes of the Black Sea Lowland and the northern Crimea and for the creation of a water route from the Dnepr River to the Sea of Azov.

Plans for the future are comprehensive. The area of irrigated land will be increased and new navigable routes will be created. The construction of the Dnepr-Donbass Canal and other canals, the development of a modern water route from the Dnepr to the Baltic Sea through the Neman River, and the reconstruction of the river above the Pripyat are among the projects contemplated.

(A.P.D.)

## Dnestr River

The Dnestr River (Greek Donaster, Romanian Nistrul, Turkish Turla, English conventional Dniester) is the second longest river in the Ukrainian Soviet Socialist Republic and the main water artery of the Moldavian Soviet Socialist Republic. It rises on the northern slopes of the Carpathian Mountains in the Lvov *oblast* (region) of the Ukrainian S.S.R. and runs 839 miles (1,350 kilometres) in a generally southeastern direction to the Black Sea near Odessa. For roughly half its length it flows through the territory of the Moldavian S.S.R.

The Dnestr and its tributaries drain a long, narrow basin of about 28,000 square miles (72,000 square kilometres), bounded on the north by the Volyno-Podolsk Upland and on the south of the upper course by the Carpathian Mountains; farther to the south are hilly plains and the Moldavian plateau; and at the southernmost end of the basin is the Black Sea Lowland.

The Dnestr has many tributaries, only 15 of which are more than 60 miles long. In the first third of its course the tributaries include the Stry, Svicha, Lomnitsa, and Bystritsa, on the right, originating in the Carpathians. In the large middle part of its course the tributaries include the Zolotaya Lipa, Strypa, Seret, Smotrich, Ushitsa, and Murafa, on the left. In the lower reaches of the Dnestr, the tributaries are mainly on the right, including the Reut, the Byk, and the Botna.

The climate of the basin is humid, with warm summers. Annual precipitation varies within a range of from 40 to 50 inches in the Carpathians down to 20 inches near the Black Sea. A large proportion of the surface of the basin is under cultivation.

The Dnestr has three parts: the upper river as far as the village Nizhny, about 170 miles; the middle river from Nizhny to Dubossary, about 450 miles; and the lower river from Dubossary to the mouth, about 210 miles. For first 30 miles of the river's course, it is a rushing mountain stream, flowing through a deep gorge, but from the mouth of the Stry through the rest of its upper course the valley is several miles wide. In its middle course the river meanders a great deal, winding for 300 miles over the 145-mile distance between Galich and Mogilyov-Podolsky.

At Dubossary there is a hydroelectric station and reservoir. Below Dubossary the valley gradually widens to 12 miles with slopes several hundred feet high, bearing orchards, vineyards, and forests. After Bendery the floor of the valley becomes marshy and broken with small lakes and islands. The estuary of the Dnestr is formed by the incursion of the sea into the lower Dnestr Valley, forming a shallow basin (no more than ten feet deep) separated from the sea by a narrow strip of land. The length of the estuary is 27 miles, and its greatest width is seven miles.

The Dnestr frequently floods, causing extensive damage to settled areas. The water level in its middle course

varies by 25–35 feet at different times of the year because of snow melting and rainfall in the upper part of its basin. The average discharge is about 10,000 cubic feet per second (300 cubic metres), but it has been known to reach 250,000 cubic feet per second or more in the middle course. Freezing usually occurs at the end of December or the beginning of January and lasts about two months, although in some years there is no ice-bound period.

Although the basin of the Dnestr is densely populated, there are no large towns on the river itself. Lvov, Ternopol, Stanislav, Kishinyov, and other urban centres lie above the main valley on tributaries.

The Dnestr is navigable for about 750 miles, from its mouth to Rozvaduv; regular passenger and freight lines run from Soroki to Dubossary and from Dubossary to the sea. Navigation is made difficult on the lower reaches by shallow water and sandbars. The river is used extensively for carrying logs, which are brought together at the mouths of the Carpathian tributaries and rafted downstream. Fishing is of little importance except near the coast. In the lower reaches and in the Dubossary Reservoir there are fish hatcheries for sturgeon, whitefish, pike perch, and carp.

The first description of the lower part of the Dnestr was published in 1711 by the Moldavian prince Dmitry Kantemir; the first hydrographic map of the Dnestr was made in 1787 under Catherine II. In the 18th century a plan was made to join the Dnestr with the Western Bug and the San (tributaries of the Vistula). Detailed studies and plans were made in the 19th century, having as their goal the protection of the upper part of the basin from flooding and the improvement of navigation conditions in the middle and lower parts.

The hydroelectric station at Dubossary, built in 1954, has a capacity of about 50,000 kilowatts. Several small water power installations exist in the upper reaches of the river. In the summer a large number of floating mills, operated by the swift current, are set up on the river. Plans in the early 1970s called for the construction of a series of five hydroelectric stations above Dubossary (at Kamenka, Yampol, Mogilyov-Podolsky, Zhvanchik, and Unizh) with a total capacity of 2,300,000 kilowatts, as well as the improvement of the irrigation system on both banks of the Dnestr.

## Dobzhansky, Theodosius

The research and publications of Theodosius Dobzhansky, prominent American biologist and geneticist, combined the study of heredity and evolution. His work has been a major influence on 20th-century thought and research on genetics, evolutionary theory, and human evolution. He also wrote extensively on the philosophical implications of biological evolution.

Dobzhansky was born on January 25, 1900, in Nemirov, Russia, where his father was a teacher of mathematics. In 1910 the family moved to Kiev, where he first went to school. In 1917 he entered the University of Kiev, where he studied during the difficult days of the Russian Revolution. After graduating in 1921, he remained to teach until 1924, when he moved to Leningrad. In 1924 he married Natalia Sivertzev, whom he met while teaching at Kiev.

In 1927 Dobzhansky went to Columbia University in New York City as a Rockefeller Fellow to work with the geneticist Thomas Hunt Morgan (*q.v.*). He accompanied Morgan to the California Institute of Technology in Pasadena and, on being offered a teaching position there, decided to remain in the United States, becoming a citizen in 1937. He returned to Columbia as a professor of zoology in 1940, remaining until 1962, then moved to Rockefeller Institute (later Rockefeller University). After official retirement, he moved in 1971 to the University of California at Davis.

Between 1920 and 1935, mathematicians and experimentalists began laying the groundwork for a theory combining Darwinian evolution and Mendelian genetics. Starting his career about this time, Dobzhansky was in-

Develop-  
ment of  
the Dnestr

The river  
basin

volved in the project almost from its inception. His book *Genetics and the Origin of Species* (1937) was the first substantial synthesis of the subjects and established evolutionary genetics as an independent discipline.

By courtesy of The Rockefeller University, New York

Dobzhansky.

Until the 1930s, the commonly held view was that most species in the wild state carried only one, either the dominant or the recessive, gene (*i.e.*, the normal type in wild populations) for each characteristic. This wild-type gene, inherited from both parents, was present in double dose in most individuals (homozygous), and variant genes usually represented a chance mutation. Most mutations would be harmful when homozygous, but rarely a mutation would appear that was advantageous in the homozygous condition. The carriers of such a gene would leave more descendants; as a result, the gene would increase in frequency in a population from generation to generation, until it finally would become, in its turn, the wild-type gene. Natural selection thus produced, as it were, something close to the best of all possible worlds, and changes would be rare and slow and not apparent over one life-span, in agreement with the observed constancy of species over historical time.

Dobzhansky's most important contribution was to change this view. In observing wild (Californian) populations of the vinegar fly *Drosophila pseudoobscura*, Dobzhansky found extensive genetic variability. Furthermore, around 1940 evidence accumulated that in a given local population some genes would regularly change in frequency with the seasons of the year. For example, a certain gene might appear in 40 percent of all individuals in the population in the spring, increase to 60 percent by late summer at the expense of other genes at the same locus, and return to 40 percent in overwintering flies. Compared to a generation time of about one month, these changes were rapid and effected very large differences in reproductive fitness of the various types under different climatic conditions. (Fitness of a type in this sense is proportional to the average number of its offspring that survive to reproduce.) Furthermore, the course of many of the changes could be observed in laboratory populations, which could be maintained for years in small cages with a continuing supply of new food. Other experiments showed that, in fact, flies of mixed genetic makeup (heterozygotes) were superior in survival and fertility to either pure type—that is, homozygous dominant and homozygous recessive.

It was already known that these superiorities of such heterozygotes would ensure the preservation of both sets of genes in the population. Dobzhansky pointed out that newly arisen genes are rare at first and that an individual is exceedingly unlikely to receive such a gene from both parents. Hence, in the beginning, the only genes that can

"get ahead" and become more widespread in the population are those that are "good mixers"—that is, those that produce superior genotypes when combined with a random gene from the population, and not necessarily when homozygous.

The picture thus developed by Dobzhansky and some of his students showed that most gene loci are represented by more than one gene in a given population, no two individuals having exactly the same genotype. Hence the so-called wild-type genotype was a myth. A genetic system of the kind proposed by Dobzhansky can change rapidly, in response to natural selection, if environmental conditions should change. Among the myriad genotypes appearing in each generation would be many that were adapted to the changed conditions and that would leave more descendants; thus, these genes would be more common in the next generation. In contrast, under the older idea of a fairly uniform population in which most gene variants occurred rarely, much more time would be needed before variants adapted to new conditions could arise and become common. Meanwhile, local populations of the species could be in danger of becoming very reduced in numbers or even extinct. Although objections have been raised to some of Dobzhansky's ideas, more and more experimental and mathematical evidence seems to support them.

Other important work of Dobzhansky dealt with speciation: the process by which a species does not merely change its characteristics over time but actually splits into two or more species, which are no longer capable of interbreeding with the parent stock or one another and, consequently, go their separate ways. When speciation occurs, then a period of time must exist during which the process is partly completed, so that there are a number of races of a species that are not yet completely separate. He studied such a species, *Drosophila paulistorum*, in parts of South and Central America, that clearly demonstrates this process.

Speciation

In extension of his work in human genetics and in human paleontology, Dobzhansky wrote on the "descent of man." His *Mankind Evolving* (1962) has proved to be almost as influential among anthropologists and other students interested in human evolution as his *Genetics and the Origin of Species* was for those primarily interested in the evolution of nonhuman organisms. Finally, his interest in the direction that human evolution might take in the future, added to a natural philosophical inclination, led him into thought on the nature of man and the purpose of life and death, as evidenced in his works *The Biological Basis of Human Freedom* (1956) and *The Biology of Ultimate Concern* (1967). *Genetics of the Evolutionary Process* (1970) reflects 33 years of scientific progress in the study of evolution, largely by Dobzhansky or under his influence.

Although pre-eminently a laboratory biologist and writer, Dobzhansky never lost his liking for fieldwork; he boasted of having collected from Alaska to Tierra del Fuego and in every continent except Antarctica. An inspiring teacher and lecturer, he received over the years a steady stream of scientists from other countries, who came to spend time in his laboratory to learn his approach to research.

Beginning in 1918, Dobzhansky published well over 400 research papers that provide an important part of the factual evidence for modern evolutionary theory. His pre-eminence, however, lay even more in the rare talent for synthesizing the masses of experimental and theoretical data in the literature into a broad, comprehensive view of the subject. Dobzhansky died at Davis on December 18, 1975.

**BIBLIOGRAPHY.** HOWARD LEVENE, LEE EHRLMAN, and ROLIN RICHMOND, "Theodosius Dobzhansky Up to Now," in *Essays in Evolution and Genetics in Honor of Theodosius Dobzhansky* (1970), includes a detailed description of his scientific work and his bibliography through 1969. See also THEODOSIUS DOBZHANSKY and L.C. DUNN, *Heredity, Race, and Society*, 3rd ed. (1956), an elementary exposition of genetics with respect to man.

## Doctrine and Dogma

The development of doctrines and dogmas—*i.e.*, the explications and officially acceptable versions of religious teachings—has significantly affected the traditions, institutions, and practices of the religions of the world. Doctrines and dogmas also have influenced and been influenced by the ongoing development of secular history, science, and philosophy.

**Nature and significance.** Doctrine in theology (Latin *doctrina*, Greek *didaskalia*, *didachē*) is a generic term for the theoretical component of religious experience. It signifies the process of conceptualizing the primal—often experiential or intuitive—insights of the faith of a religious community in support of rationally understood belief. Doctrines seek to provide religion with intellectual systems for guidance in the processes of instruction, discipline, propaganda, and controversy. Dogma (Latin *decretum*, Greek *dogma*) has come to have a more specific reference to the distillate of doctrines: those first (basic or axiomatic) principles at the heart of doctrinal reflection, professed as essential by all the faithful.

This distinction appears in Christianity in the New Testament, in which *didaskalia* means "basic teachings" (as in I and II Tim.) whereas dogma is used only in the sense of an official judgment or decree (as in Acts 16:4). Later, however, many theologians of the early church (including, for example, Origen, St. Cyril of Jerusalem, and St. Jerome) use the term dogma in the sense of doctrine. In Eastern Christianity, the theologian St. John of Damascus popularized the term "orthodoxy" (literally "correct views") to connote the sum of Christian truth. In Western Christianity, the great medieval theologian Thomas Aquinas chose the phrase "articles of faith" to denote those doctrines solemnly defined by the church and obligatory for faith. As late as the Roman Catholic reformatory Council of Trent (1545–63), "doctrine" and "dogma" were still roughly synonymous.

Most modern historians, however, have stressed their difference. According to J.K.L. Gieseler, a 19th-century German church historian, in *Dogmengeschichte*,

Dogma is not doctrinal opinion, not the pronouncement of any given teacher, but doctrinal statute (*decretum*). The dogmas of a church are those doctrines which it declares to be the most essential contents of Christianity.

A modern church historian, Adolf von Harnack, sought to explain the rise of dogma in Christianity as the specific consequence of an alien blend of Greek metaphysics and Christian thought that had been rendered obsolete by Protestantism's appeal to Scripture and history. The German Roman Catholic dogmatician Karl Rahner's contrasting definition, in *Sacramentum Mundi*, points to a perennial process:

Dogma is a form of the abiding vitality of the deposit of faith in the church which itself remains always the same.

**Functions of doctrines and dogmas.** The functions of doctrines and dogmas vary in the several religious traditions according to the stress each puts on the importance of the rational conceptualization of religious truth first glimpsed in images, symbols, and parables. In what are viewed by some scholars as the more mystical religions of the East, doctrines are usually designed to serve as catalytic clues to religious insight (*e.g.*, the notions of Nirvana, or the goal of the religious life, in Hinduism, Jainism, and Buddhism). In what are regarded as the more personalistic religions of the West, doctrines and dogmas tend to function as aids to theological reflection (*e.g.*, the concept of God's unity in Judaism, Christianity, and Islām). In all the higher religions, doctrines and dogmas emerge and develop in the service of instruction for the faithful: interpreting their sacred Scriptures, understanding their obligations and duties, and safeguarding the lines between allowable diversity and actual error—all of which help to chart the religious pathway to wisdom, rectitude, and fulfillment. Theology (which utilizes doctrines and dogmas) is, according to the medieval Christian theologian and churchman St. Anselm of Canterbury, "faith seeking rational self-understanding."

The normative function of doctrinal formulation is a

typically vain effort to fix and conserve an interpretation of the original dogmas of a given tradition. The themes of *saṃsāra* (the process of reincarnation) and *karman* (the law of cause and effect) are shared by Hinduism, Jainism, and Buddhism, though with quite different doctrinal explications and consequences. Analogous developments are evident in other traditions.

A third function of doctrine is polemical: the defense of the faith against misinterpretation and error, within or without a religious tradition. Given the invariably pluralistic character of theological reflection, there is a constant tension between the concern for identity and continuity of the tradition, on the one hand, and for deeper and richer comprehension of truth itself, on the other. Over against this there is in most cultures a concurrent rivalry with other religions, with their contrary doctrinal claims, and beyond that, the challenges of secular wisdom and unbelief. This calls forth a special sort of doctrinal formulation: **apologetics**, the vindication of the true faith against its detractors or disbelievers.

At the heart of all efforts to support religious faith lies the problem of primal authority. It is required of a doctrinal statement that it be clear and cogent, but doctrines always point past their logical surface to some primitive revelation or deposit of faith. The appeal may be to any one of a number of primary authoritative positions: to the memory of a founder (as in Zoroastrianism), or a prophet (Moses in Judaism), or to ancient Scriptures (*e.g.*, the Veda and *Upaniṣads* in Hinduism), or an exemplary event (as in Gautama, the Buddha's "enlightenment"), or to God's self-disclosure (as in the Torah, or Law, for Judaism, or in Jesus Christ in Christianity, or Muhammad's revelations to Islām). Here again, the diversity between doctrines ("allowable interpretations") and the stability of dogmas ("essential teaching") points to the vexed problem of doctrinal development in history that is apparent in all the traditions.

**The development of doctrines and dogmas.** Every religion has a history of doctrine that is more than a replication of the deposit of faith. Doctrine, as a mode of pedagogy, is conservative of its tradition; as a mode of inquiry, it may be innovative, generating new insights that alter the rhetoric of conventional teaching and, sometimes, its substance as well. There are, of course, wide variations. The persistent continuities between ancient Zoroastrianism and its modern form, Parsiism, or in Jainism, are clearer than those between primitive Hinduism and modern Vedānta (a Hindu philosophical system). All forms and sects of Buddhism appeal jointly to the Three Jewels (the Buddha; the *dharma*, or law; and the *saṅgha*, or monastic order) but are irreconcilable in their differences of interpretation and practice. In each case, the question as to what constitutes legitimate development (*e.g.*, the rival claims of Theravāda, or "Way of the Elders," and Mahāyāna, or "Greater Vehicle," in Buddhism) is left undetermined.

All Jews profess devotion to Torah, even in their disagreements over its authentic observance. Christians profess a common loyalty to the Bible and a common acceptance of the twin dogmas of the Trinity (that the one God is three Persons—Father, Son, and Holy Spirit) and the God-Manhood of Jesus (that Christ is both divine and human) but then divide in their doctrinal systems as they have developed historically. Later dogmas (*e.g.*, transubstantiation, the teaching that the substance of the bread and wine in the Lord's Supper is changed into the substance of the body and blood of Christ, with the properties of the bread and wine remaining unchanged) were defined by the Latin Church without concurrence from Eastern Orthodoxy; the modern dogmas of the Roman Catholic Church (*i.e.*, the immaculate conception of the Virgin Mary, the bodily assumption into heaven of the Virgin Mary, and papal infallibility) were defined in separation from both the Eastern and Protestant consensus. Protestantism has continued an emphasis on its distinctive dogmas of "grace alone" (*sola gratia*), "faith alone" (*sola fide*), and "Scripture alone" (*sola Scriptura*) but has nevertheless undergone immense change and proliferation.

The problem of primal authority

The rational conceptualization of religious truth

Views of  
doctrinal  
develop-  
ment

Islām lays great stress on doctrinal stability focussed in the Qurʾān, the *sunnah* (custom or tradition), and the consensus (*ijmāʿ*) of its jurists (*ʿulamāʾ*). Even so, it has produced doctrinal variants—especially in the medieval period—as disparate as the mysticism of the Iranian-born philosopher al-Ghazālī and the rationalism of the Spanish philosopher Averroës and the Persian philosopher Avicenna.

The process of doctrinal development has been explained variously as a process of logical unfolding or of organic growth, or else as a process of purgations of error and restorations of the original deposit. The notion of a logical unfolding assumes that all that has developed in a religious tradition over the course of its history was already implicit in its original foundation and subsequently had only to become more fully understood. In the case of the doctrine of the Trinity in Christianity, for example, it is argued that the abundant references in the New Testament and the earliest liturgies to God as Father, Son, and Holy Spirit required the development of the dogma as the explication of essential Christian conviction. Similarly, the dogma on the nature of Christ is understood as the logical outcome of sustained reflection on the testimony about Jesus as the Christ in the Bible and in the apostolic tradition. In the notion of logical unfolding, even in its development, truth remains forever unchanged.

Theories of organic development stress the fact that the history of doctrine includes more than explicit formulation of implicit revelation. Such theories take into account the ways in which religious thought is affected by "contemporary" science, philosophy, and historical crises (e.g., the "Copernican revolution" in astronomy, the Renaissance, and other such events). The holders of this view are convinced, however, that all such historical supplementations have been integrated into the original deposit and thus exhibit the power of the religious organization (e.g., the church) to grow and change without substantial alteration of its identity. Thus the 19th-century Roman Catholic cardinal J.H. Newman, in his *Essay on the Development of Christian Doctrine* (1845), argued that

... the highest and most wonderful truths, though communicated to the world once for all by inspired teachers could not be comprehended all at once by the recipients, but, ... have required only the longer time and deeper thought for their full elucidation (Introduction, pp. 29–30).

Newman also believed that this process was safeguarded by the authority of the teaching that would even allow for revisions and occasional corrections of antecedent.

Protestants, by and large, have been more impressed by the lapses and deviations they see in church history and doctrine and thus have tended to construe authentic "development" in terms of a perennial recourse to Scripture and apostolic tradition. Such a view takes historical flux for granted and is less sensitive to the problem of historical continuity.

In all traditions, the course of doctrinal development is crucially affected by the occasional emergence of profound and powerful thinkers who have gathered up scattered elements in their tradition in freshly relevant syntheses, altering thereby the subsequent history of that tradition. This can be seen, for example, in the North African theologian Augustine's contributions to the making of Latin Christianity and in the matching services of John of Damascus in Eastern Orthodoxy. Such also was the role and contribution of Moses Maimonides in medieval Judaism (e.g., the Thirteen Articles of Faith in his *Mishne Torah*) and of Thomas Aquinas in medieval Christianity (e.g., *Summa theologiae*). The 16th-century Reformers Martin Luther and John Calvin gave Protestantism its classical form, to be followed by yet other and different system builders (e.g., Friedrich Schleiermacher in the 19th century and Karl Barth in the 20th century).

Each theory of development has had its own distinctive prescription for doctrinal stability and doctrinal change. In Christianity, Eastern Orthodoxy locates its authority in "Holy Tradition," fixed and guided by the dogmas of the ecumenical councils. Roman Catholicism relies on

the magisterium (teaching authority) of the church, directed by the bishops as a "college" (*collegium episcoporum*) and supremely by the bishop of Rome as their collegial head. Protestantism has sought to bind both tradition and the church to the authority of Holy Scripture, with the resulting problem of specifying what is to be regarded as truly authoritative interpretations of Scripture.

**The relation of faith, reason, and religious insight to doctrine and dogma.** Insofar as doctrines and dogmas represent conceptualizations of the human encounter with the divine mystery, they are bound to reflect the interplay of faith and reason in religious experience and to imply some notion of levels and stages in the progress of believers from the threshold of faith toward its fulfillment. Doctrine is concerned with communication and consensus, with the exposure of the religious vision to rational probes and queries. There is, therefore, a tension in all religions between mystical intuition and logical articulation, between insight and dialogue. Most traditions agree that perfect understanding is a goal that lies beyond a "simple faith" and the routine observance of rites and duties. Most of them also agree that the utmost pinnacle of religious insight is ineffable. One mode of differentiation between doctrinal traditions, therefore, is their relative openness or resistance to the auxiliary services of philosophy and science of faith's fulfillment.

In the religions of the East, very broadly, reason's chief role is the purgation of illusion and self-deception so that souls may follow the ways of wisdom and right conduct to their true fulfillment in Nirvāṇa. The Hindu passes from the initiatory level of "the student" (dependent on a teacher, guru) to the ambivalent freedom of "the householder," to the great freedom of "the forest dweller," to the fullest freedom of the *sannyāsin* (enlightened ascetic). Reason, chiefly reflective, assists at every stage in perfecting faith's self-understanding. In Buddhism, one follows the dharma from saddha (practical knowledge of one's religious obligations), to *jñāna* (rational insight), to *vijñāna* (mystical illumination).

In the religions of the West, again very broadly, the primary function of reason has been that of rendering the mysteries of faith as intelligible as possible, in support of the intellectual love of God. In Judaism, progress in the knowledge of Torah is focussed in the Bible and the Talmud (commentaries on the Law), guided by the twin hermeneutical (critical interpretive) principles of Halakha (the oral precepts and decisions of the rabbis) and Hag-gada (instructive stories, parables, and other such devices).

Variations in Islām range from the rigid orthodoxy of the Hanbalites (a conservative school of law following the teachings of Ibn Hanbal), to the rational liberalism of the Muʿtazilites (a school of law utilizing Greek philosophical methods), to the dialectical doctrines (kaldm) of the Arabian theologian al-Ashʿarī and the Turkish philosopher al-Fiiribi. All of these, however, are anchored in the twin dogmas of the unity of God and the prophetic office of Muhammad. Spiritual progress is measured by the believer's faithfulness in obedience to the "Five Pillars," or religious duties, including prayer, fasting, and the pilgrimage to Mecca.

In Christianity, the dialectic between faith and reason has ranged from the fideism (emphasis on faith) of the 2nd-century North African theologian Tertullian to the intellectualism of Thomas Aquinas. An ancient distinction between faith as bare assent to orthodox doctrine (*fides informis*) and faith as existential trust in God's grace (*fides formata*) gave rise to the further distinction between faith as a set of doctrines to be believed (*fides quae creditur*) and faith as personal involvement (*fides qua creditur*). Philipp Melancthon, a 16th-century Lutheran Reformer, stressed the point that even the devils are "orthodox" (having "dead faith") but to no avail, since only those who have embraced God's reconciling love (*fiducia*) receive the benefits of salvation ("living faith"). In general, this distinction has become standard in Protestantism.

**Conclusion.** In all the great religious traditions, and between them, the clash of doctrines and dogmas has,

The inter-  
play of  
faith and  
reason in  
religious  
experience

Faith as  
assent and  
as trust

more often than not, been polemical. The *odium theologorum* ("bitterness of the theologians") of which Melancthon once complained so plaintively has been notorious. Within the several traditions, doctrinal disputes have sometimes led to division or else have accompanied divisions caused otherwise. In relationships between the great world religions, dogmas and doctrines have usually been regarded as mutually exclusive. There are, however, significant signs of change in this attitude. The rise and spread of the ecumenical movement in the 20th century and notable advances in the comparative study of world religions reflect an enlarged commitment to the widest possible community of mutual religious interests. The "Decree on Ecumenism" and its "Declaration on the Relationship of the Church to Non-Christian Religions" of the Roman Catholic second Vatican Council (1962–65) are signal instances of this new disposition.

**BIBLIOGRAPHY.** HEINRICH EMIL BRUNNER, *Dogmatik*, vol. 1 (1946; Eng. trans., *Dogmatics*, vol. 1, *The Christian Doctrine of God*, 1949), advocates the primacy of Scripture over tradition; OWEN CHADWICK, *From Bossuet to Newman: The Idea of Doctrinal Development* (1957), an excellent survey of the gradual shift from "the classical consciousness" of identity in doctrine (Bossuet) to a "historical consciousness" of growth and continuity (Newman); ADOLF VON HARNACK, *Lehrbuch der Dogmengeschichte*, 3rd ed., 3 vol. (1893; Eng. trans., *History of Dogma*, 7 vol., 1900, reprinted 1961), a massive exposition of the thesis that Christian dogma represents the process of Hellenization of the original Gospel, hence a deviation; JOHN HENRY NEWMAN, *An Essay on the Development of Christian Doctrine*, new ed. (1878), a classical statement of the emergence of the historical consciousness within the Catholic tradition; JOHN B. NOSS, *Man's Religions*, 4th ed. (1969), a general survey; J. ELIKAN, *Development of Christian Doctrine: Some Historical Prolegomena* (1969), an important current statement of the interaction of Scripture and tradition in the formation of Christian doctrines and dogmas; KARL RAHNER, "Dogma," in *Sacramentum Mundi*, vol. 1, pp. 909–917 (1968), reflects the new perspectives of Vatican II; FREDERICK J. STRENG, *Understanding Religious Man* (1969), an excellent summary of the common elements in religious experience, including those relating to doctrine and dogma; MARTIN WERNER, *Die Entstehung des christlichen Dogmas* (1941; abr. Eng. trans., *The Formation of Christian Dogma*, 1957), argues that Christian dogma displaced the original eschatological message of the early church; R.C. ZAEHNER, *Concordant Discord: The Interdependence of Faiths* (1970), helpful insights as to the various ideas of authority in the major religions of the world.

(A.C.O.)

## Dog

Dogs, along with wolves, jackals, and foxes, are members of the family Canidae. As such, they share certain features that suit them admirably for a life of active hunting; powerful jaws with teeth adapted to seizing, keen senses of smell and hearing, and a social instinct that maintains and coordinates the efforts of the pack. The family of dogs and their relatives belongs to the order Carnivora, the "flesh eaters"; for an account of the family and its relationships, see CARNIVORA. Regardless of superficial differences, all dogs belong to a single species, *Canis familiaris*, and its more than 100 breeds depend entirely on selective breeding and maintenance by man for their continued existence. The dog is an extremely social animal, whose well-being and normal psychological development are products of association with other dogs in a pack. Unlike man's other favourite domesticate, the cat, a dog adjusts with difficulty, if at all, to an independent and wild existence and draws heavily on the mutual exchange of pack members and the guidance of the pack leader, or a human master, who is in fact a surrogate pack leader.

### ORIGIN AND HISTORY

The dog is the oldest domesticated animal, having been in the company of man for at least 10,000 years and having originated probably somewhere in Eurasia 12,000 to 14,000 years ago. It belongs to the same genus (*Canis*) as do the coyote, jackal, and wolf, all of which have been considered to be his ancestors. Much farther back in time, about 40,000,000 years ago, lived a tree-climbing

carnivorous mammal called *Miacis*, from which the lineage of the canines is traced through *Cynodictis*, from whom the African Cape hunting dog, the Indian wild dog (or dhole), and the South American bush dog ultimately sprang, through *Cynodesmus*, which gave rise to the hyenas, and finally through *Tomarctus*, the progenitor of the fox, wolf, jackal, and dog. The coyote, which lives only in North America, can be eliminated as an ancestor of the early European dog.

Figure 1: Possible genealogy of the dog.

The most likely candidate is the gray wolf, which was originally found over all of Europe, Asia, and North America, with a great many highly variable subspecies and local varieties. The wolf is so variable in colour that even individual members of a pack can be easily distinguished. Northern wolves are much larger than southern ones, which makes it probable that dogs came from a smaller central or southern variety. Such a race of small wolves lives in India, and another was formerly found in China. The other possible candidate, the jackal, is primarily an African animal, although its range extends into Mesopotamia, southeastern Europe, and India. The jackal is less social than the dog; it howls in a manner unlike any domestic dog and has a narrow, foxlike head—factors that make it unlikely that it is the dog's ancestor.

**Domestication.** The wild dog, like the wolf, roams in packs in search of food, and it would seem not unlikely that some primitive dogs found food more readily available near man's encampments, where animal hides and picked-over carcasses were left to rot. The dog apparently was less wary than its canine relatives and may have ventured more boldly into man's settlements to feed. Its association with man developed gradually; the more docile and tractable dogs were tolerated; the others were run off or killed.

Man may have grown to depend on the dog to warn him of approaching threat, and the dog in turn grew to depend on man for food and shelter. Mutual bonds of benefit and affection probably strengthened gradually over the centuries until by selection for traits and appearance the domesticated dog became man's creation. In time, further attention to breeding resulted in modifications that have led to widely variant breeds.

Probable  
wolf  
ancestry

Man and  
dog as  
mutually  
dependent

After dogs became domesticated, certain traits became established that distinguish dogs from their wild relatives. One such trait is the upturned tail, ranging from a sickle shape to a tight curl. This feature probably goes back to the original stock of domestic dog, pointing to a common ancestry for all types of dog. Another characteristic that distinguishes the dog from the wolf is its smaller, less powerful dentition. There must have been an early artificial selection for those animals that were smaller, less toothy, and also more easily tamed and controlled.

Distribution

The domesticated dog apparently spread very rapidly all over the world, through both hemispheres and from tropical to Arctic climates. When the Europeans arrived in North America they brought their own dogs with them, but every Indian tribe already had them. At that time there were at least 20 distinct breeds in North and South America. Most of these have disappeared except for the Mexican hairless and the Eskimo dogs.

In Australia there is the dingo, a species separate from the domestic dog. Typically a wild animal, the dingo is sometimes found semidomesticated in the camps of the Aborigines. Its ancestors must have been brought as domestic dogs to Australia by the first immigrants several thousand years ago and later allowed to run wild.

Since the beginning of history dogs have been found all over Africa. One of the surviving native breeds is the African basenji, still used by the pygmy tribes in equatorial regions. The basenji is probably descended from an early breed adapted to tropical living, which spread through southern Asia and the East Indies and eventually to Australia, where it became the dingo. Other varieties of dogs lived throughout Asia and on most of the oceanic islands.

Most is known about the history of European dogs. From the earliest times traders and travellers not only took their favourite dogs on long journeys but often returned with new and exotic varieties. Dogs were nowhere more cultivated than in England.

By the time John Caius (the founder of Caius College at Cambridge) wrote a description of English dogs for Konrad von Gesner, a 16th-century naturalist, the English had collected at least six main varieties of dogs—greyhounds, true hounds, bird dogs, terriers, mastiffs, and shepherd dogs. A basic group of dogs not mentioned by Caius includes the sled dogs of the Eskimo, found in the Arctic in both America and Eurasia. These large curly-tailed dogs, reputedly crossed with wolves, and similar smaller dogs of northern Eurasia are sometimes called the polar, or spitz, group.

Although the same general types of dogs were found all over the world many less distinct in their physical and behavioral traits have since disappeared. Many ancient breeds have greatly changed or entirely disappeared, but in Iraq two ancient types of dog, the saluki and the Kurdish herding dog, are still found. The latter of these is a large breed somewhat resembling the mastiffs and war dogs pictured in Babylonian art in 2200 BC.

Historical records indicate that dog breeds have frequently been crossed with each other, so that it is difficult in many cases to determine the ancestors. While conscious human selection has doubtless played a part in producing genetic changes from the earliest times, the dog is also an evolving species. Just as an animal that enters a new physical habitat undergoes rapid change and differentiation, the dog on domestication entered a new biological habitat in association with the human species and underwent a similar rapid evolution assisted by man.

**Associations with man.** The dog figures prominently in many tales of courage and selfless devotion in the service of man, of steadfastness and perseverance, of attentiveness and seeming concern for his master. The romantic stories of Albert Payson Terhune are filled with the heroic deeds of the dog, as are Jack London's *White Fang* (1906) and other novels. The dog has been bred for many special tasks—hunting, guarding, herding, drafting, guiding (for the blind)—but most popularly for companionship and as a household pet.

Because the close social relationship between dogs and

man appears to many to be similar to the human parent-child relationship, dogs have been used to test various theories of child training. Dogs also have important uses in medical research, and the resulting discoveries have helped to improve both animal and human health.

#### GENERAL FEATURES AND SPECIAL ADAPTATIONS

The dog, in many of its breeds, is basically a wolf-like hunter, with physical features usually identified with such a mode of life: musculature fitting a coursing or running animal, teeth suitable for seizing and holding prey, internal adaptations to a carnivorous habit (short gut and other digestive tract features), and keen senses of smell and hearing.

**Coordination and musculature.** While the dog is no rival for the cat in fluid movement and balance, it has retained some of the wolflike aspects of deliberate tracking and cautious cunning. It moves the way a horse does when walking but prefers the trot, in which the right foreleg and left hindleg advance together, followed by the other legs; at top speed it breaks into a gallop. The dog is not as agile and foot sure as the cat, nor as flexible in body construction, but its speed and perseverance are greater than the cat's. The wolflike musculature is still found, though greatly modified in mass and development, in the different breeds. The sheetlike musculature covering the head and main body mass is particularly noticeable by its action in raising the hackles, or back hair, baring the teeth, and cocking the ears. Muscles of the hind back work the tail, which is generally wagged briskly and held high in contentment and waved slowly and in a horizontal position in attentive approach or before attack. The tail aids in balance, as when the dog dashes around a curve.

**Teeth.** A dog's first, temporary, set of teeth, or milk teeth, is replaced by a permanent set at about five months. The 42 permanent teeth include incisors, which are used to nip and bite; canines, used to tear and shred flesh; and premolars and molars, which shear and crush. The canines are upper and lower fangs for which the dog family was named. As in most carnivores, the teeth are high crowned and pointed, unlike the broad, grinding teeth of many herbivorous animals. Having less manipulative ability than the cat, the dog uses its teeth to catch and hold items, such as food or a toy, as well as to prepare food for digestion.

**Senses. Smell.** The two senses most supremely developed in the dog are hearing and, pre-eminently, smell. The dog's world is primarily one of scents, as man's is one of sights. The dog's nasal passages are so arranged that a greater volume of air can be drawn over the sensitive lining than is the case with man. Rapid sniffs carry messages to the enlarged olfactory centre in the brain where the scents are analyzed and cataloged. Practical scents seem to be of greatest interest—the smells that identify other animals: blood, sweat, excrement, urine, and the smells associated with the sex organs. Grassy smells, soil, and ripe, putrefactive odours are likewise attractive.

**Hearing.** Hearing is an acute sense in the dog; frequencies up to 35,000 vibrations per second can be detected, compared with 25,000 in the cat and 20,000 in man.

**Vision.** Sight is a relatively poorly developed faculty in the dog. Moving forms are readily discerned but a still object with no particular odour may go unnoticed. The dog is colour-blind (even guide dogs, which respond to traffic signals, do so by the position of the lighted signal rather than by the colour).

#### REHAVIOUR

**The wolf-dog pattern.** Many peculiarities of dog behaviour can be understood only in reference to the lives of their wild ancestors, the wolves. Within recent years the behaviour of wolves in undisturbed wild conditions has been studied scientifically, reducing much of the mythology surrounding them to scientific fact.

**Territory and range.** Dogs recognize a central headquarters, or den, which, with the immediate area sur-

The wolf-like heritage

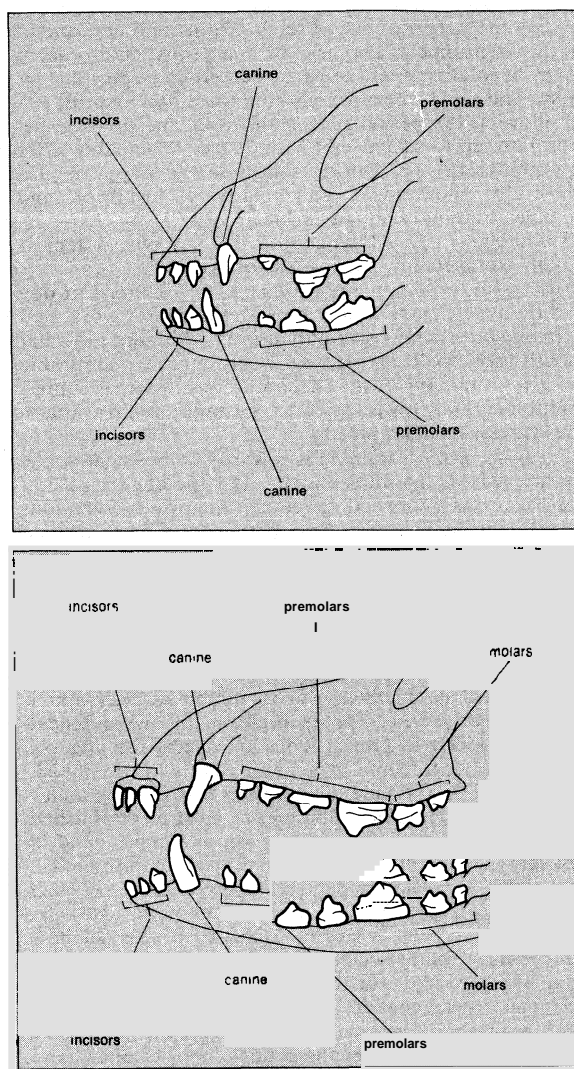

Figure 2: Dentitions of the dog. (Top) Temporary (milk) teeth of a puppy. (Bottom) Adult (permanent) teeth.

"Scent posts"

rounding, is defended as a territory from which other dogs are excluded. At various points beyond this central territory dogs will establish "scent posts," where they stop to urinate and defecate. Males lift the leg to urinate and scratch the ground after defecation. Strange dogs passing by will also mark the place in the same manner. These wolflike habits are seen especially in dogs allowed to run loose in town or country: the tendency to defend the immediate areas around the houses of their owners, but to wander much more widely, making certain "scent posts" as they go.

**Group activities.** Wolves are highly social animals. Within the pack, wolves are peaceable and highly cooperative. While feeding, they observe a dominance order, in which the most dominant animal feeds first. Parts of prey animals are often buried, either at the site of the kill or in the vicinity of the den, presumably to save the food from scavengers. Domestic dogs show the same habits, even attempting to bury such things as dry dog food.

Wolves show the same general types of sounds and communication as dogs—barking when a strange animal approaches the den, yelping in fear or distress, growling when threatening another animal, and howling, either alone or, when the pack is together, in unison.

**Combative behaviour.** Two strange male dogs usually approach each other stiffly, with tails held erect, and appear to identify each other by sniffing in the tail region. If a fight starts, they rush at each other, snapping and snarling, and the fight will last until one runs away or submits. The beaten animal will roll on its back, extend-

ing its paws, yelping, and protecting its throat by snapping. The winning animal stands over it, growling and threatening. If dominance has already been established, one dog may indicate this by placing his paws on the other's back and growling while the subordinate animal keeps his tail low. Similar behaviour is seen in wolves.

**Courtship and care of young.** In courtship dogs show a characteristic pattern of play. They crouch extending their forepaws and cocking their heads to one side, then they throw their forelegs around each other's necks and wrestle. This is followed by running and chasing and eventually mating. Like wolves, dogs show the peculiarity of the sexual tie; after copulation the two animals remain locked together for many minutes.

At first, young puppies are fed exclusively by nursing. After three weeks or so, they begin to take solid food, with final weaning at about seven weeks of age. Wolves feed the young by vomiting. Domestic dogs show this pattern more rarely but vomit readily and, like wolves, frequently eat the vomitus.

**Special traits. Intelligence.** Judging how intelligent a dog is, either in comparison to other dogs or to other animals, is difficult. Obviously, a dog will be able to perform as well as a monkey any task involving complex manipulation or colour vision. Intelligence is measured primarily by the ease with which a dog can be trained. This may vary in a breed, however, on the degree of motivation. In general, when individual dogs are sufficiently motivated there appear to be no wide differences in intelligence between breeds.

There are big differences, however, in the ease with which breeds and individual dogs will accept training. Certain breeds, particularly the shepherd dogs and poodles, have reputations for being intelligent. These animals have a high capacity for developing motivation and attention toward their handlers. A similarly high capacity for training is found in most of the "wonder dogs" famous for their intelligence belong to these groups. A highly trained dog is capable of mastering many different tasks.

At the same time there are definite limitations on canine intelligence. Like other mammals (excluding man), a dog cannot be taught to talk and indeed learn to bark on command only with great difficulty. There is no evidence that dogs are able to recognize the meanings of words when they are used in new combinations (i.e., to understand new sentences); thus the amount of information that actually can be conveyed to a dog is quite limited. A well-trained dog, however, is capable of such attentiveness to his owner's slightest movement and mannerisms that he almost seems to read the owner's mind.

**Emotions.** Most of a dog's emotional reactions are readily understandable. Growls and snarls are threats, and barking is usually an alarm signal. Rapid horizontal tail wagging indicates a friendly approach and is roughly the social equivalent of the human smile. High-pitched yelping occurs in situations involving pain or terror. The rapid yelps and whines of puppies indicate distress, which may have many causes. Solitary howling usually indicates loneliness or may be a reply to another howling dog.

Some other reactions are less easy to interpret and can be understood only in terms of the behaviour of dogs toward each other. Jumping up and offering the forefoot is usually an attempt to initiate playful fighting so often seen between dogs. A stiff-legged approach with erect and slowly wagging tail indicates aggressiveness and may be followed by an attack. A "worried" dog holds his ears down, so that his forehead is smooth. An attentive dog often displays a wrinkled forehead, usually the result of the erection of the ears.

The external expression, however, is not always a true guide to internal emotional state. A serious prolonged internal emotional disturbance will often show up in depressed activity and loss of appetite.

**Abnormal behaviour: neuroses.** It is difficult to interpret any behaviour of a dog as abnormal, because the animal will adapt to a situation in any way that gives him satisfaction, however bizarre this may appear to the on-

Dominance and subordination behaviour

looker. Unusual behaviour may also result from organic disease. Any marked changes in behaviour, such as convulsions (often called fits), staggering gait, and the like, are usually indications of serious disease.

A neurosis may be defined as a kind of behaviour that gives relief from tension without adaptation to the cause of tension. Dogs confined to small pens for long periods, for example, will often develop the habit of running in circles or jumping from side to side whenever a person approaches. The dog is stimulated to respond to the person but because of confinement can only make what appear to be useless and inappropriate movements. Similarly, a dog left by itself in a house for long periods will often chew furniture and rugs. This behaviour can be understood as a thwarted attempt to escape.

The effect  
of  
complete  
isolation

Psychotic behaviour, defined as a general disruption of adaptation to social situations, is seldom seen in dogs. A puppy reared in complete isolation during the period of socialization, however, will avoid all human and canine contacts, showing more severe symptoms than the kennel-dog syndrome that arises from being reared in a limited environment. When dogs closely attached to their masters are separated from them for long periods, they may show symptoms of depression very similar to those exhibited by human beings.

#### DOGS AS PETS

The ideal time to acquire an individual puppy is between six and eight weeks of age, in order to permit normal psychological development. Since neither physical nor behavioral development is complete at this time, the best guide to the puppy's future behaviour is that of its parents.

As adults, males are usually larger than females, more active, and tend to wander more.

A mongrel is a dog of unknown ancestry. First-generation hybrids between two pure breeds show a great deal of hybrid vigour and are usually more healthy and hardy than either parent breed. Their appearance and behaviour traits may be like one or the other parent, or neither. Some dog breeders regularly produce such hybrids for special purposes when the result can be predicted.

**Developmental periods.** The early development of a dog is divided into several distinct periods: (1) neonatal, (2) transition, (3) socialization, and (4) juvenile. In the neonatal (newborn) period, the puppy's activity is largely confined to nursing and sleeping.

The newborn puppy is blind and deaf and is consequently largely isolated from the external world. In about 14 days its eyes will open, marking the beginning of the transition period. During the third week the puppy undergoes a rapid change in behaviour and in sensory and motor abilities. Toward the end of the week, when its ears open, the puppy begins to react to sound. At the same time its first teeth appear, and it will attempt to eat solid food if it is offered.

Socializa-  
tion

Meanwhile it has begun to walk instead of crawl and to show social responses to humans and to other dogs. This marks the beginning of the period of socialization, at approximately three weeks after birth. The puppy will now slowly approach a strange person, nosing and wagging its tail. Another social response is playful fighting with its littermates. At any time during this period, which lasts up to 12 weeks of age, it is easy to form a close social relationship between a puppy and its owner, the maximum favourable response being obtained between six and eight weeks of age.

By removing a puppy from its litter early in the socialization period all social relationships are transferred to human beings. Emotional disturbance and prolonged yelping is a normal reaction to removal from the litter and can be relieved by fondling and companionship. The puppy soon associates its owner with relief from distress. Adopting a puppy late in the period will throw the balance in the opposite direction, so that the puppy's strongest relationships are with dogs rather than with human beings. Puppies raised in large fields apart from human beings will become almost completely wild by 14 weeks of age. This period is therefore a critical one for deter-

mining the nature of social relationships and adjustment to the environment. Puppies left in a kennel environment much beyond 12 weeks of age are likely to be permanently shy and timid when brought into the outside world.

Following the period of socialization, the juvenile period lasts up to sexual maturity, usually sometime after six months of age. During this time the puppy is still physically undeveloped and relatively unskillful, and complex training is not advisable.

**Trainability.** Development of the nervous system is largely completed by eight weeks of age.

Successful training methods vary with the breed of dog and the type of activity desired. Methods that work well with one breed may work only poorly with another. Mild punishment, for example, can easily inhibit undesirable behaviour in many of the shepherd dogs, whereas similar punishment may only stimulate resistance and fighting in the aggressive terrier breeds.

Punish-  
ment  
versus  
reward

The basis of most training is reward. To be effective the reward must come immediately after the action, so that the dog forms a connection between the two. Good habits formed in this way also help prevent the formation of bad habits, since one interferes with the other. The rewards used vary with breeds and individuals, and the trainer must study the animal to determine which type of prize is most effective. For the hunting breeds food is usually a very strong reward. For many breeds praise and fondling is reward enough.

Punishment is chiefly useful to inhibit activity and is ineffective otherwise. For example, if an owner repeatedly calls a dog to punish it for misdeeds, the dog will soon learn not to come. A general rule is to use punishment sparingly and only in situations that the dog understands. At the same time dominance must be established; it is best accomplished over very young puppies, and by restraint and handling rather than outright punishment.

**Specializations of breeds.** The psychology of each breed can be best understood in terms of the work for which it has been selected. Hunting breeds such as hounds have been selected to work independently of human handlers and are therefore somewhat difficult to keep under strict control. They have also been selected to work peaceably in packs or groups; aggressive behaviour is seldom a problem. Shepherd dogs, on the other hand, have been selected for their ability to learn to work under direction and to form firm habits. It is therefore easy to teach them restraint.

Breed  
psychology

**Hunting dogs.** The hound breeds of dogs have been selected to hunt primarily by sight or by scent and are used to find and run down various sorts of land mammals. Dogs such as the greyhound, which were originally adapted to desert and plains, are representative of the sight hounds, or gazehounds. The bloodhound and related breeds are examples of the scent hounds. Both types track down their quarry.

A different type of hunting is found among bird dogs. When the bird is detected on the ground, the dog, if it is a pointer or setter, is trained to stop and wait; other breeds, such as the spaniels, simply flush the birds so that they can be shot. Another problem in bird hunting is to find the shot and wounded birds and return them to the hunter. For this job several special breeds of retrievers have been developed, some of which are used for both finding and retrieving.

The spaniels appear to have been the original bird dogs, and according to tradition they originated in Spain. They were used for various types of hunting in the Middle Ages. Water spaniels were used for retrieving birds from the water. Land spaniels were used for falconry, being trained to find and flush birds off the ground so that the falcons could attack them. Others were used in setting birds for the net; *i.e.*, on finding birds, they lie flat on the ground while the net is thrown over them and the birds. This was the original meaning of "setter." Later, when shotguns were developed for use in bird hunting, this behaviour trait was useless, and setter breeds were then selected for pointing instead. The original pointers were developed about the same time, probably from a mixture of hound and spaniel breeds.

Hunting game on open plains or deserts is not so much a problem of finding the game as of catching it. Various greyhounds have been selected and bred for great speed and running down game of different sorts by sight.

The final part of hunting is the attack on the prey, and terrier breeds have been bred as attack dogs. The fox terriers were used to drive foxes out of their dens, and the larger Airedale terriers were, and still are, sometimes used to attack mountain lions and bring them to bay.

**Guard dogs and watchdogs.** Although guard dogs and watchdogs have had limited uses under modern civilized conditions because their owners are responsible for the damage they do, almost any breed of dog will still sound an alarm when strangers approach. Breeds such as the German shepherd dog (or Alsatian) and the Doberman pinscher are sometimes used in police work and by night watchmen. Dogs find certain use in modern warfare, chiefly in night patrols and in scouting, mine detection, and sentry duty.

**Herding dogs.** Under primitive conditions herding dogs were used to protect flocks of sheep or goats from predators, and they consequently had to be large and aggressive animals. Many of the modern shepherd breeds, such as the border collies, are now small or medium-size animals that have been selected for the ability to learn commands and obey them from a distance. Dogs are still used for herding cattle.

**Sled dogs.** One use of dogs that has no counterpart in the behaviour of wolves is as draft animals. With the domestication of larger animals and the development of modern systems of transport, this use has largely disappeared, surviving chiefly in Arctic sled dogs. Before the European carried the horse to North America, Indians used dogs to pull their wheelless vehicles (*travois*).

**Companions and pets.** An important modern use of dogs is as companions and household pets.

The popularity of dog breeds as pets seems to vary from year to year reflecting a current taste. The most popular are usually small or medium sized. Within the last half-century fox terriers, cocker spaniels, and beagles have been favourites, with some of the working, toy, and hound breeds such as collies, boxers, German shepherds, chihuahuas, Pekingese, miniature schnauzers, dachshunds, and basset hounds being runners-up. Among non-sporting breeds, poodles were registered in numbers more than twice as great as those of the nearest competitor, the German shepherd. Guide dogs for the blind are particularly valuable and devoted companions. Several breeds have been used successfully as guide dogs, but the German shepherd dog is most commonly employed.

#### NUTRITION AND GROWTH

**Adult dogs.** Dogs are basically carnivorous hunting animals and as such are physiologically adapted to going for long periods without food or water. Many adult dogs can go without eating for a week without serious harm. When food is available, a hungry dog will gulp down large quantities as rapidly as possible.

The amount of food a dog needs depends upon the amount of exercise it gets, but a rough guide is one-half pound of dry dog food or its equivalent for a 20-pound dog. Smaller breeds generally require more food per pound of body weight than do larger breeds, and puppies need more food than mature dogs, especially during the period of rapid growth between six weeks and six months of age.

A well-balanced diet for a dog is not too different from that for a human being, except that the dog's intestine is not well equipped for handling roughage, so foods like bran and certain vegetables containing an excess of fibre should be avoided. Dogs digest bones easily and can live almost exclusively upon fresh ones that contain marrow. Splintery bones, such as those of poultry or chops are, however, dangerous. Dogs, because they can produce their own vitamin C, have no need for vegetables and fruits but can eat them if there is nothing else available. They can also readily digest cooked starchy foods.

**Puppies.** Puppies naturally have special nutritional requirements. In normal development, the young puppy

gets all of his food from the mother's milk during the first few weeks of life. The mother then begins to supplement this with vomited food and completely weans the puppies at seven to ten weeks of age. Most mothers are unable to feed their puppies adequately by natural means throughout this whole period, and food supplementation is usually necessary at about three or four weeks of age.

The best supplement is some sort of mash containing milk and meat with large quantities of high-grade protein and also iron. A puppy's diet may be supplemented with vitamin D to prevent rickets. This is particularly important in the large breeds such as the Great Dane.

A normal rate of growth is the best indication of good health in a young puppy. For the first three weeks puppies gain between 50 and 100 percent of their birth weight each week. Once supplementary feeding is begun they gain weight very rapidly up to four months of age, then more slowly, reaching nearly adult size by six months of age. Growth thereafter is quite slow, and the dog reaches full development at approximately two years. The prime of adult life extends through the fifth year, though many dogs live more than twice that long, and some last well into the teens.

#### REPRODUCTION

**Sexual maturity.** The ancestral wolves do not become sexually mature until nearly two years of age. However, females of most breeds of domestic dogs will show their first heat (or estrus) period before they are a year old and sometimes before six months. There is considerable variation both between breeds and individuals. The African basenji has a seasonal cycle, in which the females come into heat in the autumn of each year. A similar cycle is found in the Australian dingo when taken into northern latitudes. Most domestic breeds come into heat at any season of the year, at approximately six-month intervals. The pattern of any individual dog is usually fairly consistent, but longer and shorter cycles are common. The reproductive powers of females diminish after five years of age and reproductive cycles usually cease entirely by the age of eight. Males usually remain capable of breeding to a more advanced age, but a male of six years is entering middle age.

Spaying the female (removing the ovaries) or castrating a male (removing the testes) before maturity affects the normal pattern of growth; such animals usually become taller and more obese than the average. Spaying terminates the sexual cycle in the female, but castration may have little effect on the sexual behaviour of an experienced male.

**Receptivity and gestation.** The first sign of estrus in the female is a gradual enlargement of the external genitalia, followed after several days by the discharge of a small amount of blood. At the same time an odorous substance highly exciting to males is secreted in the urine. If the female is not allowed to urinate where males can find it, there will be little trouble, but if she is allowed to run freely, males will gather from miles around. Bleeding may continue for a week or more and at its end the female will accept the male. She may be receptive for a few days or as much as two weeks. Ovulation occurs 72 hours before the last point of receptivity. Conception may occur from matings at any time in the cycle. Many breeders make a practice of repeating matings every other day throughout the receptive period.

The period of gestation is approximately nine weeks counting from the time when the animal is first receptive. The embryos develop quite slowly at first, not becoming implanted until about 21 days after fertilization. The greatest intra-uterine growth of the puppies occurs in the last half of pregnancy, during which the female requires an increased diet. Occasionally a female that has not been bred will show a pseudopregnancy, with swelling of the abdomen and enlargement of the mammary glands.

Litter size varies roughly with the size of breed, but there is great individual variation. Some toy breeds rarely have more than one or two puppies, whereas the setters and larger breeds may have eight to ten, with some rec-

Rate of growth

Heat, or estrus, periods

Guide dogs

Litter size

ord litters going much higher. Four to six is a good average; in very large litters the pups are frequently small and weak.

#### AILMENTS

**Parasites.** Worms. There are many intestinal worms that attack dogs. The most serious one is a variety of *Ascaris*, a roundworm that can cause a high percentage of fatalities in young puppies. Most puppies acquire considerable resistance to them after three months of age, but the majority of dogs have at least light infections. Females about to be bred are usually wormed, bathed, and transferred to thoroughly clean quarters. They can also be wormed as late as seven weeks in pregnancy. If this is not done, the puppies can become infected from the mother, even before birth. Puppies can be given a mild worm expellant (vermifuge) if symptoms develop. Other parasitic roundworms that attack dogs include heartworms, hookworms, and whipworms.

With the exception of rabies, most diseases of dogs are not transmissible to human beings. A rare exception is a tapeworm, *Echinococcus granulosus*, normally transmitted from dogs to sheep through fecal matter but which can accidentally be transmitted to human beings, particularly children. The parasite grows as a cyst and may enter the brain or other vital organs and cause severe symptoms. It is found only where dogs have access to the bodies or entrails of sheep and cattle. Other less harmful varieties of tapeworms occur commonly in dogs and yield to treatment with appropriate worm expellents, or vermifuges. Dogs may become infected with these tapeworms by eating fleas and the uncooked bodies of food animals in which the tapeworms spend part of their life cycle.

**Mange.** Mange is caused by two varieties of mites that live in the hair follicles. An afflicted dog loses his hair, and the affected area is itchy and inflamed. The mites are difficult to kill, successful treatment requiring many weeks.

**Lice.** Lice spend their entire life cycle on the dog and are transferred to new hosts by direct contact. Successful treatment usually requires two or more applications of some oily substance that smothers the lice, or of an insecticide. The developing lice (or nits) are highly resistant, but adult lice are controlled readily, even with soap and water.

**Fleas.** Fleas present a different problem, since they leave the dog during part of their life cycle in order to breed. Those on the animal are easily eliminated with commercial preparations (sprays and powders), but their breeding areas must also be eliminated for control. Larval fleas live on filth and commonly breed around barnyards or other places where animals deposit feces.

**Ticks.** Ticks, which breed in grassy or bushy areas, may attach themselves to a dog as it brushes against the vegetation. Individual ticks are easily removed by applying kerosene or some other oily substance to the ticks' bodies, thus suffocating them and causing them to release their hold.

**Diseases.** Canine distemper. One of the most important diseases of domestic dogs is canine distemper, an airborne, highly infectious virus disease that attacks the nervous system. It runs a long course, with a high proportion of fatalities. The disease can be prevented by inoculation with an attenuated virus.

Puppies nursing on immune mothers are protected by the antibodies obtained in the mother's milk for a few weeks after birth and can be successfully vaccinated only after these antibodies have disappeared.

**Infectious canine hepatitis.** This disease attacks the liver primarily. The early symptom of high fever resembles that of distemper but the disease, which is often fatal, runs a much shorter course. Transmitted by contact through urine, it is less infectious than distemper. Many dogs are carriers, however, and spread the disease long after they have recovered. It can be prevented by inoculation.

**Rabies (hydrophobia).** Rabies (*q.v.*) is an invariably fatal disease that is highly dangerous because it can be

spread to human beings as well as to other dogs and other mammals. The disease attacks the nervous system, chiefly, causing animals to become highly irritable. Infected dogs are so fearless that they bite anything they come across, spreading the disease through the saliva entering the wounds. Many wild animals, such as foxes and rodents, provide a reservoir for rabies. Dogs can readily be inoculated (see INFECTIOUS DISEASES).

**Other ailments.** Finally, dogs are susceptible to many other less common bacterial and parasitic diseases, which vary according to the life of the animal and the climate in which it lives. Dogs are also subject to constitutional ailments such as heart disease and cancer. Congenital defects such as crooked legs and cleft palates are common. As in other traits, dogs show hereditary differences in their resistance to disease, but this trait is greatly aided by good nutrition and proper exercise.

#### GENETICS

Not only are there wide differences between breeds but there is also great individual variability within each breed. All traits are genetically determined, but their expression is more or less modified by the environmental circumstances; behavioral traits especially are influenced by training and experience.

**Colour.** There are certain physical characters the inheritance of which is well-known and highly predictable in breeding experiments. Most of these are based on genes affecting colour. Only a few of the major colour-influencing genes are described below.

The basic wolf-gray or wild-type coat consists of long guard hairs, banded with black and red, and a lighter coloured undercoat, which grows heavily in winter and is shed in summer. The colour is distributed in a basic pattern of "countershading"; more black hair on the top of the body and more red underneath, becoming almost white on the belly. Thus there are two basic pigments, black and red, with the absence of pigment producing white.

In domestic dogs the original coat has been modified in length, texture, pattern, and colour, in a wide variety of combinations. The A series is the major series of genes that modify colour. Given in order of relative dominance, these genes are: coal black, *a\**; red, varying from clear red to red with some dark hair (the so-called sable colouring), *a'*; the wild type or wolf gray, *a"*; and bicolor (black-and-tan), having a clear black on the upper part of the body and clear red below, with red dots over the eyes, *a<sup>1</sup>*.

Other genes may influence the A series: the recessive *ee* changes all black hair to red, and *bb* changes black hair to brown or liver colour. These pigments may be modified still further by other genes to produce all shades from dark to very light.

Another important series of genes produces various degrees of white spotting, ranging from small spots on the tail, feet, and belly through piebald (heavy mottling over the entire body) to almost completely white animals, as in white bull terriers. Hair length and coat texture are also influenced genetically, but less precisely than coat colour. In general, short hair is dominant over long, coarse over fine, straight over curly, wire coat is incompletely dominant over smooth, sparse over dense. There are an enormous number of possible combinations, each breed having a limited but often confusing number.

**Shape and weight.** In body form, there is an ancient mutation for the **upcurved** tail. This is a physiological trait, since the dog can usually straighten his tail; its inheritance is not well-known. There is major mutation for short legs, seen in such breeds as dachshunds and basset hounds; the first-generation hybrids of a mating of a short-legged dog with a normal-legged one have legs that are intermediate in length. The bulldog mutation chiefly affects the head, producing a short and flattened snout accompanied by an undershot jaw. Again, the first generation of a cross between a bulldog and a normal-faced dog has an intermediate appearance. Still another inherited trait is ear carriage, varying from lop ears to erect ones, the lop-eared condition being dominant.

The wild-type coat

One of the outstandingly variable characteristics of dogs is body weight, ranging from as little as 0.9 kilograms (two pounds) in dwarf breeds such as the chihuahua, to 68 kilograms (150 pounds) in some of the large breeds such as the mastiff and St. Bernard. Offspring from crosses between large and small breeds tend to be intermediate in size, and the trait is affected by large numbers of genes.

**Other traits.** The inheritance of behavioral and temperamental characteristics is highly complicated. The behaviour characteristic of a particular breed consists of a combination of several independently inherited traits, each of which is affected by one or two major genes and perhaps other minor ones. The tendency to crouch or sit in cocker spaniels, for example, depends on two independent traits: the crouching posture itself and the tendency to remain quiet.

The danger of preserving unfavourable traits

It is very likely that more than one combination of genes will produce a desirable trait in a dog; therefore, two excellent dogs bred together may produce somewhat inferior offspring, and vice versa. Consequently, most successful dog breeders experiment with matings that give the highest proportion of desirable progeny. Since dogs are long-lived and often fertile, this method of progeny testing can be highly successful. At the same time there is in most pure breeds a large number of undesirable recessive traits of form and behaviour that crop out in certain matings. Many of these are preserved and may be spread throughout a breed if, for instance, a champion male carrying an undesirable recessive trait is widely bred to numerous females. Furthermore, many of the traits desired by dog fanciers, such as the bulldog head, which would be a defect in a wild animal and promptly "selected out" in nature, are perpetuated by man through special care and attention.

#### BREEDS

The British classification, revised periodically by the Kennel Club of England, set the standard that other countries have followed, with some modifications. The Kennel Club recognizes two major classes of breeds: sporting and nonsporting. The sporting division includes the hound, gundog, and terrier groups; the nonsporting division includes the working, utility, and toy groups.

Variations in breed classification

Classifications of recognized breeds vary widely in other countries. The French list recognizes, in addition to hunting dogs, watchdogs, running dogs, 17 kinds of shepherd dogs, and 24 "ladies' dogs," including toy dogs and lapdogs. The German list emphasizes utility dogs and watchdogs, whereas the Swedish list includes nine different spitz breeds.

The current American classification, devised by the American Kennel Club, is somewhat different from the British. It lists six groups of breeds and embraces most of the breeds of other countries. Some breeds on the British list are not recognized in America and vice versa. The American Kennel Club provides registry service for the more than 100 breeds listed below, with the number still increasing.

**Sporting breeds.** These are primarily bird dogs or gun-dogs. The basic breeds were the medieval spaniels, from which the modern setters and pointers were developed—the latter with some admixture of hound ancestry.

Griffon (wirehaired pointing)	Spaniel (American water)
Pointer	Spaniel (Brittany)
Pointer (German shorthaired)	Spaniel (clumber)
Pointer (German wirehaired)	Spaniel (cocker)
Retriever (Chesapeake Bay)	Spaniel (English cocker)
Retriever (curly-coated)	Spaniel (English springer)
Retriever (flat-coated)	Spaniel (field)
Retriever (golden)	Spaniel (Irish water)
Retriever (Labrador)	Spaniel (Sussex)
Setter (English)	Spaniel (Welsh springer)
Setter (Gordon)	Vizsla
Setter (Irish)	Weimaraner

**Hound breeds.** This group includes two main types: (1) sight hounds and (2) scent hounds. The greyhounds are of the first sort, and the closely related saluki and Afghan hound are probably nearest to the original type. The borzoi and Irish wolfhound, as well as the Scottish

deerhound, are related animals. The second main type comprises the scent hounds, of which the foxhounds and beagles are excellent examples. The basset hound, otter hound, bloodhound, and harrier are closely related. Other animals in this group are more miscellaneous.

Afghan hound	Foxhound (English)
Basenji	Greyhound
Basset hound	Harrier
Beagle	Norwegian elkhound
Bloodhound	Otter hound
Borzoi (or Russian wolfhound)	Rhodesian ridgeback
Coonhound (black and tan)	Saluki
Dachshund	Whippet
Deerhound (Scottish)	Wolfhound (Irish)
Foxhound (American)	

**Working breeds.** The largest number of these breeds are derived from various sorts of herding and farm dogs. The second largest group are the guard dogs, again of miscellaneous origin. Finally there are the sled dogs from various Arctic regions.

Alaskan Malamute	Kuvasz
Belgian Malinois	Mastiff
Belgian sheepdog	Newfoundland
Belgian Tervuren	Old English sheepdog
Bernese mountain dog	Puli
Bouvier des Flandres	Rottweiler
Boxer	St. Bernard
Briard	Samoyed
Bullmastiff	Schnauzer (giant)
Collie	Schnauzer (standard)
Doberman pinscher	Shetland sheepdog
German shepherd dog	Siberian husky
Great Dane	Welsh corgi (Cardigan)
Great Pyrenees	Welsh corgi (Pembroke)
Komondor	

**Terrier breeds.** These are typically dogs developed to attack vermin living in the terre, or earth.

Airedale terrier	Lakeland terrier
Australian terrier	Manchester terrier
Bedlington terrier	Norwich terrier
Border terrier	Schnauzer (miniature)
Bull terrier	Scottish terrier
Cairn terrier	Sealyham terrier
Dandie Dinmont terrier	Skye terrier
Fox terrier	Staffordshire terrier
Irish terrier	Welsh terrier
Kerry Blue terrier	West Highland White terrier

**Toy breeds.** These are very small dogs of various origins. Some are merely dwarf editions of larger breeds, in fairly normal form and proportion. Others have heads of the bulldog type, with short flat noses.

ARenpinscher	Pekingese
Chihuahua	Pinscher (miniature)
English toy spaniel	Pomeranian
Griffon (Brussels)	Poodle (toy)
Italian greyhound	Pug
Japanese spaniel	Silky terrier
Maltese	Toy Manchester terrier
Papillon	Yorkshire terrier

**Nonsporting breeds.** This is a miscellaneous group used entirely for companions and show dogs.

Boston terrier	Keeshond
Bulldog	Lhasa Apso
Chow chow	Poodle (miniature)
Dalmatian	Poodle (standard)
French bulldog	Schipperke

**Other breeds.** The Kennel Club (Great Britain) greatly expanded its list in the 1960s and recognized the following breeds not found in the American classification. Hounds: dachshbracke, Finnish spitz, Ibiza hound, Pharaoh hound. Gundogs: German longhaired pointer, Italian spinone, kleine Munsterlander. Terriers: Glen of Imaal, miniature bull, Norfolk, soft-coated wheaten terrier. Utility dogs: Iceland dog, Japanese akita, Leonberger, Mexican hairless, Shih Tzu, Tibetan spaniel, Tibetan terrier. Working dogs: Anatolian sheep-dog, Australian kelpy, bearded collie, beauceron, Maremma Italian sheepdog, Norwegian buhund, Polish sheepdog, Portuguese water dog, Tibetan mastiff. Toys: bichon frise, Chinese crested dog, lowchen. Many American breeders have not sought recognition for certain pure-

bred varieties that they have developed. Others have registered their distinct breeds in organizations other than the American Kennel Club. There are many special strains of hounds, often originating from certain famous packs and some named after their owners. Among American foxhounds, the Walker, Trigg, July, Trumbo, and Birdsong strains are well-known, and coonhounds include the Bluetick, Redbone, Plotthound, and Treeing Walker varieties as well as the black and tan variety recognized by the American Kennel Club.

Other breeds found in various parts of the world include the border collie, Australian cattle dog, Drahthaar, Drechtsche partrijshond, Catalan sheep dog, Istrian pointer, lurcher, Portuguese pointer, Rumanian sheepdog, Sealydale, Svensk vallhund, and many more.

#### BREEDERS' ASSOCIATIONS AND DOG SHOWS

In western Europe and North America, dog breeding has been highly developed as a pastime and business. Dog shows and systematic attempts to improve and maintain dog breeds originated in the latter half of the 19th century. The first recorded dog show was held in Newcastle, England, in 1859, and the first large show was held in Chelsea in 1863. About the same time, the showing of dogs became popular in the United States, and by 1880 an annual show in New York included about 29 breeds.

As dog shows grew in number, a need was felt for some kind of regulating body. The Kennel Club of England filled this need in Great Britain; it was founded in 1873 and became the supreme governing body of dog breeders' associations in that country. A few years later, in 1884, the American Kennel Club was formed, becoming the ruling body of breeders' associations in the United States. Soon thereafter similar organizations were formed in many other countries.

Dog shows are organized by local or national dog clubs. Some dog clubs are devoted to only one breed, whereas others include any breed. Rules for holding shows in the United States are made by the American Kennel Club, and in Britain by the Kennel Club of England.

Show dogs are judged on the basis of breed standards, the various physical characters considered desirable and those considered faults in any particular breed. These standards are not directly concerned with health, vigour, or ability to reproduce; in fact, the quality of the show breeds sometimes suffers in these respects. A popular feature of many shows is the obedience trial, in which dogs are judged on performance rather than appearance.

Field trials, held for hunting breeds, give an opportunity for dogs to compete against members of their own breeds in the performance of hunting duties such as trailing, pointing, and retrieving. There are also standard field trials for shepherd dogs, in which the dog has to herd a small flock of sheep along a prescribed course, cut sheep out of a flock and drive them in a small pen, relying only on signals given by the shepherd. Other working trials are popular in many parts of the world.

**BIBLIOGRAPHY.** The rules applying to registration and dog shows, lists of registered breeds, and information about specialty breeding clubs may be obtained from the American Kennel Club, New York, and the Kennel Club, London.

## Domestication, Plant and Animal

Domestication is the process of hereditary reorganization of wild animals and plants into domestic and cultivated

forms according to the interests of man. In its strictest sense it refers to the initial stage of man's mastery of wild animals and plants. The fundamental distinction of domesticated animals and plants from their wild ancestors is that they are created by man's labour to meet his specific requirements or whims and are adapted to the conditions he alone maintains for them. Without man's continuous care and solicitude, domesticated animals and plants could not exist.

#### GENERAL FEATURES

Domestication has played an enormous part in the development of mankind and its material culture. It has provided man with improved sources of food, materials for clothes and shelter, and means of conveyance and physical work. These benefits contributed enormously to the liberation of man from elemental natural forces and, together with the mastery of fire, were the decisive factors in the passing of mankind from wildness to civilization.

Domestication has resulted in the appearance of agriculture as a special form of animal and plant production. It is precisely those animals and plants that became objects of man's agricultural activity that have undergone the greatest changes when compared with their wild ancestors. Other animal and plant species are bred by man merely to satisfy his whims or aesthetic desires, such as, for example, the pigeons, aquarium fishes, and garden and house plants. While these organisms played no role in the development of the material culture of mankind, they are still considered as domesticated because of the profound changes they have undergone in comparison with their wild ancestors. Animals and plants that are bred by man as objects for scientific studies, however, are not considered as domesticated.

The domestication of most animals and plants is rooted in the remotest past. The history of domestication, which remains in many points obscure, disputable, and contradictory, is gradually being reconstructed from evidence obtained from archaeological studies and from modern systematic, morphological, cytological, and genetic data. The study of ancient literatures and ancient languages sometimes also provides material for the understanding of domestication.

The first attempts at domestication of animals and plants apparently were made in the Old World by peoples of the Mesolithic Period. The tribes that engaged in hunting and in gathering wild edible plants made attempts to domesticate dogs, goats, and possibly sheep as early as 9000 BC. It was not until the Neolithic Period, however, that primitive agriculture appeared as a form of social activity, and domestication was well under way. Although the great majority of domesticated animals and plants that still serve man were selected and developed during the Neolithic Period, a few notable examples appeared later. The rabbit, for example, was not domesticated until the Middle Ages; the sugar beet came under cultivation as a sugar-yielding agricultural plant only in the 19th century; and mint became an object of agricultural production as recently as the 20th century. Also in the 20th century, a new branch of animal breeding was developed to obtain high-quality fur. The objects of fur breeding—the silver fox, polar fox, mink, and coypu, to name a few—are now at the first stage of domestication, as are also some deer bred by man for the alleged curative properties of their antlers. New plant species have also been introduced to cultivation relatively recently, among them the ginseng, which is intensively cultivated in Eurasia as a medicinal plant. Thus, the process of domestication of animals and plants continues to meet the many different material and aesthetic requirements of man.

#### THE CIRCUMSTANCES SURROUNDING DOMESTICATION

**Human settlements as a precondition.** Plant and animal breeding, even under conditions of primitive agriculture, required a settled way of life and a certain number of people in settlements, which, in turn, would be impossible without sufficient food resources. Settlements,

The significance of domestication

Types of shows

## The beginnings of domestication

therefore, were located near rivers and other freshwater reservoirs, which offered possibilities for fishing. Mountain valleys and their plateaus, which contain a great variety of plant and animal forms, offered many candidates for domestication. It is, therefore, supposed that the first domestication centres were forested valleys with clearings that could be used for primitive agriculture.

The reasons that impelled man to domesticate the first plants and animals and the circumstances that contributed to it are unknown. The idea that the beginnings of domestication were imposed on many by hunger does not seem plausible. A man living under permanent pressure of hunger would very likely not engage in domestication, which involves the storage of seeds and the breeding of animals. It is far more likely that a hungry man would eat the means of continued production—the seeds and the stock. More plausible is the hypothesis that domestication was initiated by people already organized in settled communities that had access to the necessary minimum of food, probably from nearby lakes or rivers. Decisive in the development of the domestication process was the gradually acquired understanding that domesticated plants and animals are the most reliable sources of many of man's vital requirements.

**The impulsion to domesticate.** It is difficult to tell precisely what were the direct reasons that impelled primitive settlers to undertake the first domestication experiments. Perhaps having already experienced the taste of certain wild plants, especially those that reproduce themselves by tubers or rootstocks, man tried to grow them near his dwelling place. The very first success of this experiment convinced the settler of the usefulness of cultivation and naturally led to repetitions and, subsequently, to improvement of its methods. In this initial stage of plant domestication, using mainly vegetatively reproducing plants, particularly the tuberous sorts, man first assured himself of a reasonably reliable source of carbohydrates.

Next came domestication of the seed plants—cereals, legumes, and other vegetables. Some plants were domesticated for the strong fibres in their stalks, which man used for such purposes as making fishing nets. Hemp, one of the most ancient plants domesticated in India, is an example of a multipurpose plant: oil is obtained from its seeds, fibres from its stalk, and the narcotic hashish from its flowers and leaves.

Some plants were domesticated especially for the production of narcotics; such a plant is tobacco, which was probably first used by American Indian tribes for the preparation of a narcotic drink and only later for smoking. The opium poppy is another example of a plant domesticated solely for a narcotic. Beverage plants of many kinds were discovered and cultivated, including tea, coffee, and cola. Only when man reached a sufficiently high level of culture did he begin to domesticate to fulfill his aesthetic requirements for the beautiful and the bizarre in both plants and animals. Thus, plant domestication and, later, plant breeding became possible because man, at the dawn of his culture, could appreciate the properties and qualities of many wild plants and use those that met his special needs in the best way.

The direct reasons that impelled man to domesticate the first animal are less understandable than the reasons for plant domestication. The process may have begun as the result of sporadic cases of man rearing an animal. There is a widespread and quite understandable idea that hunters who killed an adult animal would take along any young ones, which would become children's and women's pets. Lending credence to this notion is the fact that even today the women of some peoples of tropical America and Polynesia nurse certain animals who may have lost their mothers.

## Economic application of domestication

The specific economic application of domesticated animals did not appear at once. Dogs probably accompanied hunters and helped them hunt wild animals; they probably also guarded human settlements and warned the inhabitants of possible danger. At the same time, they were eaten by man, which was probably their main importance for man during the first stages of domestication.

Sheep and goats were also eaten in the initial stages of domestication but later acquired those qualities of milk production and of wool and down that made them valuable for those commodities.

One point of view concerning the domestication of cattle is that such animals were first used as sacrificial animals, and thus religion was the impelling force for domestication. Despite documentation of such ritual use of cattle, the principal aim of cattle breeding in ancient times was to obtain meat and skin and to produce work animals, which greatly contributed to the development of agriculture. Cattle, at the initial stages of domestication, produced a small amount of milk, sufficient only to rear their calves. The development of high milk yield in cows with their breeding especially for milk production is a later event in the history of domestication.

The first domesticated horses were also used for meat and skin. Later the horse played an enormous role in the waging of war. Peoples inhabiting the Middle East in the 2nd millennium (2000–1000 BC) used horses in chariot battles. With time the horse began to be used as transportation. In the 1st millennium (1000–1 BC), carts appeared, and the horses were harnessed to them; other riding equipment, including the saddle and the bit, seems to have appeared in later centuries.

The donkey and the camel were used only for load transport and as means of conveyance; their unpalatability ruled out their use as a preferred food.

The first domesticated hens perhaps were used by man for sport; cockfighting was instrumental in bringing about the selection of these birds for larger size. Cocks later acquired religious significance. In Zoroastrianism the cock was associated with protection of good against evil and was a symbol of light. In ancient Greece it was also an object of sacrifice to gods. It is probable that egg production of the first domesticated hens was no more than five to ten eggs a year; high egg yield and improved meat qualities of hens developed at later stages of domestication.

Early domestication of the cat was probably the result of the pleasure experienced from keeping this animal. The cat's ability to catch mice and rats was surely another reason that impelled man to keep cats at his home. In ancient Egypt the cat was considered a sacred animal.

Some animals were domesticated for utilitarian purposes from the very beginning. Here belongs, first of all, the rabbit, whose real domestication was carried out from the 6th to the 10th centuries AD by French monks. The monks considered newborn rabbits fish and ate them when the church calendar indicated abstinence from meat.

For the sake of honey, the bee was domesticated at the end of the Neolithic Period. Honey has played an enormous role in man's nutrition since ancient times; it ceased being man's sole sweetening agent only about 200 years ago. Bees also provided man with wax and with bee venom, which was used as medicine. Bees were used also, to a limited extent, in warfare, hives being thrown among enemy troops to rout them.

To obtain silk, the silkworm was domesticated in China no later than 3000 BC, and by 1000 BC the technology of silkworm breeding and raising had been thoroughly documented.

Thus, domestication, which appeared under the influence of different circumstances as a natural event in the social and cultural evolution of mankind, has involved increasingly larger numbers of wild animals and plants and has resulted today in the creation of many thousands of varieties of domesticated and cultivated forms without which man's existence is unthinkable.

## THE MAIN CENTRES OF DOMESTICATION

Domestication of plants and animals was not a onetime event, and it was not a prerogative of any one people. The existence of centres of origin of plants and animals, however, does not mean that domestication was realized within narrow geographical zones.

**Centres of origin of cultivated plants.** Contributions to the modern knowledge of the main centres of origin of

cultivated plants were made by the Soviet biogeographer N.I. Vavilov. His works, coupled with later archaeological findings, indicate the main areas of domestication and the formation of primary plant-breeding cultures.

As the main criterion for localization of the centres of origin of cultivated plants, Vavilov investigated the geographical locales of wild ancestors of modern cultivated plants. He called these locales "genecentres" and distinguished between primary genecentres, regions where the ancestors of modern cultivated plants are still present, and secondary genecentres, regions where certain plant species found their greatest expansion and where the greatest number of their varieties appeared. Many plants and animals appear from the evidence to have arisen in more than one genecentre. Accumulated evidence since Vavilov's time has suggested the following eight principal genecentres of plant origin and domestication: Indonesia-Indochina, China-Japan, middle Asia, Middle East, Mediterranean, Africa, South America, and Central America.

**Indonesia-Indochina.** This genecentre occupies vast areas of Southeast Asia and is the area of origin mainly of vegetatively propagating plants, such as the banana, sugar palm, sago palm, coconut palm, breadfruit, bamboo, sugarcane, taro, yam, and durian.

According to the U.S. biogeographer C.O. Sauer, the most ancient domestication appeared within this genecentre, perhaps near what is now India-Indochina, probably in the early Neolithic Period. After many generations of purely vegetative propagation, many plants that had been able to propagate themselves by seeds lost this ability under continued selection by man. They changed in other respects, as well, and formed what are called clones of cultigens, plants vegetatively related and maintained by man. Among man's cultigens are the banana, taro, yam, sugarcane, sago and sugar palms, durian, and mangosteen.

**China-Japan.** The China-Japan genecentre (east China, Korea, and Japan) produced such plants as rice, millet, soybean, perilla, tea, tung, and mulberry. Some of the above-mentioned plants have important secondary genecentres; such is the soybean, which, after entering North America in the 19th century, began a diversification into a great number of varieties.

**Middle Asia.** This is the southwest Asia genecentre of Vavilov. It includes Afghanistan, Tajikistan, Uzbekistan, and west Tien Shan and is the genecentre for peas, flax, carrot, onion, almond, walnut, grape, alfalfa, and a number of fruit trees and berries.

**Middle East.** This area includes Turkmeniya, Iraq, Transcaucasia, Asia Minor, and Arabia. It is the primary centre of origin of wheat, rye, barley, oats, chick-pea, lentil, vetch, melon, chestnut, pear, quince, and hazelnut. Independently of the middle Asia genecentre, peas and onions were also domesticated in the Middle East genecentre.

**Mediterranean.** This region is the primary centre of origin of oats, olive, cabbage, rutabaga, flax, lupines, oak, and lavender.

In addition, the Mediterranean area is a secondary genecentre for many plants primarily domesticated in the Orient, including large-seeded pod-bearing plants and improved wheats in a large number of varieties.

**Africa.** Africa is the primary genecentre for sorghum, African rice, sesame, castor bean, cotton, watermelon, cowpea, coffee, oil palm, and kola nut, and a secondary genecentre for many varieties of wheat, barley, and oats.

**South America.** The South American genecentre, extending over Brazil, Argentina, Peru, and Chile, seems to be the most ancient focus of plant domestication and primitive agriculture of the New World. Here, in the 3rd and 2nd millennia (3000-1000 BC), there already existed settled tribes engaged in plant cultivation. It is possible that some plants had been cultivated still earlier. As in the Old World, the first domesticated plants were vegetatively propagated tuberous species rich in starch: manioc, sweet potato, yautia (*Xanthosoma*), sorrel (*Mollina*), ullucu (*Ullucus tuberosus*), and tuberous nasturtium (*Tropaeolum*).

Later, seed plants, such as the tomato, peanut (groundnut), and pineapple, were also domesticated. A large number of potato varieties appeared, but the one that was cultivated became the domestic potato now used over most of the world.

**Central America.** This genecentre spreads over the area of Mexico, Guatemala, Costa Rica, Honduras, and Panama. Settled agriculture in this area developed in the 2nd millennium, but as early as the 6th millennium (6000-5000 BC) some domesticated plants (e.g., pumpkin and peppers) were known and used.

This region is the origin of such plants as corn (maize), kidney bean, pumpkin, and cotton. In the same region a series of potato species was domesticated, some of them still being cultivated in Central and South America. This genecentre is the homeland also of red pepper, avocado, sunflower, agave, cocoa, and tobacco.

**Plant-animal complexes.** According to Sauer, animals that lived near man's dwellings (such as dogs and pigs and, later, chickens, ducks, and geese) were domesticated in the regions of domestication of vegetatively propagating plants. Thus, in Southeast Asia there appeared a peculiar complex of domesticated animals and plants that spread in three main directions: northward to the territory of modern China and Japan; westward and southward to Equatorial and South Africa; northwestward to Central Asia and Asia Minor and farther on, across the Mediterranean coast toward the Atlantic.

The pig spread especially far northward—to China, where it gave origin to many domestic breeds. The distribution of the pig to northwest Africa and to middle Asia and Asia Minor, however, met with serious obstruction. The obstacles consisted, on the one hand, of unfavourable climate and disease organisms and, on the other hand, of the religious laws of certain faiths that prohibited the eating of pork. In this connection, the Asian pig in Africa either died out or became wild; nevertheless, it penetrated into the Middle East and farther on into the Mediterranean area and the Caucasus.

The chicken, goose, and duck, domesticated at first in Southeast Asia, spread all over the world; however, the goose and duck, which were bred in great numbers in Egypt, Greece, ancient Rome, and China, were probably domesticated in those countries during the 1st millennium BC independently of the Southeast Asian centre.

In southwest Asia, in the regions of domestication of seed plants, the domestication of herd animals, such as cattle, sheep, goats, and horses, took place.

It is difficult to tell which of the centres of domestication and of primary agriculture is more ancient, the east Asian or the west Asian. Sauer claimed that the east Asian was the more ancient. Later investigations suggest that the west Asian agriculture began earlier, in the Mesolithic or early Neolithic Period. Possibly, both of these centres appeared and developed simultaneously and independently of each other; in any case, there is no recorded evidence that the east Asian domestication centre is more ancient than the west Asian.

Shepherdy and nomadic animal breeding, which determined the social and economic organization and the way of life of some peoples to a great extent, appeared at later stages of human development, after the accumulation of a large number of domestic animals. Rudiments of nomadic animal breeding in Eurasia appeared no earlier than 1000 BC, considerably after the domestication of animals took place. The only exception seems to be the deer, whose domestication was carried out by nomadic tribes of central and north Europe.

The process of domestication and formation of primary agricultural and animal-breeding cultures in the New World took place somewhat later than in the Old World and independently of the latter. This is connected with the fact that man first appeared in the New World only during the Pleistocene, long after he had settled vast areas in the Old World.

#### A SURVEY OF SELECTED DOMESTICATED ORGANISMS

In the following section a few prominent plants and animals will be considered to exemplify the method of in-

The spread  
of domesti-  
cation

vestigation of origin, the special biological event that gave rise to the domesticated animal or plant when evidence is clear enough to warrant it, and the movements of organisms from their points of origin.

Traditionally, the main criteria for judging relationships between domestic or cultivated organisms and wild ancestors are similarities of structure and function, but cytogenetical examinations, particularly comparisons of chromosomes and chromosome sets, also are adding to the knowledge of the origins of domesticated organisms.

**The rise of cultivated crop plants.** *Wheat.* Cytogenetics helped to establish the origin of wheat, one of the world's most important food crops. Species of wheat differ in the degree of ploidy—i.e., in the number of chromosome sets in their cell nuclei. The einkorn wheat, for example, which seems to have been involved in cultivation earlier than all other wheats, has 14 chromosomes (the common diploid set). There then developed tetraploid wheat, with 28 chromosomes, such as durum wheat, which is used mainly for macaroni products, and hexaploid wheat, with 42 chromosomes, to which belong all the varieties of common wheat.

The einkorn, which is now cultivated only in some parts of Spain and Transcaucasia, takes its origin from a diploid 14-chromosome wild species. The tetraploid wheats appeared as the result of crossing the einkorn with a wild, 14-chromosome cereal, *Aegilops* (or *Triticum*) *speltoides*. Some of the tetraploid species seem to have been domesticated between 8000 and 7000 BC and certainly have been domesticated in the Orient for a few thousand years. Subsequent natural crossing of tetraploid wheats with another wild cereal (*Aegilops squarrosa*, or *Triticum tauschii*) resulted in the appearance of 42-chromosome, or hexaploid, wheats. These crossings all took place directly in nature in the zone of the primary origin of wheat, and man simply domesticated already existing, though still primitive, forms of wheat. With subsequent selection of wheat in many countries for many centuries, great variety and high perfection of forms of this plant have resulted.

**Rice.** Rice is another most important crop, consumed by almost half the world's population. Of about 20 wild rice species known in Asia, Africa, America, and Australia, only two have been cultivated: the Asian species *Oryza sativa* and the African species *O. glaberrima*, both of which spring from perennial rice, *O. perennis*. In Southeast Asia the cultivation of rice has been known for 4,000 to 5,000 years and seems to have begun still earlier.

**Corn.** Corn (maize), a New World plant, belongs to a genus having only one species, *Zea mays*, with a series of subspecies differing in morphological peculiarities of the grain. In the process of domestication, man selected corn for well-developed husks, which protected the ear from breaking, and for ears surrounded by leaf sheath. During domestication, corn hybridization seems to have taken place with such cereals as teosinte and gama grass, with which some forms of corn still show similarities. Corn spread into Europe through Spain after Columbus' second voyage (1494) and then spread all over Eurasia and Africa.

**Barley.** Barley belongs to the genus *Hordeum*, which includes more than 20 wild species, mostly perennial; the domesticated forms, however, are annual. As shown by cytogenetical studies and archaeological findings, only one species seems to have been domesticated (as early as the period 7000 to 6000 BC), namely, *H. spontaneum*, which bore grain in two vertical ranks. Modern barley, with six vertical ranks, appeared in the process of further domestication as a result of genetic mutations.

**Oats and rye.** Oats and rye were domesticated much later, in the epoch when man had already mastered metals. Before that, these grains existed as wild plants contaminating wheat sowings. As the wheats spread to the north, the volunteer oats and rye, being cold resistant, survived, while the wheat perished. In such a manner, natural selection helped man involve oats and rye in his cultivation.

Modern cultivated oats (*Avena sativa*) seem to take their

origin from *A. byzantina*, and cultivated rye, which is now represented only by *Secale cereale*, springs probably from the *S. segetale*.

**Potato.** The origin of the potato is a more complex matter. Among the many species of this plant found in Central and South America, cultivated varieties and forms are represented primarily by the tetraploid, 48-chromosome species *Solanum tuberosum*. This species, which has not been found wild, has not yet been related clearly to an ancestral form. In South America another 48-chromosome potato, *S. indigenum*, is also cultivated; it differs from *S. tuberosum* in certain structural and functional features but so slightly that some experts consider them a single species.

**Soya.** Soya, one of the most ancient leguminous plants, belongs to the genus *Glycine*, which numbers more than 40 wild species. The ancestor of cultivated soya is probably *G. ussuriensis*, which was domesticated in China in about 3000 BC and then penetrated, already as a cultivated form, into Korea and Japan and, in the 19th century AD, into other countries.

**Sunflower.** One of the main oil-producing plants is the sunflower, whose genus, *Helianthus*, numbers about 50 wild species in its homeland, North America; more than 15 more species grow in South America. The cultivated sunflower is considered to have sprung from the wild species *H. lenticularis*, inhabiting the dry plains of North America. Much breeding and selection of the sunflower to yield varieties containing seeds with more than 50 percent oil have been carried on in the Soviet Union.

**Pumpkin.** The origin of the pumpkin, one of the most important ancient vegetables, is obscure. In Central and South America there are a few pumpkin species; two have been cultivated, *Cucurbita pepo* and *C. moschata*.

**Cotton and flax.** Among fibrous plants, the most important is cotton (*Gossypium* species), wild species of which inhabit all the continents except Europe. Four species have been cultivated: two 26-chromosome species in the Old World (*G. herbaceum* and *G. arboreum*) and two in America (*G. raimondii* and *G. thurberi*). Currently, two tetraploid species (*G. hirsutum* and *G. barbadense*), which originated in South America, are cultivated. Cytogenetical analysis has shown that both species originated from a cross between diploid cottons of the Old World and the New World, with subsequent duplication of chromosome number. Where and when this hybridization took place, however, remains obscure. In Mexico, products of cotton have been found in excavations dating from about 2400 BC. The seeds of tetraploid cotton were carried to Africa and Asia after the discovery of America by Columbus.

The second most important fibrous plant is flax (*Linum* species). Cultivated flax (*L. usitatissimum*), which has differentiated into oil-producing and fibre-producing forms, is considered to take its origin from the wild flax, *L. angustifolium*. Flax was first cultivated in mountainous regions of India and China in about 5000 BC; it spread westward, where, in the mountains of middle Asia, there appeared the oily-crown flax, and, farther on, in the Mediterranean area, fibre flax.

**Tobacco.** Tobacco belongs to the genus *Nicotiana*, which includes more than 60 species spread over North America and Australia. The homeland of the cultivated tetraploid tobacco, *N. tabacum*, is Mexico, where it originated from a cross between *N. silvestris* and *N. otophora* (or *N. tomentosiformis*), with subsequent duplication of chromosome number. It reached the Old World after Columbus.

**Tea.** Tea is a shrub of the genus *Thea*. According to some experts, at least four species of cultivated tea occur in east Asia. In south China the ancestor of cultured species, *Thea monticola*, is widespread. Tea was taken into culture in south China and, perhaps independently, in Indochina.

**Coffee.** Coffee belongs to the genus *Coffea*, the 50 or 60 species of which inhabit Africa. Most of the species are diploid and have 22 chromosomes. The cultivated species *C. arabica* also includes forms with chromosome numbers 44 and 66. It grows in Ethiopia in a wild or es-

**caped** state and is cultivated in the tropical countries of Africa, Asia, and America. It was first taken into culture in the 15th century AD, in Arabia. From there coffee passed to Europe and, in the 18th century, to America.

**Apple tree.** One of the oldest fruit trees is the apple (*Malus* species), with a few dozen wild species in east and west Asia, in Europe, and in North America. The great majority of current varieties are hybrids; some developed as the result of bud mutations, or sports, on an otherwise uniform tree.

**Grape.** Grape belongs to the genus *Vitis*, which includes about 50 species inhabiting the Northern Hemisphere, mainly North America, where some wild species have been cultivated since ancient times for both food and wine production.

In Eurasia the grape was domesticated independently and was introduced into cultivation 7,000 to 9,000 years ago. The cultivated grape of the Old World *V. vinifera* seems to have originated from a wild species, *V. sylvestris*, which spread from Gibraltar to middle Asia. From different local forms of this species originated various protected cultivated forms.

**The rise of domestic animals.** The questions of the origin of domestic animals are also worked out on the basis of comparative morphological, physiological, and partly genetical and cytogenetical studies. Biochemical methods, including studies on blood composition, are also used.

**Dog.** The origin of the dog has provoked much dispute, which is understandable when the enormous variety of modern breeds is considered. It has been supposed that man domesticated wolves and jackals in different locales or that there existed a special ancestor of the modern dog (see also DOG). Currently, another point of view holds that the wolf (*Canis lupus*) was the only wild ancestor of the domestic dog. It was domesticated in different places by different tribes. Then the domesticated wolf dog (*C. familiaris*) seems to have backcrossed repeatedly with the wolf in different places.

**Sheep.** The domestic sheep originated from different subspecies (or races) of the Eurasian wild sheep *Ovis ammon*. Another wild sheep, *O. canadensis*, uniting a series of subspecies in northeast Asia and America, seems not to have played an important role in the origin of domestic sheep. There seem to have been two main domestication centres of wild sheep: the Middle East and middle Asia. The earlier prevailing idea about a south European centre of sheep domestication is now doubtful. Under intensive domestication a great variety of specialized breeds appeared for the production of different kinds of wool, of meat, and sometimes of milk.

**Goat.** The wild ancestor of the domesticated goat is *Capra hircus*, belonging to the same subfamily (Caprinae) as the sheep. It is supposed that the only wild subspecies from which the domestic goats took their origin was *C. hircus aegagrus*, inhabiting the mountainous regions of Asia Minor, which seem to have been the main focus of its domestication.

**Cattle.** Modern cattle appear to have descended from the aurochs (*Bos primigenius primigenius*). There seem to have been several centres of domestication: eastern Europe, middle Asia, and Southeast Asia.

The hump characteristic of zebu-like cattle appeared early during domestication. It is thought that India was the homeland of primitive cattle and that they then expanded to Eurasia and North Africa. These primitive cattle were characterized by a great variety of forms, from which, by subsequent selection, man obtained many breeds with high degrees of specialization and uniformity as meat or milk producers or as beasts of burden.

Some species allied to the aurochs also underwent domestication; e.g., the yak (*Poephagus grunniens*), ranging in the mountains of Tibet, in Pamir, in some regions of middle Asia, and in south Siberia. In India, Indochina, and the islands of the Malay Archipelago, species belonging to the genus *Bibos* were domesticated, including the banteng (*B. banteng*), also called Bali cattle, and the gayal (*B. frontalis*), especially selected and bred in India and Burma.

**Horse.** The origin of the domestic horse (*Equus caballus*) is extremely problematic. The ancient ancestors of modern horses possibly originated in Asia, flourished during the Oligocene Epoch (about 38,000,000 to 26,000,000 years ago) in North America, and then died out, but not before their representatives migrated to the Old World. They quickly spread all over Eurasia, some even reaching Africa. The direct ancestor of the modern domestic horse is thought to have inhabited a wide area from western Europe to northern Asia. One of the races of this ancestor, Przewalski's horse (*E. caballus przewalskii*), is believed to be the form that was domesticated by man. Przewalski's horse ranged the steppes of south Siberia, Mongolia, and northeast China, where small herds are now protected. On the basis of chromosome-number studies, some experts believe that Przewalski's horse is a different species, though they do not deny the origin of the domestic horse from Przewalski's horse. Other experts suggest that both Przewalski's and the domestic horse originated from a common ancestor and have evolved independently of each other.

**Camel.** There are few conclusive data on the origin of the domestic camel. Although the two-humped camel (Bactrian) was domesticated in the Middle East and the one-humped camel (Arabian) was domesticated in middle Asia, they are both assigned to the genus *Camelus*. An allied genus, *Lama*, includes the guanaco, llama, alpaca, and vicuña. Not much is certain about their origins except that both of these genera are believed to have originated from North American ancestral forms.

**Pig.** Until recently it was supposed that the domestic pig originated from different species of wild pigs belonging to the genus *Sus*. Now, however, it is believed that the only ancestor of the domestic pig is the wild species *Sus scrofa*, whose geographic range is very wide throughout Eurasia. In Southeast Asia and Indochina a few local forms of the wild pig were domesticated; of them, *Sus vittatus* provided the greatest contribution in the formation of domestic breeds. Independently in Europe, the local race of *Sus scrofa* was domesticated and gave origin to a great number of European breeds. Many modern breeds are the result of hybridization between breeds of Asian and European origins.

**Cat.** The domestic cat, *Felis catus*, originated from the African wildcat, *Felis lybica*, whose area included the Balearic Islands, Corsica, Sardinia, Africa, Arabia, and India. The domesticated cat seems to have been crossed repeatedly with the European wildcat, *F. silvestris*, which itself has never been domesticated.

**Chicken.** The main ancestor of domestic chickens is the red jungle fowl *Gallus gallus*, whose original home is chiefly India. It is possible that, at early stages of domestication, *G. gallus* crossed with a kindred species, *G. sonnerati*, and that the resulting form gave rise to later breeds.

**Rabbit.** The only ancestor of the domestic rabbit, *Oryctolagus cuniculus*, is a wild species whose area, after the last glaciation, occupied the Iberian Peninsula but then spread southward to Morocco, Algeria and northward over Europe.

**Bee and silkworm.** Two bee species are involved with man: *Apis mellifera*, whose natural range is Africa, Europe, and the Middle East, and *A. cerana*, native to India, Indochina, and Japan. Of the greatest economic importance all over the world is *A. mellifera*, and several distinct bee breeds have been created from geographical varieties.

Out of about ten silk-producing lepidopteran species, only one has been domesticated, the silkworm moth (*Bombyx mori*), whose caterpillars feed on mulberry leaves. Although other moths spin silk cocoons, these species have not been truly domesticated and have no economic importance.

#### THE BIOLOGICAL CHANGES ACCOMPANYING DOMESTICATION

Expressed alterations. During the 10,000 or 11,000 years that have passed since the beginning of domestication, the animals and plants that man has selected as useful to him have undergone profound changes. The con-

Consequences of domestication

sequences of domestication are so great that the differences between breeds of animals or varieties of plants of the same species often exceed those between different species under natural conditions. Even the most superficial comparison of the tremendous range of shapes and sizes of modern dog breeds or of garden plants is sufficient to establish the extent of the alterations brought about by domestication and the rate at which evolution accelerated under domestication.

Domesticated animals differ from their wild ancestors and from each other in a number of physical and biochemical features and, most importantly, in behavioral traits. Especially changed are the characters for which man originally chose to domesticate the animals. The wild ancestors of cattle gave no more than a few hundred grams of milk; the best milk cow now can yield 12,000 to 15,000 litres of milk during its lactation period.

The character of sheep wool has thoroughly changed since sheep underwent domestication. In the ancestors of domestic sheep, wool (which served as protection for the skin and as a means of insulation) consisted mainly of thick, rough hairs and a small amount of down; the total weight of wool grown per year never reached one kilogram (2.2 pounds). The wool of present-day fine-fleeced sheep consists of uniform, thin down fibres; the yearly total weight may reach 20 kilograms (44 pounds).

The behaviour of domesticated animals differs from that of wild animals. Wild animals tend to avoid man and, as a rule, fear him; domestic animals not only live with man and submit to him but, in some cases, actively seek his approval and affection.

The most important consequence, and perhaps the most demonstrative manifestation, of domestication of animals consists of a sharp change in their seasonal biology. The wild ancestors of domesticated animals are characterized, for example, by strict seasonal reproduction and molting rhythms. Most domesticated species, on the contrary, can reproduce themselves at almost any season of the year and molt little or not at all, according to a seasonal pattern.

No less characteristic are the changes that occur in plants as a result of domestication. Their structure and general appearance may be drastically changed. The enormous variety of cultivated cabbages—with respect to form and colour of leaves, size and form of the heads and stalks, and degree of development and form of the flowers—is one of the many examples of the kinds of changes that can occur when a single wild species is domesticated.

Still more demonstrative are the dramatic changes that have occurred in decorative plants, whose qualities of flower form and colour have been developed to great lengths under intensive selection by man. Not so apparent but still significant are the many physiological and biochemical changes that plants undergo with domestication. Some of these changes are most notable in cultivated cereals. Wild and primitive cereal forms, particularly wheat, are characterized by fragility of the spike, which is a natural adaptation for the spread of seeds. Cultivated cereals, however, are characterized by the strength of the spike and the clinging of the grain, without which harvesting would be all but impossible. In all cultivated legumes and oilseed plants, covered and indehiscent (closed) fruits are characteristic, whereas the wild ancestors showed dehiscent fruits, the splitting open of which ensured the dispersal of seeds. Among seed-crop plants generally, large seed size is characteristic, as well as simultaneous germination of seeds and simultaneous ripening of fruits. The chemical composition of domesticated plants is frequently different from the wild ancestors. Primitive sugar beets, for example, contained only 3–4 percent of sugar in their roots, whereas modern varieties contain as much as 17 percent.

Even at the initial stages of domestication, some morphological changes in animals and plants are apparent. In mink, for example, which became objects of breeding for fur in about 1920, there have already appeared more than 20 different variations of fur colour and several variations in fur texture.

**The underlying genetic alterations.** Genetic analysis has shown that domestic forms develop on the basis of mutations of certain genes existing in a hidden (or recessive) state in the wild species; these genes assert themselves when matings are restricted and when selection by man is exerted on small groups of animals at the very first stages of domestication.

The elementary genetic mechanism that draws the recessive genes out from the cover of the wild genotype of the natural species also brings about the first domestication-dependent changes and the initial differentiation of a wild species into types that can serve as the basis for superior breed formation. This mechanism is characteristic in both animals and plants. In rye, for example, cultivation has uncovered hidden genes that result in plants that differ from wild rye in seed colour, in having short and strong straw, and in lacking a waxy film on plant parts.

Nature, in effect, has a store of various types and forms hidden as recessive mutations in every natural population of wild animals and plants. It is this accumulated mutation pool that man exploits when he selects and breeds organisms. Such interference by man, called artificial selection, plays a truly creative role in the formation of modern animal breeds and plant varieties to suit the needs of man. In selecting, first without any definite aim and then consciously, the forms that have best met his requirements, man has gradually created, by emphasizing features he has desired and de-emphasizing features he has disliked, a long list of plants and animals he cannot now live without. The material for natural and artificial selection is constantly being replenished in all populations of organisms.

Important in domestication-induced changes is the role played by a special category of chromosomal variability called polyploidy; *i.e.*, the multiplying of chromosome sets. A great portion of cultivated plants are allopolyploids, forms that appeared as the result of hybridization of different species, with subsequent duplication of chromosome number in hybrids; such are wheat, oats, cotton, potato, rutabaga, cabbage, plum, and strawberry.

As indicated above, domestication has sped up the evolutionary process. Important factors in this acceleration are the protection that man afforded his domesticates, thus allowing them to survive, and the specific consequences of artificial selection, which, especially at the first stages of domestication, seems to have been particularly influential on the character of individual development and variability of organisms. In this sense it differs considerably from natural selection, which creates stabilized biological systems that ensure the development of a normal, or so-called wild, phenotype; *i.e.*, an organism containing a wealth of properties that preadapt it to a wide variety of environmental conditions and ensure continuation of the species. Artificial selection breaks down precisely these stabilized systems, thereby creating gene combinations that could not survive in nature and providing a range of new possibilities.

Destabilization phenomena are especially clear in studies of the role of selection for behaviour in domestication. There can be no doubt that taming was one of the very first conditions of animal domestication. Docility and the capacity to be tamed seem to be genetically determined, like other aspects of behaviour; however, they are associated also with levels of regulatory substances called hormones, including those that regulate seasonal activity. A shift in hormonal levels as a result of selection for docile behaviour during the first stages of domestication brought about destabilization and rearrangement of some of the most vital functions of animals.

Since hormones influence all the vital processes in animals and in plants, selection involving the hormonal system cannot help affecting the basic mechanisms of individual development. It is possible that on this basis and by the accumulation of different mutations, selection has operated to provide the necessary raw material for domestication.

## Dominic, Saint

St. Dominic, the founder of the Order of Friars Preachers, known also as the Dominicans, introduced in the 13th century a dramatically new form of religious order that had a universal mission of preaching (to pagans as well as to Christians), a centralized organization and government that included democratic elements, and a great emphasis upon scholarship. Dominic's innovative leadership, together with that of St. Francis of Assisi, the founder of the Franciscan Order, greatly influenced the rapid development of the orders of mendicant friars, whose members were not attached to any particular monastery and thus were free to be sent wherever their services were needed; the friars renounced all property through a vow of poverty and depended upon active work, such as preaching and teaching, and charity to subsist.

Domingo de Guzmán was born at Caleruega in Castile,

possibly a year or two later than 1170, the traditional date. His father was lord of the manor in the village, and his mother was also from the local nobility. He studied at Palencia and then joined the canons regular (a religious community attached to the cathedral of a diocese) of Osma about 1196 and he became subprior, or assistant to the superior, a few years later. In 1203, Diego, bishop of Osma, was sent on a royal mission abroad and took Dominic with him.

This journey first made Dominic aware of the threat posed to the church in the south of France by the Albigensian heretics, or Cathari, who were reviving and developing the Manichaean teaching that two supreme beings, Good and Evil, dominate spirit and matter respectively, so that whatever concerns the body-eating, drinking, marriage and procreation, and the possession of worldly goods—is essentially evil, and the ideal is the renunciation of these things and even of life itself. Thus, there arose among them a caste of the "perfect," who led a life of great austerity, while ordinary people were regarded as reprobates. A regularized Albigensian hierarchy had come into existence, and local feudal lords, especially the count of Toulouse, supported the Albigenses. Pope Innocent III had launched a mission to preach against the heresy.

On a second journey Dominic and the Bishop visited the Pope, who refused their request to preach to the pagans, so they returned to France. In 1206 the papal legates and preachers, depressed at the failure of their mission, consulted the Bishop and Dominic, who reasoned that the heretics would be regained only by an austerity equal to their own; the preachers must tramp the roads barefoot and in poverty. This was the birth of Dominic's "evangelical preaching." An important part of his campaign was the establishment of a convent of nuns at Prouille, formed in 1206 from a group of women converted from the heresy.

In 1208 the papal legate, Peter de Castelnau, was murdered by an emissary of the Count of Toulouse. The Pope called upon the Christian princes to take up arms. The leader on the papal side was Simon de Montfort, earl of Leicester and a subject of the King of France. The Albigensian leader was Raymond VI, count of Toulouse, an opponent of the King of France and brother-in-law of King John of England, lord of neighbouring Aquitaine. Dominic's work, though confined to the Prouille area, continued, and six others eventually joined him. Meanwhile, the civil war dragged on until Simon's victory at Muret in 1213. The Catholic party entered Toulouse, and Dominic and his friends were welcomed by the bishop, Foulques, and established as "diocesan preachers" in 1215.

From Foulques's charter in that year Dominic's design for an order devoted to preaching developed rapidly. A characteristic concern was for the theological formation of his men, whom he therefore took to lectures given at Toulouse by an Englishman, Alexander Stavensby. Still in 1215, he went to Rome with Foulques (bound for the Fourth Lateran Council) to lay his plans before the Pope, who, however, recommended adoption of the rule of one of the existing orders. It was, perhaps, at this time that Dominic met Francis of Assisi (though the meeting may not have taken place until 1221), and the friendship of the two saints is a strong tradition in both the Franciscan and the Dominican orders. In the summer of 1216 Dominic was back at Toulouse conferring with his companions, now 16 in number. This meeting has been called the *capitulum foundationis* ("chapter, or meeting, of foundation"). The rule of St. Augustine was adopted, as well as a set of *consuetudines* ("customs"), partly based on those of the canons regular, concerning the divine office, monastic life, and religious poverty; these are still the core of Dominican legislation. In July, Innocent III died, and it was from his successor, Honorius III, that Dominic, once more in Rome, finally received on December 22, 1216, formal sanction of his order.

The order was now an established body within the church, and Dominic returned to Toulouse. On August 15, 1217, he sent his men to Paris and to Spain, leaving

Early life and career

Foundation of the Dominicans

two each at Toulouse and Prouille, while he and another went to Bologna and Rome. He placed his two principal houses near the universities of Paris and Bologna and decided that each of his houses should form a school of theology. This at once determined the capital role that the Dominicans would play in university studies. In setting up his houses in the larger cities, especially in those that were teaching centres, he involved his order in the destiny of the medieval urban movement.

Dominic was gifted in being able to conceive his ideal, to form his men to that ideal, and then to trust them completely. His leadership had great clarity of vision (even to the geographical distribution of his forces and precise details of legislation), firmness of command, and certainty of execution. At the same time it was said of him that his gentleness was such that anyone who came to speak to him, even for reproof, went away happier.

The rest of Dominic's life was spent either in Rome, where he was given the Church of S. Sisto, or travelling. In 1218–19 he made a great tour (3,380 miles entirely on foot) from Rome to Toulouse and Spain and back, via Paris and Milan, and in 1220 a tour of Lombardy. Everywhere his communities were growing, and he planned many new foundations covering the key points of France and northern Italy. In Rome the Pope gave him the delicate task of reforming various groups of nuns, whom he finally gathered at S. Sisto in 1221, when the men moved to Sta. Sabina, which is still the residence of the master general of the order.

At Pentecost in 1220 the first general chapter of the order was held at Bologna, and a system of democratic, representative government was devised. At the second general chapter, held on Pentecost in 1221, also at Bologna, the order was divided geographically into provinces. After a visit to Venice, Dominic died at Bologna on August 6, 1221. He was canonized in 1234.

**BIBLIOGRAPHY.** The fully documented modern biography is that of M.H. VICAIRE, *Histoire de Saint Dominique*, 2 vol. (1957; Eng. trans., *Saint Donzinc and His Times*, 1964); the companion volume, *Saint Dominique de Calverga d'après les documents du XIII<sup>e</sup> siècle* (1955), provides the documents edited by Vicaire. *Saint Dominic: Biographical Documents*, ed. by F.C. LEHNER (1964), is a translation from 13th-century sources. The best biography in English is BEDE JARRETT, *Life of Saint Dominic, 1170–1221*, 2nd ed. (1934). W.A. HINNEBUSCH, *The History of the Dominican Order*, vol. 1 (1966), provides a good presentation of Dominic's life and the development of the order.

(S.Bh./Ed.)

## Dominican Republic

The Dominican Republic (República Dominicana) occupies the eastern two-thirds of Hispaniola, the second largest island of the Greater Antilles archipelago in the Caribbean Sea. Haiti (q.v.), also an independent republic, occupies the western third of the island. Hispaniola lies between the islands of Cuba to the west and Puerto Rico to the east and is situated about 600 miles southeast of Florida and 310 miles north of Colombia and Venezuela. The northern shores of the Dominican Republic are washed by the Atlantic Ocean, while the southern shore is bordered by the Caribbean Sea. Between the eastern tip of the island and Puerto Rico runs a channel called the Mona Passage. The republic has an area of 18,704 square miles (48,442 square kilometres; including 46 square miles of adjacent islands) and a population that in 1970 numbered a little more than 4,000,000. The capital is Santo Domingo.

The country, although small and underdeveloped, occupies a strategic position on major sea routes leading from both Europe and the United States to the Panama Canal. Between 1930 and 1961 the republic's history was dominated by the repressive dictatorship of Rafael Trujillo—a ruler who nevertheless maintained internal stability, managed to pay off the national debt, and introduced a measure of prosperity and modernization. Yet, the human costs were excessive; today, large numbers of Dominicans remain in misery, and many feel their situation worsening.

With the rise of Socialism in neighbouring Cuba, politi-

cal affairs in the Dominican Republic have assumed an even greater international importance (see the city article SANTO DOMINGO; for historical aspects, see DOMINICAN REPUBLIC, HISTORY OF THE).

### THE LANDSCAPE

**The natural environment.** *Relief, drainage, and soils.* Topography is complicated and varied and includes five distinct highland or upland areas running along a north-west to southeast axis. The Pico Duarte in the major Cordillera Central (Central Highlands) is the highest mountain in the West Indies, rising to a height of 10,417 feet (3,175 metres). There is also a smaller range, the Cordillera Septentrional, running parallel to the north-west coast, and two lesser ranges in the southwest. Another minor upland area, the Cordillera Oriental (Eastern Highlands), lies in the northeastern portion of the country. The extreme northwest and the extreme southwest are dry, low, and desertlike. The southeastern region consists of rolling lowlands.

The Río Yaque del Sur empties into the Bahía de Neiba (Bay of Neiba), draining the Cordillera Central to the south, while the Río Yaque del Norte drains the northern slopes, flowing into the Bahía de Montecristi. The eastern part of the island is drained by the Río Yuna, which flows into the Bahía de Samaná, and by the Río Ozama, the mouth of which is near Santo Domingo, on the south coast. The salt lake of Enriquillo, 23 miles long and about 11 miles wide at its widest point, located near the Haitian border in the southwest, is a distinctive landmark.

Soils vary, but those of the upland areas are mostly of residual origin, deriving from metamorphic and sedimentary rocks. Soils in the lowlands are of recent alluvial origin, except in the southeastern savanna (grassland) area, where they consist of sedimentary deposits of recent marine origin. In general all the soils are quite fertile except in the far southwest, in the Pedernales region, where the sedimentary soils are relatively barren.

*Climate, vegetation, and animal life.* The Dominican Republic lies well within the tropic zone, but the hot, moist climate typical of this zone is tempered in many areas by the altitude and in other areas by the insular character of the republic and by the Northeast Trade Winds that blow steadily from the Atlantic all year long. The heaviest precipitation is in the northeast, where the average rainfall is 100 inches a year. As the trade winds pass over the various mountain ranges, they lose their moisture until, in the far western part of the country, along the Haitian border, only a little more than 30 inches of rainfall is received annually. The island is constantly in danger from tropical storms and hurricanes, which originate in the mid-Atlantic from August until October each year.

In spite of local variations, the country as a whole enjoys a relatively mild and pleasant climate. The national mean temperature is 77° F (25° C). Temperatures rarely rise above 90° F (32° C), and, even in the heart of the highest central mountain range, the overall mean is only about 69° F (21° C). Very cold temperatures are literally unknown.

Vegetation varies considerably. The mountains are still largely forested with pines and hardwoods, although during the past century the lower and more accessible slopes were practically denuded of trees by commercial lumbering operations. In the drier regions, low shrubs and scrubby trees predominate, but, as rainfall increases—for example on the Samaná Peninsula—grasslands and dense rain forests occur.

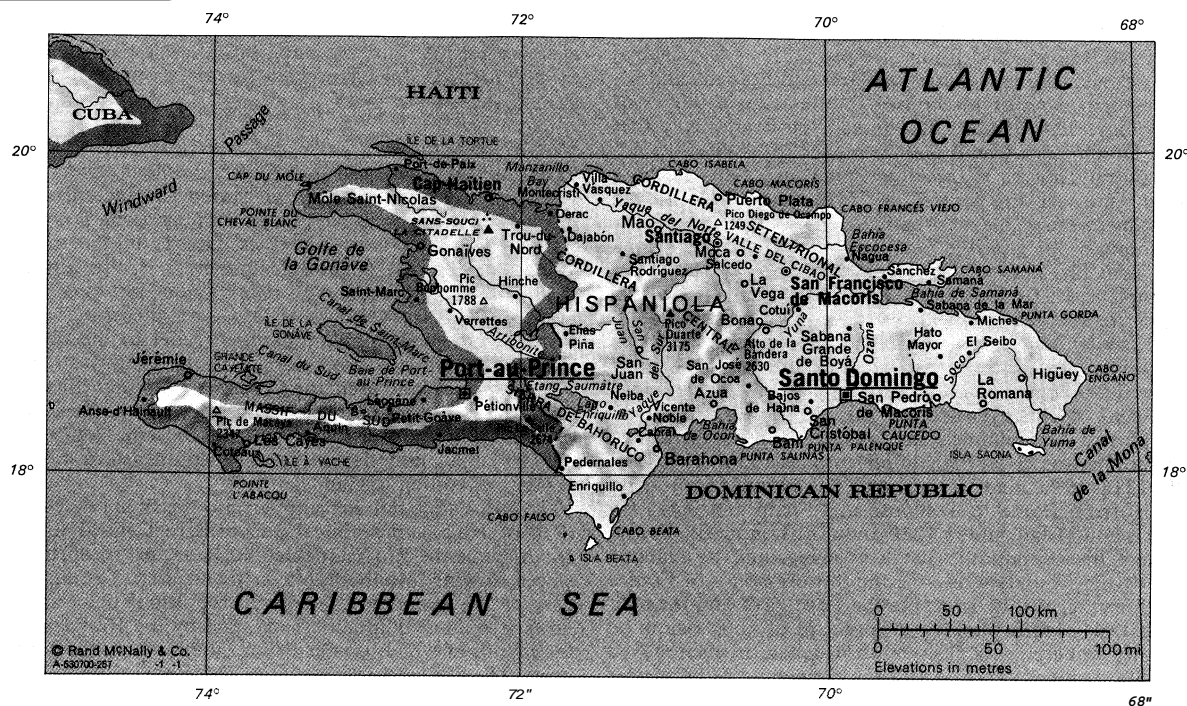

Cultivation of a wide variety of crops has largely replaced the natural vegetation in many areas—particularly in the more fertile upland valleys and on the lower mountain slopes. Mangrove swamps line some coastal areas, while elsewhere, particularly along the northern shore, sandy beaches of great beauty are to be found.

Wild-animal life is not abundant, although for several centuries cattle and goats, introduced by the early Spanish colonists, ran wild on the grasslands and in the desert areas. Alligators are found near the mouths of the Yaque del Norte and the Yaque del Sur and in the waters of

Lago Enriquillo. There is a great variety of birds, including ducks, that are hunted. Fish and shellfish inhabit the surrounding waters but have not been exploited commercially.

**The human imprint.** *Traditional regions.* Until well into the 20th century, the Dominican people felt little national unity. Loyalties to traditional regions and to local chieftains (*caudillos*) were stronger than national allegiance. These regions correspond roughly to natural ecological zones and have changed little in the course of time.

The greatest population density is in the area referred to as the Cibao, which extends across the north from the Samaná Peninsula in the northeast, north of the eastern and central mountain ranges, and south of the Septentrional range, to Monte Cristi in the far northwest.

South of the Cordillera Central lies an alluvial plain where rice is grown; the population is centred on San Juan de la Maguana. Many of the inhabitants of the town of Azua and its environs are the descendants of immigrants from the Canary Islands.

The area surrounding Santo Domingo is often referred

to simply as "the capital." "Capitaleños" are considered distinctive in culture and personality, although the massive rural-to-urban migration occurring in the country in the early 1970s seemed likely soon to erase this image.

Finally, the eastern savannas, now largely under sugar cultivation, are inhabited by settlers of predominantly European ancestry—descendants of cattle herders and families who owned small ranches. The eastern coastline itself, however, is increasingly inhabited by black-skinned natives of other West Indian islands who have come to work on the sugar plantations, in the mills, or on the docks. Most of these are temporary or seasonal workers, many from Haiti.

**The landscape under human settlement.** Although villages exist, the more common rural settlement pattern is a scattered neighbourhood—perhaps clustered about a small store or church. Settlements frequently stretch along roadsides, with cultivated patches behind the houses; there are still many households so isolated from major or even minor roads that they can be reached only on foot or by horseback.

The country is still largely rural, although since 1950 it

The rural settlement pattern

has exhibited one of the highest urbanization rates of any country in the world.

The capital city, Santo Domingo, is an increasingly cosmopolitan city in which manufacturing and other industry vie in importance with commerce, education, and governmental business. The second largest city is Santiago, located inland in the heart of the Cibao.

#### THE PEOPLE

The Spanish language has always been predominant, although other tongues can also be heard. Various European languages are often spoken; among those who have migrated from Haiti, a French patois is common.

The racial composition is predominantly mestizo (*i.e.*, of mixed blood) with a small number of persons claiming to be of European descent and an even smaller black minority group. The racial categories are roughly associated with economic and social class status, with more blacks at the bottom and more whites at the top. In addition, there is a small colony of German Jews, now beginning to break down as a distinctive unit, and a small group of Japanese in the Constanza Valley, most of whom are engaged in agriculture. During the 19th century, large numbers of persons immigrated from the Mediterranean area, especially from Lebanon; this group has today blended culturally and socially with the remainder of the population.

Although it is generally supposed that the original Taino (Arawak) Indians were annihilated during the early Spanish occupation, it is probable that the present-day Dominican population includes some genetic components deriving from this group, although no identifiable Amerindian ethnic group remains.

Religious  
groups

Approximately 95 percent of the population is Roman Catholic. The Catholic Church is highly esteemed and exerts a marked influence on cultural life at national, local, and family levels. Approximately 2 percent of the population is Protestant; the remaining 3 percent is Jewish, practices other religions, or professes no religion.

In 1969 the crude birth rate was about 39 per thousand, having fallen from a high of 49 per thousand in 1960. The crude death rate, however, also fell during the same period from about 14 to about 7 per thousand. This gave the country a continuing high rate of natural increase, the effects of which are reflected in a marked preoccupation with emigration, the actual rate of which is unknown because of repeated trips, and in the low standard of living of most of the people.

One of the most significant features of the population is its extremely youthful character. In 1970, about 47 percent of the population was under 15 years of age.

#### THE NATIONAL ECONOMY

**Resources and resource exploitation.** *Agriculture.* The economy is based primarily on agriculture. About 90 percent of all foreign exchange comes from the country's farms and pastures. Sugar, tobacco, cacao, **coffee**, hides, fruits, and tomato paste are the most important exports. The country imports most manufactured goods and some foodstuffs. The gross national product (GNP) and the per capita income remain low. Agricultural production constitutes about 22 percent of the GNP, commerce 18 percent, manufacturing 17 percent, government 12 percent, and other sectors 31 percent. In the early 1970s the economy was only beginning to recover from the political upheavals following the fall of Trujillo in 1961 and the civil war of 1965.

Agricultural  
products

**Mineral resources.** A number of minerals are known to be present but—with the exception of bauxite, gypsum, iron ore, and nickel—have not yet been highly developed commercially. Salt, largely from salt deposits near Lago Enriquillo, is also produced in commercial quantities. A smaller salt-producing enterprise, based on the evaporation of sea water, has also been of some importance at Monte Cristi. Other minerals that might be developed in the future include sulfur, coal, molybdenum, cobalt, tin, oil, and zinc.

The Dominican Republic is one of the relatively few sources of quality amber in the Western Hemisphere. Al-

though it has not yet been extensively exploited, craftsmen produced distinctive jewelry for the local and tourist trade.

**Biological resources.** Unexploited biological resources are few, but proper management of agricultural lands, forests, and grazing areas could result in far greater productivity. Although the possibilities for a large-scale fishing industry seem limited by the relative scarcity of marketable fish in nearby waters, the potential for the development of tourism and big-game fishing in several of the southern bays was being explored in the early 1970s.

**Hydroelectric resources.** In order to utilize fully the agricultural lands now available, as well as to open new lands, the irrigation system needs much improvement. Two multipurpose hydroelectric dams were being built in the early 1970s. The Presa (dam) de Tavera will provide electrical power and increase the availability of water for irrigation in the Cibao. The Presa de Valdesia, to be installed on the Río Nizao, will serve the dry southwestern area and provide power for Santo Domingo and its environs.

**Management of the economy.** *The public and private sectors.* During the Trujillo regime, from 1930 to 1961, the government (which was, in effect, the Trujillo family) largely controlled both agriculture and industry and, thus, the economy. Since 1961, most Trujillo enterprises have remained under governmental control. Two holding corporations were formed to manage them. The first, the Industrial Development Corporation (Corporación de Fomento Industrial), was created in 1962 and handles all the Trujillo industrial holdings other than sugar mills. This was replaced in 1966 by the creation of the Dominican State Enterprise Corporation (Corporación Dominicana de Empresas Industriales, CORDE). There is also the State Sugar Council (Consejo Estatal del Azúcar, CEA), which in 1966 replaced the former Dominican Sugar Corporation (Corporación Azucarera Dominicana). It manages the national sugar mills. In spite of managerial failure and despite a study that suggested they be returned to the private sector, in the early 1970s the government was apparently determined to retain control over these public companies.

In addition to the government, several foreign com-

Control of  
the sugar  
industry

panies and one local family dominate the sugar industry. Since 1965 the United States has made loans to increase industrial activity throughout the country. The processing of foods and beverages is especially well developed. Textiles and finished clothing—particularly shoes, shirts, and hats—are beginning to be produced locally and to replace some imports.

Many industries are characterized by their small size. These include, among others, manufacturers of furniture, soap, candles, rope, some food products, and paper clips, as well as building materials, such as concrete blocks and tiles.

**The monetary system.** The monetary system is based on a managed gold-bullion standard. The peso has been maintained at par with the U. S. dollar since the 1940s. The banking system is well developed, and there are several loan companies and more than 20 insurance agencies, most of the latter foreign owned.

**Taxation.** In the early 1970s, import duties had, for some years, comprised as much as 40 percent of the entire public revenue. Other government income derives from sales tax, vehicle licenses, and road taxes. Income taxes are levied but are unpopular and relatively unimportant.

**Trade unions and employer associations.** Trade unionism has not been important historically in the Dominican Republic. During Trujillo's rule, there was one so-called confederation of workers, which, in fact, was no more than a company union. After 1961 the labour movement developed rapidly, with unions tending to organize on the basis of political affiliation. Many affiliated with international labour organizations. As the agricultural sector continues to decline, trade unionism may be expected to become increasingly important.

There are also a number of employer associations, including the U.S. and Dominican chambers of commerce, as well as associations of cattle growers, sugar producers, and tomato growers. A number of factories and industries have associations that include both the workers and management.

**Transportation.** Santo Domingo is the hub of a transport system that is generally more than adequate to assure the flow of both people and goods to virtually all parts of the republic. Although certain routes are time consuming and indirect because of the inadequacy of the linkage through the central mountain system, the road network throughout the country is, nevertheless, generally good. Major highways of concrete or asphalt extend in three directions from Santo Domingo, and secondary roads branch out from these major arteries.

Although buses are rare, a system of private taxicabs provides rapid and relatively inexpensive transportation both within and between cities. Most goods are transported by truck to the important market centres.

A government-owned railroad line runs through the eastern half of the Cibao from La Vega to the port of Sánchez on Bahía de Samaná. This carries both passengers and freight, but, with the decline of Sánchez as a commercial port, the railroad has practically ceased functioning.

The only international airport is at Punta Caucedo, about 15 miles east of Santo Domingo. It is capable of handling all types of modern jet craft. A secondary airport in Santiago handles small jets and propeller planes. Fifteen other airfields around the country are open to small civilian craft. The government-owned airline, *Compania Dominicana de Aviación* (CDA), operates between Santo Domingo and San Juan, Puerto Rico; Curaçao, New York City, and Miami, and also makes local flights.

Airlines now handle most passenger traffic to and from the Dominican Republic, but goods are exported and imported primarily by sea. The Bahía de Samaná is perhaps the finest and largest natural harbour in the entire Caribbean area. Until the 20th century, the primary commercial ports lay along the northern coast, but, with the rise of the sugar plantations in the south, the ports of Santo Domingo, San Pedro de Macoris and La Romana have increased in importance. Most general goods pass through Santo Domingo, but sugar is largely exported through the

ports of San Pedro de Macoris and La Romana. Once important historically, the ports of Monte Cristi and Sánchez in the north are now almost defunct. Only Puerto Plata retains its commercial importance, and it, too, has declined since the 1930s. It is still viable largely because of the tobacco, coffee, and cacao interests in the Cibao region. Barahona ships bauxite, gypsum, and salt but receives few imports.

#### ADMINISTRATION, SOCIAL CONDITIONS, AND CULTURAL LIFE

**The structure of government. The constitutional framework.** There is a Senate and a Chamber of Representatives. The Senate is composed of one representative from each province, and one from the National District. The Chamber of Representatives reflects the size of the population, but has no fewer than two representatives from each province, and two from the National District. The present (1966) constitution, like its 28 predecessors, guarantees human rights, prescribes the division of governmental powers, and provides for popular sovereignty. It also accords suffrage to all Dominicans of either sex over 18 years of age, unless they are members of the armed forces or the police.

Historically, the various constitutions have provided special emergency powers for the president that have made it possible for the executive to supersede the legislative and judicial branches of the government should the president deem it necessary. While retaining provisions for emergency executive powers, each successive constitution has, nevertheless, expanded the social and economic rights guaranteed in earlier documents. A formal relationship between the Catholic Church and the government, incorporated in earlier constitutions, has now been eliminated. The right to private property is guaranteed but is limited by the right of the state to expropriate for the general good. Terms for national elected offices are four years, and incumbents may seek re-election for an additional term.

**Local government.** The nation is divided into 26 provinces and one National District (*Distrito Nacional*). The central government administers the outlying provinces through governors appointed by the president. Each province elects representatives to the bicameral national congress. Internally, each province is subdivided into municipalities that elect their own councils and enjoy considerable local autonomy.

**Elections and de facto political developments.** Even though recent elections have been run democratically (as has been observed by international representatives), the nature of Dominican social and economic organization imposes conditions inimical to the development of democratic organization. Many less educated persons, for instance, vote as their employers (*patrones*) tell them, having few sources of information upon which to base decisions. Many also fear losing jobs or patronage if they do not follow the wishes of their mentors. Most lower-income Dominicans are convinced that their votes will be identifiable. The bulk of the current adult population has never known freedom in the electoral process, and it may take considerable time before truly representative elections can be expected. On the other hand, the elections of 1966 and 1970 showed that lower-income urban dwellers, especially in Santo Domingo, had developed considerable political consciousness and organization.

The re-election in 1970 of the essentially conservative regime headed by President Joaquín Balaguer, meanwhile, illustrated the power of the business, commercial, industrial, and agricultural establishment. It seemed clear in the 1970s that the support, both economic and political, of the United States and its allies would remain an important consideration in Dominican politics for some time, as has been evident since the military intervention of 1965 to 1966. Even though many liberal Dominicans chafe under the lack of strict autonomy, most seem to believe that economic prosperity can only be achieved through alignments with the United States.

**Justice.** The legal system is based upon the Code Napoléon. There is a series of regular courts, the judges of which are appointed by the Senate and may have no other

The 1966 constitution

The road system

The legal system

public employment. These courts, with the exception of the land and commercial courts, have jurisdiction over both criminal and civil matters.

In criminal cases the judicial process begins with an investigation, generally conducted by an investigating judge. This is followed by the trial proper, conducted by the appropriate court. Both fact and law are taken into account in all cases. Appeals are made to the appropriate superior court and may finally be considered by the Supreme Court, composed of nine justices.

**The armed forces.** It was not until the United States occupation of 1916 to 1924 that a modern military body was formed in the Dominican Republic. Today, the army, navy, and air force are organized separately, each being headed by its own chief of staff.

During the Trujillo regime, the armed forces were used to preserve the dictatorship, and their members enjoyed a status and power unusual in Latin American states of the 20th century. Even today, it is clear that no government can remain in power long if it does not have the support of at least a portion of the armed forces.

**Administrative services.** **Education.** The more isolated and rural the population, the less accessible are educational institutions. Primary schooling ordinarily lasts six years, although in rural areas only three may be offered; this is followed by a two-year intermediate school and a four-year secondary course, after which a diploma called the *bachillerato* is awarded. Relatively few lower-income-group students, however, succeed in reaching this level, since the system is designed to encourage middle- and upper-income-group students to prepare for admittance to a university. Most richer students attend private schools, which are frequently sponsored by religious orders. Some public and private vocational education is available, particularly training in the field of agriculture, but this too reaches only a very small percentage of the population.

There are three universities in the country, two in Santo Domingo and one in Santiago. The Universidad Autónoma de Santo Domingo (UASD) is proud of being the first university in the New World. It is also the largest of the three and is autonomous, being free of both governmental and religious control, although most of its funds are from the national budget. Costs are low and even poor students may attend, if they have been fortunate enough to have secured the requisite primary and secondary preparation.

The Universidad Nacional "Pedro Henríquez Ureña" (UNPHU), located in Santo Domingo, enjoys the support of not only the Catholic Church but also of some private endowments, as well as receiving funds from the national government. The Universidad Católica "Madre e Maestra" (UCMM) in Santiago is similarly supported both by the Catholic Church and through private and public endowments.

The traditional tendency of Latin American university students to engage in political activity has been discouraged in the two newer universities, though with little success. Student political organizations, most of them affiliated with national political parties, are large and active, especially at UASD.

**Health.** Health conditions among the poorer classes in both rural and urban zones are characterized by a generally unsanitary environment, inadequate health services, and poor nutrition. As a result of these conditions, both infectious and parasitic diseases are rampant, and infant mortality is high.

Hospital and trained medical personnel are available only in the larger cities and towns. In the rural areas, home remedies and the professional services of practitioners of traditional local medicine are the only means of preserving or restoring health. Cases of severe illness may be taken to the nearest urban centre, where hospitalization is free. The tendency, however, is to take this measure only in extreme cases, often when death is already imminent.

Medical care for the more affluent is available through private physicians, many of whom maintain clinics, small nursing homes, and maternity units.

**Housing.** Housing is considered by Dominican planners to constitute one of the most serious problems in the country. In 1963 it was estimated that more than 200,000 new units—about 145,000 in rural areas alone—were needed to take care of the population at that time. Sixty-five percent of existing residences were considered substandard in 1962, meaning that they were either unsafe or inadequate in size.

On the sugar plantations in the south, barracklike housing is provided for temporary workers, but more permanent employees frequently have their own small huts, or *bohios*, often on company-owned land. These may be little more than a lean-to of palm leaves and bamboo. Others, more sturdy, may have double walls filled with rubble and plastered with mud.

In the Cibao, a relatively prosperous zone, houses are built solidly of palm board or pine and are frequently painted and decorated, with shutters and lintels in contrasting colours. Roofs are most often covered with sheets of zinc or tin but, in poorer households, may be thatched. A prosperous family will have a concrete floor, but most are of packed earth.

In the cities are to be found the squatter settlements and poverty-stricken inner-city ghettos characteristic of most rapidly urbanizing underdeveloped countries of the world. In some cases these may be built of cardboard, tin cans, discarded inner tubes, and any other materials the inhabitants may scavenge. Most houses have a small religious shrine with holy pictures, candles, and other objects on it which often shares a place of honour with a portrait of the current president.

Also in the cities are districts with well-appointed modern houses, occupied by members of the new commercial and industrial elite, as well as by the more traditional land-based oligarchy. Government programs, often funded with international loans, have financed housing construction for lower- and middle-income families.

**Police services.** The police are frequently associated in the minds of the people with the army and, indeed, have served similar functions. Civil and political offenses frequently merge into one, and arrests for criminal offenses are often politically motivated. Most of the populace, even the middle- and upper-income groups, consequently fear the police, in spite of efforts to improve their image.

Police are poorly paid, but, since most are drawn from the lower-income groups, for them the position represents security and prestige and may well serve to improve their social and economic status. Through graft, which may be considered a systematic mechanism of distribution, their standards of living rise in spite of low wages.

**Social conditions.** Social conditions in the Dominican Republic resemble those found in other underdeveloped American nations. The small farmers rarely eke out more than a subsistence crop and most often must supplement this by the sale of handicrafts; products include baskets, pottery, rocking chairs, straw hats, and foodstuffs. These items are either sold to middlemen, who market them in towns, or else are displayed and sold along the roads and highways, frequently by children.

**Wages and cost of living.** Wages in the Dominican Republic tend to be low. In the sugar industry, which is one of the largest employers in the country, wages range from 90 cents per day for unskilled cane cutters to U.S. \$5 per day for semiskilled workers in the mills. Skilled laborers, such as bricklayers, may earn up to U.S. \$10 a day. White-collar workers with professional degrees, generally paid by the month, may earn U.S. \$600 or \$700 per month.

The cost of living is high, and in the early 1970s prices were rising steadily.

**Economic and social divisions.** Although most Dominicans, as well as some social scientists, have insisted that there is no traditional oligarchy, there nevertheless exists an intellectual and economic elite that constitutes less than 5 percent of the total population. Today there also appears to be an emergent middle-income group.

By far the largest proportion of the population belongs to the lower-income group. This category includes small farmers, landless agricultural workers, itinerant mer-

Rural  
housing

The  
universities

Wage rates

chants, and unskilled manual labourers in domestic and maintenance occupations, as well as in construction, industry, and shipping. This group is underpaid, poor in health, and apathetic concerning its future. Many of them see emigration as the only way out of their poverty.

**Cultural life and institutions.** *The folk arts.* It is difficult to define any particular and unique cultural tradition that may be labelled Dominican. There are, nevertheless, some cultural items worthy of special mention. Music, especially when accompanied by dancing, is important at all social levels and in all regions. The most typical forms are those with clear African antecedents, especially in their rhythms. There are also folk songs and tunes deriving from Spain and the Middle East. The merengue is a particularly popular dance, followed closely by the bolero. The guitar is probably the most popular instrument, but in some rural areas flutes and homemade marimbas are also found. There is no such thing as an indigenous national costume, although an elaborate fiesta dress reminiscent of Spanish flamenco styles is sometimes worn by wealthier women and proclaimed to be "Dominican."

During the month preceding Lent, a Carnival season is celebrated, during which parades are held in the streets; the somewhat distinctive costumes worn probably derive from medieval Europe.

**Recreation.** Organized sports are popular, especially baseball. In the more rural areas, cock fighting remains a traditional and popular spectator sport. Soccer is also played but seems to have been eclipsed by baseball in recent years.

Literary clubs are popular, and some of them have remained in existence for nearly a century. There are many fine painters whose work is, although little known outside of the country, well appreciated there.

**Press and broadcasting.** Bookstores abound in every major city. In the rural zones and among poorly educated urban dwellers, newspapers and paperback novels are popular.

In 1969 there were six daily newspapers, and in 1972 several more were being published, most of them in Santo Domingo.

Radio and, to a lesser extent, television have, in recent years, also contributed to the cultural life of the country. The number of licensed transmitters climbed from 25 in 1950 to more than 80 in 1963 and over 120 in 1971. Most of these were located in Santo Domingo or in Santiago but were readily heard throughout the country.

**Prospects for the future.** The modern Dominican nation is complex and often difficult for the stranger to understand. It presents many faces, based not only upon regional variations but also upon social and ethnic differences. Though small, it has no single traditional culture, and its people frequently display greater loyalties to other nation-states, either in Europe or in the Americas, than to their own country. For some, the greatest goal in life is emigration; yet, this may be coupled with a fervent patriotism such as that which caused many to lay down their lives in the civil war of the mid-1960s.

The primary obstacles to progress in the early 1970s seemed to lie in the area of social organization, rather than in any lack of natural resources. The close interdependence of the Dominican Republic with larger nations, such as the United States, is a factor that colours nearly every event occurring there.

The long history of despotism under Trujillo has not been forgotten and has clearly made its mark upon the land. Many wish to return to what seemed to them a period of peace and prosperity, even at the cost of freedom and dignity for the individual. On the other hand, it is also clear that, since Trujillo's death, the economic situation has declined. Population pressure is great and becomes more intense as public-health measures reduce mortality. Economic development has so far enabled the rich to become richer but has produced few benefits for the poor. Until now, there has been the safety valve of emigration to the United States. Whether, as in the case of Puerto Rico, this will prove to be a viable temporary solution remains to be seen. Unlike Puerto Ricans, Do-

minicans are not citizens of the United States nor does the country enjoy other special benefits available to Puerto Rico because of its special political status. On the other hand, it is clear that the Dominican Republic is also economically and socially dependent upon its powerful northern neighbour. So long as leading citizens and governments try to imitate the economic and social structure of the United States, it seems likely that the fate of the masses will not improve. The theory that this will result in the wider distribution of economic benefits has not been justified by results in the Dominican Republic. A new means of economic organization seems to be called for, and whether this can be accomplished under the present political regime remains to be seen.

## Dominican Republic, History of the

Very little is known of the island of Hispaniola's pre-Columbian history. At the time of Columbus' first landing in 1492, the Caribs, a marauding tribe that had apparently originated on the South American mainland and conquered its way up from the Lesser to the Greater Antilles (and for whom the Caribbean Sea is named), were preying upon the more peaceable Tainos, who had previously settled there. Estimates of the size of the indigenous population range from 300,000 to 3,000,000; other features of pre-Columbian Indian life are similarly shrouded in uncertainty. Part of the uncertainty stems from the fact that the Indians on Hispaniola were primitive and backward; they were not a part of a large-scale and advanced Indian civilization—as in Mexico, Guatemala, or Peru, for example—with a long history and proud tradition of their own.

Hispaniola was discovered by Columbus on his maiden voyage. A colony was established on the north coast, but the first settlers were slaughtered by the Indians. Returning, Columbus established a second colony; but reports of abundant gold farther south quickly led to the abandonment of the northern outpost and to the founding of Santo Domingo city on the Caribbean coast.

Hispaniola was the first area in the New World to receive the full imprint of Spanish colonial policy. The oldest cathedral, monastery, and hospital in the Americas were established on the island, and the first university chartered. The earliest experiments in Spanish imperial rule were conducted here. Class and caste lines were rigidly drawn; the Roman Catholic Church served as the strong right arm of the temporal authority. A cruel, exploitative, slave-based society and economy came into being. The first "revolution" in the New World was also recorded on Hispaniola.

During the first half-century of Spanish rule, Hispaniola flourished, for its rich mines and lush lands yielded abundant wealth, and it served as the administrative centre for Spain's burgeoning American empire. But the more lucrative conquests of Mexico and Peru soon turned it

Period of  
Spanish  
rule

into a poor way station. Its Indians were decimated, gold and silver were more easily available elsewhere, and the more ambitious Spaniards emigrated.

For the better part of the next three centuries, Hispaniola remained a neglected, poverty-ridden backwater of the Spanish Empire in the Americas. Successive raids by British, Dutch, and French marauders and buccaneers devastated the island still further. Socially and economically, it retrogressed, reverting to a more primitive form of existence. Eventually, French claims to the western third of the island were recognized, and a prosperous sugar-producing colony based on black slavery grew up in the area that was later to become the independent nation of Haiti. As a by-product of Haiti's prosperity, the Spanish colony also experienced a modest boom in the 18th century.

In 1795, as a result of its defeat in the wars that had been raging in Europe, Spain ceded the eastern two-thirds of Hispaniola to France. Meanwhile, inflamed by the revolutionary currents then sweeping France and stirred to revolt by the inhuman conditions under which the slaves were forced to labour, a slave uprising had begun in Haiti. Led by Toussaint-Louverture (*q.v.*), the blacks not only succeeded in throwing off French rule but soon overran the previously Spanish eastern end of the island as well, burning the plantations and instilling terror in the white ruling class. With the aid of the British fleet, the Haitians were driven back, and in 1809 the colony was reunited with Spain. In 1821, following the lead of the countries on the mainland, the Dominican Republic declared its independence. The new republic comprised approximately the eastern two-thirds of the island.

**The Dominican Republic to 1930.** Within a matter of weeks, Haitian columns under Jean-Pierre Boyer (president of Haiti, 1818–43) again overran the entire island. Dominican historians have portrayed this occupation (1822–44) as cruel and barbarous. Haitians held the highest offices, closed the university, severed the church's ties with Rome, forced out the traditional ruling class, and all but obliterated the western European and Hispanic traditions. But Boyer also freed the slaves, and his administration was generally more efficient and his troops less uncontrolled than Dominicans like to admit.

In the 1830s Juan Pablo Duarte—known as the father of Dominican independence—organized a secret society to fight the Haitians, and in 1844, after a long struggle and aided by the outbreak of civil war in Haiti itself, independence was finally achieved. But Duarte and the other young idealists who had led the independence movement were soon exiled, and the new nation quickly fell into other, less noble hands.

From 1844 until 1899 the Dominican Republic was dominated by a succession of dictatorial "men on horseback," who prevented the growth of the genuine representative democracy that the constitution proclaimed and who were not above selling out the country to foreign "protectors" and commercial interests. Pedro Santana and Buenaventura Baez emerged as the two most prominent figures, alternating in the presidency for nearly 30 years. In order to ward off continuous assaults by Haiti, Santana returned the country to Spain (1861–65) and arranged to have himself named governor-general. After a series of battles, Spain withdrew its troops; but the idea of a protectorate remained, and Baez now approached the United States with a plan. Pres. Ulysses S. Grant favoured annexation, but after the questionable activities of a United States land-speculating company became public, the Senate failed to ratify the treaty.

During the 1870s the instability continued. Baez returned to the presidency for the fifth time, and the country's first, but short-lived, democratic government came to power. The instability culminated in the emergence of a new strong man, Ulises Heureaux, who dominated the country from 1882 to 1899. Heureaux ruled as a dictator, but he presided over a period of unprecedented stability and national growth. New roads were built, communications improved, production rose, foreign capital entered, population increased. The Dominican Republic began its process of modernization.

Following Heureaux's assassination in 1899 the country returned to the chaotic, unstable politics of the past. New men on horseback galloped in and were in turn forced out of the presidential palace. For a brief time, under Ramón Caceres (1906–11), the country seemed to be recovering; but he too was assassinated, and political chaos ensued once more. Even the accession of the archbishop Adolfo Nouel to the presidency in 1912 failed to stem the disorder; within four months he, too, was forced to resign and civil war broke out again.

Meanwhile, the deteriorating financial situation, plus the expanding interests of the United States in the Caribbean area, had drawn its large North American neighbour ever deeper into Dominican affairs. By this point, the United States had replaced Europe as the major importer of Dominican products as well as the chief supplier of Dominican imports. United States private investments were also rising rapidly. In 1905, threatened with the possibility that European creditors would use force to collect some unpaid Dominican debts, the United States took over the administration of the Dominican customs revenues. Over the next decade the United States influence increased, and in 1916, as the fragile political structure collapsed again, the United States assumed complete control.

The United States occupation (1916–24) saw the building of some new roads, schools, and communications and sanitation facilities, and there were other constructive projects. But the occupation forces had assumed arbitrary control and frequently abused their authority. In addition, the creation by the United States Marines of a modem, unified, military constabulary provided the instrument by which future Dominican strong men could seize power and dominate the country.

In 1924, in United States-supervised elections, Horacio Vasquez was elected president. His rule eventually proved incompetent and corrupt, and the stock market crash of 1929–30 undermined the Dominican economy. In 1930 a revolution was launched against his rule. The military forces, now under the firm control of Rafael Trujillo, held the balance of power; but rather than defend the government, they stood by and let the revolution succeed. Then Trujillo moved to take power himself.

**The Dominican Republic since 1930.** The dictatorship of Rafael Trujillo (1930–61) was one of the longest, cruellest, most absolute dictatorships the world has ever seen. For more than three decades Trujillo ruled his country with an iron hand; virtually everything he touched had to belong to him. Trujillo dominated the armed forces, government, economy, church, education, intellectual life, sports, everything. Under Trujillo, however, as under Heureaux, the economy prospered, social change was accelerated, and the Dominican Republic in 1961 was a far more complex and "modern" society than it had been in 1930.

Following Trujillo's assassination in 1961, his heirs and followers attempted to hang on to the reins of power. But they were also driven out, and the country embarked on a more democratic course. In 1963 Juan Bosch and his moderately reformist Dominican Revolutionary Party (*Partido Revolucionario Dominicano*, or PRD) took power, the first democratically elected and progressive government in the country's history. Conservative forces remained strong, however, and after seven hectic months Bosch was overthrown. As the country returned to conservative, do-nothing rule, the frustrations and pressures began building up; in 1965 the Dominican Republic exploded in a popularly based and democratic social revolution. Fearing a second Cuba, however, the United States again occupied the country and snuffed out the revolution.

After a stormy interim, new elections were held in 1966. The winner was Joaquín Balaguer, a former Trujillo puppet now presenting himself as a moderate and a symbol of orderly change. Under Balaguer some economic gains were registered and a number of social reforms partially implemented, but the level of tension remained high and the problems brought dramatically to the surface in the 1965 revolution continued unresolved. In 1978 Balaguer,

United  
States  
influence

Slave  
revolt

19th-  
century  
dictators

old and enfeebled, was defeated in a presidential election by Antonio Guzman Fernandez and the PRD. Guzmán moved cautiously to implement reforms, but conservative elements remained powerful and the economy fragile. Hurricane "David" devastated the country in 1979, and there were rumblings of discontent with the new democracy. It remained to be seen whether the Dominican Republic could break out of its vicious circles of dependency, authoritarianism, and underdevelopment.

**BIBLIOGRAPHY.** JUAN BOSCH, *Crisis de la democracia de America en la República Dominicana* (1964; Eng. trans., *The Unfinished Experiment: Democracy in the Dominican Republic*, 1965), a perceptive analysis by one of the country's most important and controversial figures; ROBERT D. CRASSWELLER, *Trujillo: The Life and Times of a Caribbean Dictator* (1966), a superb biography of the late Generalissimo; PIERO GLIESES, *La Crise Dominicaine, 1965* (1973; *The Dominican Crisis*, 1978), a stimulating account of the revolution of 1965 and American intervention; JOHN BARTLOW MARTIN, *Overtaken by Events: The Dominican Crisis from the Fall of Trujillo to the Civil War* (1966), a fascinating account by the former U.S. ambassador to the Dominican Republic; JEROME SLATER, *Intervention and Negotiation: The United States and the Dominican Revolution* (1970), a perceptive, balanced study; HOWARD J. WIARDA, *The Dominican Republic: Nation in Transition* (1969), a general overview focussing on problems of national development, and *Dictatorship, Development, and Disintegration: Politics and Social Change in the Dominican Republic* (1975), a large and detailed study of the political system.

## Domitian

Domitian, Roman emperor AD 81–96, is chiefly remembered for the reign of terror under which prominent members of the Senate lived during his last years.

Domitian, marble bust in the Palazzo dei Conservatori, Rome.

Titus Flavius Domitianus was born October 24, AD 51, the second son of the future emperor Vespasian and Flavia Domitilla. During the civil war of 69 over the imperial crown, Domitian remained unharmed in Rome, but on December 18 he took refuge in the Capitol with his uncle Flavius Sabinus, escaping into hiding when the Capitol was stormed by supporters of Vitellius. On the entry of his father's supporters into Rome two days later he was saluted as Caesar, and he became praetor next year. He attempted to turn the repressive campaign of Petillius Cerialis in the Rhineland into a triumphal operation of his own, and for this and other excesses he is said to have required his father's pardon when the latter arrived at Rome in autumn AD 70. Domitian, however, was *princeps iuventutis* (an imperial prince) and was consul six times in Vespasian's lifetime; moreover, it was recognized that he would eventually succeed his brother Titus, who had no son and was 11 years older than Domitian. On Vespasian's death Domitian expected the same position as Titus had received under Vespasian, in particular, tribunician power and some form of *imperium*. These were not granted, and Domitian was evidently antagonistic to his brother and is alleged to have hastened his death, which occurred on September 13, 81.

As emperor, Domitian was hated by the aristocracy. From the Trajanic writers Tacitus and Pliny the Younger (Suetonius is less partisan) it is hard to disentangle stock vituperation from genuine belief, but it seems certain that cruelty and ostentation were the chief reasons for Domitian's unpopularity rather than any military or administrative incompetence. Indeed, his strict control over magistrates in Rome and the provinces won Suetonius' praise. In his secretariat he used both freedmen and knights, some of whom retained their posts after his death; and his *consilium* of close advisers, including senators, involved no departure from precedent. In legislation he was severe, and he incurred censure for attempting to curb vices from which he himself was not immune. It might be fairer to criticize him for undue paternalism. An edict ordaining destruction of half the provincial vineyards was typical: it was designed to encourage the growing of grain and to limit the importing of wine into Italy (where, meanwhile, no increased output was permitted), but Domitian was unable to carry the matter through.

His military and foreign policy was not uniformly successful. Both in Britain and in Germany advances were made early in the reign, and the construction of the Rhine-Danube *limes* ("fortified line") owes more to Domitian than to any other emperor. But consolidation in Scotland was halted by serious wars on the Danube, where Domitian never achieved an entirely satisfactory settlement and, worse still, lost two legions and many other troops. This, though admitted even by Tacitus to be attributable to the slackness or rashness of his commanders, was naturally held against Domitian at Rome. It did not affect his popularity with the army, however, whose pay he had wisely raised by one-third in AD 84.

The real issue was his own constitutional and ceremonial position. He continued his father's policy of holding frequent consulates (he was consul *ordinarius* every year from 82 to 88); he became censor for life in 85, with consequent control over senatorial membership and general behaviour; he wore triumphal dress in the Senate; and he presided, wearing Greek dress and a golden crown, over four yearly games on the Greek model, with his fellow judges wearing crowns bearing his own effigy among effigies of the gods. A grave source of offense was his insistence on being addressed as *dominus et deus* ("master and god").

The execution of his cousin Flavius Sabinus in 84 was an isolated event, but there are hints of more general trouble about 87. The crisis came with the revolt of Antonius Saturninus, governor of Upper Germany, on January 1, 89. This was suppressed by the Lower German Army, but a number of executions followed, and the law of *majestas* (treason) was later employed freely against senators. The years 93–96 were regarded as a period of terror hitherto unsurpassed.

Among Domitian's opponents was a group of doctrinaire senators, friends of Tacitus and Pliny and headed by the younger Helvidius Priscus, whose father of the same name had been executed by Vespasian. Their Stoic views were probably the cause of his expulsions of "philosophers" from Rome on two occasions. It is unlikely that he was carrying out any considered policy on the organization of thought any more than that his condemnation in 95 of his cousin Flavius Clemens for *atheotēs* ("irreligion") was part of a deliberate attack on Christianity.

Domitian's financial difficulties are a vexed question. Cruelty came earlier in his reign than rapacity, but eventually he regularly confiscated the property of his victims. His building program had been heavy: Rome received a new forum (later called Forum Nervae) and many other works. Then there were Domitian's new house on the Palatine and his vast villa on the Alban Mount. Meanwhile, the increased army pay was a recurrent cost. Probably only his confiscations averted bankruptcy in the last years. The conspiracy that caused his murder on September 18, 96, was led by the two praetorian prefects, various palace officials, and the Emperor's wife Domitia Longina (daughter of Gnaeus Domitius Corbulo). Nerva, who took over the government at once, must clearly have been privy. The Senate was overjoyed at Domitian's

Opposition to Domitian

death, but the army took it badly; and next year they insisted on the punishment of those responsible.

## Donatello

The greatest sculptor of the 15th century and one of the towering figures of Italian Renaissance art, Donatello was among the founders of the new style—ranking second only to the architect Filippo Brunelleschi, who was his senior by a decade and to whom he was linked by friendship during the first half of his long career. Donatello's statues embody the new image of man conceived by the Italian Humanists, the creators of Renaissance scholarship and philosophy. His influence pervaded both sculpture and painting throughout the 15th century and beyond.

Donatello's life and artistic career are known in considerable detail. Unfortunately, however, there is little information on his character and personality, and what is known is not wholly reliable. Some anecdotes of the late 15th century, for instance, reflect his reputation as a "lover of beautiful apprentices." He never married, and he seems to have been a man of simple tastes in his daily habits. Patrons often found him difficult to deal with; apparently he demanded a measure of artistic freedom beyond what most of them were accustomed to grant at a time when artists' conditions of work were still regulated by guild rules. Although on intimate terms with a number of Humanists, Donatello himself was not a man of literary culture. No letters by him exist or are referred to in the correspondence of those who knew him. Yet the inscriptions and signatures on his works are masterly in design and among the earliest examples of the revival of classical Roman lettering. That he was a connoisseur of ancient art is attested to by his Humanist friends. In fact, 20-century research has shown that he had a more detailed and wide-ranging knowledge of ancient sculpture than any other artist of his day, and that his own work was inspired by ancient visual examples (which he often daringly transformed) to a far greater extent than had hitherto been assumed. The traditional view of Donatello as essentially a realist, therefore, has been modified in the light of these findings.

Anderson—Alinari

Equestrian statue of Gattamelata, bronze sculpture by Donatello, 1447–53. In the Piazza del Santo, Padova, Italy. Height about 3.35 m.

**Early career in Florence.** Donatello (diminutive of Donato) was born about 1386 the son of Niccolò de Betto di Bardo, a Florentine wool carder. Nothing is known about the beginnings of his career, but it seems likely that he learned the draft of stone carving from one of the sculptors working for the cathedral of Florence around 1400. At some time between 1404 and 1407, he was a member of the workshop of Lorenzo Ghiberti, a sculptor in bronze who in 1402 had won the public competition for the doors of the Florentine baptistery. Donatello's earliest work, of which there is certain knowledge, a marble statue of David, betrays an important artistic debt to Ghiberti, who was then the leading exponent in Florence of the so-called International Gothic, a style of graceful, softly curved lines strongly influenced by northern European art. The "David," originally intended for the cathedral, was transferred in 1416 to the Palazzo Vecchio, the city hall of Florence, where it stood for many years as a civic-patriotic symbol, although from the 16th century on it was eclipsed by the gigantic "David" of Michelangelo, which served the same purpose. Other early works by Donatello, still partly Gothic in style, are the impressive seated marble figure of St. John the Evangelist for the facade of the cathedral and a wooden crucifix in the church of Sta. Croce. The latter, according to a persistently repeated though unproved anecdote, was made in friendly competition with Brunelleschi, who was a sculptor as well as an architect.

The full power of Donatello's genius was first seen in the two marble statues "St. Mark" and "St. George" (both completed about 1415) for niches on the exterior of Or San Michele, the church of Florentine guilds ("St. George" has been replaced by a copy; the original is now in the Bargello). Here, for the first time since classical antiquity and in striking contrast to medieval art, the human body is rendered as a self-activating, functional organism, and the human personality is endowed with a confidence in its own individual worth. These figures can stand on their own legs, physically as well as spiritually. The same qualities came increasingly to the fore in the series of prophet statues that Donatello did beginning in 1416 for the niches of the campanile, the bell tower of the cathedral (all these figures, together with their companions by lesser masters, have been removed to the Museo dell'Opera del Duomo). According to the payment records, Donatello executed five statues altogether: a beardless and a bearded prophet as well as the group of Abraham and Isaac (1416–21) for the niches on the east side, and the so-called "Zuccone" ("pumpkin," because of its bald head) and the so-called "Jeremiah" (actually Habakkuk) for those on the west side. The "Zuccone" well deserves its fame as the finest of the campanile statues and one of the artist's masterpieces. Both it and the "Jeremiah" (1427–35) show highly individual features inspired by ancient Roman portrait busts. Their entire appearance, which suggests classical orators of singular expressive force, has so little in common with the traditional image of Old Testament prophets that by the end of the 15th century they could be mistaken for portrait statues even though they clearly had not been so intended.

In his narrative relief panels for the north door of the baptistery, Ghiberti had begun to extend the apparent depth of the scene by placing the boldly rounded foreground figures against more delicately modelled settings of landscape and architecture. Taking this pictorial tendency as his point of departure, Donatello in his marble panel "St. George Killing the Dragon" (1416–17, base of the St. George niche at Or San Michele) invented a bold new mode of relief known as *schacciato* ("flattened out"). Its actual depth of carving was extremely shallow throughout, yet for that very reason the effect of deep atmospheric space was far more striking than before, since the sculptor no longer modelled his shapes in the usual way but rather seemed to "paint" them with his chisel. Tonal values (or shades) were created through subtle modulations of the relief surface that were meant to control the angle at which the light was reflected by the carved forms. A blind man could "read" a Ghiberti relief with his fingertips; a *schacciato* panel, on the con-

naissance  
style

Invention  
of  
*schacciato*

trary, must be seen, for it depends on visual rather than tactile perceptions.

After the pioneer effort of the St. George relief, Donatello continued to explore the possibilities of the new technique in his marble reliefs of the 1420s and early 1430s. The most highly developed of these are "The Ascension, with Christ Giving the Keys to St. Peter," which is so delicately carved that its full beauty can be seen only in a strongly raking light, and the "Feast of Herod" (1433–35; Musée des Beaux-Arts, Lille, France) with its perspective background. The large stucco roundels with scenes from the life of St. John the Evangelist, below the dome of the old sacristy of S. Lorenzo, Florence, show the same technique, but with the addition of colour for better legibility at a distance (about 1434–37).

In the meantime, Donatello had also become a major sculptor in bronze. His earliest work in that material was the over life-size statue of St. Louis of Toulouse, executed about 1423 for a niche at Or San Michele (replaced half a century later by Verrocchio's bronze group of Christ and the doubting Thomas). Toward 1460 the "St. Louis" was transferred to Sta. Croce; and it is now in the museum attached to that church. Contrary to the unfavourable opinion of older scholars, the "St. Louis" is acknowledged today as an achievement of the first rank, artistically as well as technically. Even though the garments completely hide the body of the figure, Donatello succeeded in conveying the impression of harmonious organic structure beneath the drapery. Unlike Ghiberti, Donatello never maintained a bronze foundry of his own but used the casting facilities of others (usually bell founders). This, however, was a matter of convenience rather than evidence of lack of technical competency and does not justify the view that the master's bronzes were the result of collaboration with other sculptors better versed in the requirements of the medium.

If Donatello needed a collaborator at the time he was engaged on the "St. Louis," it was probably a specialist in decorative architecture, since he had been commissioned to do not only the statue but also the niche and its framework. This niche is the earliest of its kind to display the new Renaissance architectural style created by Brunelleschi without residual Gothic forms. It could hardly have been designed by Donatello alone; he may have been assisted by Michelozzo, a sculptor and architect with whom he entered a limited partnership one or two years later. To the joint enterprises of the two masters, Donatello contributed only the sculptural centre: the fine bronze effigy on the tomb of the schismatic pope John XXIII in the baptistry, the relief of the "Assumption of the Virgin" on the Brancacci tomb in S. Angelo a Nilo, Naples, and the balustrade reliefs of dancing angels on the outdoor pulpit of Prato Cathedral (1433–38). Michelozzo was responsible for the architectural framework and the decorative sculpture, although the actual carving was often left to workshop assistants. The architecture of these partnership projects follows the lead of Brunelleschi and differs sharply from that of comparable works undertaken by Donatello alone in the 1430s, all of which show an unorthodox ornamental vocabulary drawn from both classical and medieval sources as well as an un-Brunelleschian tendency to blur the distinction between the sculptural and architectural elements. The graceful and lyrical figures of the Annunciation tabernacle in Sta. Croce are set against a background of the same ornament that occurs on the framework, and there is a frieze of ecstatically dancing angels on the singers' pulpit, or "Cantoria," in the Duomo (now in the Museo dell'Opera del Duomo). Both of these works show a vastly increased repertory of forms derived from ancient art, the harvest of Donatello's long sojourn in Rome between 1430 and 1433. The master must have returned to Florence with countless sketches after ancient monuments and with a new confidence in his ability to design the architectural framework for his own sculpture. His departure from the standards of Brunelleschi in such works as the "Cantoria" produced an estrangement between the two old friends that was never repaired. Brunelleschi even composed epigrams against Donatello.

During his partnership with Michelozzo, Donatello carried out a number of independent commissions of a purely sculptural character, including several works in bronze for the baptismal font of S. Giovanni in Siena. The earliest, and most important, of these was the "Feast of Herod" (1423–27), an intensely dramatic relief with an architectural background that for the first time displayed Donatello's command of scientific linear perspective; this mathematically precise system of foreshortening and space projection had been invented only a few years earlier by Brunelleschi. To the Siena font Donatello also contributed two statuettes of Virtues, austere beautiful female figures whose style points toward the Virgin and angel of the Sta. Croce Annunciation, and three nude putti or child angels (one of which was stolen and is now in the Berlin museum). These putti, evidently influenced by Etruscan bronze figurines, prepared the way for the bronze David, the first large-scale, free-standing nude statue of the Renaissance. Well proportioned and superbly poised, it was conceived independently of any architectural setting. Its air of harmonious calm makes it the most classical of Donatello's works. The statue was surely done for a private patron, but his identity remains in doubt. Its recorded history begins with the wedding of Lorenzo the Magnificent in 1469, when it occupied the centre of the courtyard of the Medici palace in Florence. It could not have been made for this location, however, since the palace was not begun until 1444, during Donatello's absence in Padua. After the expulsion of the Medici in 1495, the bronze "David" was placed in the courtyard of Palazzo Vecchio.

Whether or not the bronze "David" was commissioned by the Medici, Donatello did work for them between 1433 and 1443. This was the decade during which he produced sculptural decoration for the Old Sacristy in S. Lorenzo, the Medici church. His works there included ten large reliefs in coloured stucco and two sets of small bronze doors, which show paired saints and apostles disputing with each other in extraordinarily vivid and even violent fashion.

**Paduan period.** In 1443 Donatello was about to start work on two much more ambitious pairs of bronze doors for the sacristies of the cathedral when he was lured to Padua (modern Padova) by the commission for a bronze equestrian statue of a famous Venetian condottiere (mercenary soldier), Erasmo da Narni—popularly called "Gattamelata" ("the honeyed cat")—the commander of the Venetian army who had died shortly before. Such a project was unprecedented—indeed, scandalous—at that time. Since the days of the Roman Empire, bronze equestrian monuments had been the prerogative of rulers. To extend the same privilege to a mere professional military leader, however meritorious, must have seemed the height of presumption. In any event, the execution of the monument was plagued by delays of many kinds. Donatello did most of the work between 1447 and 1450, yet the statue was not placed on its pedestal until late in 1453, ten years after the master had left Florence. It represents Gattamelata, in pseudoclassical armour, calmly astride his mount, the baton of command in his raised right hand. The head is an idealized portrait with intellectual power and Roman nobility. This statue was the ancestor of all the equestrian monuments erected since the mid-15th century. Its fame, enhanced by the controversy surrounding it, almost at once spread far and wide. Even before it was put on public view, the King of Naples wanted to secure the services of Donatello for a royal equestrian statue of the same kind, a telling commentary on the importance attached to artistic achievements in Renaissance Italy.

While he was awaiting the resolution of the difficulties surrounding the Gattamelata monument, Donatello undertook some important works for the Paduan church of S. Antonio: a splendidly expressive bronze crucifix and a new high altar, the most ambitious of its kind, unequalled anywhere in 15th-century Europe. It consisted of a richly decorated architectural framework of marble and limestone containing seven life-size bronze statues, 21 bronze reliefs of various sizes, and a large limestone

The first free-standing nude statue since antiquity

The "Gattamelata" and its influence

Partnership with Michelozzo

relief of the "Entombment of Christ." Unfortunately, the housing was destroyed a century later, and the present arrangement of the sculpture, dating from 1895, is wrong both aesthetically and historically. Recent attempts to reconstruct the original appearance of the altar agree on certain basic features but vary widely in detail. Among the statues, the majestic Madonna and the delicate, sensitive St. Francis command particular notice; the Madonna's austere frontal pose would seem to be a conscious reference to a much earlier venerated image of the Virgin that then existed in the same church. Of the reliefs, the finest are the four miracles of St. Anthony, wonderfully rhythmic compositions of great narrative power. Donatello's mastery in handling large numbers of figures (one relief has more than 100) anticipates the compositional principles of the High Renaissance.

The last three years of Donatello's Paduan sojourn are puzzling because of the master's apparent inactivity. He had delivered the sculptures of the high altar of S. Antonio in mid-1450, apparently in considerable haste (some of the statues are technically unfinished) and without a financial settlement; six years later, he was still trying to collect money he claimed the authorities owed him for the altar. The Gattamelata monument was finished and waiting to be placed on its pedestal. The master had dismissed the large force of sculptors and stone carvers he had employed on these major projects. Offers of other commissions reached him from Mantua, Modena, and Ferrara, perhaps even from Naples, but nothing came of any of them. Clearly, Donatello was passing through a crisis that prevented him from working. In part, his troubles seem to have been physical; an acquaintance quoted him some years later as having said toward the end of his Paduan stay that he did not want to die "among those frogs in Padua, which he almost did," and in 1456 the Florentine physician Giovanni Cellini recorded in his account book that he had successfully treated the master for a protracted illness. Poor health may in turn have set off an emotional crisis. Such, surely, is the impression conveyed by the only two works Donatello completed between 1450 and 1455: the wooden statue "St. John the Baptist" in Sta. Maria dei Frari, Venice, dating shortly before his return to Florence, and the even more extraordinary wooden figure of Mary Magdalen in the Florentine baptistery. Both are marked by a new depth of insight into psychological reality. The powerful bodies found in Donatello's previous work have become withered and spidery, overwhelmed, as it were, by tremendous emotional tensions within. The "Magdalen" was damaged during the flood that inundated Florence in 1966. Subsequent restoration revealed the original painted surface, which includes realistic flesh tones and golden highlights on every strand of the saint's hair.

**Late Florentine period.** The unbridled expressive force of the "Magdalen" must have been a shock to the Florentines. During the decade of Donatello's absence, a new generation of sculptors had arisen—the most talented were Antonio Rossellino and Desiderio da Settignano—that excelled in the sensuous treatment of marble surfaces. Their work, and the public's taste for it, had little in common with the savage intensity of Donatello's late work. Between 1455 and 1460, therefore, Donatello's important commissions all came from outside Florence. They included the dramatic bronze group "Judith and Holofernes" (later acquired by the Medici and now standing in front of the Palazzo Vecchio) and a bronze statue of St. John the Baptist for Siena Cathedral. In the late 1450s, Donatello was living in Siena, where he was at work on a pair of bronze doors for the cathedral. This ambitious project, which would have rivalled Ghiberti's doors for the Florentine baptistery had it been carried to completion, was abandoned by the master about 1460 for reasons unknown (most likely technical or financial). Only two of the reliefs were executed; one of them is probably the "Lamentation" panel now in the Victoria and Albert Museum, London.

Donatello spent the last years of his life in Florence designing twin bronze pulpits for S. Lorenzo, so that at the

time of his death on December 13, 1466, he was once again in the service of his old patrons, the Medici. Covered with reliefs showing the passion of Christ, the pulpits are works of tremendous spiritual depth and complexity, even though some parts were left unfinished and had to be completed by lesser artists.

#### MAJOR WORKS

All the following are sculpture, in marble unless otherwise stated. "David" (1408–09, 1416; Bargello, Florence); "St. John the Evangelist" (1408–15; Museo dell'Opera del Duomo, Florence); "Crucifix" (wood; c. 1410–15; Sta. Croce, Florence); "St. Mark" (1411–c. 1415; Or San Michele, Florence); "St. George Tabernacle" (c. 1415–17; Bargello, Florence); "Pazzi Madonna" (marble relief; c. 1422; Staatliche Museen Preussischer Kulturbesitz, Berlin); "St. Louis Tabernacle" (the statue in bronze; 1423; Or San Michele, Florence); "Lo Zuccone" (1423–25; Museo dell'Opera del Duomo, Florence); sculpture for the font, Siena baptistery (bronze; 1423–29; baptistery, Siena); Tomb of John XXIII (the effigy in bronze; 1425–27; baptistery, Florence); "The Ascension with Christ Giving the Keys to St. Peter" (1428–30; Victoria and Albert Museum, London); "David" (bronze; c. 1430–35; Bargello, Florence); "Annunciation Tabernacle" (limestone; 1428–33; Sta. Croce, Florence); "Cantoria" (1433–39; Museo dell'Opera del Duomo, Florence); sculptural decoration of the Old Sacristy (stucco, bronze; S. Lorenzo, Florence); "Crucifix" (bronze; 1444–47; S. Antonio, Padova); equestrian monument of Erasmo da Narni called "Gattamelata" (bronze; 1447–53; Piazza del Santo, Padova); high altar, S. Antonio, Padova (bronze, stone; 1446–50; S. Antonio, Padova); "Mary Magdalen" (wood; 1454–55; baptistery, Florence); "Judith and Holofernes" (bronze; 1456–57; Palazzo Vecchio, Florence); "Lamentation" (bronze relief; 1458–59; Victoria and Albert Museum, London); twin pulpits (bronze; c. 1460–70; S. Lorenzo, Florence).

## Donizetti, Gaetano

One of the most prolific of 19th-century Italian opera composers, Domenico Gaetano Maria Donizetti played a significant role in the progress of operatic history; his works represent a transitional stage between Rossini and Verdi's further development of Italian opera. His works are both valuable in their own right and interesting for their influence on his younger contemporary, Verdi. In his serious operas he developed considerably the dramatic weight and emotional content of the genre, and his comic operas have a sparkling wit and gaiety all their own.

The youngest of three sons of the caretaker of the *monte di pietà* (the municipal pawnshop), Donizetti was born on November 29, 1797, at Bergamo in Lombardy, Italy. He began his musical studies with Giovanni Simone Mayr, a Bavarian priest who was musical director of Sta. Maria Maggiore, Bergamo's chief church, and also a successful composer of opera. As a choirboy Donizetti did not shine, but Mayr perceived in him a nascent musical ability and secured his entry into the Liceo Filarmonico (the music school) at Bologna, where he had a thorough training in fugue and counterpoint. His father hoped he would become a church composer, but, though he did compose a vast quantity of sacred music, his natural instinct was for the theatre.

Donizetti scored his first success with *Enrico di Borgogna*, which was premiered in 1818 at the Teatro San Luca, in Venice, and during the next 12 years he composed no fewer than 31 operas, most of them produced at Naples and now forgotten. In 1830 his *Anna Bolena*, produced in Milan, carried his fame abroad to all the European capitals and eventually across the Atlantic.

Two years later he scored another lasting success with *L'elisir d'amore* (The Elixir of Love), a comedy full of charm and character with a libretto by Felice Romani, the best theatre poet of the day. *Lucrezia Borgia* (1833), also with a libretto by Romani, consolidated his reputation at La Scala opera house in Milan and elsewhere. Like the opera composers Gioacchino Rossini and Vincenzo Bellini before him, he next gravitated to Paris, where his *Marino Faliero*, though not a failure, suffered from comparison with Bellini's *I Puritani*, produced a few weeks before. Donizetti then returned to Naples for the production of his tragic masterpiece, *Lucia di Lammermoor* on September 26, 1835.

In 1828 Donizetti had married Virginia Vasselli, the sister of one of his closest friends in Rome; they made their home in Naples. He was deeply devoted to her and never really recovered his spirits after her death, soon after the stillbirth of a son, in 1837. His distress was exacerbated by the fact that none of the three children born to them survived birth. It seems clear that syphilis, to which Donizetti himself later succumbed, was already taking its toll of his family.

Donizetti continued to work in Naples until 1838, when municipal censorship objected to the production of his *Poliuto*, which dealt with a Christian martyr, on the ground that the sacred subject was unsuitable for the stage. He thereupon returned to Paris, where the field had been cleared for him by Bellini's early death and Rossini's retirement. There he revived some of his best operas, though *Lucrezia Borgia* had to be withdrawn because of objections by Victor Hugo, on whose drama the libretto was based. *Poliuto* was produced in 1840 as *Les Martyrs* with a French text by Eugène Scribe. It was preceded two months earlier by the opéra comique, *La fille du régiment* (The Daughter of the Regiment), which gained enormous popularity over the years through the performances of the leading sopranos of the day, including Jenny Lind, Adelina Patti, Marcella Sembrich, Emma Albani, and other divas of the 19th century. Later in the same year the Paris Opéra produced *La Favorite*, Donizetti's first essay in French grand opera.

Bartolomeo Merelli, a fellow pupil of Donizetti, was now director of La Scala and also of the Karntnerthor Theater, in Vienna. He engaged Donizetti to compose an opera for La Scala. The work, *Maria Padilla*, was produced in 1841 only a few weeks before the famous première of Verdi's *Nabucco*. Merelli also commissioned an opera for his Viennese theatre. There, *Linda di Chamounix*, a romantic opera *semiseria*, was produced in 1842 and dedicated to the empress Maria Anna. Donizetti had already been brought to the notice of the emperor Ferdinand I by his chancellor, Prince Metternich, and had conducted Rossini's *Stabat Mater* in his presence. He now received the appointment of official composer to the Emperor, which obliged him to be in Vienna for six months in the year but left him free to

work elsewhere during the rest. At the same time Rossini, who had always furthered Donizetti's interests in Paris and entrusted to him the first performance of his *Stabat Mater* at Bologna, urged him to undertake the vacant directorship of the Liceo in that city. But Donizetti felt that he could not undertake this responsibility and preferred to continue his profitable operatic career. Back in Paris, he produced at the Théâtre Italien the delightful and witty comic opera, *Don Pasquale*.

But Donizetti was already in the grip of his fatal disease. He produced his last important opera, *Dom Sébastien*, with a libretto by Scribe, at the Paris Opéra in 1843 under the strain of constant headaches and occasional lapses of mental capacity. He suddenly aged, lost his good looks and his equability of temper, which had hitherto seen him through the trials of operatic production. *Dom Sébastien*, though unfavourably reviewed in the press, was nonetheless a success with the public.

The remaining years were a story of degeneration into hopeless insanity, first in a private asylum near Paris, where, after considerable difficulties with the French police, who were supported by the doctors, he was at last taken home to Bergamo by his devoted nephew Andrea, son of his eldest brother. He lingered on until April 8, 1848, a victim of general paralysis of the insane, deprived of willpower, speech, and physical control. It was a pitiable end for a gay and handsome man who, unlike Bellini, was never envious of the successes of other composers and at all times displayed an openhearted generosity. To the French composer Hector Berlioz, for example, whose criticisms in *Le Journal des Débats* were consistently hostile, he spontaneously sent a letter of introduction to Prince Metternich, when Berlioz was about to leave for Vienna.

Donizetti always won more favour with the public than with the critics. During his lifetime his success was enormous and the rewards considerable. His popularity continued until the end of the century, but by 1914 his operas had almost disappeared from the repertory, overshadowed by the more substantial masterpieces of Verdi and Richard Wagner. In the 1950s there was a revival of interest in his works, after which it seemed unlikely that, at least, *Lucia di Lammermoor*, *L'elisir d'amore*, and *Don Pasquale* would be allowed to pass into oblivion.

#### MAJOR WORKS

OPERAS: 75 including *Alfredo il Grande* (1823); *Emilia di Liverpool* (1824); *Le convenienze ed inconvenienze teatrali* (1827); *Il borgomastro di Sardaam* (1827); *La regina di Golconda* (1828); *Il giovedì grasso* (1828); *Il castello di Kenilworth* (after Scott, 1829); *Anna Bolena* (1830); *L'elisir d'amore* (1832); *Il furioso all'isola di San Domingo* (1833); *Torquato Tasso* (1833); *Lucrezia Borgia* (1833); *Maria Stuarda* (1834); *Gemma di Vergy* (1834); *Marino Faliero* (after Byron, 1835); *Lucia di Lammermoor* (after Scott, 1835); *Belisario* (1836); *Il campunello di notte* (1836); *Betty* (1836); *Pia de' Tolomei* (1837); *Roberto d'Evereux*, *Conte d'Essex* (1837); *Poliuto* (1840); *La fille du régiment* (1840); *La favorite* (1840); *Linda di Chamounix* (1842); *Don Pasquale* (1843); *Maria di Rohan* (1843); *Dom Sébastien, roi de Portugal* (1843).

OTHER WORKS: Two oratorios, several cantatas, religious pieces, at least 20 string quartets, three string quintets, and numerous songs.

BIBLIOGRAPHY. GUGLIELMO BARBLAN, *L'opera di Donizetti nell'età romantica* (1948), the standard work on Donizetti's operas; ARNALDO FRACCAROLI, *Donizetti* (1944), the authoritative Italian biography; WILLIAM ASHBROOK, *Donizetti* (1965), a detailed study of the man and his works; HERBERT WEINSTOCK, *Donizetti and the World of Opera in Italy, Paris and Vienna in the First Half of the Nineteenth Century* (1963), the most comprehensive biography in English.

(D.Hus.)

#### Donne, John

As both poet and prose writer John Donne has had an especially powerful influence on writers of the 17th and the 20th centuries, who have found stimulus in his fusion of witty argument with passion, his dramatic rendering of complex states of mind, his daring and unhackneyed images, and his ability (little if at all inferior to Shake-

spare's) to make common words yield up rich poetic meaning without distorting the essential quality of English idiom. As a leading churchman and preacher, he helped to mold the outlook of the Church of England. He was, furthermore, engaged upon so many activities characteristic of his times that his career has an unusually strong historical interest.

Donne, oil painting by an unknown artist, after I. Oliver, c. 1616. In the National Portrait Gallery, London.

**Early life and career.** Donne was born in London at some time between January 24 and June 19, 1572, of Roman Catholic parents. His mother, the daughter of John Heywood, epigrammatist and playwright, was a descendant of Henry VIII's chancellor, Sir Thomas More. Donne rightly claimed that no family had suffered more for its religious beliefs than hers. His father, descendant of an ancient Welsh family whose arms the poet bore, was a successful London merchant. Six months after his death in 1576 his widow married Dr. John Syminges, several times president of the Royal College of Physicians, who brought up the Donne children. According to Izaak Walton (whose charming *Life of Donne* was first published in 1640), Donne was educated at home by a Catholic tutor until, with his brother Henry, he matriculated at Hart Hall (later Hertford College), Oxford, in October 1584. After three years, according to Walton, Donne transferred to the University of Cambridge, though no surviving records confirm this. He did not take a degree from either university, however, for this would have required his accepting the Act of Supremacy and recognizing the Thirty-nine Articles of religion, to neither of which conditions, as a Catholic, he could subscribe. Extensive travels in Europe probably followed, but by May 1591 he was enrolled as a student of the law at Thavies Inn, whence he proceeded to Lincoln's Inn (May 6, 1592). In 1593 his brother Henry was arrested for harbouring a Catholic priest and died in prison of the plague. In June of the same year Donne, being now of age, received his portion of his father's estate. He remained at Lincoln's Inn until at least the end of 1594, having fulfilled the conditions necessary to proceed to final training for the profession of law. Like many others at that time, however, he regarded the Inns of Court only as a gateway to a state office and as a means of making contacts with men of affairs.

In 1596 Donne joined the gentlemen adventurers (many of them, like himself, aspirants to a position in public service) as a volunteer in the successful naval and military expedition against Cádiz. In the following year he took part in the Islands expedition, hunting for Spanish treasure ships in the Azores. One of his companions was Thomas Egerton, who recommended Donne to his father, Sir Thomas Egerton, lord keeper of the great seal. By the beginning of 1598 Donne had become a secretary to Sir Thomas in an office that was a recognized path to

high public appointments. Sir Thomas thought well enough of Donne to send him into Parliament in 1601. He took no part in the debates or committees there, however, his function apparently being to keep his finger on the pulse of the House and report to his master. At this time began Donne's rejection of Catholicism (see below).

Donne was well on the way to achieving his ambitions. He had also by this time written much of his poetry, most of it in imitation of ancient Latin poets: there were verse letters to male friends (the earliest dating from about 1592); five formal verse satires in the modes of Horace and Juvenal (c. 1593–98) and one canto of a satirical epic (*Metempsychosis*, 1601); a "book" of love-elegies in part modelled on Ovid's; and epigrams that to some extent imitated those of Martial. The classical models, however, are so transformed by the wit and daring of Donne's imagination that the verses are thoroughly original. By 1601, he had also composed numerous love lyrics in various moods, which are among his most famous poems. Such are the vigour, realism, and passion of his work at this period that they have sometimes been thought to reflect Donne's own youthful outlook and conduct. His contemporary, Sir Richard Baker, wrote of him as "not dissolute (*i.e.*, careless), but very neat; a great visitor of Ladies, a great frequenter of Plays, a great writer of conceited Verses." The moral fastidiousness and earnestness that Donne displayed throughout his life, however, make it difficult to believe that he was a youthful rake. His visits to the theatre in that great age of English drama reflected but one of the many aspects of literature and learning in which he interested himself. Walton emphasizes Donne's unusual studiousness throughout his life; and he was engaged, at least as early as 1593, in a deep consideration of the points at issue between the English and Roman churches. The "Ladies" he visited were doubtless noblewomen like those who were later to become his patrons.

His wit and charm made him a favourite with the ladies in the lord keeper's household. He was particularly attracted to Anne More, daughter of Sir George More of Loseley Park and niece and protégée of Egerton's second wife. Anne's father had brought her to London for the assembling of Parliament in 1601. She and Donne met secretly, and since there was little chance of winning the consent of so ambitious and important a man as Sir George, they agreed to marry without it, apparently early in December 1601. This was an offense against both civil and canon law, and Donne's risking so much for love was truly what Walton called "the great error of his life." When in February 1602 Donne told Sir George of the marriage, his irate father-in-law had the poet imprisoned for a time, persuaded Egerton to dismiss him, and brought the matter before the Court of High Commission. Though the commissioners judged the marriage valid, there now began for Donne a long and difficult period of unemployment, during which, however, his love for his wife never faltered.

**Churchman and preacher.** Donne first found shelter in the house of Lady Egerton's son, Sir Francis Wolley, at Pyrford, Surrey. Here he left his family for about a year (1605–06) while he travelled in France and Italy. From 1606 until 1611 he had his own house at Mitcham, south of London, and an apartment in London itself. For some time he seems to have assisted Thomas Morton (later bishop of Durham) in controversial tracts against the Catholics, more particularly in defense of King James I's exaction of the oath of allegiance as head of the Church of England. Donne's own contribution was an effective piece of propaganda in support of the King called *Pseudo-martyr* (1610), in recognition of which the Oxford University conferred on him the degree of master of arts. An offshoot of the controversy was his satiric fantasy against the Jesuits, *Ignatius his Conclave* (published in Latin and in English in 1611).

Donne often felt despondent at the lack of direction in his life. He had thoughts even of suicide, but these were exorcised in a casuistical work, *Bianthanasos* (written c. 1608; published 1646), in which he argued the grounds on which one could rightly take one's own life. More

Marriage to Anne More

especially, he experienced a deep personal religious struggle. Morton had more than once urged him to enter the ministry of the Church of England, most strongly in 1607, when he offered Donne a benefice he was himself vacating. Donne refused as being unworthy and as having no convincing vocation for holy orders. He tried unceasingly to secure secular employment but without success. By the time he had written Pseudo-martyr, moreover, King James made it clear that he wished Donne to enter the church and that he did not favour secular employment for him.

Theological views

Donne had, of course, been for some time a convinced Anglican. In 1596–97 he had served a Protestant queen against her Catholic enemies, and he must have at least formally renounced Catholicism before he could enter Egerton's service. He eventually maintained that any church asserting the main tenets of the Christian religion was a true church; in "indifferent" matters (government, ritual, and so on) the practice of one's own nation should be followed. Though he never doubted the truth of Christianity, his lack of complete conviction concerning his own salvation persisted. His struggle for assurance is expressed in religious poems written between 1607 and 1613, which include some of the finest in English. Donne was able to support his growing family by means of the belated payment of his wife's dowry and by the patronage (after 1607) of Lucy Russell, countess of Bedford. To her and to other noble ladies he wrote characteristically original verse letters, and he composed elegies on the deaths of some of Lady Bedford's kinsfolk.

In 1611 Donne found another patron, Sir Robert Drury, with whom he toured in France and the Low Countries in 1611–12, who provided the Donne family with accommodations (until 1621) attached to the Drury residence in London. The death of Drury's young daughter, Elizabeth, in 1610 had called forth a funeral elegy from Donne; and in 1611 and 1612 he wrote Anniversaries, also in commemoration of her death, though here the theme is used mainly as a pretext for a profound satirical "anatomy" of a decaying world, a contemplation of the soul's flight to share the joys of heaven. Still seeking state employment, Donne wrote verses on the death of Prince Henry (1612) and on the marriage of Princess Elizabeth to Frederick V, elector of the Palatinate (1613). He sat in the "Addled" Parliament of 1614 and served on four select committees. He wrote an epithalamion (a nuptial poem) in celebration of the wedding of the notorious Countess of Essex to the court favourite, Robert Carr, earl of Somerset, whom Donne had been cultivating for help in securing an official position. Late in 1614 a court post seemed at last within his grasp, but the King again refused to appoint Donne to any position outside the church. Convinced finally that he was called to the ministry at the hands of God's representative, the King, Donne completed studies in Greek and Hebrew, finished the *Essays in Divinity*, and began a new career in the church.

Ordination into the Church of England

He was ordained deacon and priest by Bishop John King on January 23, 1615. Preferment soon followed. He was made a royal chaplain and received, at the King's command, the degree of doctor of divinity from the University of Cambridge. He occupied the rectory of Keyston, in Huntingdonshire (the King's gift) from 1616 until 1621; the rectory of Sevenoaks in Kent (an unsolicited gift from his old master, Egerton) from 1616; that of Blunham, in Bedfordshire, from 1622; and the vicarship of St. Dunstan-in-the-West, London, from 1624 until his death. He was scrupulous, however, in confining his tenure of those benefices that carried "cure of souls" to the two allowed by law to royal chaplains. From October 1616 he occupied the important post of reader (preacher and spiritual director) at Lincoln's Inn. His preaching soon developed great power and eloquence.

In August 1617, Donne's wife died in giving still-birth to their 12th child. Her loss caused him great sorrow but also deepened the devotion and dedication of his religious life. For a long time after his bereavement Donne's health gave his friends concern, and in 1619 he was freed from his duties at Lincoln's Inn to go as chaplain with the embassy of James Hay, Viscount Doncaster to the princes

of Germany and Bohemia on the eve of the Seven Years' War, the great conflict involving all the major European powers except Turkey. On November 22, 1621, Donne was installed as dean of St. Paul's Cathedral. Many duties fell to him, and Donne was most conscientious in performing them. The register of his administration at St. Paul's proves his efficiency and integrity.

Dean of St. Paul's Cathedral

The death of King James in 1625 made little difference to Donne's status. The new king, Charles I, admired him as preacher and as poet. The only poems that Donne wrote after his ordination, however, were three fine "Hymns," two or three Holy Sonnets, and an elegy on the death of Lord James Hamilton. His creative talents were occupied almost wholly in preaching and in composing the prose Devotions upon Emergent Occasions, written during his recovery from a serious bout of relapsing fever (1624). He published only a few more important sermons; but in 1625, when he was sheltering in the house of Magdalen Herbert (Lady Danvers) from the severe plague that scourged London, and again in 1630, when he was trying to recover from his last illness at the home of his son-in-law, Donne transcribed from his notes more than 100 other sermons, which were published after his death by his son. His last years were saddened by the death of friends and patrons, of children (only six of whom survived their father) and, in January 1631, of his aged mother. Though emaciated by illness, Donne preached at court his last sermon (published posthumously as *Death's duell*) on February 25, 1631; the next day he attended his last meeting of the governors of the Charterhouse. He conducted cathedral business for the last time on March 21. On March 31, 1631, Donne died, and on April 3 he was buried in his cathedral. According to Walton, Donne had caused a drawing to be made of himself in his shroud during his last illness; from this Nicholas Stone carved an effigy in white marble, which, alone of all the monuments, survived the destruction of old St. Paul's in the Great Fire of 1666 and which may still be seen in the south aisle of the present cathedral.

**Posthumous reputation.** When Donne published his Anniversaries he apologized to his friends for having "descended to print anything in verse," for, at the time in which he lived to print one's verses smacked of commercialism. Only one of his poems in English survives in his own handwriting; most were preserved in manuscript copies made by and passed among a relatively small but admiring coterie of poetry lovers. The contents of the first two (posthumous) editions of his Poems (1633, 1635), apart from the few already printed, were in fact derived from collections of such transcripts. The Poems were sufficiently popular to be published eight times within 90 years of Donne's death, but his work was not to the general taste of the next century, when he was regarded as a great but eccentric "wit." From the beginning of the 19th century, however, perceptive readers began to recognize Donne's poetic genius. In the 20th century his sermons as well as his poems have attracted great attention but have had little literary influence upon other writers. He has, however, been established as a poet of great distinction (though uneven in quality), and as the master of what has been called the Metaphysical school of poets, has again been a strong influence both in the writing of poetry and in determining the emphases of literary critics and historians.

#### MAJOR WORKS

**POEMS:** The two Anniversaries (*An Anatomie of the World and Of the Progres of the Soule*; 1611 and 1612) were published during Donne's lifetime. The first (incomplete) collection of his verse was published posthumously in 1633. To the period before Donne's marriage (1601) belong most of his satires and elegies and many of his songs and sonnets. To the period between his marriage and ordination (1615) belong the verse letters, the rest of the elegies and songs and sonnets, and the first religious verses. Among these works are many of Donne's finest poems, including (titles followed by first lines): "Song" ("Goe, and catche a falling starre"); "The good-morrow" ("I wonder by my troth, what thou, and I/Did, till we lov'd?"); "The Exstasie" ("Where, like a pillow on a bed"); "A Valediction: forbidding mourning" ("As virtuous men passe mildly away"); "The Baite" ("Come live

with mee, and bee my love"); "The Sunne Rising" ("Busie old foole, unruly Sunne"); "The Canonization" ("For God-sake hold your tongue, and let me love"); "The triple Foole" ("I am two fooles, I know, /For loving, and for saying so"); "Twickenham garden" ("Blasted with sighs, and surrounded with teares"); "A nocturnall upon S. Lucies day . . ." ("Tis the yeares midnight, and it is the dayes"); "The Will" ("Before I sigh my last gaspe, let me breath"); "The Funerall" ("Who ever wmes to shroud me, do not harme/ Nor question much"); and "The Relique" ("When my grave is broke up again /Some second ghest to entertain"). To the period of Donne's life between 1607 and his death (1631) belong the Divine poems, including the Holy Sonnets (notably I, "Thou Hast made me"; VII, "At the round earth's imagin'd corners blow"; X, "Death be not proud"; XI, "Spit in my face yee Jewes"; XIV, "Batter my heart, three-person'd God"; XVIII, "Show me deare Christ, thy spouse"). Numbering per H.J.C. Grierson (see Bibliography below).

PROSE: Dome's prose published during his lifetime includes *Pseudo-martyr* (1610); *Ignatius his Conclave* (1611; the Latin version, *Conclave Ignati*, had appeared that same year); *Devotions upon Emergent Occasions* (1624); *Four Sermons on Speciaall Occasions* (1625; reprinted with corrections and one further sermon, 1626); *Death's duell* (1630). Posthumous editions of Donne's prose include *Juvenilia* (1633); *LXXX Sermons* (1640); *Biathanatos* (1646); *Fifty Sermons* (1649); *Essays in Divinity* (1651); *Letters to severall persons of honour* (1651); *Paradoxes, problems, essays, characters . . .* (1652); *XXVI Sermons* (1661). The principal editor of these writings was John Dome the younger.

**BIBLIOGRAPHY.** GEOFFREY L. KEYNES, *A Bibliography of Dr. John Donne*, 4th ed. (1972), contains full details of manuscripts, editions, and scholarly works. ROBERT C. BALD, *John Donne: A Life*, ed. by W. MILGATE (1970), is the definitive biography, and mentions all the available sources and documents. The fullest collection of Donne's letters is that in EDMUND W. GOSSE, *The Life and Letters of John Donne, Dean of St. Paul's*, 2 vol. (1899, reprinted 1959). The standard edition of the *Poems* is that of H.J.C. GRIERSON, 2 vol. (1912), but it is being replaced by four volumes: *The Divine Poems* (1952) and *The Elegies and the Songs and Sonnets* (1965), ed. by HELEN GARDNER; and *The Satires, Epigrams and Verse Letters* (1967) and the *Epithalamions, 'Anniversaries' and Epicedes* (forthcoming), ed. by W. MILGATE. The best introduction to the poems is JAMES B. LEISHMAN, *The Monarch of Wit: An Analytical and Comparative Study of the Poetry of John Donne*, 7th ed. (1965). Standard editions of the prose works are: *The Sermons of John Donne*, ed. by GEORGE R. POTTER and EVELYN M. SIMPSON, 10 vol. (1953–62); *Devotions upon Emergent Occasions*, ed. by JOHN SPARROW (1923); *Ignatius His Conclave*, ed. by T.S. HEALY (1969); *Essays in Divinity*, ed. by EVELYN M. SIMPSON (1952); and *Paradoxes and Problems*, ed. by GEOFFREY L. KEYNES (1923). There is a facsimile of *Biathanatos*, with a bibliographical note by J. WILLIAM HEBEL (1930); *Pseudo-Martyr* (1610) has never been reprinted. The best guide to the prose is in EVELYN M. SIMPSON, *A Study of the Prose Works of John Donne*, 2nd ed. (1948).

(W.Mi.)

## Don River

One of the great rivers of the European portion of the Soviet Union, the Don has been a vital artery in that nation's history ever since the days of Tsar Peter the Great, who initiated a 14-map hydrographic survey of its course. Throughout the world, the river is associated with images of the turbulent and colourful Don Cosacks, a famous series of novels by Mikhail Sholokhov, a Nobel Prize winner, and a series of large-scale engineering projects that have enhanced the waterway's economic importance. The Don rises in the small reservoir of Svat, located in the central Russian uplands near the city of Novomoskovsk. It flows first in a generally southerly direction for 1,162 miles (1,870 kilometres), draining a basin of 163,000 square miles (422,000 square kilometres), before it enters the Gulf of Taganrog (Taganrogsky Zaliv) in the Sea of Azov. It is one of the major rivers of the Russian Soviet Federated Socialist Republic, lying between the equally important basins of the Volga (to the east) and the Dnepr. In its middle and lower courses, from the confluence with the Chernaya Kalitva to its mouth, the Don describes an enormous eastward-bulging arc as far as its junction with the Ilovlya. Near the top of the arc, the vast Tsimlyansk Reservoir (Tsimlyanskoye Vodokhanilishche) begins, joined at the city

of Kalach-na-Donu by the important Volga–Don Canal. Between the Ilovlya and the canal, the westward-swinging Volga approaches to within a mere 50 miles or so of the Don. From its source in the Tula Oblast (region), the Don crosses the Lipetsk, Voronezh, Volgograd, and Rostov Oblasti, through the forest-steppe and renowned steppe zones of the Soviet Union. It gathers in the waters of numerous tributaries, the most famous of which are the Krasivaya Mecha, Sosna, Chernaya Kalitva, Chir, and Donets (right bank), and the Voronezh, Khoper, Medveditsa, Ilovlya, Sal, and Manych (left bank). The river winds throughout its course, and the fall along its length is about 620 feet (190 metres). (For related information, see RUSSIAN SOVIET FEDERATED SOCIALIST REPUBLIC; SOVIET UNION; RUSSIAN STEPPE.)

**The river course.** In the upper portion of the Don—that is, as far downstream as the southeastward bend—the river flows along the eastern edge of the central Russian heights through a generally narrow valley. The right bank is well developed, reaching heights of 160 feet at the cities of Dankov and Lebedyan, and its limestone and chalk rocks are cut into by ravines and gullies. The left bank borders a flatter floodplain, and the river itself widens intermittently into small lakes; its low water depth ranges from less than a few feet on the shoals to 33 feet, with a breadth widening to 650–1,300 feet.

In the middle course, to the beginning of the Tsimlyansk Reservoir, the valley widens to about four miles, and its path is marked by floodplains, more small lakes, and dried-up old courses; the banks, especially the right bank, become steeper, with chalk, limestone, and sandstone predominating. The river width narrows to 330–1,300 feet, and the low-level depth is about 50 feet.

The lower course is dominated by the 160 miles of the Tsimlyansk Reservoir, named after a giant hydroelectric plant built between 1952 and 1955. Up to 24 miles in width, the reservoir has an average depth of 28.9 feet. Finally, the lower section of the Don has a valley width of 12–19 miles, with a huge floodplain and a braided river channel as much as 66 feet deep.

**The river basin.** The landscape of the upper and middle Don Basin is characterized on the right bank by undulating plains cut into by jagged gorges and on the left bank by the smoother, pond-dotted topography of the Oka-Don Plain (Oksko-Donskaya Nizmennost). Farther downriver the vast open landscapes of the steppes predominate. Rich, black soils fill almost the entire basin, though there are patches of gray forest soil in the north, where forests cover up to 12 percent of the area.

The climate of the basin is moderately continental, with average January temperatures ranging from 18° F to 12° F (–8° C to –11° C), while July readings reach 66° F to 72° F (19° C to 22° C). Annual precipitation diminishes from 23 inches in the north to 14 to 15 inches in the south.

The Don runs mostly through treeless countryside, but plantations have been made in parts of the upper reaches in the hope that tree roots will help bind together and strengthen the riverbanks. In the gentler lower regions the banks themselves have been tilled. The river is rich in fish, especially in the lower course.

**Water flow.** The long-term fluctuations in the water level of the Don reach about 39 feet in the upper course, 26 feet in the middle course, and 20 feet in the lower. The highest levels are in the springtime, the lowest in autumn and winter. At the mouth of the Don strong winds from the sea cause increases in the water level. Interesting variations occur in the amount of water flowing past given points along the river course: in the upper course, at the city of Georgy-Dezh, an average flow of 8,857 cubic feet per second is achieved by flows ranging from 1,480 to approximately 395,000 cubic feet per second, and there are corresponding variations as the total volume recorded increases at stations downstream. At the city of Kalach-na-Donu it has been calculated that about 65 percent of the annual flow occurs during April and May, with about 7 percent in March, before the influx of melted snow. Below Tsimlyansk Reservoir, the flow has been brought under partial control: at Nikolay-

Important tributaries

Fluctuating water levels

evskaya, for example, 34 percent of the annual volume occurs in spring, 33 percent in summer, 22 percent in autumn, and 11 percent in winter.

The Don begins to freeze, in its northern portion, about the middle of November and is clear of ice by about April 10. In the lower course the river is frozen between the end of November and the end of March at Kalach-na-Donu, and from mid-December to the beginning of April at Rostov-na-Donu.

*The imprint of man.* In the upper river basin an extensive network of ponds aids irrigation. The ponds are also used for building up stocks of fish. In the lower course of the Don an extensive irrigation network has been developed, channelled through the main Don canal, which emerges from the reservoir at the Tsimlyansk hydroelectric plant, branching out into, among others, the Lower Don, Upper Sal, and Proletariat canals. The plant at Tsimlyansk incorporates a hydroelectric station, a fish elevator, two navigable sluices, an irrigation canal, a 1,581-foot concrete overflow dam, and an eight-mile earthen dam. The full capacity of the reservoir is less than five cubic miles (22 cubic kilometres), but the average capacity is about half this amount.

The significance of the Don as a navigable waterway greatly increased with the construction of the Volga-Don Canal (Volgo-Donsky Kanal). The river itself is navigable from the mouth to the city of Georgy-Dezh (a distance of 842 miles [1,355 kilometres]) and in the spring as far as the village of Khlevnoye, 990 miles (1,590 kilometres) from the sea. Navigation in the lower course has been facilitated greatly by the Tsimlyansk project. At the mouth of the Don, navigational difficulties occasionally occur as a result of a fall of water level following a wind-induced water movement away to the south, while many strengthening and dredging operations are necessary to maintain and improve navigation in the upper reaches. The largest ports are Kalach-na-Donu, Tsimlyansk, and Rostov-na-Donu. (A.M.Ga.)

## Dorgon

Although he never bore the title of emperor during his lifetime, the Manchu prince Dorgon played a leading part in establishing the Ch'ing dynasty in China and was the first of his house to wield effective power there.

Dorgon was born in Yenden, Manchuria, on November 17, 1612, the 14th of the 16 sons of Nurhachi, founder of the Manchu state, who in 1616 proclaimed himself emperor of China but died in 1626 before making good his claim to imperial title. Under his successor, Abahai, Dorgon received the title of an imperial prince, *hosoi beile*. He distinguished himself in the wars against the Chahar Mongols that began in 1628 and was elevated to prince of the first degree (*jui ch'in-wang*). Dorgon commanded one of the two army groups that breached the Great Wall and sacked 40 cities in the Chinese provinces of Hopeh and Shantung during Abahai's campaigns to subjugate China in 1638–39. He also participated in the capture of the cities of Sung-shan and Chin-chou that resulted in a significant expansion of Manchu authority.

On Abahai's death in 1643, Dorgon was nominated his successor but declined, reportedly because of loyalty to the dead emperor. Instead, he and the older Prince Jirgalang became regents for Abahai's five-year-old son, Fu-lin. The fact that Dorgon executed two princes when he discovered their plot to put him on the Imperial throne is characteristic of the high moral standards for which he is praised by historians.

When in April 1644 the troops of the Chinese rebel Li Tzu-ch'eng conquered Peking (the capital of China then ruled by the Ming dynasty), Dorgon, on the advice of a Chinese counsellor, led an expeditionary force into China. His former principal enemy, the Chinese general Wu San-kuei, joined forces with him rather than allow Li Tzu-ch'eng to establish his own dynasty; and the combined armies inflicted a heavy defeat on Li Tzu-ch'eng's troops. Dorgon entered Peking in June 1644, but the last emperor had already hanged himself in April. After pursuing the fleeing troops of Li Tzu-ch'eng, Dorgon

turned his attention to the stabilization of his administration, prudently enlisting the cooperation of several outstanding Chinese experts. He established Peking as the capital and, adopting many Chinese customs, laid the basis for Manchu rule in China.

The youthful Fu-lin entered Peking on October 19, 1644, and 11 days later was proclaimed emperor under the name Shun-chih. In 1644 Dorgon subdued the provinces of Shensi, Honan, and Shantung; Kiangnan, Kiangsi, Hopeh, and part of Chekiang followed in 1645; and the provinces of Szechwan and Fukien were added in 1646. Rebellious Ming troops were pushed back into the southwestern provinces of the country, and Dorgon suppressed revolts of the Mongolian tribes in Central Asia.

He took over the highly developed administrative system of his Chinese predecessors, re-engaging Chinese experts and recruiting new civil servants through the proven method of selection and examination. Adam Schall von Bell, a German Jesuit missionary, served him as mathematician, director of the Imperial Board of Astronomy, and adviser on the manufacture of artillery. All these measures contributed to the generally favourable acceptance of the new dynasty, notwithstanding the forcible expropriation of land and the introduction of Manchurian customs, such as the pigtail.

Relegating Prince Jirgalang to the functions of assistant prince regent, Dorgon in 1644 began to gather more and more power in his hands, even venturing to impose humiliations on his nephew Hage and other Imperial princes who opposed him. Receiving the title of Imperial father regent in 1648, he personally led the campaign against a-rebellious Chinese general in Shansi. He also designed the plans for the construction of his own palaces in Jehol; here he intended to spend his remaining years as feudal overlord, but he died on December 31, 1650, during a hunt at Kharahotun, near the Great Wall. He was posthumously proclaimed emperor and given the temple name of Ch'eng Tsung.

Dorgon's sudden death created confusion and disorder in the empire. Since he had left no male heirs, disturbances broke out, especially among the corps of the white banner unit that had been under his command. Internal shifts on the political scene brought his former enemies to power; they had succeeded in obtaining the promulgation of an Imperial decree of March 1651 declaring that Dorgon had been a usurper. He was posthumously deprived of his princely rank, along with other honours; his relationship to the Imperial house was disavowed; and a petition of two officials attempting to redeem his reputation was rejected. Only after the Ch'ien-lung emperor, in 1773, honoured Dorgon's services in establishing the new dynasty and restored his neglected grave was Dorgon finally fully rehabilitated.

## Dormancy

There are few environments in which organisms are not subject to some kind of environmental stress. Some animals, such as birds, migrate vast distances to avoid unfavourable situations; others reduce environmental stresses by modifying their behaviour and the habitats (immediate surroundings) that they occupy. Arctic lemmings, for example, are able to avoid severe winter weather by confining their life in winter to activities beneath the snow cover.

Still another mechanism used by some organisms to avoid stressful environmental conditions is that of dormancy, an inactive state accompanied by a lower than

Post-humous reputation

Rise to power

Entry into Peking

normal rate of metabolism—the chemical processes responsible for the activity, nourishment, and growth of an organism—during which an organism conserves the amount of energy available to it and makes few demands on its environment. Most major groups of plants and animals have some representatives that can become dormant; more species hibernate than become dormant, however. Periods of dormancy vary in length and in degree of metabolic reduction, ranging from only slightly lower metabolism during the periodic, short-duration dormancy of deep sleep to more extreme reductions for extended periods of time. The longest recorded period of dormancy is that for the seeds of *Spergula arvensis*, which sprouted after being dormant for 1,700 years.

#### GENERAL FEATURES

*Value of dormancy.* In terms of evolution, dormancy seems to have evolved independently among a wide variety of living things, and the mechanisms for dormancy vary with the morphological and physiological makeup of each organism. For many plants and animals, dormancy has become an essential part of the life cycle, allowing an organism to pass through critical environmental stages in its life cycle with a minimal impact on the organism itself. When lakes, ponds, or rivers dry up, for example, aquatic organisms that can enter a period of dormancy survive, while others perish. Moreover, animals that can become dormant during the extreme cold of winter can extend their ranges into regions where animals incapable of dormancy cannot live. Dormancy also ensures that these animals will be free from competition during their periods of activity. Thus, dormancy is an adaptive mechanism that allows an organism to meet environmental stresses and to take advantage of environmental niches that otherwise would be untenable at certain times.

*Causes of dormancy.* The dormant state that is induced in an organism during periods of environmental stress may be caused by a number of variables. Those of major importance in contributing to the onset of dormancy include changes in temperature and photoperiod (length of exposure to light) and the availability of food, water, oxygen, and carbon dioxide. In general, because organisms normally exist within a relatively narrow temperature range, temperatures above or below the limits of this range can induce dormancy in certain organisms. Temperature changes also affect such other environmental parameters as the availability of food, water, and oxygen, thus providing further stimuli for dormancy. In Arctic regions, for example, certain animals become dormant during the winter months because food is less abundant. In desert biomes, on the other hand, the summer months, which may be periods of reduced food availability, intense heat, or extreme aridity, stimulate some desert organisms to become dormant. The lack of water during summer periods of drought or winter periods of freezing, as well as annual changes in the duration and intensity of light, particularly at high latitudes, are other environmental factors that can induce dormant states.

Under natural conditions, most of the environmental variables that influence dormancy are interrelated in a cyclical pattern that is either circadian (daily) or annual. Fluctuations in the major daily variables—light and temperature—can induce rhythmical changes in the metabolic activity of an organism; annual fluctuations in temperature and photoperiod can influence the availability of food and water. Concentrations of oxygen and carbon dioxide normally do not vary on a cyclical basis but as a result of habitat selection, such as burrowing in the mud, seeking a den, or other similar activities, in which the metabolic responses of the organism can alter the oxygen and carbon dioxide concentrations in its environment.

In an attempt to determine the relative influence of environmental factors upon dormancy, they have been varied experimentally. Investigations indicate that an organism, after it has adapted to a sequence of cyclical rhythms, tends to maintain its adaptive behaviour even though the environmental stimulus that originally elicited such behaviour is no longer present. For example, the

Arctic ground squirrel (whose winter period of dormancy is referred to as hibernation), when taken into the laboratory, supplied with adequate amounts of food and water, and exposed to constant temperature and light, exhibits periodic torpor (extreme sluggishness)—an innate behavioural pattern that operates independently of environmental cues. Other animals frequently will continue to respond as if they were exposed to the cyclical changes of their home environments after they are removed from their natural habitats.

#### DORMANCY IN BACTERIA AND FUNGI

Once in a dormant state, such organisms as bacteria and certain parasites are resistant to a wide variety of environmental conditions that otherwise would be fatal. While dormant, they can withstand boiling temperatures or the harmful effects of acids and other hostile chemicals. Moreover, the protective mechanisms of dormancy have in many cases extended far beyond those needed for adapting the stressful environmental situation that originally induced it; for example, dormancy makes certain organisms particularly immune to the effects of environmental pollution.

Bacteria and fungi become dormant by forming small, generally rounded spores (bodies that can develop into new organisms without fertilization) that are highly resistant to both physical and chemical agents. Yeast cells, for example, are usually killed in five to ten minutes by moist heat at temperatures of 50°–60° C (120°–140° F). To kill their spores, however, temperatures of 70°–80° C (160°–180° F) for a similar time-span are required. Cells of many other fungi are killed in 30 minutes by moist heat at a temperature of 62° C (144° F), but their spores can withstand 80° C heat for 30 minutes before being killed. Similarly, bacterial cells that can be destroyed in five to ten minutes by moist heat at temperatures of 55°–65° C (130°–150° F) have spores that can withstand temperatures of 120° C (250° F) for approximately 15 minutes or longer before being killed. In order to destroy the spores of *Clostridium botulinum*, the bacterium responsible for botulism, they must be heated to temperatures of 180° C (360° F) for ten minutes. The resistance of spores to high temperatures explains the care necessary in the preparation of canned foods, which otherwise might harbour spores that survive and germinate to produce toxins (poisons).

Although heat may destroy micro-organisms, low temperatures, no matter how extreme, seldom kill all members of a sporeforming microbial population. Micro-organisms maintained at subfreezing temperatures display no detectable metabolic activity, but they become active again when the temperature is increased. Similarly, dried spores of micro-organisms remain viable indefinitely; some can be subjected to extreme dehydration in the frozen state and sealed under a vacuum, yet the desiccated organisms remain viable for many years.

#### DORMANCY IN VASCULAR PLANTS

Vascular plants, such as ferns, conifers, and flowering plants, contain special tissues or vessels for the circulation of fluids. Found everywhere on land except at very high altitudes and latitudes and in permanently arid deserts, such plants respond in various ways to cold.

**Responses to cold.** Among the annuals, the entire plant dies in the fall; only its dormant seed survives the winter (overwinters) to produce a new generation. In biennials, such as carrots, the plant overwinters by using food reserves stored in the roots; the leaves die off during the first winter. The second-year plant, which arises from the root and a small piece of stem, produces seeds that survive during the second winter; the rest of the plant dies. Only the perennial plant can overwinter in a dormant state and survive for centuries. As winter approaches, the amount of colloid (substances divided into fine particles that are dispersed in a medium) in the cells of perennial plants increases, with a subsequent reduction in the amount of free water in them. Thus, there is less damage to the cell if freezing occurs. In herbaceous perennials, such as the dandelion, seeds are produced an-

Cyclical  
environ-  
mental  
changes

Spores

nually. The aboveground parts of the plant persist only through the relatively short growing season and then die off in the fall, leaving the roots and underground stems; these contain sufficient stored food to last through the winter and to produce new shoots in the spring.

Among trees and shrubs, evergreens retain their leaves, and the entire plant overwinters at a reduced metabolic rate. Deciduous plants shed their leaves in the fall, and the rest of the plant winters at a lower metabolic level, using the stored food reserves accumulated during the growing season.

Buds

The buds and embryonic leaves that develop during the growing season remain dormant until they sprout in the spring to produce new branches and foliage. Buds of bulbs, tubers, and other plant organs may also display dormancy. Some plant buds, known specifically as dormant buds, may never develop except under unusual conditions, such as when a small branch is broken off. Then the dormant bud begins to grow.

The role of seeds. That the annual and biennial plants overwinter as seeds indicates that the seed is a fairly resistant part of a plant's life cycle. Plant seeds hold the record for the longest known periods of dormancy: well-documented cases have established that seeds of the Manchurian lotus were still fertile after 1,000 years; and, as mentioned above, seeds of *Spergula arvensis* found in Denmark germinated after 1,700 years. Seeds buried to a depth of more than eight centimetres (three inches) normally do not germinate, apparently because the carbon dioxide level is too high and the oxygen level too low to allow germination. The ideal environment for seed survival over long periods of time seems to be in soils that are slightly to moderately moist and deficient in oxygen.

Dry seeds can withstand temperature extremes better than any other plant part without losing their viability. If, for example, dry sugar beet seeds are exposed to a temperature of  $-180^{\circ}\text{C}$  ( $-290^{\circ}\text{F}$ ) for 30 minutes, 96 percent of them will still germinate. Furthermore, these seeds will also germinate if subjected to a temperature of  $103^{\circ}\text{C}$  ( $217^{\circ}\text{F}$ ) for 16 hours.

Although the majority of seeds germinate readily as soon as environmental conditions are appropriate, many seem to require a distinct dormant period. Even with proper environmental conditions, such seeds will not germinate until they have first gone through a dormant stage. The length of seed dormancy may be one winter or may extend for several years. There are two major types of seed dormancy, seed-coat and embryo.

**Seed-coat dormancy.** Seed-coat dormancy occurs when the seed coat either is impermeable to water or oxygen or is resistant to the expansion of the embryo. That carbon dioxide cannot escape from a seed must also be considered as a factor contributing to its dormancy. Seeds that are impermeable to water include those of many legumes, such as the locust, clover, and alfalfa. The spiny fruit of the common cocklebur (*Xanthium*) produces two seeds the coats of which are impermeable to oxygen. In nature, germination of the cocklebur seeds is aided by frost, heat, or other environmental conditions that gradually erode the seed coat and allow oxygen to enter. Because the upper seed of the cocklebur fruit requires more oxygen for germination than the lower one, the lower seed usually germinates the first year; the upper seed germinates a year later. Although the coats of seeds such as pigweed (*Amaranthus*) allow the passage of both oxygen and water, the embryos are unable to break through, and the seeds do not germinate. In such cases the seed coat must be cracked or weakened so that the embryo is not injured, after which germination readily takes place. Various conditions serve to crack seeds in nature: e.g., fire, being stepped on, freezing, being ingested and passing through a digestive tract, and chemical or physical abrasion.

**Embryo dormancy.** Embryo dormancy may result from either an undeveloped (rudimentary) embryo or the failure of the embryo to begin growing. In the case of a rudimentary embryo, several months may elapse before the embryo has developed to the point of emerging from the seed; the buttercup (*Ranunculus*) is an example.

There are also certain seeds in which the embryo does not respond even if the seed coat is removed and the seed placed in optimal germinating conditions. In these seeds germination occurs only after a series of changes have taken place in the embryo; this process is referred to as afterripening. Afterripening sometimes occurs during the winter, allowing the seed to germinate in the spring. Often, however, afterripening continues over a period of years; some seeds from the plant germinate each year. This seems to be a mechanism for enabling a species to survive unfavourable growth conditions that may extend over several growing seasons. Afterripening is initiated by a variety of conditions, depending on the seed. In the hawthorn, an increase in acidity is required; in peaches and cherries, the requirement seems to be moist soil and exposure to temperatures ranging from  $0^{\circ}$  to  $10^{\circ}\text{C}$ . In such cases, afterripening may take from one to six months. Chemical treatment may also encourage it.

After-  
ripening

#### DORMANCY IN PROTOZOANS AND INVERTEBRATES

**Cysts and cystlike structures.** *Protozoans.* Many parasitic and free-living protozoans (one-celled animals) exhibit a dormant stage by secreting a protective cyst. The stimulus for cyst formation in free-living protozoans may be temperature changes, pollution, or lack of food or water. *Euglena*, a protozoan that encysts to avoid environmental extremes, apparently has two kinds of cysts. Apparently one is formed only to avoid stressful conditions; the other is formed for the same reason but also involves asexual reproduction, resulting in a cyst that may contain up to 32 daughter organisms, which emerge under proper environmental conditions.

Free-living protozoans form cysts around themselves to avoid environmental extremes, but cysts are a part of the life cycle of parasitic protozoans. The causative agent of amebic dysentery, *Entamoeba histolytica*, is found in the intestine of infected individuals, in whom it forms cysts that pass to the outside in feces. When food or water containing cysts enters the digestive tract of another person, the amoebas are released from the cysts and infect the new host. Without encystment, which allows the organism to live in a dormant state in an unfavourable environment (e.g., water), amebic dysentery could be much more easily controlled. Protected by the cyst wall, however, the dormant contents of the cyst can survive for weeks. Although they are not particularly resistant to drying, the cysts of *E. histolytica* can withstand temperatures of up to  $68^{\circ}\text{C}$  ( $154^{\circ}\text{F}$ ) for five minutes. They are also resistant to certain chemicals.

The role  
of cysts in  
parasitic  
protozoans

*Invertebrates.* Dormant cysts are formed during the life cycles of invertebrate parasites such as the oriental liver fluke (*Clonorchis sinensis*). The cyst stage of this organism develops in fish muscle; if the fish is eaten raw or undercooked, the encysted fluke is transferred to a new host. The encysted stage of the trichina worm (*Trichinella spiralis*), which causes trichinosis, is found in the muscle cells of hogs; it is also an invertebrate parasite in which the dormant stage is an essential part of the life cycle. When undercooked pork is eaten, the cyst wall is dissolved by digestive juices, and the worm is able to make its way into the tissues of a new host.

The cystlike forms found in many other invertebrate groups are all dormant stages that preserve the species during times of environmental stress. All freshwater sponges and some marine species survive cold or drought by forming **gemmules** within the body of the adult sponge. These structures, which are surrounded by a resistant covering, are released when the sponge dies and disintegrates. When conditions are appropriate, the cell mass escapes from the covering and forms a new sponge.

Rotifers are microscopic aquatic animals that produce winter eggs with thick and resistant coverings similar to protozoan cysts; the eggs may remain dormant for long periods. They can survive drought or freezing and may be dispersed by wind or carried by animals. Thus, the cyst serves not only for survival of the egg under adverse conditions but also for dispersal. Some freshwater bryozoans develop disklike buds, or statoblasts, that are surrounded by a hard, chitinous (horny) shell. These statoblasts are

the dormant structures that survive when the bryozoan dies in the fall or during a drought; they form a new bryozoan colony when favourable environmental conditions again prevail.

Among mollusks, land snails remain largely dormant throughout the day, with the soft head and foot withdrawn into the shell. During periods of drought or cold, they retreat into their shells and secrete a membrane (the epiphragm) of mucus and lime that covers the opening of the shell and resists desiccation. Slugs, on the other hand, bore into the ground and secrete a mucus mantle around themselves for protection during periods of unfavourable environmental conditions. Among the arthropods, many freshwater forms develop dormant cystlike stages that resist desiccation and allow the species to survive unfavourable periods.

**Diapause in insects.** Many insects undergo periods of reduced metabolic activity called diapause. Diapause, which may occur during any stage of the life cycle—egg, nymph, larva, pupa, or adult—is usually characterized by a cessation of growth in the immature stages and a cessation of sexual activity in adults. In some insects, it is a reaction to unfavourable environmental conditions; in others, such as certain moths and butterflies, diapause is a necessary stage of the life cycle. The 17-year larval and pupal periods of the cicada are examples of diapause. This form of dormancy is particularly common among insects that live in arid desert areas, where during the dry and hot summers, the insects usually hide themselves in the soil at suitable depths or under any available protective objects.

Insects may overwinter as egg, larva, nymph, pupa, or adult; because they can stand very low temperatures, few of these forms die if the winter temperatures are within their normal range. Even rather fragile forms, such as mosquitoes and butterflies, survive in sheltered, relatively dry places out of doors. Some butterflies even survive the winter in low shrubbery, where they may be completely covered by snow and ice for three or four months. Other insects prepare for winter by constructing nests or cocoons; still others seek suitable hiding places.

Among some insect species, diapause lasts only until favourable environmental conditions return, after which the insect immediately resumes its normal activities. In other species, favourable environmental conditions alone do not break the diapause; some other stimulus, such as cold or food, is necessary. The eggs of the mosquito *Aedes vexans*, for example, remain in diapause until the damp soil on which the eggs are laid is flooded to form a pool suitable for the larvae. Although the eggs of another mosquito, *Aedes canadensis*, are laid in the same soil as those of *Aedes vexans*, they will not hatch—even after flooding—until they have been subjected to cold. Thus, when both species lay their eggs together in early summer, those of *Aedes vexans* hatch in pools formed by late summer rains, but those of *Aedes canadensis* overwinter and hatch in the spring rain pools. Not only are certain conditions required to break diapause but in some species, such as certain cutworms, a specific length of time must elapse before the stimuli are effective.

The onset of diapause depends upon a combination of environmental factors operating on the regulatory mechanisms—i.e., nervous and endocrine systems—of the insect. Photoperiod and temperature influence the endocrine function of the brain, which synthesizes and secretes a substance (hormone) that controls other endocrine organs, specifically the prothoracic glands. Under the stimulation of the brain hormone, the prothoracic glands secrete a hormone called ecdysone. When stimulation by the brain hormone ceases, ecdysone is no longer secreted, and, in its absence, all insect growth and metamorphosis are halted. Thus, provision is made for the overwintering of immature insects in a state of developmental standstill. With the arrival of more favourable conditions, ecdysone is again secreted, and development resumes. Because many insect species have more than one generation of progeny per year, the prothoracic glands do not cease functioning except at some stage in the life cycle of the brood that must overwinter.

#### DORMANCY IN COLD-BLOODED VERTEBRATES

Two kinds of dormancy can be distinguished in vertebrates on the basis of body temperature. Most vertebrates are poikilothermous, or cold-blooded, because the body temperature follows that of the environment and is not kept constant by internal (homeostatic) mechanisms. The second group, the homoiotherms, maintain a constant body temperature regardless of the environmental (ambient) temperature; called warm-blooded animals, they include birds and mammals.

**Fishes and amphibians.** The metabolism of poikilothermous animals is most influenced by the environmental variables of temperature, nutrition, and photoperiod. Photoperiod, the daily length of light exposure, has a marked metabolic effect in both fishes and amphibians; fishes, however, remain active throughout the year, although the activity may be limited by temperature, as in those fish that rest on the bottom or in mud during cold periods. Brief superficial freezing and supercooling (without freezing) to temperatures below the freezing point of body fluids are experienced by resistant species, but it has not been established that fishes that have been frozen solid can become active when thawed. In the Arctic, no fishes are found in lakes that freeze solid in the winter. Because most fishes do maintain some kind of activity year round, they cannot be said to become dormant in the sense in which the word is used in this article.

In addition to light and temperature, another environmental stress imposed upon fish is drought. Lungfishes, as represented by the African lungfish (*Protopterus*), burrow deeply into the mud when their water supply is diminished. They surround themselves with a cocoon of slime and remain inactive, using a lunglike air bladder for respiratory purposes because their gills are nonfunctional during this period of dormancy. They rely on fat reserves as an energy source, and in order to conserve water, they excrete urea rather than ammonia. This is because ammonia as an excretory product is highly toxic; animals that excrete ammonia require large quantities of water to dilute it below toxic levels. Urea is a semi-solid substance of low solubility, and requires little or no water for its excretion. (Desert animals and many insects excrete urea.)

During periods of drought or cold, amphibians seek protective niches (i.e., habitats that supply the factors necessary for existence) in which to remain dormant until the return of favourable environmental conditions. Overwintering of frogs and salamanders frequently involves their aggregation in large numbers in a moist terrestrial niche, such as a rotting log, the mud on banks or bottoms of marshes and ponds, or in springs. The more terrestrially oriented amphibians, such as toads, may pass the winter in solitary burrows on land. During dry seasons, frogs may be dormant in a mud cocoon.

**Reptiles.** Effects of temperature. Because reptiles depend on external sources of heat to keep warm, they survive during periods of low temperature by seeking a place where the temperature will not fall below freezing, except temporarily. The commonest niche for reptilian dormancy is almost always found underground at a depth dependent on the thermal conductivity of the soil relative to the minimum temperature reached. This factor alone can control the distribution of reptiles. None can survive in the Arctic or Antarctic in places in which the subsoil is permanently frozen; and relatively few can exist in areas near these regions, even if suitable sites for dormancy were available, because the short summers would prevent the completion of life cycles. Although the distribution of snakes at high latitudes or altitudes is limited, the adder has been found at 10,000 feet (3,300 metres) in the Swiss Alps and about as far north as the Arctic Circle. The Himalayan pit viper has been found at an altitude of 16,000 feet (5,000 metres).

Dormancy in reptiles may display a circadian rhythm, a seasonal one, or both; it is a state of torpor directly induced by low temperature. When the adder, for example, experiences temperatures of about 8°–10° C (46°–50° F), it begins to search out suitable niches in which to rest. Its dormancy ends on the first sunny days after the maxi-

Protective  
niches

Insect  
survival in  
winter

mum temperature has reached 7.5° C (45.5° F). Because these conditions vary, the adder's period of dormancy extends from 275 days in northern Europe to 105 days in southern Europe and is about two weeks in the United Kingdom, where the Gulf Stream provides warmth.

Reptiles also normally become dormant during the hottest parts of summer, but the physiology of summer dormancy is quite different from that of winter. As already mentioned, winter dormancy is a state of torpor, induced by a low temperature, that becomes more pronounced as the temperature falls. There is, however, a wide range between the animal's normal, active (coenothermic) temperature and the lowest temperature at which it can exist. At high temperatures, on the other hand, there is a much narrower range between the coenothermic temperature and temperatures that cause death. In other words, reptiles can tolerate colder temperatures much better than they can tolerate higher ones. For this reason, during hot weather they must seek refuge underground or in cool, shady places, where they remain physiologically active but must forego all normal activity because of the restricted nature of the cooler niche. Desert reptiles, in particular, exhibit such temperature responses daily.

During its dormancy, the amount of water needed by a reptile is less than at other times and is normally supplied by water produced from the metabolism of the animal's own stored food reserves, particularly fat. In areas in which alternating wet and dry seasons occur, reptiles maintain a longer period of dormancy during the dry season. This behaviour may be related more to the lack of available water than to temperature, because in such areas the onset of the seasonal monsoons elicits a period of increased reptile activity.

Because there is only a limited number of suitable sites available for dormancy, several snakes, usually of the same species, may be found in each niche. As many as 100 or more snakes have been taken from one winter den. Occasionally, lizards and toads may also be found in the same den, but stories of snakes that share denning sites with small birds and mammals have been difficult to substantiate. It is much more usual to find that the entry of snakes into the burrow of a prairie dog or some other warm-blooded animal is followed by the evacuation of the original occupant.

**Effects of latitude.** Changes in latitude not only alter the lengths of the dormant and active periods of reptiles but also affect their circadian rhythms because of the changes in the proportions of night to day. Many species of snakes, including the adder, are normally active in the early evening. In the northerly latitudes (e.g., northern Europe, such as Scandinavia and Finland), where the length of the active season is reduced by as much as two-thirds, these snakes become active throughout the day to take advantage of every warm hour in order to complete the necessary portions of their life cycle. Even this increased activity during the shorter summer season, however, does not compensate for the latitude. Growth and development slow to such a point that sexual maturity is delayed, and the reproductive period requires two years rather than one; young are produced only every other year instead of every year, as at lower latitudes.

#### DORMANCY IN WARM-BLOODED VERTEBRATES

The term hibernation is often loosely used to denote any state of torpor, inactivity, or dormancy that an organism might exhibit. Properly speaking, however, use of the term should be confined solely to warm-blooded **homeotherms**; i.e., birds and mammals whose feathers or fur serve as insulation to reduce heat radiating from the body and aid in the maintenance of constant body temperatures, which normally are independent of those of the environment. Because warm-bloodedness gives animals an internal physiological stability, they are less dependent on many environmental restrictions, particularly those limitations imposed on organisms by ambient temperatures. For example, only two species of reptiles are found north of the Arctic Circle, but great numbers of birds live and breed there. Warm-bloodedness also signifies a high metabolic rate, a factor that undoubtedly in-

fluences normal learning, which depends heavily on the frequency and recency of experiences. Because periods of lowered metabolism interrupt continuous learning experiences, they may explain in part why birds and mammals are so much easier to train than any other animal. The benefits of warm-bloodedness require the expenditure of large amounts of energy through the year and make a heavy demand on available food supplies.

The term hibernation is also used to delineate the dormant state only during winter. In arid regions a reverse phenomenon is seen in which the animal becomes torpid during the hot, dry, barren summer; such hibernation is called estivation. As a means of avoiding environmental stresses, hibernation and estivation are not common devices among warm-blooded animals and they are far less common among birds than among mammals.

Some warm-blooded organisms exhibit thermic instability, a heterothermous condition that allows their metabolic rate to be reduced, with a commensurate reduction in body temperature. Heterothermy is a transitional state between cold-bloodedness and warm-bloodedness; the animal is awake and moving during its temperature fluctuations. The body temperature, although not as constant as in humans, is not so low as to force the organism into deep hibernation. Among mammals, two monotremes, the spiny anteater and the duckbill platypus, are thermally unstable; many of the marsupials, including the opossum, the pouched mouse, and the native cat (a **weasel**-like spotted marsupial of the family Dasyuridae), are also unable to maintain a fixed body temperature.

The true hibernator not only possesses adaptations that enable it to respond as a homeiothermous animal during certain periods of the year but can also adapt to stressful environmental situations and become essentially a **poikilothermous** animal during other periods. An animal exposed to food shortages, low temperatures, or lack of water, for example, may "turn off its thermostat" and hibernate until the environment becomes more favourable. Unlike poikilotherms, however, hibernators still retain a measure of temperature control and can change their metabolic levels as required. They can arouse themselves to full activity, whatever the environmental temperature, whereas the arousal of a poikilotherm is dependent upon increased environmental temperatures.

During the period prior to hibernation an animal must make a considerable number of gradual physiological and metabolic adjustments that appear to be correlated with temperature, light, and the availability of food. No one set of conditions applies equally to all hibernators: some store food, others do not; some become excessively fat, others gain a more moderate amount of weight. Generally, as the season advances and as the hibernator becomes progressively more prepared for hibernation, there is an increase of fat deposition and a general readjustment of body temperature, metabolism, and heart rate to lowered levels of activity.

Although no single factor or condition can be said to determine when an animal will go into hibernation, specific changes include an increase in the quantity of magnesium in the blood and a reduction in the activity of endocrine glands, such as the pituitary, thyroid, and **adrenals**. A reduction in gonadal activity has also been observed; hibernation does not occur when the gonads are in an actively functional state. Perpetuation of the species requires that the animal be warm and active during the mating and pregnancy periods.

There appears to be a relationship between sleep and hibernation; available evidence suggests that hibernation is entered into from a state of sleep. If hibernation is to be considered a form of sleep, then it must be considered a remarkably complex one. Hibernation and sleep are somewhat similar in that essential body processes continue during both periods at a lowered level. In sleep, the heart beats less rapidly, and breathing is slower; the body produces less heat, necessitating that a sleeping person be protected from the cold.

**Hibernation in birds.** Temperature variations. Birds normally have higher and more variable temperatures than do mammals. Whereas mammalian temperatures

in prepa-  
ration for  
hiberna-  
tion

normally range between 36° and 39° C (97° and 102° F), avian temperatures range between 37.7° and 43.5° C (99.9° and 110.3° F), with the majority between 40° and 42° C (104° and 108° F). Although the nesting temperature of most passerine species (perching songbirds) is about 40.5° C (104.9° F), primitive bird species—like primitive mammals—have lower temperatures than do the more advanced species. The kiwi, for example, has an average coenothermic body temperature of 37.8° C (100° F). In general, the temperatures of small birds fluctuate more than do those of large birds. The temperature of a house wren (*Troglodytes*) may fluctuate 8° C (14° F) in 24 hours, that of a robin (*Turdus*) fluctuates about 6° C (11° F), and that of the domestic duck only about 1° C (2° F).

The circadian period of activity and rest in birds is accompanied by a temperature cycle. Birds active in the daytime have their highest temperatures late in the afternoon and their lowest in the early morning. Nocturnal species, however, such as owls and the kiwi, have their maximum body temperatures at night, when they are most active. Seasonal temperature variations are also found in birds, and, like mammals, certain birds exhibit thermic instability. Although some are capable of maintaining a highly stable body temperature, others have a fluctuating body temperature. A torpid poorwill (*Phalaenoptilus nuttallii*) is an example of a bird that demonstrates both thermic instability and true hibernation. Its coenothermic body temperature is relatively constant; it can, however, through the influence of a thermoregulatory centre (the hypothalamus) in the floor of the brain, become essentially poikilothermous. Under such influence, its body temperatures approximate those of the environment.

**Energy conservation.** Considering that hibernation and estivation are devices to avoid such factors as stressful extremes of temperature, lack of water, unavailability of food, or lessened photoperiod, they also must be energy-conservation devices for the animals concerned. Even short periods of torpor can conserve energy. The efficiency of this energy-conservation system can be demonstrated by comparing the smallest bird, the hummingbird, which exhibits circadian torpor, with the shrew, the smallest mammal, which remains active throughout a 24-hour period. Oxygen consumption is an indicator of metabolic rate, and at an environmental temperature of 24° C (75° F) during the day, an awake but resting hummingbird consumes about 14 millilitres of oxygen per gram per hour. At dusk, the rate drops first to a sleeping level and then plunges to a torpid level of about 0.8 millilitre of oxygen per gram per hour. Just before daybreak, the bird awakens for another activity period. The hummingbird has the highest metabolic rate and the greatest metabolic range of any vertebrate. The shrew, in contrast, consumes about the same amount of oxygen as the hummingbird does during the day and even increases the amount slightly at night.

The hummingbird uses about 10.3 calories (units of heat energy) during each 24-hour period if it sleeps at night without becoming torpid but only 7.6 calories if it becomes torpid. As it wakes from the torpid state, its temperature increases about 1° C (2° F) per minute to a maximum; the entire process takes less than 30 minutes and sometimes as little as ten minutes. The energy required to warm the tissues of the hummingbird is relatively small; a hummingbird that weighs four grams expends only 0.114 calorie to warm its body from 10° to 40° C (50° to 104° F). This is only  $\frac{1}{85}$  of the total 24-hour expenditure of energy of a hummingbird in nature.

The behaviour of the hummingbird can be contrasted to that of a larger bird, such as the poorwill, which is a nocturnal, insect-catching bird. During an average 24-hour day, the poorwill has brief periods of activity at dusk and just before dawn, the total of which is scarcely more than an hour. The temperature of the poorwill during these periods of activity, which are correlated with the bird's feeding habits, is between 40.5° and 43.1° C (104.9° and 109.6° F). Between periods of activity, the bird rests quietly, and its body temperature drops 1° to 3° C (2°–

5° F). During periods when a supply of flying insects is not available, the bird hibernates in depressions in rocks or other suitably protected places, to which it returns each year. When hibernating, the bird's temperature is frequently within 1° C (2° F) of that of the environment; as a result, the energy saved is great. A poorwill whose body temperature is 5° C (41° F) has a metabolic rate only 3 percent of that at normal body temperature. Because the poorwill is a larger bird than a hummingbird, it may take more than an hour for it to emerge from hibernation.

**Hibernation in mammals.** It takes longer for larger animals than for smaller ones to go into hibernation because heat must radiate from the body before the temperature can be lowered. Thus, it would require a considerable amount of time for large birds or mammals to go into and emerge from hibernation each day, as do bats and hummingbirds. A 200-kilogram (440-pound) bear, for example, would need 5,100 calories to warm from 10° to 37° C (50° to 99° F). Unlike the hummingbird, which uses only  $\frac{1}{85}$  of its total daily energy expenditure to emerge from hibernation, the amount expended by a bear would be equivalent to its full 24-hour energy budget. Even if there were enough time in 24 hours for a large animal to enter into and emerge from dormancy, therefore, it would be metabolically extravagant, thus defeating the purpose of hibernation.

Actually, the most common misapplication of the term hibernation is in relation to the bear, which is not a true hibernator. Its body temperature, which normally averages 38° C (100° F), drops during its winter lethargy to about 34° C (93° F), seldom getting below 31.2° C (88.2° F). Hence, a bear's temperature during the winter does not approximate that of the environment. This is indicative of winter rest rather than true hibernation. During this inactive period, the bear sleeps but is, nonetheless, warm and capable of activity when stimulated, unlike a true hibernator. Moreover, it is also during this period when females give birth to cubs that suckle and are maintained by maternal warmth until they emerge from the den in the spring. This behaviour is in contrast with that of the Arctic ground squirrel, whose normal temperature is the same as that of the bear but whose temperature during hibernation drops to near freezing and, in some cases, to a degree or two below 0° C (32° F).

Although certain mammals are said to hibernate, they do not necessarily enter a state of deep hibernation during winter. Instead, for weeks at a time they may be inactive and lethargic in behaviour, with a slightly depressed body temperature. The chipmunk (*Eutamias*) is an example of what has been termed a shallow hibernator, as are bears and raccoons. Superficial hibernation, apparently a compromise between the minimum energy requirements of a deep hibernator and the high energy expended by an animal that remains active during the winter, saves energy without the stress of hibernation. The animal can thus conserve food, while still being able to escape from predators and such dangers as flooding of its burrow. The main energy source during the winter in this shallow hibernation state is food stored in the winter nest. There are instances, however, of shallow hibernators, such as the chipmunk, that enter a state of deep hibernation, particularly if without food.

**True mammalian hibernation.** Omitting the thermally unstable mammals, the true mammalian hibernators are those whose lowered body temperatures approximate that of the environment and those who require extensive and complex physiological changes to turn from a warm-blooded animal into an essentially cold-blooded one for an appreciable length of time. Only three orders of placental mammals display such behaviour: the Insectivora, as exemplified by the hedgehog; the Chiroptera, the bats; and the Rodentia, including the marmot, hamster, dormouse, hazel mouse, and ground squirrel.

A typical mammalian hibernator, such as the Arctic ground squirrel, finds a protected environmental niche—in this case, a burrow beneath the surface—and builds a nest of grass, hair, and other materials to provide still

further insulation. The usual hibernating position is one of being curled up in a ball with the extremities tucked tightly against the body so there is a minimal surface-to-volume ratio. After the temperature of the animal has dropped near that of the ambient temperature, it appears to be dead: its respiration is imperceptible, about three irregular breaths per minute; it does not react to outside stimuli in an observable fashion; nor does it react to being handled and uncurled, although such handling will trigger waking mechanisms.

The internal organs, such as the digestive tract and the endocrine glands, are almost totally inactive. Because the process of hibernation necessitates the mobilization of all body resources, it places great demands on the tissues, all of which are directed toward the problem of maintaining the animal's metabolism at the minimal level necessary for life during the hibernating period. This means that all activity not immediately germane to the process of living at the lowest possible metabolic level ceases. Even bones and teeth deteriorate during hibernation. The hibernator apparently is balanced on a very narrow line between the maintenance of life at a level that makes recovery from hibernation possible and a reduction of metabolism to a level that will lead to death. Evidence obtained from tissues indicates that the process of hibernation is a precarious method of survival at best and one from which many animals do not awaken. As a mechanism of species survival, hibernation seems effective; for the survival of the individual, however, it is an uncertain and dangerous process.

The hibernator does not remain in a continuous state of hibernation from the time it enters in the fall until it emerges in the spring. Hibernating Arctic ground squirrels, for example, awaken at intervals of every three weeks or less. During this time the animals may move about and sometimes emerge from the burrow. These periods of arousal are more frequent at the beginning and end of a hibernation period than in mid-hibernation; and the lower the temperature at which an animal hibernates, the fewer the awakenings.

During the period of hibernation about 40 percent of the total body weight is lost, an average of about 0.2–0.3 percent per day. One period of arousal and wakefulness consumes more heat and energy than many days in hibernation. About 90 percent of the total heat production and weight loss during hibernation takes place during the arousal periods; only 10 percent is required to maintain the animal in hibernation. Thus, in the case of an unusually long or hard winter, the animal may be called upon to use all of its available energy sources in periodic arousals; it then enters one final hibernation period from which it does not awaken. Animals that store food in the nest have a chance to renew their energy requirements by eating when they awaken periodically.

Entrance into hibernation. Hibernating mammals can be divided into four major groups according to the way they enter hibernation. One group is exemplified by the golden hamster; it waits a variable time of from one to three months in the cold and then enters hibernation in one major temperature reduction. This is accomplished when the biochemical and physiological preparations have been sufficient to lower the animal to a level at which it is receptive to the hibernating stimulus, which causes the abandonment of the temperature differential between ambient and body temperatures.

A second group, of which the pocket mouse (*Perognathus*) is an example, prepares for hibernation relatively rapidly, waiting only a few days before becoming torpid in one major temperature decline. The third group, which constitutes most of the mammalian hibernators, includes ground squirrels and marmots. These animals wait only a few days before entering hibernation and then go through a series of steps of torpor and arousal, each one at successively lower body temperatures, until the level dictated by the stage of preparation for hibernation is reached.

The fourth group, which includes most of the bats, becomes inactive in the poikilothermous manner; that is, the body temperature follows the ambient temperature.

Even though the bat seems ready to hibernate at any season, survival during hibernation depends upon more adequate preparation than is necessary for the transitory periods of torpor. Bats not only exhibit true hibernation during the winter but also have natural periods of hypothermia (subnormal temperature), which are unrelated to hibernation, during the remainder of the year.

The woodchuck, the dormouse, and the California ground squirrel enter hibernation in successive stages, with a complete or nearly complete awakening between each one. In the woodchuck, an initial decline in temperature is followed by an arousal. During the second decline there is a lower and more pronounced fall in body temperature, followed by a less pronounced rise. This process continues until the body temperature is essentially the same as that of the environment.

Heart rate and circulation. The body temperature of a hibernating mammal is affected by changes in respiration, heart rate, and oxygen consumption; all are apparently mediated by a part of the nervous system. The heart rate decreases prior to a decline in body temperature. In the woodchuck, the rate may drop from 153 to 68 heartbeats per minute within 30 minutes. In the California ground squirrel, the heart may beat as slowly as once a minute at 5° C (41° F). In contrast, the hearts of non-hibernators generally will not beat at all at temperatures below 10°–20° C (50°–70° F).

As an Arctic ground squirrel prepares for hibernation, its heart rate and its blood pressure decrease. Both may be detected before a decrease in body temperature can be noted. When the animal enters hibernation, temperatures of both the heart and abdominal regions are identical, indicating an even blood flow between the anterior (front) and posterior (rear) parts of the body. As the body temperature drops, the resistance to blood flow in the peripheral parts of the circulatory system increases because of the increased viscosity (resistance to flow) of the chilled blood and the constriction of the distal arterioles (small arteries) of the body. This peripheral resistance maintains blood pressure at relatively high levels in the deeply hibernating squirrel, even when the heart beats only three or four times a minute.

Neural changes. The nervous system of hibernators also is acclimated; certain specific structures and pathways are seemingly maintained to regulate and coordinate metabolism as temperatures drop. This adaptation of the nervous system enables changes in the environment to be perceived, even when the animal is torpid. In the Arctic ground squirrel, measurements of the general electrical activity of the brain indicate a 90 percent reduction when the animal is in hibernation, at which time brain temperatures approximate 6° C (43° F). During hibernation, both the peripheral nervous system (all the nerves outside the brain and spinal cord, which constitute the central nervous system) and the spinal cord have an increased sensitivity to certain stimuli; in addition, the areas of the brain that regulate temperature as well as cardiac (heart) and respiratory function remain active at ambient temperatures, below which the mammalian nervous system normally ceases to function.

Changes in the circulatory system involving constriction (narrowing) of posterior vessels and the favouring of anterior circulation allow the brain temperature of hibernators to remain a few degrees warmer than the environmental level. This enables the temperature of the brain to remain constant despite fluctuations in the temperature of the skin.

Endocrine activity. The male sex hormone testosterone stimulates reproductive activity. The golden hamster will not hibernate if injected with more than five milligrams of a hormonal preparation. Hibernation is also prevented if the animal is fed or injected with thyroid hormones or thyroid-stimulating extracts. The latter would seem to implicate the thyroid as another endocrine gland that plays an important role in hibernation. There is, in fact, a seasonal progression and regression of thyroid activity in hibernators; maximal activity occurs in the spring and minimal activity in the fall. And because hibernation does not take place in the absence of the

Preparation of the Arctic ground squirrel for hibernation

Types of mammalian hibernators

adrenal glands, it appears that a minimal adrenal activity is also necessary for hibernation and survival.

The importance of timing in the annual rhythm of activity and dormancy can be demonstrated: when hibernators are exposed to cold temperatures in spring and summer, they react as do all homoiotherms by increasing their thyroid activity and metabolic rate to maintain normal body temperature. But if they are exposed to cold temperatures in the fall, the thyroid activity and metabolic rate of hibernators are lowered. In some species, a combination of decreased food and lower ambient temperature is required to reduce activity of the thyroid gland and to produce hibernation, although cold alone is sufficient in ground squirrels and the dormouse.

Although hibernation does not take place during periods of gonadal activity or stimulated thyroid activity, it can occur during increased activity of the pituitary gland. This would suggest that there is a dissociation of cellular growth and hormone synthesis that is normally controlled by hormone secretion of the pituitary and its target organs. Thus, the triggering mechanism for the resumption of normal endocrine activity apparently resides elsewhere than in the pituitary. The function of the hypothalamic region of the brain in regulating appetite, fat deposition, water intake, and diuresis (increased excretion of urine), as well as in the control of temperature and sleep, would appear to make it a key area in directing life processes of the hibernator. Furthermore, the fact that the hypothalamus regulates the pituitary and other endocrine glands not only supports this thesis but also indicates that this area of the brain is the prime, or master, regulator of the entire hibernation process.

**Reproductive cycles.** The Arctic ground squirrel may spend more than half its life in hibernation (see Figure).

From W. V. Mayer, *Hibernation*

The annual cycle (top) in the life of a typical mammalian hibernator, the Arctic ground squirrel. The graphs show typical weight patterns of young and adult males and females during the aboveground activity period (see text).

It thus must be able to breed, rear young, maintain its home burrow, and prepare for the period of hibernation during an activity period of less than six months. This requires considerable adaptation of both metabolic and behavioral patterns. Prior to entering hibernation in late September or early October, there is a renewal of sexual activity in the testes of males, and, throughout the period of hibernation, they continue to grow. On the Arctic slope in early May, the male ground squirrel emerges from its burrow. As it utilizes the remaining fat and eats the stores of seeds and other food still in the nest, the male reaches a period of reproductive readiness. Mating takes place in the middle of May, and the young are born in the middle of June, after a gestation period of about 25 days. By the middle of July the young are above ground and eating the green Arctic vegetation, which they continue to eat until the onset of hibernation. By October, both the young of the year and the adults from the previous year weigh nearly 1,000 grams.

In the bat, the reproductive cycle is interrupted by hibernation. Gonadal activity in the male reaches its maxi-

mum in the fall, when copulation with the female occurs. The animals then hibernate, and the production of sperm in the male ceases. The sperm deposited in the female are stored in her reproductive tract throughout the period of hibernation; fertilization occurs the next spring, when the eggs are ovulated (released from the ovaries) within a few days after awakening from hibernation.

The only exception to the general hibernation-reproduction pattern of bats is the vespertilionid bat (*Myotis*), in which there is no delayed ovulation and fertilization. In this species the eggs are ovulated soon after copulation, in the fall, and fertilized immediately. During the ensuing period of hibernation embryonic development is initiated and slowed, but it does not actually cease. The young are born in the early summer, soon after hibernation ends. The introduction of hibernation during pregnancy makes the gestation period several months longer than in non-hibernating tropical members of the same genus.

Cyclical reproductive activity has thus become adapted to the shortened activity season available to the hibernator. But although the annual sequence of reproductive events is known, the external stimuli that regulate the reproductive cycles of bats and other hibernators are not known. More knowledge is needed concerning the endocrine and nervous mechanisms that presumably regulate reproductive processes internally. It has been suggested that the pituitary-gonadal relationship influences the hibernating cycles as well as the reproductive cycle, hence both the latter and homoiothermism are controlled by a common mechanism. Such a suggestion is attractive in that the mechanism solves the regulation problems, but more needs to be known of the way in which hibernation directly or indirectly modifies the action of endocrine and neural mechanisms that direct the reproductive cycle.

**Protection from disease and radiation.** Hibernating organisms have a certain degree of resistance to infectious diseases that appears to be attributable to at least three factors, all of which are related to temperature. One is the fact that the lowered temperature of the host and the commensurate slowing of its metabolic processes prevent the multiplication of parasites to a greater extent than they affect the host's defensive mechanisms. Second, lower temperatures are more harmful to the development of a disease organism than to the host, as has been shown with the parasite *Trichinella spiralis*. In bats hibernating at 5° C (41° F), only larvae have been recovered from the intestines; but mature adult worms have been recovered from the intestines of bats kept at 35° C (95° F). The third factor is that the influence of low temperature on the chemical composition of the host tissues may also affect infectious organisms.

Hibernation also seems to protect animals from radiation. When ground squirrels are irradiated with radioactive cobalt while hibernating, they are found to be more resistant to the effects of the radiation than are squirrels irradiated while warm and active. This resistance, which is apparent over a wide range of doses, suggests that protective mechanisms function in the hibernating animal. In both hibernating and non-hibernating animals, repair processes within cells occur the first day after irradiation; however, when the metabolic requirements of cells are small, as in hibernation, the injured cells seem to be more capable of repair, and survival is greater. The large metabolic requirements imposed on injured cells of warm and active animals appear to render them incapable of an adequate repair response.

**Awakening from hibernation.** The process of awakening in the Arctic ground squirrel takes about three hours. There is a rapid rise in heartbeat and a decrease in peripheral circulatory resistance; the area around the head and heart warms more rapidly than the posterior part of the animal. This differential vasodilatation (widening of the blood vessels) in the anterior part of the body is a unique and vital part of the awakening process. The concentration of active circulation in this region results in a high blood pressure and an efficient and rapid warming. If a drug is administered during awakening

that causes vasodilatation throughout the body, there is a marked drop in blood pressure even though the heart may almost double its rate; thus, the heart cannot maintain a high blood pressure at this time if all blood vessels are dilated. Later during the arousal process, after the anterior part of the body has been warmed, the posterior part of the animal warms rapidly.

Despite the deterioration of glands and tissues and the drastic reduction of all metabolic activity during hibernation, within 24 hours after arousal, all the squirrel's physiological processes are essentially normal. This rapid repair and recovery mechanism is one that requires further study.

## Dostoyevsky, Fyodor

Dostoyevsky's *Crime and Punishment*, *The Idiot*, *The Possessed*, and *The Brothers Karamazov*, in all of which art is used as a medium for conveying the wisdom of life and the emotions of the soul, have won him a reputation as one of the world's greatest novelists.

Dostoyevsky, 1880.

By courtesy of the Literary Museum of the Institute of Russian Literature, Leningrad

**Early life and literary beginnings.** Fyodor Mikhailovich Dostoyevsky was born in Moscow on November 11 (October 30, old style), 1821. His father, a former army surgeon, was a stern man and rigid in domestic matters. Years later, the son, mindful of his insecure, middle class family, called himself an "intellectual proletarian." The background that influenced his literary interests was en-

tirely different from that of his rivals, Ivan Turgenev and Leo Tolstoy, who were members of the cultured gentry class. Finishing his early education in Moscow, Dostoyevsky entered the military engineering school of St. Petersburg (now Leningrad) at 16. What time he could steal away from drill and the science of fortifications, he spent reading Russian and other European literature, especially melodramatic fiction that encouraged his taste for plots of violence and crime. Little is known about these formative years, but he appears to have enjoyed nights out with his fellow cadets, good food and drink, interesting conversation, music, the theatre, and the company of girls. He was also a passionate dreamer about fame, self-sacrificing deeds, and idealistic friendships.

Shortly after graduating, Dostoyevsky took the bold step of resigning his commission to devote all his time to writing. He had hardly any financial means—his mother had died, and his father, who had been murdered by serfs, left little money. He had, however, already finished the manuscript of a short novel, *Poor Folk* (1846), and with misgivings he allowed a young friend to submit it to a renowned literary critic, Vissarion Belinsky. Many years later Dostoyevsky recalled the ecstasy he experienced when the critic summoned him and praised the artistic instinct with which he had revealed the hidden nature of his hero. "The truth has been revealed and announced to you as an artist, it has been brought as a gift; value the gift and remain faithful to it, and you will be a great writer!"

*Poor Folk* is hardly a major effort and is marred by a beginner's technical faults, but Belinsky's praise was prophetic. He had recognized in the work the first Russian social novel, for it tells of an impoverished, elderly clerk's hopeless struggle for respectability while concealing his love for an orphaned girl in a sentimentally expressed, paternal affection. An uncommon insight into the tragic futility of poor people in love is revealed, people victimized by cruel circumstances of contemporary society. Dostoyevsky's handling of the subject won an enthusiastic response from readers, for he added a new dimension—an intense psychological interest in which the hero's conflicts are studied from within. In a letter to his brother Mikhail, he explained his approach: "I proceed by analysis and not by synthesis, that is, I plunge into the depths, and, while analyzing every atom, I search out the whole." In fact, he had begun his own school of Russian realistic fiction.

In contrast, the youthful author did not create an impressive personal image in literary circles and society salons, where he was lionized after his initial success. This short, fair-haired man with small, gray eyes, sickly complexion, and nervously twitching lips was awkward in his movements and ill at ease in such social situations. He took refuge in his writing and quickly produced another short novel, *The Double* (1846). This literary exploitation of the "split personality" (Golyadkin, a minor civil servant, suffers growing persecution mania, leading him to encounter another man looking exactly like him who is the leader of a conspiracy against him) bored readers and cost him Belinsky's critical support. In its less clinical aspects, however, the "double," the man or woman of divided self, played a significant role among the characters of his famous novels.

A series of sketches, short stories, and another short novel, published between 1846 and 1849, received little notice. He might have won back his audience with an ambitious full-length novel that he planned, *Netochka Nezvanova* (1849), the story of a young girl's love for her wayward stepfather, a preview of ideas, images, and devices that would repeatedly appear in later works; but only three lengthy episodes had been published when his arrest for alleged subversion brought an end to its writing, as well as to this first literary period. These early tales reflect both literary influences and his own observations of St. Petersburg life. Psychological and spiritual self-examination, however, also entered into the intense analysis of the thought and feelings of his characters. If only in a fugitive manner, this first period suggests the main direction of his future creative development.

First novel's psychological fore-shadowings

Radical leanings

**Exile to Siberia.** Caught up in the movement for political and social reform during the repressive rule of Tsar Nicholas I, Dostoyevsky had participated in weekly discussions at the home of an idealist, Mikhail Petrashevsky, in which the ideas of French utopian Socialists were debated. There is also evidence that he took part in secret meetings of a smaller inner group that planned to print illegal radical pamphlets. The government, fearful of revolutionary contagion from the West, ordered the arrest of members of the Petrashevsky Circle in April 1849. After a long investigation, 21 of them, including Dostoyevsky, were condemned to be shot. Memory of the experience during the grisly preparations for the execution, before the Tsar's commutation was announced, haunted the pages of his later fiction. His sentence was changed to four years of hard labour in a prison at Omsk, in Siberia, and thereafter four more years as a soldier in the ranks.

Dostoyevsky accepted his punishment as a necessary atonement for what he believed a serious crime. He came to regard as "extraordinary people" many of the simple convicts among whom he lived in chains, stench, and hard labour; but spiritual agony overwhelmed him at times, and he dates his first attack of epilepsy, an affliction that persisted for years, to this period. The only book allowed in prison was the New Testament, which he read frequently. It assuaged the bitterness of prison and taught him a new faith in Christ, who alone could raise up the sinner and promise the humble of heart a new existence. His prison experience was important for his future development as a writer and thinker. Youthful radicalism gave way to respect for established order and belief in the messianic mission of the common people; Christ's teaching, in the sense of salvation by suffering, and the spirituality of the Russian Orthodox Church took on deeper meaning; and prison provided him with rich material for further study of the insulted and injured.

After his release in 1854, he found serving as a soldier in the Siberian town of Semipalatinsk more boring, in a sense, than prison. He worked hard at his duties, eventually became a junior officer, made a few friends, and repeatedly begged his brother to send him books and periodicals to repair the huge gaps in his reading. The only event of consequence was his marriage in 1857 to a consumptive widow with one son, which turned out to be an unhappy union. Added financial responsibilities intensified his desire to resume writing and regain his literary position after years of enforced silence. He began with a comic short story that had no connection with various designs for fiction he had thought out in prison. "Uncle's Dream" (1859) is an amusing tale, a satire written in the manner of the earlier Russian novelist Nikolay Gogol on the snivelling society of a provincial town for which Semipalatinsk must have been the model. This story was quickly followed by a more ambitious short novel, *The Friend of the Family* (1859), the main character of which, Opiskin, another dual nature, saves the work from mediocrity. Critics paid attention to neither story. Not long after their publication, Dostoyevsky was allowed to return to his beloved St. Petersburg, a free man, just ten years after he had left it in chains.

**Literary renewal.** Radicals in the capital were eager to glorify him as a former political prisoner, but he spurned them and their ideas, especially their ridiculing of religion: His sympathies were on the side of the social reforms advocated by the new emperor, Alexander II. The first collected edition of his writings appeared in 1860, and the next year, with the cooperation of his brother, he began the magazine *Vremya* ("Time"). Its announced position was the ideological reconciliation of the leading intellectual groups—Westernizers and Slavophiles. Both factions were urged to unite with the masses on behalf of Russia's national salvation. His elaboration of this popular approach in journalism and fiction contributed to the magazine's success. Old and new like-minded friends, such as the poet Apollon Maykov and the critics Apollon Grigoryev and Nikolay Strakhov, rallied around him and *Vremya*, and they had considerable influence on his future political, social, and artistic views.

*The House of the Dead* (1861–62) revived Dostoyevsky's earlier literary fame and helped the initial popularity of *Vremya*, in which it appeared. Turgenev acclaimed the work, and Tolstoy valued it as Dostoyevsky's best production. Though represented as the memoirs of a man condemned to penal servitude for murdering his wife, it is really a vivid account of Dostoyevsky's prison experiences. Striving for objectivity, he describes prison existence and offers penetrating psychological studies of unusual convicts, symbolically suggesting in moving incidents the pain of lost liberty among these human outcasts. At about the same time, he published serially in *Vremya* his novel *The Insulted and Injured*, the story of a woman's right to offer her love to a man in defiance of family and convention. It annoyed critics but delighted the reading public. At least several portrayals, such as the heroine Natasha, his first fully drawn female representative of emotional ambivalence, little Nelly, a character reflecting his deep understanding of child psychology, and the self-willed villain Valkovsky, are harbingers of more impressive characters in the major novels.

By the summer of 1862, *Vremya's* earnings enabled Dostoyevsky to realize an old dream—his first trip abroad. The visit provoked his notable magazine article "Winter Notes on Summer Impressions" (1863), in which he declared that the evils of European civilization that he had observed fortified his faith in Russia's high destiny if it could escape the poison of the West. In that year, however, the government banned *Vremya* for what it considered an unpatriotic article by Strakhov. In this crisis Dostoyevsky went abroad again on borrowed money, ostensibly for treatment of his epilepsy but really to try his luck at the gaming tables of Wiesbaden in Germany and to keep a rendezvous with Polina Suslova, a young contributor to his magazine with whom he had already become intimate. His luck with both was execrable, but continued experience with this strange woman's mixed feeling of love and hate entered into his conception of the "infernal women" of his novels.

After his return to Russia, a small legacy enabled Dostoyevsky and his brother to start a new magazine, *Epokha* ("Epoch"), in the first issue of which appeared the beginning of his extraordinary *Notes from the Underground* (1864). Though in part a satire on radical Socialists who believe that man can be governed by rational self-interest, the nameless hero is also a profound analyst of himself, a supremely alienated individual for whom no truth is absolute and every good is relative. His dualism is caused by a fundamental conflict between will and reason. The work marks an altered approach to characterization in the hero's emphasis on self-examination in which the focus is on the spiritual life of dislocated man in a real and acceptable world. In essence, *Notes from the Underground* is a philosophical introduction to the forthcoming cycle of great novels, for nearly all their motifs involving moral, religious, political, and social ideas appear in it.

**Period of the great novels.** Between 1864 and 1865 misfortunes overwhelmed Dostoyevsky—his wife and brother died, and the debt-ridden magazine collapsed. Threatened by debtor's prison, he fled abroad with an advance on a novel from a dubious publisher. Again, his hope was in gambling, to which he had become a passionate devotee. Perhaps with marriage in mind—he had had several unsuccessful love affairs in St. Petersburg—he had once more arranged a meeting with Polina Suslova. Deserted by her at Wiesbaden, he also lost all his money at roulette and was reduced to pawning his clothes. He begged friends for loans to pay hotel bills and return to Russia. One letter was to the editor of a periodical for an advance on still another novel, which he described as *Crime and Punishment*. Money eventually arrived, and he returned to Russia in October 1865.

The conception of *Crime and Punishment* (1866) probably dates back to Dostoyevsky's prison days. Infinite concern for its artistic details is reflected in many notebook pages on the novel's planning (such notebooks, which also exist for later novels, shed much light on his

First trip abroad

Founding of *Vremya*

creative methods). In part, the work is a social novel in which money is a basic problem. Related to it is the materialistic thinking of radical youth, one of whom is the work's impoverished hero, Raskolnikov. A nihilist in intellectual rebellion against society, he struggles between good and evil, reason taking the place of the living process of life; and his destructive theory that humanitarian ends justify evil means leads him to murder. In prison his intellectual pride, which had driven him to violate the moral law, gives way to a realization that happiness cannot be achieved by a reasoned plan of existence but must be earned by suffering. Such secondary characters as Marmeladov, his wife, the prostitute Sonya, and Svidrigaylov are also brilliantly portrayed. The work provides a new dimension to the suspense of the familiar murder mystery by infusing into it compelling philosophical, religious, and social elements. The novel achieved immediate success. Critics and readers were captivated by its innovations, narrative intensity, and the spiritual glow that illumines the darkest recesses of the criminal and the morally debased.

Before completing *Crime and Punishment*, Dostoyevsky recalled that he risked severe financial penalties for failure to fulfill within a month his earlier contract with the unethical publisher. He hired a young stenographer, Anna Snitkina, and dictated a short novel in time. *The Gambler* (1866) is a minor effort with several powerful scenes that were inspired by his passion for gambling and his love-hate relations with Polina Suslova. The next year he married the stenographer, and, to escape creditors and begging in-laws, they went abroad, remaining away four years. Often they lived in abject poverty, moving from country to country. His young wife endured all this, his epileptic seizures, incessant gambling, and the tragic death of their firstborn, her devotion to him and his genius never faltering. This second marriage was one of real love and the most fortunate event of his life.

Out of these harsh circumstances emerged Dostoyevsky's second masterpiece, *The Idiot* (1868–69). Its starting point was the account of a criminal trial in the Russian press. Such events he called "fantastic realism," but, in his fictional use of them, he shifted the emphasis from the external world to that of the mind and heart of his characters. Though concerned with problems of average Russians, he elevates them to universal significance in his search to find "man in man." He wrote in his notebook: "They call me a psychologist. It is not true. I'm only a realist in the higher sense; that is, I portray all the depths of the human soul." The chief idea of *The Idiot*, he wrote to his niece, "is to portray a positively beautiful man [i.e., in a moral sense]. . . . There is only one positively beautiful man in the world—Christ." But human weaknesses mar the pure moral nature of his hero, Myshkin, and they condition his involvements with the Yepanchin and Ivolgin families, with Rogozhin, and with those two unusual rivals for Myshkin's love, Aglaya and Nastasya. In superb scenes these and other characters, who are given to sensuality, acquisitiveness, and crime, test Myshkin's moral feelings. Though his faith and radiant personality draw them to him, his message of service, compassion, and brotherly love fails. His experiences are symbolic of Christ's among the Pharisees. In the end the sinning people he moved by his goodness are rendered unhappy, and he himself lapses into idiocy.

Having already spent the advance on another novel, of which he had written nothing, Dostoyevsky accepted ready cash from a new publisher for a short story that turned into a short novel. *The Eternal Husband* (1870), a subtle psychological study of a betrayed husband who seeks revenge on his wife's seducer, represents no particular advance in the author's creative art. Meanwhile, his thoughts concentrated on a vast plan, a series of possibly five connected novels under the title *The Life of a Great Sinner*, the notes for which are extant. Its protagonist would be guilty of heinous crimes against God and man, but, at the end of his spiritual pilgrimage, he would redeem himself and achieve salvation. This work was never written, but from its outline Dostoyevsky borrowed ideas, scenes, and characters for his last three

novels, the first of which was *The Possessed*, begun in 1869 and completed in 1872.

The main plot of *The Possessed* was suggested by sensational press reports of a Moscow student's murder by fellow revolutionists who suspected he intended to betray them. Worked into this plot are certain features and figures of the plan of *The Life of a Great Sinner*, especially aspects of the novel's central character, Stavrogin. In a work packed with action and drama, the revolutionary plotters are satirized as dolts and rascals. Their intended victim, the reformed Shatov, reflects Dostoyevsky's ideological opposition to revolution—an expression of nationalist faith in tsarist Russia's future that can have meaning only as a part of the country's faith in the Christ of the Orthodox Church. The enigmatic Stavrogin dominates the novel. His magnetic personality influences the amusing old liberal Stepan Verkhovensky and his revolutionary son Pyotr, as well as the renegade radicals Shatov and Kirilov, and he has a fatal attraction for the principal female characters Lizaveta, Darya, and Marya. With his loss of faith in God, however, the innate goodness of his nature has atrophied. His violation of the little girl symbolizes his complete submission to evil. Despite Dostoyevsky's didactic intention, the work is saved from becoming an inflated purpose novel by the sheer force of his art. Rarely had he handled with such artistic skill his favourite combination of sensational and ideological elements.

Long before he finished *The Possessed*, Dostoyevsky fell ill, desperately needed money, and insisted he could not complete the novel abroad. His worried publisher sent funds to enable him to return to St. Petersburg. The novel's success was enhanced by impressive public readings from his works, and Dostoyevsky was again in demand at social gatherings. In 1873 prominent friends helped to secure for him the editorship of the conservative weekly *Grazhdanin* ("The Citizen"). After a year he resigned because he found the work too confining and the publisher excessively reactionary. By this time his capable wife had undertaken the publication of his writings, from which a substantial profit was realized.

In 1876 Dostoyevsky revived as a separate monthly publication a column, "The Diary of a Writer," which he had contributed to *Grazhdanin*. He continued it for over a year, with a few additional issues in 1880 and 1881. It is devoted mostly to his views on significant current events, literary reminiscences and criticism, and occasional sketches and short stories, of which two are among his best: "A Gentle Spirit" (1876) and "The Dream of a Ridiculous Man" (1877). He also used it, however, as a medium for his striking ideas on broad social, political, and religious problems. Journalism and literature were closely allied in his mind, for he believed that the interrelation of art and reality must be based on observation of daily existence. *The Diary* attracted numerous readers and is of importance for the study of his life, philosophy, and fiction, especially of his last two novels.

In *The Diary* he describes the theme of *A Raw Youth* (1875)—the confession of an illegitimate son, Arkady Dolgoruky, about his adventures in St. Petersburg, where he seeks to win the affection of his father, Versilov, another dualist character and mouthpiece of Dostoyevsky's favourite convictions—for instance, the conviction that the Russian is unique, the perfect cosmopolitan, whereas the European intellectual stands on the brink of destruction because of his revolutionary materialism and denial of Christ. In stressing Versilov's ambivalence, Dostoyevsky for the first time clarifies his special interest in the subject. The psychological determinants of dualism as reflected in the thoughts, feelings, and actions of his imaginary men and women were observed by him in self-examination of the dualism of his own nature as well as that of others. Dostoyevsky recognized the main plot's strangulation by several subplots, telling his wife in some despair: "There are four novels in *A Raw Youth*." The novel is usually ranked below his others.

By the time Dostoyevsky began *The Brothers Karamazov* (1879–80), he was nationally recognized as a celebrated author. Important people sought him out; he

National  
renown

was asked to give the public eulogy at the funeral of a famous editor and writer, N.A. Nekrasov; the Academy of Sciences elected him as an associate member in literature; and his speech at the 1880 commemoration of the poet Aleksandr Pushkin electrified a distinguished audience with its ringing prophecy of Russia's world mission. He preferred, however, to live quietly at Staraya Russa, a small resort town some distance from St. Petersburg, with his wife and two children, Fyodor and Lyubov. There he followed a strict regimen of walks and writing, with his devoted wife as his amanuensis. She took down in shorthand his dictation of *The Brothers Karamazov*, the literary effort for which he had been preparing for most of his creative life. It is a story of patricide into the sordid unfolding of which Dostoyevsky introduces a love-hate struggle with profound psychological and spiritual implications. Throughout the whole novel persists a search for faith, for God—the central idea of the work. Alyosha, the youngest brother, identified with the Christian ideal, loves life more than its meaning; Dmitry loves life but its meaning evades him; Ivan, who is more concerned with life's meaning than with life itself, is the most absorbing character and the mental image of his creator. Ivan's ambivalence is centered in the cosmic struggle of man with God. He begins with an act of rebellion and ends in metaphysical insurrection against God's world. Ivan is concerned with those "accursed questions" that motivated Dostoyevsky's own search for faith—the problems of sin and suffering and their relation to the existence of God. The dramatization of Ivan's repudiation of God's world is concentrated in the famous "Legend of the Grand Inquisitor." The answer follows in the novel's next section in the preaching of the monk Zosima that the secret of universal harmony is not achieved by the mind but by the heart, by feeling, and by faith.

Dostoyevsky intended to exemplify Zosima's precepts in action in a sequel to the novel in which Alyosha would become the hero. A few months after the completion of *The Brothers Karamazov*, however, he died in St. Petersburg, on February 9 (January 28, old style), 1881.

Today, Dostoyevsky is among the most widely read 19th-century novelists, perhaps because he effectively dramatized in his fiction moral, religious, and political problems that disturbed generations between World Wars I and II and afterward. Friedrich Nietzsche, the German philosopher and poet, admitted indebtedness to him, and one pre-Nazi German critic declared that after Martin Luther there had been no greater spiritual influence in Germany. The 20th-century novelist André Malraux asserted that in France Dostoyevsky had deeply affected the intellectual history of his generation. The 20th-century French philosopher Jean-Paul Sartre paid tribute to Dostoyevsky's condemnation of the tyranny of reason as having helped inspire his own Existentialist beliefs. Though Lenin is reported to have said of his fiction, "I have no time for such trash," Dostoyevsky is widely read in the U.S.S.R., and notable Soviet novelists have been influenced by his works. If the test of a great author is his capacity to impose his vision on his readers and to transform their experiences, then Dostoyevsky's anti-heroes have had an effect on the creation of many characters in 20th-century U.S. fiction, portrayals that seem overwhelmed by the infirmity of doubt.

#### MAJOR WORKS

*Bednye lyudi* (1846; *Poor Folk*); *Dvoynik* (1846; *The Double*); *Netochka Nezvanova* (1849; *Netochka Nezvanova*); "Dyadyushkin Son" (1859; "Uncle's Dream"); *Selo Stepanchikovo i ego obitateli* (1859; *The Village of Stepanchikovo and Its Inhabitants*—known in its English translation as *The Friend of the Family*); *Zapiski iz myortvogo doma* (1861–62; *Notes from the House of the Dead*—familiar in English as *The House of the Dead*); *Unizhennye i oskorblennyye* (1861; *The Insulted and Injured*); "Zimniye zametki o letnikh vpechatleniyakh" (1863; "Winter Notes on Summer Impressions"); *Zapiski iz podpolya* (1864; *Notes from the Underground*); *Prestupleniye i nakazaniye* (1866; *Crime and Punishment*); *Igrok* (1866; *The Gambler*); *Idiot* (1868–69; *The Idiot*); *Vechny muzh* (1870; *The Eternal Husband*); *Besy* (1871–72; *The Devils*—well known in English as *The Possessed*); *Dnevnik pisatelya* (1873–74, 1876, 1877–81; *The*

*Diary of a Writer*); *Podrostok* (1875; *A Raw Youth*); "Krotkaya" (1876; "A Gentle Spirit"); "Son smeshnogo cheloveka" (1877; "The Dream of a Ridiculous Man"); *Bratya Karamazovy* (1879–80; *The Brothers Karamazov*).

**BIBLIOGRAPHY.** Substantial bibliographical listings may be found in various English and Russian works cited below.

*Editions, journalistic writings, letters, and notebooks:* *Полное собрание сочинений Ф.М. Достоевского*, 30 vol. (first four volumes dated 1972), is the most complete edition, with all texts corrected on the basis of original manuscripts and extensive commentary provided. This edition contains a great deal of hitherto unpublished material. The only edition in English that contains most of the fiction is *The Novels of Fyodor Dostoyevsky*, trans. by CONSTANCE GARNETT, 12 vol. (1921–23). Many separate novels and collections of tales have repeatedly appeared in English. Some journalistic writings have also been published in English: *The Diary of a Writer*, trans. by BORIS BRASOL, 2 vol. (1949); *Winter Notes on Summer Impressions*, trans. by R.L. RENFIELD (1955); and *Dostoyevsky's Occasional Writings*, trans. by DAVID MAGARSHACK (1963). The fullest edition of letters, pending completion of the Soviet definitive edition, is *Ф. М. Достоевский, Письма*, ed. by A.C. Долинин, 4 vol. (1928–59). In English selections have appeared: *Letters of Fyodor Mikhailovich Dostoyevsky to His Family and Friends*, trans. by ETHEL C. MAYNE (1914); *Dostoyevsky: Letters and Reminiscences*, trans. by S.S. KOTELIANSKY and J. MIDDLETON MURRY (1923, reprinted 1971); *The Letters of Dostoyevsky to His Wife*, trans. by ELIZABETH HILL and DORIS MUDIE (1930); *Dostoyevsky: A Self-Portrait* (1962). Valuable Russian editions of notebooks on the five major novels have been translated into English: *The Notebooks for "Crime and Punishment,"* ed. and trans. by EDWARD WASIOLEK (1967); *The Notebooks for "The Idiot,"* ed. by EDWARD WASIOLEK, trans. by KATHARINE STRELSKY (1967); *The Notebooks for "The Possessed,"* ed. by EDWARD WASIOLEK, trans. by VICTOR TERRAS (1968); *The Notebooks for "A Raw Youth,"* ed. by EDWARD WASIOLEK, trans. by VICTOR TERRAS (1969); *The Notebooks for "The Brothers Karamazov,"* ed. and trans. by EDWARD WASIOLEK (1971).

*Biography and reminiscences:* The latest and best informed biography is in Russian: Л.П. Гроссман, *Достоевский*, 2nd ed. (1965). Other works of importance include N.N. СТРАКHOV, *Fyodor Dostoyevsky: A Study* (1921; orig. pub. in Russian, 1883); А.П. Суслова, *Годы близости с Достоевским* (1923); ANNA DOSTOYEVSKY, *Dostoyevsky Portrayed by His Wife: The Diary and Reminiscences of Mme. Dostoyevsky*, trans. by S.S. KOTELIANSKY (1926); Андрей Достоевский, *Воспоминания* (1930); HENRI TROYAT, *Dostoyevsky* (1939; Eng. trans., *Firebrand: The Life of Dostoyevsky*, 1946); E.H. CARR, *Dostoyevsky* (1949); AVRAHM YARMOLINSKY, *Dostoyevsky: His Life and Art*, 2nd rev. ed. (1957), a standard, up-dated biographical treatment in English; ROBERT PAYNE, *Dostoyevsky: A Human Portrait* (1961); Ф.М. Достоевский в воспоминаниях современников, 2 vol. (1960); А.Г. Достоевская, *Воспоминания* (1971).

*Criticism and interpretation:* *Творчество Достоевского. Сборник статей и материалов*, ed. by Л.П. Гроссман (1921); Ф.М. Достоевский, *Статьи и материалы*, 2 vol., ed. by A.C. Долинин (1922–24); JOHN MIDDLETON MURRY, *Fyodor Dostoyevsky: A Critical Study* (1923), a view of early English reaction; Л.П. Гроссман, *Поэтика Достоевского* (1925); ANDRÉ GIDE, *Dostoyevsky* (1923; Eng. trans., 1925); М.М. Вахтин, *Проблемы творчества Достоевского* (1929); JANKO LAVRIN, *Dostoyevsky: A Study* (1943); NIKOLAI BERDYAEV, *Dostoyevsky* (1957; orig. pub. in Russian, 1923), a philosophic review of his works; VYACHESLAV IVANOV, *Freedom and the Tragic Life: A Study in Dostoyevsky*, 3rd ed. (1960; orig. pub. in Russian, 1932), a symbolic and mythic study; RE MATLAW, *The Brothers Karamazov: Novelistic Technique* (1957); VLADIMIR SEDURO, *Dostoyevski in Russian Literary Criticism, 1846–1956* (1957); GEORGE STEINER, *Tolstoy or Dostoyevsky: An Essay in the Old Criticism* (1959), stimulating but impressionistic; В.У. Кирпотин, *Ф.М. Достоевский, творческий путь* (1960); ERNEST J. SIMMONS, *Dostoyevsky: The Making of a Novelist* (1950, reprinted 1962), a critical study of the development of Dostoyevsky's creative art that makes extensive use of his notebooks; EDWARD WASIOLEK, *Dostoyevsky: The Major Fiction* (1964); DONALD FANGER, *Dostoyevsky and Romantic Realism* (1965); ROBERT L. JACKSON, *Dostoyevsky's Quest for Form* (1966); R.L. BELKNAP, *The Structure of The Brothers Karamazov* (1967); KONSTANTIN MOCHULSKY, *Dostoyevsky: His Life and Work* (1967; orig. pub. in Russian, 1947), one of the best and most comprehensive works on Dostoyevsky's life and writings; RICHARD PEACE, *Dostoyevsky: An Examination of the Major Novels* (1971).

(E.J.Si.)

## Draft Animals

Before the Romans developed the waterwheel, man's only supplements to or replacements for his own muscle power were animals he trained to work for him. Even now, after the harnessing of steam, oil, and electricity, over 80 percent of the world's cultivable land is still tilled by men with the help of animals. This article surveys the animal species used and the ways man has used them, for traction, as pack animals, and for other agricultural operations not involving traction. For the use of horses for riding see the articles entitled RIDING AND HORSEMANSHIP; and HORSE RACING. For information on the biology of the various species see HORSE; ARTIODACTYLA; etc. Care and feeding are covered in LIVESTOCK AND POULTRY FARMING; and ANIMAL FEED.

Draft animals were in use long before man began to keep written records, as indicated from the remains of animals, harness, and chariots in ceremonial graves and from tomb paintings, temple decorations, statuettes, coins, and seals (*e.g.*, signet rings). Though animals were first domesticated some 9,000 to 11,000 years ago, there is no evidence of their exploitation for work until many years later. Archaeological records suggest that reindeer sledges were used in northern Europe before 5000 BC, and land sledges drawn by oxen were used in ancient Mesopotamia before 3500 BC. Pack asses are represented in ancient Egyptian art of about the same period. With the invention of the plow and the wheel (before 3000 BC) the use of animals for draft became common in Mesopotamia and spread outward from there in all directions. Wheeled vehicles drawn by animals reached the Indus Valley by 2500 BC, Europe by 2000 BC, Egypt by 1600 BC, China by 1300 BC, and Britain about 500 BC.

### BOVINES

Cattle were the first animals used for work and have always been the most important farm animal the world over. In the West, during the last few centuries, they were replaced by horses and these in turn by tractors.

Common cattle. Though the earliest archaeological records of domestic cattle date back to the 7th millennium BC, the first representations of plows do not appear until some 3,000 years later. It is not known whether this is simply a gap in the records or whether cattle were first domesticated for some other purpose, such as religious ritual, and only later adopted for farm work. Until 1000 BC cattle were the only animals used for heavy transport.

The original draft team, for sledge, cart, or plow, consisted of a pair of oxen. This pattern continued through Greek and Roman times. In many Mediterranean countries the situation is little changed even today. For the heavier soils of northern Europe, a larger team was needed; there the normal complement was four or eight.

Only after the Norman Conquest (1066) was the horse used for farm work in Britain. At that time began the long competition between horse and ox, which was finally settled in favour of the swifter horse, though in a few places the ox team survived into the 20th century, some as sentimental anachronisms.

Both draft oxen and draft horses were brought to the New World. In the early days of America, in fact, cattle were valued more for draft than for meat. Covered wagons on the western trails were largely drawn by oxen. The use of cattle for heavy work continued at least until the end of the 19th century. Competitive ox-pulls, using a sledge loaded with stones, were still a feature of local fairs in New England as late as the 1930s.

While the horse revolution came (and went) in western Europe, oxen remained the standard draft team throughout Asia and North Africa. South of the Sahara, particularly in tsetse fly areas where livestock do not thrive, native agriculture still relies primarily on human muscle power (hoe cultivation). Though the ox is used as a pack and riding animal by nomadic cattle owners in countries such as Chad, Cameroon, and Senegal, the idea of using oxen as draft animals was introduced comparatively re-

cently (1920s) by Europeans in limited areas of East and West Africa.

The greatest users of ox power in Africa south of the Sahara were the Dutch colonists. Soon after they settled at the Cape of Good Hope in 1652, they obtained cattle from the Hottentots and quickly developed them into an excellent breed of draft oxen—the Africander, which played a crucial role in opening up the country.

Selection of work oxen is based chiefly on their conformation. For rapid work in light soils, the rangy long-legged type is chosen. For slow, heavy work a correspondingly heavy, thick-set animal is preferred. Some trials with scientific performance tests have been made. In India a dynamometer has been used to measure the draft power of oxen. At livestock markets in Taiwan, cattle show their strength by pulling a cart with locked wheels. Temperament is also of vital importance.

Though cows, bulls, and castrates are all used for work, the castrate (the ox) is much the most favoured. In central Europe many breeds are still used for milk and meat as well as draft. Experiments, both in central Europe and India, have shown that even cows in milk can work a normal day with little effect on milk yield.

Water buffalo. In southern Asia and in Egypt, the domesticated Asiatic buffalo (*Bubalus bubalis*) is an important work animal. There are two main types: the dark gray "swamp" buffalo (which still closely resembles the wild animal in appearance) and the black "river" buffalo. In the rice-growing countries of southeast Asia, the swamp buffalo is the principal draft animal. It is rarely milked, but is usually eaten at the end of its working life. In India, Pakistan, southwest Asia, and Egypt, where various dairy breeds of river buffalo have been developed, their use for meat and draft is secondary to milk production. The buffalo is also raised in some countries of southeast Europe, where it is now being transformed from a draft into a meat animal.

The water buffalo is very suitable for work in humid climates and on water-logged land. Although (unlike the zebu) not adapted to dry conditions, it is used for draft work on roads because it can pull heavy loads.

Yak. On the cold high plateaus of Tibet, and the neighbouring provinces of China (especially Tsinghai and Szechwan), as well as on the southern slopes of the Himalayas (northern Nepal, Bhutan, and the North East Frontier Agency of India), the yak (*Bos grunniens*) is the principal beast of burden. It is also used for riding, draft, and milk. Its hybrid with cattle, the dzo (also spelled zho and zo), is used similarly. In Tibet the dzo is often preferred to the yak for plowing.

### EQUINES

Wild horses are native to northern Asia and Europe, onagers ("half-asses" or "half-horses") to central and southwest Asia, and wild asses to North Africa. Each was domesticated in its native area and was first used for load carrying or traction.

Donkey or ass. The ass is the oldest pack animal. It was used in Egypt possibly as early as 3500 BC, and certainly by 2500 BC. From the Nile Valley its use gradually spread westward around the Mediterranean, southward in Africa as far as Kenya, and eastward across Asia to China. Although the donkey has been primarily a load carrier, it has been ridden and used for draft (*e.g.*, plowing) as well. Donkeys were recently introduced into southern Africa for draft purposes.

Though essentially a beast of arid regions, the ass is not as specialized as the camel. The very modesty of its food requirements makes it an ideal poor man's animal.

Mule. The mule is the infertile hybrid between mare and jackass. It combines the size and strength of the horse with the resistance of the donkey. The surefooted mule is still popular, both for pack and draft, in rugged terrains and mountainous areas, particularly in the Mediterranean and South America.

Onager. In the 3rd millennium BC, onagers served as draft animals in ancient Mesopotamia. There are representations in Sumerian art of a yoke of four onagers

Types of  
buffalo

Competition  
between  
horse  
and ox

abreast pulling a heavy two-wheeled chariot or a four-wheeled cart. At the beginning of the 2nd millennium, the more amenable horse was introduced from the north and replaced the onager, whose domestication then ended.

**Horse.** The horse was domesticated in the Ukraine or Central Asia, probably toward the beginning of the 3rd millennium BC. It was probably ridden before being harnessed to a vehicle. Introduced to the Middle East, it was taken by invading Hyksos to Egypt, where it first appears in art about 1580 BC. Subsequently the horse and chariot spread over the whole of the ancient world from the Mediterranean to China. In contrast to the situation in their northern homeland, however, horses were not used for riding or agricultural work until much later.

Horse  
plowing

In England, the horse was first used for harrowing, which it could do faster than an ox. Horse plowing did not start until the end of the 12th century. At first horses joined the ox team; mixed yokes were common.

Disagreement over the relative merits of horse and ox as draft animals has lasted for 500 years and in some countries (*e.g.*, Japan) has not yet ended. The ox has a long strong pull for the old heavy plow, and does not require shoeing. As a ruminant it can be fed on coarse fodder (roughage). It can even be eaten at the end of its working life. With the wheeled plow, however, the horse is a much quicker worker, and in medieval northern Europe, where an oat crop could easily be grown, the horse largely supplanted his slow-gaited rival.

In the 17th century, the heavy horses that had been developed in northwest Europe for carrying feudal knights became available for agriculture, where they formed the basis of heavy draft breeds such as Belgian, Percheron, and Clydesdale.

The reign of the plow horse in western Europe and North America was ended in the 20th century by the large internal-combustion engine. Changeover was particularly rapid in the large farms of the U.S. By contrast, in the small peasant properties of central and eastern Europe, the horse is still an important farm animal.

In central and eastern Europe, the Netherlands, Sweden, and Finland special performance tests with a dynamometer measure pulling and carrying ability of farm horses. It is interesting to note that, in proportion to its body weight, a small horse can pull a heavier load than a large horse. In the Western world, the horse has returned to its original role as a sport animal, although the sports are now riding and racing rather than war and hunting.

**Zebra.** The zebra, the equine native to eastern and southern Africa, has never been systematically domesticated, but occasionally individuals have been tamed and teams trained to pull carts or carriages for amusement.

#### OTHER DRAFT ANIMALS

**Dog.** The use of dogs to pull sledges in the Arctic is well known—whether it be the Husky of North America or the Samoyed and Laika of Siberia. In America the original arrangement was a fan hitch of 12–15 dogs, each with its separate attachment to the sledge. More usual now is a pair hitch involving about eight dogs in double file which may pull loads of 675 kilograms (1,500 pounds) or more. In the U.S.S.R. smaller teams (4–6 dogs) and lighter loads (up to 158 kilograms or 350 pounds) are more usual.

It is less well known that dogs were used until recently in western Europe for pulling small carts. In Britain this practice was forbidden by law in 1885 (since then "dog-cart" has meant a light pony-drawn carriage with a box under the seat for carrying dogs). In Belgium, the Netherlands, and parts of France, Germany, and Switzerland, small carts drawn by one or two dogs were used by farmers to bring their produce (especially fruit, vegetables, and dairy products) to the town market until just after World War II. The dogs used were of Mastiff type and pulled loads of 135–180 kg (300–400 lb).

**Reindeer.** Reindeer drew sledges in northern Europe long before horses were harnessed for the task. In Lapland, a single reindeer harnessed to a sledge can pull a load of 75 kg (165 lb), or even 100–150 kg (220–330

lb) at a slower pace under good conditions. The Samoyeds harness two to four or even more animals per sledge; these pull heavier loads. The Lapps use their animals for packing in summer. In Siberia, reindeer are also used as pack animals and for riding; a good male carries 65 kg (150 lb) for 80 kilometres (50 miles) a day.

**Camel.** The camel is the desert animal par excellence. As a beast of burden it is irreplaceable. The one-humped camel or dromedary supplies all the needs of the pastoralists in the semidesert areas of North Africa and southwest Asia as far east as Rajasthan in India. In neighbouring agricultural areas, though chiefly used for carrying bulky loads (cotton, groundnuts, straw, green forage), it also turns the sakia (Persian wheel) to lift loads and drive mills. It is sometimes yoked to a plow, occasionally teamed with ass or ox.

In Central Asia, northern China, and Mongolia, the two-humped or Bactrian camel is used as a pack animal. In China an average load is 115–135 kg (250–300 lb) carried at 3 km per hour (2 mi per hour) for 40 km (25 mi) a day; the strongest animals can carry 270 kg (600 lb) and cover 1,050 km (650 mi) in 30 days. In India, an adult male dromedary can carry a load of 225–295 kg (500–650 lb) at 3–4.5 km per hour (2–3 mi per hour) and cover 32 km (20 mi) per day; the best animals can manage up to 405 kg (900 lb) over short distances.

**Elephant.** Domesticated Indian elephants are represented on seals from the Indus Valley civilization dating from 2500 BC; they have presumably been used for riding and as beasts of burden ever since. In India, Sri Lanka (formerly Ceylon), and Burma, their chief use now is in lumbering—they drag logs through the jungle and push floating logs around bends and off sandbanks ("aunging"). They also serve as baggage animals. Mature elephants can carry a load (excluding gear) of 180–360 kg (400–800 lb) depending on their size.

The African elephant was used in war both in Ptolemaic Egypt and in Carthage, playing a notable role in Hannibal's invasion of Italy in 218 BC. But excessive exploitation and increasing desiccation of the environment led to extinction of the North African variety. South of the Sahara, elephants have not been domesticated.

**Llama.** The llama is the only large animal domesticated in pre-Columbian America. Its habitat is restricted to the Andean highlands. Since the Incas did not have wheeled vehicles, they used the llama exclusively as a pack animal. In its present area of distribution in south Peru and Bolivia, its chief use is still as a pack animal. Normal load is only 25–30 kg (55–66 lb), exceptionally up to 35 kg, or 77 lb. It cannot travel more than 25–30 km (15–20 mi) per day.

**Sheep and goat.** Some large breeds of sheep and goat are used as beasts of burden at altitudes of 3,500–5,500 metres (12,000–18,000 feet) in Tibet and over the Himalayan passes between Tibet and India. In northern Kashmir these pack animals are of the Chanthan breed of sheep and Kel breed of goat. In the Punjab they are known as Kangra Valley animals and belong to the Biangi and Gaddi breeds of sheep and the Chigu breed of goat. They can carry a load (*e.g.*, of salt) of 4.5–18 kg (10–40 lb) for 15 km (10 mi) a day.

It is not known whether fact or fancy inspired the scene portrayed on a signet ring from Crete (15th century BC) that shows a pair of wild goats drawing a chariot, but it is true that domestic goats have been used as draft animals in western Europe.

#### USE OF DRAFT ANIMALS

**In agriculture.** Use without implements. For some agricultural operations, the herd animals' feet alone are sufficient. In ancient Egyptian tomb paintings sheep are shown being driven over the fields to tread in the seed corn after it has been broadcast. Later in the year the same procedure was used for threshing—animals were driven around the threshing floor treading out the grain. In the East this method of threshing is still employed using either cattle or buffalo.

In Southeast Asia, water buffalo may be used for culti-

Use of  
animal  
feet

Dogcarts

vating the rice fields by puddling the flooded fields with their large hoofs. In Sri Lanka the same activity is used in puddling clay for bricks.

**Draft power for agricultural implements.** The first cultivating tool was a hoe pushed or pulled by a man or (more commonly) a woman. Later, two oxen were attached and the hoe became a plow. Since then the plow has been the principal agricultural implement; even as late as 17th-century England, plowing and carrying in the harvest were the only farm tasks for which animals were used. There was no spring cultivation and seeds were broadcast by hand. Parallel with the introduction of horses, the number of operations and implements increased. Horses were first used for harrowing and later for sowing (pulling the seed drill), rolling (to break up clods), hoeing, haymaking (pulling the mowing machine, the swathe turner, and the rake), harvesting (pulling the reaper or reaper-binder), in addition to pulling carts and plowing.

In less sophisticated agricultures, where cattle still dominate, the range of operations is smaller. Around the Mediterranean and in Asia, cattle or buffalo are used for plowing and for subsequent cultivation with the harrow. They are also used for threshing by pulling a sledge through the grain on the threshing floor. This method is still standard in Egypt and, until recently, was common (often with mules) in other Mediterranean countries.

**Stationary machinery.** Animals have been used to pull rotary devices at least since Roman times. In India and the Sudan, camels still turn the sugarcane crusher and oil-extraction mill. There and elsewhere animal power still lifts irrigation water out of wells, rivers, or canals. The blindfolded animal, whether horse or mule as in Spain, ox or buffalo as in Egypt, still endlessly turns the waterwheel, or *sakia*. In the West mechanical power has long since replaced the ass that turned a treadmill to raise water from the well, as well as the hard-worked dog that used to run in a wooden wheel to turn the spit, the butter churn, or the blacksmith's bellows.

**In transport.** *Pack animals.* Before the invention of the sledge and the wheel, loads were carried first by man and then on his animals. Humans still fulfill this function all over Africa and the Orient. Donkeys were the first pack animals and are probably still the most important, though mules can carry heavier loads. Horses are rarely employed. Camels and elephants are invaluable for bulky and heavy loads. Yaks, llamas, sheep, and goats carry light loads in high mountains. Cattle are used in West Africa.

**Pulling wheelless vehicles.** Animals were used for drawing sledges before invention of the wheel made the more efficient cart possible. The snow sledge or sleigh drawn by dogs, reindeer, or horses remains in use where wheels slip, get stuck, or break the ice. Over rock or soil the sledge is now only encountered in rare situations where the going is so rough or muddy that wheels are useless. In Thailand, the Philippines, and Borneo, for instance, buffalo draw a light wooden sledge through forest or over cultivated land; the ox-drawn sledge is seen in Botswana. Elephants, oxen, or buffalo may draw logs on a sledge or may pull the log itself as a skid. Even in England, the agricultural sledge was used until recently.

Barges on the canals of Europe were commonly towed by horses; the towpath beside the canal was designed for these animals. The load that one horse could pull on a canal was of the order of 50 metric tons (55 short tons) (30 metric tons [33 short tons] on a river), compared with only 126 kg (280 lb) on a pack horse. For wagons the load varies from one to eight metric tons (one to nine short tons) according to the nature of the road. Oxen still haul fishing boats ashore along the Portuguese coast.

**Wheeled vehicles.** In primitive agriculture, carts and wagons are the chief forms of transportation on the farm and from farm to market. With the development of macadamized roads in the 18th century, the horse-drawn carriage became an important means of transport for mails and passengers. During the 19th century, heavy horses pulled carts and drays on farms, coach horses

drew stagecoaches and post chaises between cities, ponies were hitched to wagons in coal mines and traps on country roads, and light horses pulled innumerable cabs, carriages, carts (later, even fire engines and omnibuses) within towns (see WAGONS AND CARRIAGES).

In the West only an occasional horse-drawn milk delivery cart or brewer's dray is seen today; the last pit ponies will shortly vanish from English coal mines. Farther east in Europe, horses still pull the farm wagon. In Egypt there is a division of labour: the farm work is done by cattle or buffalo; on the roads the wagons are pulled by horses. In Asia the ox carts penetrate the cities, and the horses are restricted to passenger transport.

#### DRAFT HARNESS AND ACCESSORIES

**Harness.** The original ox team was harnessed by a simple wooden yoke to the pole of the cart or plow. In this antique but still used harness, the yoke rests on the back of the animal and the pull is on the projecting withers. Vertical bars on each side of the neck prevent side-slip and a rope round the neck holds the yoke in place and prevents a cart being tipped up. The hump of the zebu gives a larger projection for the yoke to rest on. With a single ox, the yoke can be attached to the shafts of a cart or to the plow by ropes. Alternatively the yoke can be attached to the head or horns; this is common in southern Europe. Another type of attachment occasionally used is the breastband.

With equines a yoke cannot be used because the withers are not sufficiently prominent. So with the introduction of onagers and horses for draft the breastband was employed. Unfortunately, as the horse pulls, the band presses on its windpipe and chokes it. This inefficient harness limited the use of horses for heavy draft work until the introduction of the rigid padded collar, invented in China in the 1st century BC and introduced in Europe about the 10th century AD. With a horse collar pressure falls on the front of the shoulders (*i.e.*, on the skeleton); the only limit to load or speed is the strength and willingness of the horse.

The modern draft harness is based on the collar, usually with the addition of a saddle to support the shafts of a cart and hence take some of the weight. Wooden hames (projections) fit into the collar and the shafts are attached to the harness by straps or chains (the traces). The crupper (loop passing under a horse's tail and buckled to the saddle) prevents the saddle riding forward and the breeching (part of the harness that passes over the animal's buttocks) prevents the vehicle forcing the saddle forward when backing or going downhill.

In the absence of shafts, the traces are joined directly to the vehicle or to swingletrees (pivoted swinging bars to which the traces of a harness are fastened) to give an even pull. Two horses are harnessed to a plow by means of two sets of swingletrees.

Though collars have been tried on oxen to prevent sores caused by galling of the yoke or the choking effect of the breastband, the old system is still the most popular.

**Packsaddles.** A proper packsaddle consists of a pad to protect the back, a wooden framework to support the pack (with straps around neck and tail), and a pack frame that is loaded and placed on the animal's back.

For camels the pack is very extensive and consists of two bags filled with grain or straw, one on each side of the animal. The framework, reduced to one or two wooden bars fastened to each bag, is held in place by ropes around neck, belly, and tail.

**Control.** Cattle and camels are guided by a single nose rope, horses by a bit and reins. The nose rope, or guiding rein, is threaded through the nasal septum; a wooden peg or plug prevents it from pulling through. In China (including Hong Kong and Taiwan) the buffalo's nose is ringed and the cord attached to the ring. Sometimes control is effected by a rope looped around the horns.

Horses are controlled by a metal bit through the mouth to which the reins are attached. The bridle holds the bit in position. This system dates from 1500 BC. Blinkers may be added so that the horse can only see ahead.

Towing  
barges

The horse  
collar

*Shoes.* On the paved Roman roads, horses needed foot protection to prevent wear and slipping. The iron shoe was used in Rome from the 1st or 2nd century BC and in northern Europe from the 8th century AD. Where oxen are used on roads they too are shod. In Italy and Portugal, for instance, oxen wear special double shoes to fit their divided hoofs. In the Far East, shoes tend to be more primitive; in Java *trompahs* for buffalo are made from old automobile tires.

#### CONCLUSION

While animals are actually working their efficiency is as high as a tractor's (about 25 percent), but over their lifetime their energy output in useful work represents only a small percentage of the potential energy of their fuel. It is especially low if they are used for only a short period each year. On the other hand, animals supply milk and manure as well as power, require only modest protection from the weather, and, compared with tractors, require little skilled maintenance. Animals can use local products as fuel and are self-reproducing. A tractor requires expensive (often imported) fuel and its capital cost is high. For these reasons, it is only when the standard of living is high and agriculture is on a large scale that farmers can afford to replace draft animals by tractors. Though they have virtually disappeared from the Western world, elsewhere draft animals' numbers are declining only slowly and will long retain the place they held in agriculture for the last 5,000 years.

**BIBLIOGRAPHY.** The history of domestic animals is fully documented in F.E. ZEUNER, *A History of Domesticated Animals* (1963); and in R. TROWSMITH, *A History of British Livestock Husbandry to 1700* (1957). The history of their utilization for work is surveyed in C.J. SINGER *et al.* (eds.), *A History of Technology*, 5 vol. (1954–58). Information on the management of specific draft animals may be found in the following: W.C. MILLER and E.D.S. ROBERTSON, *Practical Animal Husbandry*, 7th ed. (1959); B.S. VESEY-FITZGERALD (ed.), *The Book of the Horse* (1946); G. WILLIAMSON and W.J.A. PAYNE, *An Introduction to Animal Husbandry in the Tropics*, 2nd ed. (1965); W.R. COCKRILL, "Observations on Control, Restraint and Slaughter of the Water Buffalo in the Far East," *Vet. Rec.*, 80:225–229 (1967); CLB. HUBBARD, *Working Dogs of the World* (1947); and A.J. FERRIER, *The Care and Management of Elephants in Burma* (1947).

(I.L.M.)

## Drafting

Drafting is the act of delineating a drawing of an object, its structure, or its parts in the graphic language universally employed to communicate the engineering intent of a design, or problem. Engineering drawings consist of lines representing surfaces, edges, and contours of objects, supplemented by symbols, dimensional sizes, and notes. In a broad sense, drafting is the graphical development of an engineering problem or record.

The term engineering graphics has come into use in place of engineering drawing because a wide range of related graphic detail must often be included, such as wood trim, ornate brickwork patterns, corbelling instructions, and even load-design formulas for certain cantilevered beams.

#### HISTORY

Among the earliest records of engineering graphics is a stone engraving of a fortress plan made by the Babylonian engineer Gudea about 2000 BC. The Roman architect Vitruvius, in his treatise on architecture (c. 27 BC), referred to technical drawing, emphasizing that the architect should have a working knowledge of drawing so that he could better show the work to be constructed. He also discussed the procedures and practices to be followed in making drawings, thus providing the first textbook of engineering drawing.

Villard de Honnecourt's *Sketchbook* (c.1225–50), well known to students of medieval art and technology, has been the subject of extensive research and commentary. Although small in comparison with the works of Vitruvius and Leonardo da Vinci, it contains several technical

drawings of church structures, church furniture, and geometrical devices. Leonardo da Vinci (1452–1519) illustrated his work profusely with technical drawings. His treatise on painting is regarded as the first book printed on the theory of projection drawing. Gaspard Monge (1746–1818), however, is regarded as the first to make an organized record of the principles of engineering drawing that are used today. His *La Géométrie descriptive* (1801) was the first formal treatise on modern engineering drawing. In it he developed the theory of projecting views of an object onto three mutually perpendicular coordinate planes (such as are formed by the front, side, and top of a cube), and then revolving the horizontal (or top) and profile (side) planes into the same planes as the vertical (front) plane.

Most original ideas for mechanical devices are first expressed in a freehand drawing made simply with a pencil. Freehand drawings and sketches can clarify and record various technical ideas and verbal expositions. With them the designer can organize his thoughts, record his ideas, and quickly lay out various solutions to a problem.

The fundamental theory for all orthographic (mutually perpendicular) projection drawing is derived from descriptive geometry as organized by Monge.

In a broad sense, the subject of engineering drawing includes many different kinds of projection, descriptive geometry, and graphics; but its most common form currently is orthographic projection drawing. In orthographic projection, any object, regardless of its complexity, can be viewed from any direction.

#### CLASSIFICATION OF DRAWINGS

**Mechanical drawing.** Most engineering drawings are made with instruments, hence the name mechanical drawing. Instrument-made drawings provide the greatest accuracy, neatness, and legibility.

Various instruments are available to simplify the making of drawings, such as pencils with varying degrees of hardness; T-squares and triangles for drawing parallel, perpendicular, and diagonal straight lines; scales for measuring; dividers for transferring distances; compasses for constructing circles and arcs; a drawing board to provide a flat surface for the paper; drafting tape to hold the paper on the board; and erasers. Other instruments include templates (patterns) for drawing irregular curves and various symbols, protractors to measure angles, erasing shields, and pencil sharpeners.

In orthographic projection drawing, an object is viewed with a point of sight set at infinity, making the visual rays, or lines of sight, from the eye to the object parallel. Since the visual rays are parallel, distances on the object in a direction perpendicular to the line of sight will show true lengths; surfaces of the object in a plane perpendicular to the line of sight will show true size and shape; distances on the object in a direction parallel to the line of sight will show as zero; and any surface of the object parallel to the line of sight will show as a line. Distances and plane surfaces inclined to the line of sight will appear foreshortened.

To show the distances in three coordinate directions (height, width, and depth), two views of an object will be required. With lines of sight perpendicular to each other, each view will show two of the three coordinate distances. Adjacent views have lines of sight perpendicular to each other to show these distances in three mutually perpendicular directions, again citing the front, side, and top of a cube as an example.

Any two adjacent views with lines of sight perpendicular to each other have their common dimension in alignment with each other in the two views, as is shown in Figure 1. Thus, at any distance the top or bottom view is in vertical alignment with the front view. The side view, either right or left, is in horizontal alignment with the front view; and an auxiliary view is in alignment with the view from which it is projected.

The views are placed on the sheet in sequence of adjacent sides of the object. Main views are the so-called principal views: the top (or bottom), front (or rear),

The first organized thesis

Point of sight

Figure 1: Views in alignment.

and right side (or left side). Other views, which can be taken from any direction, are known as auxiliary views.

**Arrangement of views.** The arrangement of views may be in either of two systems: third-angle projection or first-angle projection. In both systems, the principal views, the front, top, and side, are obtained by looking directly at the front, top, and side, respectively.

In third-angle projection, the top view is drawn in a location vertically above the front view, and the side view is placed horizontally in direct line with the front view. In both the top and the side views, the front of the object is positioned toward the front view; thus the right side view is that seen to the right of the front view, and the left side view is that seen to the left of the front view. Third-angle projection is an almost universally accepted method in the United States.

In first-angle projection the top view is drawn in a location vertically below the front view; the right side view is placed horizontally in line with the front view but located on the left of the front view; and the left side view is located at the right of the front view. In depicting both the top and side views, the front of the object is facing away from the front view. First-angle projection is the commonly accepted method in many European countries.

An auxiliary view is taken from any direction except that of one of the three principal views. A first-auxiliary view is one with a line of sight perpendicular to the line of sight of one of the principal views. A second-auxiliary view is a view with a line of sight that, in turn, is perpendicular to the line of sight of a first auxiliary view.

Many objects have curved or angular surfaces that are not perpendicular to the line of sight of any of the principal views; therefore, they do not appear in their true size and shape in the principal views. In order to show the true size and shape of such surfaces, it is necessary to obtain a view with a direction of sight perpendicular to the surface.

Auxiliary views are constructed by projecting from a given view to obtain measurements at right angles to the projecting lines that are common to the two adjacent views. In the auxiliary view, measurements parallel to the projecting lines are the same as the corresponding measurements in the other views adjacent to the one from which the projection is made.

**Working drawings.** A working drawing describes an object so completely that it can be produced without further information. It provides specifications as to shape, size, material, and finish. It may suggest the shop processes required for production of the object, but it does not specify that only certain processes may be used.

In general, the main (or front) view should show the object in its operating or usual position, or in the position it occupies in the assembly. In many cases, however, its position is not important, and the view that shows the characteristic shape of the object is selected for the front view. One-view drawings are used whenever views in more than one direction are unnecessary, *e.g.*, for flat parts made of thin material. Many parts, such as cylinders, require only two views. More views would merely duplicate the views already shown. More than two views are necessary for objects that are made up of combined geometric shapes.

One-view drawings

Lines that make up a drawing have been thoroughly standardized, and their use on drawings is universally recognized. Visible object lines are continuous thick lines. Hidden lines are broken, or dashed, medium thick lines. Dimension lines, extension lines, leaders, and section crosshatch lines are thin continuous lines. Centre lines are alternate long-short dashed thin lines. Phantom lines are long dashed thin lines. Cutting plane lines are medium dashed heavy lines.

To save drafting time, many standard features, such as threads that frequently occur on machine parts, are represented by conventional symbols. In the conventional representation, the helical curves of the thread for both the crest and the root may be represented by straight lines drawn at right angles to the length of the thread; or, for further simplification, threads may be represented by hidden lines parallel to the axis at the root diameter of the thread, as shown in Figure 2.

Figure 2: Thread representation.

Standards have been developed for a considerable number of graphic symbols to be used on drawings and diagrams, for gear teeth, pipe fittings, hydraulic fixtures, electrical devices, and other units.

**Sections.** By means of properly selected views, the external features of the most complicated objects may be fully described. The showing of complicated interiors of many parts, however, results in a confusion of hidden lines that may be extremely difficult to interpret. Such objects can be adequately described by the use of sectional views. The object is imagined as cut through the interior by a cutting plane, and the resulting object is shown as a view. The portion of the object cut by the cutting plane is crosshatched by section lining.

Various conventional methods of passing cutting planes result in certain sectional views, such as half section, full section, broken-out section, revolved section, removed section, auxiliary section, offset section, aligned section, and partial section, as shown in Figure 3.

Figure 3: Conventional sections.

Drawings should be completely dimensioned so that it will not be necessary for the reader to scale the drawing or assume any dimensions. Drawings should be made accurately to scale, however, to maintain correct proportions between the various features of the object. The scale is usually selected to be some convenient multiple or fraction of full size, such as full size, half size, quarter size, one-tenth size, double size, or ten times full size, although any intermediate scale may be used.

**Dimensions.** Dimensions, the size specifications added to the shape description as shown by the orthographic drawings, consist of the numerical values of the measurements, directed to the proper location on the part by means of dimension lines to indicate the extent of the measurement and by extension lines to indicate the relevant surfaces or locations on the object. The units of measurement must also be specified (see Figure 4).

In the past, common fractions were considered adequate for dimensions; but as products became more complicated and precise sizes became necessary in order

to have interchangeable parts, more accurate specifications were required. It then became necessary to turn to the decimal system. Today, decimal dimensions are widely and increasingly being used in industry.

There are many types of manufacturing in which units and common fractions are still used, however, because extreme accuracy is not required or is relatively unimportant. Architectural and structural work is an example. Such work is usually one of a kind, and much fitting is done in the final assembly. These drawings are commonly dimensioned in units and common fractions.

**Tolerances.** It is impossible to produce products to an exact size. In actual practice, exact sizes are not essential. Only varying degrees of accuracy are necessary according to the functional requirements of the product. Tolerances are therefore the means of specifying dimensions to the degree of accuracy required.

A tolerance is the specification of the permissible variation in the size of a part or in the location of a feature with reference to other features of a part. Tolerances are expressed in the same units and to the same degree of accuracy—that is, the same number of decimal places—as the dimensions to which they apply. Tolerances may be expressed either as plus-and-minus values to be added to the basic dimension or as maximum-and-minimum values of the dimension (Figure 4).

It usually is necessary to supplement the direct dimensions with notes, which should be brief and carefully worded to permit no misinterpretation. Local notes are directed to the proper place on the drawing by means of leaders. General notes, applying to the entire drawing rather than to a specific portion of it, are placed either in one corner of the drawing or centred beneath the views to which they apply.

**Lettering.** Dimensions and notes are lettered on the shape description shown on the drawing in order to complete the size description. Lettering should be suitable for easy and rapid execution. It must also be legible after reproduction, particularly for photographic reduction and subsequent enlargement where small spaces between the letter elements may tend to fill in.

The form of lettering generally recognized as standard for use on drawings is single-stroke Gothic. Single stroke refers to the width of a single stroke of the pen or pencil used in making the line elements of the letters.

All lettering that is a part of the drawing should be in capital letters. Lowercase letters may be used for notes and memorandums.

Either vertical or inclined letters may be used. Vertical letters are slightly more legible than inclined letters but more difficult to execute.

A detail drawing is the complete representation of a single part, including all necessary views, dimensions, and notes. Frequently, each individual part is shown on a separate sheet.

An assembly drawing shows the assembled machine or structure with all detail parts in their functional positions. Assembly drawings vary in character according to use: design assemblies or layouts, general assemblies, working drawing assemblies, outline or installation assemblies, and check assemblies.

**Diagrams.** Diagrams are simplified drawings of electrical or hydraulic circuits describing the connections and functions of such circuits. Standards also have been developed for a number of graphic symbols used on these diagrams. A circuit diagram shows, by means of single lines and graphic symbols, the course of an electric or hydraulic circuit or system of circuits and the connections of an installation or its component devices or parts. A connection diagram usually shows the general physical arrangement of the component devices, but the internal connections of the unit assemblies or equipment may be omitted. A schematic diagram shows, by means of lines and graphic symbols, the connections and functions of a specific circuit arrangement. It facilitates tracing through the circuit and its functions.

**Pictorial drawing.** Pictorial representation designates the method of projection that shows the object approxi-

Standard  
lettering

Use of  
decimal  
dimensions

Figure 4: Expression of (A) dimensions and (B) tolerances.

mately as it would be seen by the eye. There are three main divisions: axonometric, oblique, and perspective.

**Axonometric.** Axonometric is a type of pictorial orthographic projection drawing where the line of sight is inclined to the principal faces of the object and to the principal axes of the object. Thus, all dimensions in the direction of the principal axes are foreshortened. The faces of the object not perpendicular to the line of sight are distorted.

Often, axonometric projections are most easily constructed by taking a second-auxiliary view of the object (Figure 1). If the second-auxiliary view is taken in such a direction that all three principal axes are foreshortened by different amounts, the resulting view is a trimetric projection. If the second-auxiliary view is taken in such a direction that two of the three principal axes are foreshortened the same amount and the third by a different amount, the resulting view is a dimetric projection. If the second-auxiliary view is taken in such a direction that all three principal axes are foreshortened the same amount, the resulting view is an isometric projection.

With the geometric method of positioning ordinary orthographic views of an object on a sheet, axonometric projections can be produced directly by projection from the views, without a first-auxiliary view.

By setting up scales to be used in the directions of the three principal axes, axonometric drawings can be produced directly without projection from the orthographic views. Since distances are proportional only in the direction of the principal axes, all measurements must be parallel to these axes. Such drawings are not true to scale, but this is seldom important because the main purpose of axonometric drawings is to show relationships. The most common drawing is isometric; the three axes are equally foreshortened and may be laid off to the same scale.

**Oblique.** Oblique projection is another form of pictorial representation, much like axonometric, employing a point of sight at infinity with parallel visual rays. Unlike axonometric, however, oblique projection requires a plane of projection, or picture plane, on which the view is projected.

The picture plane is set at an angle other than 90 degrees with the visual rays. It usually is parallel to one of the principal faces of the object, the face showing true size and shape in the oblique projection. The view is projected to the picture plane along the visual rays (Figure 5).

Oblique drawings also may be produced directly by repeating the width and height measurements as shown on an ordinary orthographic drawing and converting depth dimensions to any scale desired along a receding axis drawn at any angle except horizontal or vertical.

**Perspective.** Perspective drawings are the most realistic of any mechanically drawn pictorial representations, since they show the apparent convergence of parallel lines as they recede. Perspective drawing, like oblique, utilizes a picture plane on which the view is projected. The point of sight (or vanishing point) is at a finite location, however, and thus the visual rays are not parallel but converge at the point of sight.

A perspective drawing can be projected by the ordinary methods of multiview orthographic projection from the top and side views by constructing the front view as a view only of the picture plane (Figure 6). A more realistic view results if the object is turned so that two of the principal faces are inclined to the picture plane.

**Architectural and structural drawings.** Architectural and structural drawings embrace some standard practices and conventions unique to this field of drafting and unlike those in machine drawing. The fundamental principles, however, are the same as in ordinary machine drawing. In general, architectural and structural drawings are third-angle projection, but there are occasions when first-angle projection is used. Because of the size of the structure and the practical drawing sheet size, the architect or engineer cannot relate his views on one sheet as in a machine drawing in third-angle projection.

Figure 5: Oblique projection.

Instead, he uses one sheet at a time, constructing the plan view or building elevation he wishes to show. Rather than projecting directly from view to view as in machine drawing, the draftsman must resort to measurements made according to the rules of projection.

In machine drawing it is customary to show individual parts separately, but in architectural and structural drawing the common practice is to show the individual parts assembled. In other words, all the parts of a built-up structural member are detailed as far as possible in the places they occupy in the structure.

In addition to the usual two or three views, it frequently is desirable to show a bottom view of structural members. In architectural and structural drafting, such a view is made as a horizontal section looking down, instead of the regular bottom view looking up as is common in ma-

Figure 6: Perspective by projection.

chine drawing. The horizontal cutting plane is passed to show as little other detail as possible.

**Charts and graphs.** A chart or graph is a simple pictorial representation of a group of related facts, statistics, or records, drawn so that the relationship may be understood at a glance. A pictorial or graphic description is easier to understand than a numerical tabulation or a verbal description.

**Line graph.** In a line graph, values of two related variables are plotted on coordinate-ruled paper and the points joined together consecutively to form a continuous jagged line or smooth curve. Line graphs can be drawn quickly and accurately; they permit a large number of plotted values in a compact space; they permit the comparison of the relative movements, or trends, of several curves on the same graph; intermediate values can be interpolated; and external values beyond the range of the plotted points can be extrapolated.

If one of the variables of a line graph is a unit of time, the graph is known as a time-series chart.

**Polar charts.** In a polar chart, two variables, one of linear magnitude and the other of angular magnitude, are plotted on a polar coordinate grid with respect to a pole, or origin, to form a continuous line, or curve. The angular variable is frequently a unit of time.

**Bar charts.** A bar chart is a graphic representation of numerical values by lengths of bars beginning at a base line, indicating the relationship between two or more related factors.

**Circle charts.** A circle chart, or sector chart, sometimes called a pie chart, is a circle divided into wedge-shaped portions to show the relative percentage of the component parts in relation to their total. Circle charts are a ready method for presenting data on a percentage basis and for emphasizing amounts rather than trends.

**Flow charts.** Flow charts are predominantly schematic representations of the flow of a manufacturing or chemical process.

**Nomographs.** A nomograph is a combination of functional scales arranged to represent a mathematical law or equation for computational purposes.

Basically, a nomograph is designed to solve a three-variable equation. A straight line joining known or given values on the scales of two of the variables intersects the scale of the third variable at a value that satisfies the equation represented. The scales may be either straight, curved, or circular. Two or more graphs frequently can be combined to solve an equation containing more than three variables.

Usually, nomographs have fixed scales and a movable alignment line. Movable-scale nomographs, however, can be constructed with a fixed-direction alignment line.

## COMPUTER GRAPHICS

By reason of its speed and versatility, the use of the computer in the engineering design process and the direct preparation of engineering data in the form of engineering drawings or printout data is rapidly expanding. Input to the computer is by means of punched cards or tapes, magnetic tapes, character recognition devices, direct keyboard devices, or, for direct communication between the designer and the computer, cathode-ray tube devices.

In the cathode-ray tube devices, the designer makes his sketches with a special light pen on the face of a cathode-ray tube to provide the input data for the memory units of the computer. The designer can recall his sketches, revise them, change the scale, delete portions, or add material as he wishes, developing his design directly on the tube. The final drawing displayed on the tube can be converted photographically to a permanent record.

Using card or tape-controlled computers, the input data is in numerical rather than graphical form. Data for the lines, shapes, curves, and symbols are expressed mathematically, programmed in a computer language, and fed into the computer. The computer processes the data and converts it to a punched or magnetic tape, which in turn controls an electronic plotting machine. The plotting machine operates a pen or stylus according to the con-

trol tape, and supplies to the designer or draftsman a finished drawing, complete with all required lines, dimensions, and notes. The drawing may be the final product of the computer or it may be used to check the tape and the tape then used to guide the operations of numerically controlled programmed machine tools for the manufacture of the parts.

Engineers and draftsmen must have a thorough training in the computer process to provide the correct information to the programmer who prepares the input data for the computer. The computer will do only what it is programmed to do. Regardless of how automated the process becomes, the draftsman still has the responsibility for the communication of information that will guarantee the correctness of the finished product.

## REPRODUCTION METHODS

In modern industrial practice, the engineering drawing represents a considerable economic investment, and control and protection of the original drawing are important. The original drawing is seldom handled directly by the workman, reproductions being used instead. Several methods of reproducing the original drawing are available, the most important currently being the blueprint and diazo processes.

**Blueprint process.** The blueprint process is the oldest, usually least expensive, and still a very commonly used method of reproduction. It is rapidly being replaced by the more convenient diazo process, however. The blueprint process was discovered in 1842 by Sir John Herschel, an English astronomer. The paper is sensitized with a coating of a potassium ferricyanide and ferric ammonium citrate solution, exposed to light under an original on translucent tracing paper, developed in water, and dried. The print consists of white lines on a dark-blue background. It is difficult to make highly readable changes, corrections, or additions to blueprints with an ordinary pen or pencil because of the background. Notes can be written on the print with an alkaline solution strong enough to bleach out the blue background.

**Diazo process.** The diazo process is similar to the blueprint process. The paper is coated with a light-sensitive diazo compound, exposed to light under a tracing, and developed by exposure to ammonia fumes. It provides prints with black, blue, or red lines on a white background; and changes, corrections, or additions can be added with an ordinary pen or pencil. Since the print is not immersed in a solution, the original drawing is reproduced the same size and undistorted.

**Microfilm.** Because a large number of drawings are required for a complex machine or structure, ordinary recording methods put a strain on filing, storage, and retrieval systems. The use of microfilm eases this burden.

In microfilming, the original drawings are photographically reproduced on film from  $\frac{1}{8}$  to as little as  $\frac{1}{40}$  of the original size. Film reproductions may be filed and stored in a roll, but more often frames are cut and mounted individually on aperture cards. Since the cards are essentially standard data cards used for electronic data processing, they may be handled on mechanical equipment capable of sorting, filing, and retrieving them. Cards may be viewed with a projection machine or on a microfilm reader or they may be reproduced in the original or any intermediate size on a printer.

## Drake, Sir Francis

Sir Francis Drake, a 16th-century English admiral, was the greatest, as well as the most renowned, of the English seamen of the Elizabethan age.

Born c. 1540/43 in Devonshire, in southern England, on the Crowndale estate of Lord Francis Russell, second earl of Bedford, Francis Drake was the son of one of the latter's tenant farmers. His father was an ardent Protestant lay preacher, an influence that was to have an immense effect on Drake's character. His detestation of Catholicism had its origins not only in his father's teaching but in his own early experiences, when his family had to flee the West Country during the Catholic uprising of 1549. They made their way to Kent in southeast England and, in exchange for their former country cottage home, found lodging in one of the old naval hulks that were moored near Chatham on the south bank of the Thames Estuary. Had he stayed in Devon he might have become a yeoman farmer, but his family's poverty drove him to sea while still a boy. When Drake was about 13 years old, he was apprenticed to a small coastal vessel plying between North Sea ports. Thus, sailing one of the harshest stretches of water in the world, he learned early how to handle small vessels under arduous conditions. The knowledge of pilotage he acquired during these years was to serve him in good stead throughout his life. The old sea captain left Drake his ship when he died, so that Drake, thereafter, became his own master.

Early voyages. Drake might have spent all his life in the coastal trade but for the happy accident that he was related to the powerful Hawkins family of Plymouth, Devon, who were then embarking on trade with the New World—the New World that, as Drake never forgot, had been given by Pope Alexander VI to the kingdom of Spain. When he was about 23, dissatisfied with the limited horizons of the North Sea, he sold his boat and enlisted in the fleet belonging to the Hawkins family. Now he first saw the ocean swell of the Atlantic and the lands where he was to make his fame and fortune.

voyages to  
the West  
Indies

On a voyage to the West Indies, as second-in-command, Drake had his first experience of the Spaniards and of the way in which foreigners were treated in their realms; their cargoes, for example, were liable to be impounded. At a later date he referred to some "wrongs" that he and his companions had suffered—wrongs that he was determined to right in the years to come. His second voyage to the West Indies, this time in company with John Hawkins, ended disastrously at San Juan de Ulúa off the coast of Mexico, when the English seamen were treacherously attacked by the Spanish and many of them killed. Drake returned to England in command of a small vessel, the "Judith," with an even greater determination to have his revenge upon Spain and the Spanish king (Philip II). Although the expedition was a financial failure, it served to make Drake's reputation, for he had proved himself an outstanding seaman. People of importance, including Queen Elizabeth I, who had herself invested in the venture, now heard his name. In the years that followed he made two expeditions in small boats to the West Indies,

in order "to gain such intelligence as might further him to get some amend for his loss. . . ." In 1572—having obtained from the Queen a privateering commission, which amounted to a license to plunder in the King of Spain's lands—Drake set sail for America in command of two small ships, the "Pasha," of 70 tons, and the "Swan," of 25 tons. He was nothing if not ambitious, for his aim was to capture the important town of Nombre de Dios, Panama. Although himself wounded in the attack, he and his men managed to get away with a great deal of plunder—the foundation of his fortune. Not content with this, he went on to cross the Isthmus of Panama. Standing on a high ridge of land, he first saw the Pacific, that ocean hitherto barred to all but Spanish ships. It was then, as he put it, that he "besought Almighty God of His goodness to give him life and leave to sail once in an English ship in that sea." His name as well as fortune were established by this expedition, and he returned to England both rich and famous. Unfortunately, his return coincided with a moment when Queen Elizabeth and King Philip II of Spain had reached a temporary truce. Although delighted with Drake's success in the empire of her great enemy, Elizabeth could not officially acknowledge it. Drake, who was as politically discerning as he was navigationally brilliant, saw that the time was inauspicious and sailed with a small squadron to Ireland, where he served under the Earl of Essex, who was then engaged in suppressing a rebellion in that strife-torn land. This is an obscure period of Drake's life, and he does not emerge into the clear light of history until two years later.

**Circumnavigation of the world.** In 1577 he was chosen as the leader of an expedition intended to pass around South America through the Strait of Magellan and to explore the coast that lay beyond. The object was to conclude trading treaties with the people who lived south of the Spanish sphere of influence and, if possible, to explore an unknown continent that was rumoured to lie far in the South Pacific. The expedition was backed by the Queen herself. Nothing could have suited Drake better. He had official approval to benefit himself and the Queen, as well as to cause the maximum damage to the Spaniards. It was now that he met the Queen for the first time and heard from her own lips that she "would gladly be revenged on the King of Spain for divers injuries that I have received." He set sail in December with five small ships, manned by less than 200 men, and reached the Brazilian coast in the spring of 1578. His flagship, the "Pelican," which Drake later renamed "The Golden Hind," was only about 100 tons. It seemed little enough with which to undertake a venture into the domain of the most powerful monarch and empire in the world.

The  
voyage of  
"The  
Golden  
Hind"

Upon arrival in South America, it was discovered that there was a plot against Drake, and its leader, Thomas Doughty, was tried and executed. Drake was always a stern disciplinarian, and he clearly did not intend to continue the venture without making sure that all his small company were loyal to him. Two of his smaller vessels, having served their purpose as store ships, were then abandoned, after their provisions had been taken aboard the others, and, on August 21st, 1578, he entered the Strait. It took 16 days to sail through, after which Drake had his second view of the Pacific Ocean—this time from the deck of an English ship. Then, as he wrote, "God by a contrary wind and intolerable tempest seemed to set himself against us." During the gale, Drake's vessel and that of his second-in-command had been separated; the latter, having missed a rendezvous with Drake, ultimately returned to England, presuming that the "Hind" had sunk. It was, therefore, only Drake's flagship that made its way into the Pacific and up the coast of South America. He passed along the coast like a whirlwind, for the Spaniards were quite unguarded, having never known a hostile ship in their waters. He seized provisions at Valparaíso, attacked passing Spanish merchantmen, and captured two very rich prizes. "The Golden Hind" was below her watermark, loaded with bars of gold and silver, minted Spanish coinage, precious stones, and pearls, when he left South American waters to continue his voyage around the world. Before sailing westward, however,

Drake, oil painting by an unknown artist. In the National Portrait Gallery, London.

he sailed to the north as far as 48° N, on a parallel with Vancouver, to seek the Northwest Passage back into the Atlantic. The bitterly cold weather defeated him, and he coasted southward to anchor just north of modern San Francisco. He named the surrounding country New Albion and took possession of it in the name of Queen Elizabeth. In his search for a passage around the north of America he was the first European to sight the west coast of what is now Canada.

In July 1579 he sailed west across the Pacific and after 68 days sighted a line of islands (probably the remote Palau group). From there he went on to the Philippines, where he watered ship before sailing to the Moluccas. There he was well received by the local sultan, and appears to have concluded a treaty with him giving the English the right to trade for spices. Drake's deep-sea navigation and pilotage were always excellent, but in those totally uncharted waters his ship struck a reef. He was able to get her off without any great damage and, after calling at Java, set his course across the Indian Ocean for the Cape of Good Hope. Two years after she had nosed her way into the Strait of Magellan, "The Golden Hind" came back into the Atlantic with only 56 of the original crew of 100 left aboard.

On September 26, 1580, Francis Drake brought his ship into Plymouth Harbour. She was laden with treasure and spices, and Drake's fortune was permanently made. He thus became the first captain ever to sail his own ship around the world—the Portuguese navigator Ferdinand Magellan having been killed before completing his circumnavigation—and the first Englishman to sail the Pacific, the Indian Ocean, and the South Atlantic. Despite Spanish protests about his piratical conduct while in their imperial waters, Queen Elizabeth herself came aboard "The Golden Hind," which was lying at Deptford in the Thames Estuary, and knighted the farmer's son.

Mayor of  
Plymouth

In the same year, 1581, Drake was made mayor of Plymouth, an office he fulfilled with the same thoroughness that he had shown in all other matters. He organized a water supply for Plymouth that served the city for 300 years. In 1585 he married again, his first wife, a Cornish girl named Mary Newman, whom he had married in 1569, having died in 1583. His second wife, Elizabeth Sydenham, was an heiress and the daughter of a local Devonshire magnate, Sir George Sydenham. In keeping with his new station, Drake bought himself a fine country house—Buckland Abbey (now a national museum)—a few miles from Plymouth. Drake's only grief was that neither of his wives bore him any children.

During these years of fame when Drake was a popular hero, he could always obtain volunteers for any of his expeditions. But he was very differently regarded by many of his great contemporaries. Such well-born men as the naval commander Sir Richard Grenville and the navigator and explorer Sir Martin Frobisher disliked him intensely. He was the parvenu, the rich but common upstart, with West Country manners and accent and with none of the courtier's graces. Drake had even bought Buckland Abbey from the Grenvilles by a ruse, using an intermediary, for he knew that the Grenvilles would never have sold it to him directly. It is doubtful, in any case, whether he cared about their opinions, so long as he retained the goodwill of the Queen. This was soon enough demonstrated, for in 1585 Elizabeth placed him in command of a fleet of 25 ships. Hostilities with Spain had broken out once more, and he was ordered to cause as much damage as possible to the Spaniard's overseas empire. Drake fulfilled his commission, capturing Santiago in the Cape Verde Islands and taking and plundering the cities of Cartagena in Colombia, St. Augustine in Florida, and San Domingo (Santo Domingo, Dominican Republic). The effect of his triumph in the West Indies was cataclysmic. Spanish credit, both moral and material, almost foundered under the losses. The Bank of Spain broke, the Bank of Venice (to which Philip II was principal debtor) nearly foundered, and the great German bank of Augsburg refused to extend the Spanish monarch any further credit. Even Lord Burghley, Elizabeth's principal minister, who had never approved of Drake or his meth-

ods, was forced to concede that "Sir Francis Drake is a fearful man to the King of Spain."

**Defeat of the Spanish Armada.** By 1586 it was known that Philip II was preparing a fleet for what was called "The Enterprise of England," and that he had the blessing of Pope Sixtus V to conquer the heretic island and return it to the fold of Rome. Drake was given *carte blanche* by the Queen to "impeach the provisions of Spain." In the following year, with a fleet of some 30 ships, he showed that her trust in him had not been misplaced. He stormed into the Spanish harbour of Cádiz and in 36 hours destroyed thousands of tons of shipping and supplies, all of which had been destined for the Armada. This action, which he laughingly referred to "as singeing the king of Spain's beard," was sufficient to delay the invasion fleet for a further year. But the resources of Spain were such that by July 1588 the Armada was in the English Channel. Lord Howard had been chosen as English admiral to oppose, with Drake as his vice admiral. It was, however, the latter's dash and fire that largely turned the scales, Drake himself managing to capture a rich prize during the long sea fight in the Channel. It was also Drake who prompted the use of fire ships to drive the Armada out of Calais, where it had taken refuge. Then, to delight his Protestant heart, "The Winds of God blew," so that the Spanish fleet was dispersed and largely wrecked. Drake was England's hero, achieving a popularity never to be equalled by any man until Horatio Nelson emerged more than 200 years later. Innumerable souvenirs were struck in his name, and he was immortalized in poems and broadsheets.

His later years were not happy, however. An expedition that he led to Portugal proved abortive, and his last voyage, in 1596, against the Spanish possessions in the West Indies was a failure, largely because the fleet was decimated by fever. Drake himself succumbed and was buried at sea off the town of Puerto Bello (modern Portobelo, Panama) on January 28th, 1596. Few men have been more famous in their lifetimes. As the Elizabethan historian John Stow wrote:

He was more skilful in all points of navigation than any . . . He was also of perfect memory, great observation, eloquent by nature . . . In brief he was as famous in Europe and America, as Timur Lenk (Tamerlane) in Asia and Africa.

At a later date, Dr. Samuel Johnson wrote eulogistically of his character and bravery. But to the Spaniards he was, as their ambassador to England remarked, "the master-thief of the unknown world." He was "low of stature, of strong limb, round-headed, brown hair, full-bearded, his eyes round, large and clear, well-favoured face and of a cheerful countenance." A devout churchman and an able businessman, Sir Francis Drake was one of the world's greatest seamen. He embodied many of the virtues of expansionist Elizabethan England.

**BIBLIOGRAPHY.** There is no definitive biography of Drake. Of the comparatively short biographies available, the most useful is probably that by C.C. LLOYD (1957). J.A. WILLIAMSON, *Sir Francis Drake* (1951), is the work of an author expert in the naval and exploratory history of the period. E.D.S. BRADFORD, *Drake* (1965), is light and readable. Books placing Drake in his contemporary setting include J.A. WILLIAMSON, *The Age of Drake*, 5th ed. (1965); JULIAN CORBETT's old but still valuable classic, *Drake and the Tudor Navy*, 2 vol. (1898); and K.R. ANDREWS, *Drake's Voyages: A Reassessment of Their Place in Elizabethan Maritime Expansion* (1967). Collections of documents, such as letters and narratives referring to the voyages, include *New Light on Drake: A Collection of Documents Relating to His Voyage of Circumnavigation, 1577-1580*, ed. by ZELIA NUTTALL (1914); *The World Encompassed: Analogous Contemporary Documents Concerning Sir Francis Drake's Circumnavigation of the World*, ed. by N.M. PENZER (1926, reprinted 1969); *The Last Voyage of Drake and Hawkins*, ed. by K.R. ANDREW (1972); and CALIFORNIA HISTORICAL SOCIETY, *Drake's Plate of Brass: Evidence of His Visit to California in 1597* (1937).

(E.Br.)

## Drake Passage

The Drake Passage is a deep waterway, 600 miles (1,000 kilometres) wide, connecting the Atlantic and Pacific

Last  
years

oceans south of Tierra del Fuego, on which stands Cape Horn, the southern tip of South America. To the south, the waterway is bounded by the South Shetland Islands, situated about 100 miles north of the Antarctic Peninsula. Across this stretch of ocean the climate changes from the cool, humid, subpolar type found at Tierra del Fuego to the frozen conditions of Antarctica.

The Drake Passage played an important part in the trade of the 19th and early 20th centuries before the opening of the Panama Canal in 1914. The stormy seas and icy conditions made the rounding of Cape Horn through the Drake Passage a rigorous test for ships and crews alike, especially for the sailing vessels of the day. With the advent of giant oil tankers and with the growing congestion of the Panama Canal, the Drake Passage may again become a major sea route.

Exploration

Though bearing the name of the famous 16th-century English seaman and explorer, the Drake Passage was, in fact, first traversed in 1615 by a Flemish expedition led by Willem Schouten. Drake did not sail through the passage but passed instead through the Straits of Magellan to the north of Tierra del Fuego, although he was blown back into the northern latitudes of the passage by a Pacific storm.

*Submarine topography and bottom deposits.* The passage has an average depth of about 11,000 feet (3,400 metres), with deeper regions of up to 15,600 feet near the northern and southern boundaries.

The sediments on the sea floor result from the interplay of glacial debris from Antarctica, material of biological origin, and eroded material from South America. Proceeding southward, the sediments are first mainly sandy and clayey silts, and then, later, silts with ice-rafted material (*i.e.*, material dropped from floating glacial ice as it melts). Near 58° S is a zone of numerous manganese nodules. Sediments accumulate at the rate of four inches every 1,000 years near the boundaries of the passage and at a little more than an inch every 1,000 years in the centre. The manganese nodule zone is swept clear of sediments by swift bottom currents.

*Climate and ice conditions.* The winds over the passage are predominantly from the west and are most intense in the northern half. The most commonly observed wind speeds are from 12 to 23 miles per hour, but winds of more than 45 miles per hour also occur.

The mean annual air temperature ranges from 41° F (5° C) in the north to 27° F (−3° C) in the south. The coldest temperatures, of −4° F (−20° C), occur in July. Cyclones (atmospheric low-pressure systems with winds that blow clockwise in the Southern Hemisphere) formed in the Pacific Ocean traverse the passage at the southern end. Cloud cover remains over the passage for about six-tenths of the year.

The sea ice cover extending northward from Antarctica varies from year to year as well as seasonally. In the late summer (February) the passage is ice free. In September, the maximum ice cover occurs; 25 percent to full cover extends to 60° S, with occasional ice floes reaching Cape Horn. Icebergs have been observed at different times across the whole extent of the passage and represent a danger to shipping.

*Hydrography, temperature, and salinity.* The water within the passage flows from the Pacific into the Atlantic, except for a small amount of water in the south that comes from the Scotia Sea. The general movement, known as the Antarctic Circumpolar Current, is the most voluminous in the world, moving at a rate of nearly 5,300,000,000 cubic feet a second. Surface water temperature varies from near 43° F (6° C) in the north to 30° F (−1° C) in the south, with the temperature altering sharply near 60° S. This transitional zone is called the Antarctic Convergence, or Polar Front; it separates the sub-Antarctic surface water from the colder and fresher Antarctic surface water. At depths of between about 1,600 and 10,000 feet (500 to 3,000 metres) there occurs the relatively warm and salty Circumpolar Deep Water Current.

The Antarctic Circumpolar Current, which is slightly accelerated by the passage, is strongest in the vicinity

of the convergence. Near Cape Horn is a fairly swift coastal flow that is derived from a current that hugs the Chilean coast. After traversing the passage, the Circumpolar Current turns sharply to the north.

Throughout the passage as a whole, salinity and the amount of oxygen increases as one proceeds northward.

*Fish and other wildlife.* Photographs of the sea floor show the presence of numerous animals—either directly or indirectly by their tracks and fecal remains. The most common of these are such organisms as sea urchins and starfish; sponges are also found. There is also a relatively high abundance of plankton. Krill (small shrimplike crustaceans) are very abundant in the south, as are the blue and fin whales that feed on them. Squalid also feed on krill and, in turn, form a basic food for the sperm whales. Krill are also important to the diet of the emperor penguin and the crabeater seal. Antarctic cods are the most common fish. Some of these fish and all of the cold water Chaenichthyidae (icefish) are “bloodless”—*i.e.*, they have no detectable hemoglobin in their blood.

*Prospects for the future.* The economic significance of the Drake Passage will most likely be confined to its importance as a shipping route. The mining of materials on the sea floor will probably remain uneconomic for a long time because of the difficulties of deep-sea mining in a polar environment. The importance of the passage to Antarctic oceanography and meteorology has made it the subject of frequent investigation.

HEDGPETH (eds.), *Distribution of Selected Groups of Marine Invertebrates in Waters South of 35° S. Latitude*, Antarctic Map Folio Series no. 11 (1969), a detailed description of plankton found in Antarctic waters; A.L. GORDON and R.D. GOLDBERG, *Circumpolar Characteristics of Antarctic Waters*, ed. by V.C. BUSHNELL, Antarctic Map Folio Series no. 13 (1970), on the general distributions of temperature, salinity, and oxygen at various depths within Antarctic waters; ALAN VILLIERS, “The Defeat of Cape Horn,” *The Oceans*, 2:6–16 (1969), a thrilling account of the history of man's navigation around the stormy tip of South America.

(A.L.G.)

## Dramatic Literature

The term dramatic literature implies a contradiction in that “literature” originally meant something written and “drama” meant something performed. Most of the problems, and much of the interest, in the study of dramatic literature stem from this contradiction. Even though a play may be appreciated solely for its qualities as writing, greater rewards probably accrue to those who remain alert to the volatility of the play as a whole.

In order to appreciate this complexity in drama, however, each of its elements—acting, directing, staging, etc.—should be studied, so that its relationship to all the others can be fully understood. It is the purpose of this article to study drama with particular attention to what the playwright sets down. A similar approach is taken in the separate articles on the two main types of dramatic literature, TRAGEDY, and COMEDY. For the dramatic literature of particular genres, the reader also is referred to such articles as NO THEATRE; KABUKI THEATRE; COMMEDIA DELL'ARTE; and RELATED ENTRIES under DRAMATIC LITERATURE in the *Ready Reference and Index*. This history of dramatic literature is discussed in such articles as THEATRE, WESTERN; and THEATRE AND DANCE, EAST ASIAN; as well as in articles on the history of literature such as LITERATURE, WESTERN. Regional studies of both the theatre and literature will be found in articles such as SOUTH ASIAN PEOPLES, ARTS OF; and AFRICAN PEOPLES, ARTS OF.

### GENERAL CHARACTERISTICS

From the inception of a play in the mind of its author to the image of it that an audience takes away from the theatre, many hands and many physical elements help to bring it to life. Questions therefore arise as to what is and what is not essential to it. Is a play what its author thought he was writing, or the words he wrote? Is a play the way in which those words are intended to be em-

Essential elements of a play

Surface currents

bodied, or their actual interpretation by a director and his actors on a particular stage? Is a play in part the expectation an audience brings to the theatre, or is it the real response to what is seen and heard? Since drama is such a complex process of communication, its study and evaluation is as uncertain as it is mercurial.

All plays depend upon a general agreement by all participants—author, actors, and audience—to accept the operation of theatre and the conventions associated with it, just as players and spectators accept the rules of a game. Drama is a decidedly unreal activity, which can be indulged only if everyone involved admits it. Here lies some of the fascination of its study. For one test of great drama is how far it can take the spectator beyond his own immediate reality and to what use this imaginative release can be put. But the student of drama must know the rules with which the players began the game before he can make this kind of judgment. These rules may be conventions of writing, acting, or audience expectation. Only when all conventions are working together smoothly in synthesis, and the make-believe of the experience is enjoyed passionately with mind and emotion, can great drama be seen for what it is: the combined work of a good playwright, good players, and a good audience who have come together in the best possible physical circumstances.

Drama in some form is found in almost every society, primitive and civilized, and has served a wide variety of functions in the community. There are, for example, records of a sacred drama in Egypt 2,000 years before Christ, and Thespis in the 6th century BC in ancient Greece is accorded the distinction of being the first known playwright. Elements of drama such as mime and dance, costume and decor long preceded the introduction of words and the literary sophistication now associated with a play. Moreover, such basic elements were not superseded by words, merely enhanced by them. Nevertheless, it is only when a playscript assumes a disciplinary control over the dramatic experience that the student of drama gains measurable evidence of what was intended to constitute the play. Only then can dramatic literature be discussed as such.

The texts of plays indicate the different functions they served at different times. Some plays embraced nearly the whole community in a specifically religious celebration, as when all the male citizens of a Greek city-state came together to honour their gods; or when the annual Feast of Corpus Christi was celebrated with the great medieval Christian mystery cycles. On the other hand, the ceremonious temple ritual of the early Nō drama of Japan was performed at religious festivals only for the feudal aristocracy. But the drama may also serve a more directly didactic purpose, as did the morality plays of the later Middle Ages, some 19th-century melodramas, and the 20th-century discussion plays of George Bernard Shaw and Bertolt Brecht. Plays can satirize society, or they can gently illuminate human weakness; they can divine the greatness and the limitations of man in tragedy, or, in modern naturalistic playwriting, probe his mind. Drama is the most wide-ranging of all the arts: it not only represents life but also is a way of seeing it. And it repeatedly proves Dr. Samuel Johnson's contention that there can be no certain limit to the modes of composition open to the dramatist.

**Common elements of drama.** Despite the immense diversity of drama as a cultural activity, all plays have certain elements in common. For one thing, drama can never become a "private" statement—in the way a novel or a poem may be—without ceasing to be meaningful theatre. The characters may be superhuman and godlike in appearance, speech, and deed or grotesque and ridiculous, perhaps even puppets, but as long as they behave in even vaguely recognizable human ways the spectator can understand them. Only if they are too abstract do they cease to communicate as theatre. Thus, the figure of Death in medieval drama reasons like a human being, and a god in Greek tragedy or in Shakespeare talks like any mortal. A play, therefore, tells its tale by the imitation of human behaviour. The remoteness or nearness of

that behaviour to the real life of the audience can importantly affect the response of that audience: it may be in awe of what it sees, or it may laugh with detached superiority at clownish antics, or it may feel sympathy. These differences of alienation or empathy are important, because it is by opening or closing this aesthetic gap between the stage and the audience that a dramatist is able to control the spectator's experience of the play and give it purpose.

The second essential is implicit in the first. Although static figures may be as meaningfully symbolic on a stage as in a painting, the deeper revelation of character, as well as the all-important control of the audience's responses, depends upon a dynamic presentation of the figures in action. A situation must be represented on the stage, one recognizable and believable to a degree, which will animate the figures as it would in life. Some argue that action is the primary factor in drama, and that character cannot emerge without it. Since no play exists without a situation, it appears impossible to detach the idea of a character from the situation in which he is placed, though it may seem possible after the experience of the whole play. Whether the playwright conceives character before situation, or vice versa, is arbitrary. More relevant are the scope and scale of the character-in-situation—whether, for example, it is man confronting God or man confronting his wife—for that comes closer to the kind of experience the play is offering its audience. Even here one must beware of passing hasty judgment, for it may be that the grandest design for heroic tragedy may be less affecting than the teasing vision of human madness portrayed in a good farce.

A third factor is style. Every play prescribes its own style, though it will be influenced by the traditions of its theatre and the physical conditions of performance. Style is not something imposed by actors upon the text after it is written, nor is it superficial to the business of the play. Rather, it is self-evident that a play will not communicate without it. Indeed, many a successful play has style and little else. By "style," therefore, is implied the whole mood and spirit of the play, its degree of fantasy or realism, its quality of ritualism or illusion, and the way in which these qualities are signalled by the directions, explicit or implicit, in the text of the play. In its finer detail, a play's style controls the kind of gesture and movement of the actor, as well as his tone of speech, its pace and inflexion. In this way the attitude of the audience is prepared also: nothing is more disconcerting than to be misled into expecting either a comedy or a tragedy and to find the opposite, although some great plays deliberately introduce elements of both. By means of signals of style, the audience may be led to expect that the play will follow known paths, and the pattern of the play will regularly echo the rhythm of response in the auditorium. Drama is a conventional game, and spectators cannot participate if the rules are constantly broken.

By presenting animate characters in a situation with a certain style and according to a given pattern, a playwright will endeavour to communicate his thoughts and feelings and have his audience consider his ideas or reproduce the emotion that drove him to write as he did. In theatrical communication, however, audiences remain living and independent participants. In the process of performance, an actor has the duty of interpreting his author for the people watching him, and will expect to receive "feedback" in turn. The author must reckon with this in his writing. Ideas will not be accepted, perhaps, if they are offered forthrightly; and great dramatists who are intent on furthering social or political ideas, such as Henrik Ibsen, George Bernard Shaw, and Bertolt Brecht, quickly learned methods of having the spectator reason the ideas for himself as part of his response to the play. Nor will passions necessarily be aroused if overstatement of feeling ("sentimentality") is used without a due balance of thinking and even the detachment of laughter: Shakespeare and Chekhov are two outstanding examples in Western drama of writers who achieved an exquisite balance of pathos with comedy in order to ensure the affective function of their plays.

The late arrival of words in drama

The role of style

Dramatic expression. The language of drama can range between great extremes: on the one hand, an intensely theatrical and ritualistic manner; and on the other, an almost exact reproduction of real life of the kind commonly associated with motion picture and television drama. In the ritualistic drama of ancient Greece, the playwrights wrote in verse, and it may be assumed that their actors rendered this in an incantatory speech halfway between speech and song. Both the popular and the coterie drama of the Chinese and Japanese theatre were also essentially operatic, with a lyrical dialogue accompanied by music and chanted rhythmically. The effect of such rhythmical delivery of the words was to lift the mood of the whole theatre onto the level of religious worship. Verse is employed in other drama that is conventionally elevated, like the Christian drama of the Middle Ages, the tragedy of the English Renaissance, the heroic Neoclassical tragedies of 17th-century France by Pierre Corneille and Jean Racine, the Romantic lyricism of Goethe and Schiller, and modern attempts at a revival of a religious theatre like those of T.S. Eliot. Indeed, plays written in prose dialogue were at one time comparatively rare, and then associated essentially with the comic stage. Only at the end of the 19th century, when naturalistic realism became the mode, were characters in dramas expected to speak as well as behave as in real life.

The role of  
verse

Elevation is not the whole rationale behind the use of verse in drama. Some critics maintain that a playwright can exercise better control both over the speech and movement of his actors and over the responses of his audience by using the more subtle tones and rhythms of good poetry. The loose, idiomatic rhythms of ordinary conversation, it is argued, give both actor and spectator too much freedom of interpretation and response. Certainly, the aural, kinetic, and emotive directives in verse are more direct than prose, though, in the hands of a master of prose dialogue like Shaw or Chekhov, prose can also share these qualities. Even more certain, the "aesthetic distance" of the stage, or the degree of unreality and make-believe required to release the imagination, is considerably assisted if the play uses elements of verse, like rhythm and rhyme, not found in ordinary speech. Thus, verse drama may embrace a wide variety of non-realistic aural and visual devices: Greek tragic choric speech provided a philosophical commentary upon the action, which at the same time drew the audience lyrically into the mood of the play. In the drama of India, a verse accompaniment made the actors' highly stylized system of symbolic gestures of head and eyes, arms and fingers a harmonious whole. The tragic soliloquy in Shakespeare permitted the hero, alone on the stage with his audience, to review his thoughts aloud in the persuasive terms of poetry; thus, the soliloquy was not a stopping place in the action but rather an engrossing moment of drama when the spectator's mind could leap forward.

Dramatic structure. The elements of a play do not combine naturally to create a dramatic experience but, rather, are made to work together through the structure of a play, a major factor in the total impact of the experience. A playwright will determine the shape of a play in part according to the conditions in which it will be performed: how long should it take to engage an audience's interest and sustain it? How long can an audience remain in their seats? Is the audience sitting in one place for the duration of performance, or is it moving from one pageant stage to the next, as in some medieval festivals? Structure is also dictated by the particular demands of the material to be dramatized: a revue sketch that turns on a single joke will differ in shape from a religious cycle, which may portray the whole history of mankind from the Creation to the Last Judgment. A realistic drama may require a good deal of exposition of the backgrounds and memories of the characters, while in a chronicle play the playwright may tell the whole story episodically from its beginning to the end. There is one general rule, as Aristotle originally suggested in his *Poetics*: a play must be long enough to supply the infor-

mation an audience needs to be interested and to generate the experience of tragedy, or comedy, on the senses and imagination.

In the majority of plays it is necessary to establish a conventional code of place and time. In a play in which the stage must closely approximate reality, the location of the action will be precisely identified, and the scenic representation on stage must confirm the illusion. In such a play, stage time will follow chronological time almost exactly; and if the drama is broken into three, four, or five acts, the spectator will expect each change of scene to adjust the clock or the calendar. But the theatre has rarely expected realism, and by its nature it allows an extraordinary freedom to the playwright in symbolizing location and duration: as Dr. Samuel Johnson observed in his discussion of this freedom in Shakespeare, the spectators always allow the play to manipulate the imagination. It is sufficient for the witches in *Macbeth* to remark their "heath" with its "fog and filthy air" for their location to be accepted on a stage without scenery; and when Lady Macbeth later is seen alone reading a letter, she is without hesitation understood to be in surroundings appropriate to the wife of a Scottish nobleman. Simple stage symbolism may assist the imagination, whether the altar of the gods situated in the centre of the Greek *orchestra*, a strip of red cloth to represent the Red Sea in a medieval miracle play, or a chair on which the Tibetan performer stands to represent a mountain. With this degree of fantasy, it is no wonder that the theatre can manipulate time as freely, passing from the past to the future, from this world to the next, and from reality to dream.

It is questionable, therefore, whether the notion of "action" in a play describes what happens on the stage or what is recreated in the mind of the audience. Certainly it has little to do with merely physical activity by the players. Rather, anything that urges forward the audience's image of the play and encourages the growth of its imagination is a valid part of the play's action. Thus, it was sufficient for the ancient Greek dramatist Aeschylus to have only two speaking male actors who wore various masks, typed for sex, age, class, and facial expression. In the Italian 16th- and 17th-century *commedia dell'arte*, the standard characters Pantalone and Arlecchino, each wearing his traditional costume and mask, appeared in play after play and were immediately recognized, so that an audience could anticipate the behaviour of the grasping old merchant and his rascally servant. On a less obvious level, a speech that in reading seems to contribute nothing to the action of the play can provide in performance a striking stimulus to the audience's sense of the action, its direction and meaning. Thus, both the Greek chorus and the Elizabethan actor in soliloquy might be seen to "do" nothing, but their intimate speeches of evaluation and reassessment teach the spectator how to think and feel about the action of the main stage and lend great weight to the events of the play. For drama is a reactive art, moving constantly in time, and any convention that promotes a deep response while conserving precious time is of immeasurable value.

#### DRAMA AS AN EXPRESSION OF A CULTURE

In spite of the wide divergencies in purpose and convention of plays as diverse as the popular kabuki of Japan and the coterie comedies of the Restoration in England, a Javanese puppet play and a modern social drama by the contemporary American dramatist Arthur Miller, all forms of dramatic literature have some points in common. Differences between plays arise from differences in conditions of performance, in local conventions, in the purpose of theatre within the community, and in cultural history. Of these, the cultural background is the most important, if the most elusive. It is cultural difference that makes the drama of the East immediately distinguishable from that of the West.

East-West differences. Oriental drama consists chiefly of the classical theatre of Hindu India and its derivatives in Malaya and of Burma, Thailand, China, Japan, Java, and Bali. It was at its peak during the period known in

Stylization  
of Oriental  
theatre

the West as the Middle Ages and the Renaissance. Stable and conservative, perpetuating its customs with reverence, Oriental culture showed little of the interest in chronology and advancement shown by the West and placed little emphasis on authors and their individual achievements. Thus the origins of the drama of the Orient are lost in time, although its themes and characteristic styles probably remain much the same as before records were kept. The slow-paced, self-contained civilizations of the East have only recently been affected by Western theatre, just as the West has only recently become conscious of the theatrical wealth of the East and what it could do to fertilize the modern theatre (as in the 20th-century experimental drama of William Butler Yeats and Thornton Wilder in English, of Paul Claudel and Antonin Artaud in French, and of Bertolt Brecht in German).

In its representation of life, classical Oriental drama is the most conventional and nonrealistic in world theatre. Performed over the centuries by actors devoted selflessly to the profession of a traditional art, conventions of performance became highly stylized, and traditions of characterization and play structure became formalized to a point of exceptional finesse, subtlety, and sophistication. In Oriental drama all the elements of the performing arts are made by usage to combine to perfection: dance and mime, speech and song, narrative and poetry. The display and studied gestures of the actors, their refined dance patterns, and the all-pervasive instrumental accompaniment to the voices of the players and the action of the play, suggest to Western eyes an exquisite combination of ballet with opera, in which the written text assumes a subordinate role. In this drama, place could be shifted with a license that would have astonished the most romantic of Elizabethan dramatists, the action could leap back in time in a way reminiscent of the "flashback" of the modern cinema, and events could be telescoped with the abandon of modern expressionism. This extreme theatricality lent an imaginative freedom to its artists and audiences upon which great theatre could thrive. Significantly, most Oriental cultures also nourished a puppet theatre, in which stylization of character, action, and staging were particularly suitable to marionettes. In the classical puppet theatre of Japan, the *bunraku*, the elocutionary art of a chanted narration and the manipulative skill with the dolls diminished the emphasis on the script except in the work of the 17th-century master Chikamatsu, who enjoyed a creative freedom in writing for puppets rather than for the actors of the Kabuki. By contrast, Western drama during and after the Renaissance has offered increasing realism, not only in decor and costume but also in the treatment of character and situation.

It is generally thought that Oriental drama, like that of the West, had its beginnings in religious festivals. Dramatists retained the moral tone of religious drama while using popular legendary stories to imbue their plays with a romantic and sometimes sensational quality. This was never the sensationalism of novelty that Western dramatists sometimes used: Eastern invention is merely a variation on what is already familiar, so that the slightest changes of emphasis could give pleasure to the cognoscenti. This kind of subtlety is not unlike that found in the repeatedly depicted myths of Greek tragedy. What is always missing in Oriental drama is that restlessness for change characteristic of modern Western drama. In the West, religious questioning, spiritual disunity, and a belief in the individual vision combined finally with commercial pressures to produce comparatively rapid changes. None of the moral probing of Greek tragedy, the character psychology of Shakespeare and Racine, the social and spiritual criticism of Ibsen and Strindberg, nor the contemporary drama of shock and argument, is imaginable in the classical drama of the East.

**Drama in Western cultures.** The form and style of ancient Greek tragedy, which flowered in the 5th century BC in Athens, was dictated by its ritual origins and by its performance in the great dramatic competitions of the spring and winter festivals of Dionysus. Participation in

ritual requires that the audience largely knows what to expect. Ritual dramas were written on the same legendary stories of Greek heroes in festival after festival. Each new drama provided the spectators with a reassessment of the meaning of the legend along with a corporate religious exercise. Thus, the chorus of Greek tragedy played an important part in conveying the dramatist's intention. The chorus not only provided a commentary on the action but also guided the moral and religious thought and emotion of the audience throughout the play: for Aeschylus (c. 525–456 BC) and Sophocles (c. 496–406 BC) it might be said that the chorus *was* the play, and even for Euripides (c. 480–406 BC) it remained lyrically powerful. Other elements of performance also controlled the dramatist in the form and style he could use in these plays: in particular, the great size of the Greek arena demanded that the players make grand but simple gestures and intone a poetry that could never approach modern conversational dialogue. Today, the superhuman characters of these plays, Agamemnon and Clytemnestra, Orestes and Electra, Oedipus and Antigone, seem unreal, for they display little "characterization" in the modern sense and their fates are sealed. Nevertheless, these great operatic tableaux, built, as one critic has said, for weight and not speed, were evidently able to carry their huge audiences to a catharsis of feeling. It is a mark of the piety of those audiences that the same reverent festivals supported a leavening of satyr-plays and comedies, bawdy and irreverent comments on the themes of the tragedies, culminating in the wildly inventive satires of Aristophanes (c. 445–c. 385 BC.)

The study of Greek drama demonstrates how the ritual function of theatre shapes both play and performance. This ritual aspect was lost when the Romans assimilated Greek tragedy and comedy. The Roman comedies of Plautus (c. 254–184 BC) and Terence (c. 186/185–159 BC) were brilliant but inoffensive entertainments, while the oratorical tragedies of Seneca (c. 4 BC–AD 65) on themes from the Greek were written probably only to be read by the ruling caste. Nevertheless, some of the dramatic techniques of these playwrights influenced the shape and content of plays of later times. The bold prototype characters of Plautus (the boasting soldier, the old miser, the rascally parasite), with the intricacies of his farcical plotting, and the sensational content and stoical attitudes of Seneca's drama reappeared centuries later when classical literature was rediscovered.

Western drama had a new beginning in the medieval church, and, again, the texts reflect the ritual function of the theatre in society. The Easter liturgy, the climax of the Christian calendar, explains much of the form of medieval drama as it developed into the giant mystery cycles. From at least the 10th century the clerics of the church enacted the simple Latin liturgy of the *Quem quaeritis?* (literally "whom do you seek?"), the account of the visit to Jesus Christ's tomb by the three Marys, who are asked this question by an angel. The liturgical form of Lent and the Passion, indeed, embodies the drama of the Resurrection to be shared mutually by actor-priest and audience-congregation. When the Feast of Corpus Christi was instituted in 1246, the great lay cycles of Biblical plays (the mystery or miracle cycles) developed rapidly, eventually treating the whole story of man from the Creation to the Last Judgment, with the Crucifixion still the climax of the experience. The other influence controlling their form and style was their manner of performance. The vast quantity of material that made up the story was broken into many short plays, and each was played on its own stage in the vernacular by members of the craft guilds. Thus, the authors of these dramas gave their audience not a mass communal experience, as the Greek dramatists had done, but rather many small and intimate dramatizations of the Bible story. In stylized and alliterative poetry, they mixed awesome events with moments of extraordinary simplicity, embodying local details, familiar touches of behaviour, and the comedy and the cruelty of medieval life. Their drama consists of strong and broad contrasts, huge in perspective but meaningful in human terms, religious and ap-

appropriately didactic in content and yet popular in its manner of reaching its simple audiences.

The influence of improvisation

In an account of dramatic literature, the ebullient but unscripted farces and romances of the *commedia dell'arte* properly have no place, but much in it became the basis of succeeding comedy. Two elements are worth noting. First, the improvisational spirit of the *commedia* troupes, in which the actor would invent words and comic business (*lazzi*) to meet the occasion of the play and the audience he faced, encouraged a spontaneity in the action that has affected the writing and playing of Western comedy ever since. Second, basic types of comic character derived from the central characters, who reappeared in the same masks in play after play. As these characters became well known everywhere, dramatists could rely on their audience to respond to them in predictable fashion. Their masks stylized the whole play and allowed the spectator freedom to laugh at the unreality of the action. An understanding of the *commedia* illuminates a great deal in the written comedies of Shakespeare in England, of *Molière* and Marivaux in France, and of Goldoni and Gozzi in Italy.

In the 16th century, England and Spain provided all the conditions necessary for a drama that could rival ancient Greek drama in scope and subtlety. In both nations, there were public as well as private playhouses, audiences of avid imagination, a developing language that invited its poetic expansion, a rapid growth of professional acting companies, and a simple but flexible stage. All these factors combined to provide the dramatist with an opportunity to create a varied and exploratory new drama of outstanding interest. In Elizabethan London, dramatists wrote in an extraordinary range of dramatic genres, from native comedy and farce to *Senecan* tragedy, from didactic morality plays to popular chronicle plays and tragicomedies, all before the advent of Shakespeare (1564–1616). Although Shakespeare developed certain genres, such as the chronicle play and the tragedy, to a high degree, Elizabethan dramatists characteristically used a medley of styles. With the exception of Ben Jonson (1572/73–1637) and a few others, playwrights mixed their ingredients without regard for classical rule. The result was a rich body of drama, exciting and experimental in character. A host of new devices were tested, mixing laughter and passion; shifting focus and perspective by slipping from verse to prose and back again; extending the use of the popular clown; exploiting the double values implicit in boy actors playing the parts of girls; exploring the role of the actor in and out of character; but, above all, developing an extraordinarily flexible dramatic poetry. These dramatists produced a visually and aurally exciting hybrid drama that could stress every subtlety of thought and feeling. It is not surprising that they selected their themes from every Renaissance problem of order and authority, of passion and reason, of good and evil and explored every comic attitude to people and society with unsurpassed vigour and vision.

French drama in the 17th century

Quite independently in Spain, dramatists embarked upon a parallel development of genres ranging from popular farce to chivalric tragedy. The hundreds of plays of Spain's greatest playwright, Lope de Vega (1562–1635), cover every subject from social satire to religion with equal exuberance. The drama of Paris of the 17th century, however, was determined by two extremes of dramatic influence. On the one hand, some playwrights developed a tragedy rigidly based in form upon Neoclassical notions of Aristotelian unity, controlled by verse that is more regular than that of the Spanish or English dramatists. On the other hand, the French theatre developed a comedy strongly reflecting the work of the itinerant troupes of the *commedia dell'arte*. The Aristotelian influence resulted in the plays of Pierre Corneille (1606–1684) and Jean Racine (1639–1699), tragedies of honour using classical themes, highly sophisticated theatrical instruments capable of searching deeply into character and motive, and capable of creating the powerful tension of a tightly controlled plot. The other influence produced the brilliant plays of *Molière* (1622–1673), whose training as an actor in the masked and balletic *commedia* tra-

dition supplied him with a perfect mode for a more sophisticated comedy. *Molière's* work established the norm of French comedy, bold in plotting, exquisite in style, irresistible in comic suggestion. Soon after, upon the return of Charles II to the throne of England in 1660, a revival of theatre started the English drama on a new course. Wits such as William Wycherley (1640–1716) and William Congreve (1670–1729) wrote for the intimate playhouses of the Restoration and an unusually homogeneous coterie audience of the court circle. They developed a "comedy of manners," replete with social jokes that the actor, author, and spectator could share—a unique phase in the history of drama. These plays started a characteristic style of English domestic comedy still recognizable in London comedy today.

German dramatists of the later part of the 18th century achieved stature through a quite different type of play: Johann Wolfgang von Goethe (1749–1832), Johann Christoph Friedrich von Schiller (1759–1805), and others of the passionate, poetic *Sturm und Drang* ("storm and stress") movement tried to echo the more romantic tendencies in Shakespeare's plays. Dramatists of the 19th century, however, lacking the discipline of classical form, wrote derivative melodramas that varied widely in quality, often degenerating into mere sensationalism. Melodrama rapidly became the staple of the theatre across Europe and America. Bold in plotting and characterization, simple in its evangelical belief that virtue will triumph and providence always intervene, it pleased vast popular audiences and was arguably the most prolific and successful drama in the history of the theatre. Certainly, melodrama's elements of essential theatre should not be ignored by those interested in drama as a social phenomenon. At least melodramas encouraged an expansion of theatre audiences ready for the most recent phase in dramatic history.

Melodrama

The time grew ripe for a new and more adult drama at the end of the 19th century. As novelists developed greater naturalism in both content and style, dramatists too looked to new and more realistic departures: the dialectical comedies of ideas of George Bernard Shaw (1856–1950); the problem plays associated with Henrik Ibsen (1828–1906); the more lyrical social portraits of Anton Chekhov (1860–1904); the fiercely personal, social, and spiritual visions of August Strindberg (1849–1912). These dramatists began by staging the speech and behaviour of real life, in devoted detail, but became more interested in the symbolic and poetic revelation of the human condition. Where Ibsen began by modelling his tightly structured dramas of man in society upon the formula for the "well made" play, which carefully controlled the audience's interest to the final curtain, Strindberg, a generation later, developed a free psychological and religious dream play that bordered on Expressionism. As sophisticated audiences grew interested more in causes rather than in effects, the great European playwrights of the turn of the century mixed their realism increasingly with symbolism. Thus the Naturalistic movement in drama, though still not dead, had a short but vigorous life. Its leaders freed the drama of the 20th century to pursue every kind of style, and subsequent dramatists have been wildly experimental. The playwright today can adopt any dramatic mode, mixing his effects to shock the spectator into an awareness of himself, his beliefs, and his environment.

**Drama in Eastern cultures.** Because of its inborn conservatism, the dramatic literature of the East does not show such diversity, despite its variety of cultures and subcultures. The major features of Oriental drama may be seen in the three great classical sources of India, China, and Japan. The simplicity of the Indian stage, a platform erected for the occasion in a palace or a courtyard, like the simplicity of the Elizabethan stage, lent great freedom to the imagination of the playwright. In the plays of India's greatest playwright, *Kālidāsa* (probably 4th century AD), there is an exquisite refinement of detail in presentation. His delicate romantic tales leap time and place by simple suggestion and mingle courtly humour and light-hearted wit with charming sentiment

Indian theatre

and religious piety. Quite untrammelled by realism, lyrical in tone and refined in feeling, his fanciful love and adventure stories completely justify their function as pure entertainment. His plots are without the pain of reality, and his characters never descend from the ideal: such poetic drama is entirely appropriate to the Hindu aesthetic of blissful idealism in art.

Some contrast may be felt between the idealistic style of the Sanskrit drama and the broader, less courtly manner of the Chinese and its derivatives in Southeast Asia. These plays cover a large variety of subjects and styles, but all combine music, speech, song, and dance, as does all Oriental drama. Heroic legends, pathetic moral stories, and brilliant farces all blended spectacle and lyricism and were as acceptable to a sophisticated court audience as to a popular street audience. The most important Chinese plays stem from the Yüan dynasty (1279–1368), in which an episodic narrative is carefully structured and unified. Each scene introduces a song whose lines have a single rhyme, usually performed by one singer, with a code of symbolic gestures and intonations that has been refined to an extreme. The plays have strongly typed heroes and villains, simple plots, scenes of bold emotion, and moments of pure mime. Chinese drama avoided both the crudity of European melodrama and the esotericism of Western coterie drama.

The drama of Japan may be said to embrace both. There, the exquisite artistry of gesture and mime, and the symbolism of setting and costume, took two major directions. The Nō drama, emerging from religious ritual, maintained a special refinement appropriate to its origins and its aristocratic audiences; the Kabuki (its name suggesting its composition: *ka*, "singing"; *bu*, "dancing"; *ki*, "acting") in the 17th century became Japan's popular drama. Nō theatre is reminiscent of the religious tragedy of the Greeks in the remoteness of its legendary content, in its masked heroic characters, in its limit of two actors and a chorus, and in the static, oratorical majesty of its style. The Kabuki, on the other hand, finds its material in domestic stories and in popular history, and the actors, without masks, move and speak more freely, without seeming to be realistic. The Kabuki plays are less rarefied and are often fiercely energetic and wildly emotional as befitting their presentation before a broader audience. The written text of the Nō play is highly poetic and pious in tone, compressed in its imaginative ideas, fastidious and restrained in verbal expression, and formal in its sparse plotting; the text of a Kabuki play lends plentiful opportunities for spectacle, sensation, and melodrama. In the Kabuki there can be moments of realism, but also whole episodes of mime and acrobatics; there can be moments of slapstick, but also moments of violent passion. In all, the words are subordinate to performance in the Kabuki.

**Drama and communal belief.** The drama that is most meaningful and pertinent to its society is that which arises from it and is not imposed upon it. The religious drama of ancient Greece, the temple drama of early India and Japan, the mystery cycles of medieval Europe, all have in common more than their religious content: when the theatre is a place of worship, its drama goes to the roots of belief in a particular community. The dramatic experience becomes a natural extension of man's life both as an individual and as a social being. The content of the mystery cycles speaks formally for the orthodox dogma of the church, thus seeming to place the plays at the centre of medieval life, like the church itself. Within such a comprehensive scheme, particular needs could be satisfied by comic or pathetic demonstration; for example, such a crucial belief as that of the Immaculate Conception was presented in the York (England) cycle of mystery plays, of the 14th–16th centuries, with a nicely balanced didacticism when Joseph wonders how a man of his age could have got Mary with child and an Angel explains what has happened; the humour reflects the simplicity of the audience and at the same time indicates the perfect faith that permitted the near-blasphe-my of the joke. In the tragedies Shakespeare wrote for the Elizabethan theatre, he had the same gift of satis-

fying deep communal needs while meeting a whole range of individual interests present in his audience.

When the whole community shares a common heritage, patriotic drama and drama commemorating national heroes, as are seen almost universally in the Orient, is of this kind. Modern Western attempts at a religious didactic drama, or indeed at any drama of "ideas," have had to reckon with the disparate nature of the audience. Thus the impact of Ibsen's social drama both encouraged and divided the development of the theatre in the last years of the 19th century. Plays like *A Doll's House* (1879) and *Ghosts* (published 1881), which challenged the sanctity of marriage and questioned the loyalty a wife owed to her husband, took their audiences by storm: some violently rejected the criticism of their cherished social beliefs, and thus such plays may be said to have failed to persuade general audiences to examine their moral position; on the other hand, there were sufficient numbers of enthusiasts (so-called Ibsenites) to stimulate a new drama of ideas. "Problem" plays appeared all over Europe and undoubtedly rejuvenated the theatre for the 20th century. Shaw's early Ibsenite plays in London, attacking a negative drawing-room comedy with themes of slum landlordism (*Widowers' Houses*, 1892) and prostitution (*Mrs. Warren's Profession*, 1902) resulted only in failure, but Shaw quickly found a comic style that was more disarming. In his attack on false patriotism (*Arms and the Man*, 1894) and the motives for middle class marriage (*Candida*, 1897), he does not affront his audiences before leading them by gentle laughter and surprise to review their own positions.

#### INFLUENCES ON THE DRAMATIST

The author of a play is affected, consciously or unconsciously, by the conditions under which he conceives and writes, by his social and economic status as a playwright, by his personal background, by his religious or political position, by his purpose in writing. The literary form of the play and its stylistic elements will be influenced by tradition, a received body of theory and dramatic criticism, as well as by the author's innovative energy. Auxiliary theatre arts such as music and design also have their own controlling traditions and conventions, which the playwright must respect. The size and shape of the playhouse, the nature of its stage and equipment, and the actor–audience relationship it encourages also determine the character of the writing. Not least, the audience's cultural assumptions, holy or profane, local or international, social or political, may override all else in deciding the form and content of the drama. These are large considerations that can take the student of drama into areas of sociology, politics, social history, religion, literary criticism, philosophy and aesthetics, and beyond.

The role of theory. It is difficult to assess the influence of theory since theory usually is based on existing drama, rather than drama on theory. Philosophers, critics, and dramatists have attempted both to describe what happens and to prescribe what should happen in drama, but all their theories are affected by what they have seen and read.

**Western theory.** In Europe, the earliest extant work of dramatic theory, the fragmentary *Poetics* of Aristotle (384–322 BC), chiefly reflecting his views on Greek tragedy and his favorite dramatist, Sophocles, is still relevant to an understanding of the elements of drama. Aristotle's elliptical way of writing, however, encouraged different ages to place their own interpretation upon his statements and to take as prescriptive what many believe to have been meant only to be descriptive. There has been endless discussion of his concepts *mimēsis* ("imitation"), the impulse behind all the arts, and *katharsis* ("purgation," "purification of emotion"), the proper end of tragedy, though these notions were conceived, in part, in answer to Plato's attack on *poiēsis* as an appeal to the irrational. That "character" is second in importance to "plot" is another of Aristotle's concepts that may be understood with reference to the practice of the Greeks, but not more realistic drama, in which character psychology has a dominant importance. The concept in the *Poetics* that has

Didactic  
drama

Nō and  
Kabuki

"Rules"  
of drama

most affected the composition of plays in later ages has been that of the so-called unities—that is, of time, place, and action. Aristotle was evidently describing what he observed—that a typical Greek tragedy had a single plot and action that lasts one day; he made no mention at all of unity of place. Neoclassical critics of the 17th century, however, codified these discussions into rules.

Considering the inconvenience of such rules and their final unimportance, one wonders at the extent of their influence. The Renaissance desire to follow the ancients and its enthusiasm for decorum and classification may explain it in part. Happily, the other classical work recognized at this time was Horace's *Art of Poetry* (c. 24 BC), with its basic precept that poetry should offer pleasure and profit and teach by pleasing, a notion that has general validity to this day. Happily, too, the popular drama, which followed the tastes of its patrons, also exerted a liberating influence. Nevertheless, discussion about the supposed need for the unities continued throughout the 17th century (culminating in the French critic Nicolas Boileau's *Art of Poetry*, originally published in 1674), particularly in France, where a master like Racine could translate the rules into a taut, intense theatrical experience. Only in Spain, where Lope de Vega published his *New Art of Writing Plays* (1609), written out of his experience with popular audiences, was a commonsense voice raised against the classical rules, particularly on behalf of the importance of comedy and its natural mixture with tragedy. In England both Sir Philip Sidney in his *Apologie for Poetry* (1595) and Ben Jonson in *Timber* (1640) merely attacked contemporary stage practice. Jonson, in certain prefaces, however, also developed a tested theory of comic characterization (the "humours") that was to affect English comedy for a hundred years. The best of Neoclassical criticism in English is John Dryden's *Of Dramatic Poesie, an Essay* (1668). Dryden approached the rules with a refreshing honesty and argued all sides of the question; thus he questioned the function of the unities and accepted Shakespeare's practice of mixing comedy and tragedy.

The lively imitation of nature came to be acknowledged as the primary business of the playwright and was confirmed by the authoritative voices of Dr. Samuel Johnson, who said in his *Preface to Shakespeare* (1765) "there is always an appeal open from criticism to nature," and the German dramatist and critic Gotthold Ephraim Lessing, who in his *Hamburgische Dramaturgie* (or *Hamburg Dramaturgy*; 1767–69) sought to accommodate Shakespeare to a new view of Aristotle. With the classical straitjacket removed, there was a release of dramatic energies in new directions. There were still local critical skirmishes, such as Jeremy Collier's attack on the "immorality and profaneness of the English stage" in 1698; Goldoni's attacks upon the already dying Italian *commedia* on behalf of greater realism; and Voltaire's reactionary wish to return to the unities and to rhymed verse in French tragedy, which was challenged in turn by Diderot's call for a return to nature. But the way was open for the development of the middle class *drame* and the excursions of romanticism. Victor Hugo, in his Preface to his play *Cromwell* (1827), capitalized on the new psychological romanticism of Goethe and Schiller as well as the popularity of the sentimental *drame* in France and the growing admiration for Shakespeare; Hugo advocated truth to nature and a dramatic diversity that could yoke together the sublime and the grotesque. This view of what drama should be received support from Émile Zola in the preface to his play *Thérèse Raquin* (1873), in which he argued a theory of naturalism that called for the accurate observation of people controlled by their heredity and environment. From such sources came the subsequent intellectual approach of Ibsen and Chekhov and a new freedom for such seminal innovators of the 20th century as Luigi Pirandello, with his teasing mixtures of absurdist laughter and psychological shock; Bertolt Brecht (1898–1956), deliberately breaking the illusion of the stage; and Antonin Artaud (1896–1948), advocating a theatre that should be "cruel" to its audience, employing all and any devices that lie to hand. The modern

dramatist may be grateful that he is no longer hidebound by theory and yet also regret, paradoxically, that the theatre of his time lacks those artificial limits within which an artifact of more certain efficiency can be wrought.

**Eastern theory.** The Oriental theatre has always had such limits, but with neither the body of theory nor the pattern of rebellion and reaction found in the West. The Sanskrit drama of India, however, throughout its recorded existence has had the supreme authority of the *Nāṭya-śāstra*, ascribed to Bharata (c. 1st century AD), an exhaustive compendium of rules for all the performing arts, but particularly for the sacred art of drama with its auxiliary arts of dance and music. Not only does the *Nāṭya-śāstra* identify many varieties of gesture and movement but it also describes the multiple patterns that drama can assume, similar to a modern treatise on musical form. Every conceivable aspect of a play is treated, from the choice of metre in poetry to the range of moods a play can achieve; but perhaps its primary importance lies in its justification of the aesthetic of Indian drama as a vehicle of religious enlightenment.

In Japan, the most celebrated of early Nō writers, Zeami Motokiyo (1363–1443), left an influential collection of essays and notes to his son about his practice, and his deep knowledge of Zen Buddhism infused the Nō drama with ideals for the art that have persisted. Religious serenity of mind (*yūgen*), conveyed through an exquisite elegance in a performance of high seriousness, is at the heart of Zeami's theory of dramatic art. Three centuries later, the outstanding dramatist Chikamatsu (1653–1725) built equally substantial foundations for the Japanese puppet theatre, later known as the *bunraku*. His heroic plays for this theatre established an unassailable dramatic tradition of depicting an idealized life inspired by a rigid code of honour and expressed with extravagant ceremony and fervent lyricism. At the same time, in another vein, his pathetic "domestic" plays of middle class life and the suicides of lovers established a comparatively realistic mode for Japanese drama, which strikingly extended the range of both the *bunraku* and the Kabuki. Today, these forms, together with the more aristocratic and intellectual Nō, constitute a classical theatre based on practice rather than on theory. They may be superseded as a result of the recent invasion of Western drama, but in their perfection they are unlikely to change. The Yüan drama of China was similarly based upon a slowly evolved body of laws and conventions derived from practice, for, like the Kabuki of Japan, this too was essentially an actors' theatre, and practice rather than theory accounts for its development.

**The role of music and dance.** The Sanskrit treatise *Nāṭya-śāstra* suggests that drama had its origin in the art of dance, and any survey of Western theatre, too, must recognize a comparable debt to music in the classical Greek drama, which is believed to have sprung from celebratory singing to Dionysus. Similarly, the drama of the medieval church began with the chanted liturgies of the Roman mass. In the professional playhouses of the Renaissance and after, only rarely is music absent: Shakespeare's plays, particularly the comedies, are rich with song, and the skill with which he pursues dramatic ends with musical help is a study in itself. Molière conceived most of his plays as comedy-ballets, and much of his verbal style derives directly from the balletic qualities of the *commedia*. The popularity of opera in the 18th century led variously to John Gay's prototype for satirical ballad-opera, *The Beggar's Opera* (1728), the opera buffa in Italy, and the *opéra comique* in France. The development of these forms, however, resulted in the belittling of the written drama, with the notable exception of the parodistic wit of W.S. Gilbert (1836–1911). It is worth noting, however, that the most successful modern "musicals" lean heavily on their literary sources. Today, two of the strongest influences on contemporary theatre are those of Bertolt Brecht, who believed that a dialectical theatre should employ music not merely as a background embellishment but as an equal voice with the actor's, and of Antonin Artaud, who argued that the the-

Twentieth-century  
views

atre experience should subordinate the literary text to mime, music, and spectacle. Since it is evident that drama often involves a balance of the arts, an understanding of their interrelationships is proper to a study of dramatic literature.

The influence of theatre design. Though apparently an elementary matter, the shape of the stage and auditorium probably offers the greatest single control over the text of the play that can be measured and tested. Moreover, it is arguable that the playhouse architecture dictates more than any other single factor the style of a play, the conventions of its acting, and the quality of dramatic effect felt by its audience. The shape of the theatre is always changing, so that to investigate its function is both to understand the past and to anticipate the future. Today, Western theatre is in the process of breaking away from the dominance of the Victorian picture-frame theatre, and therefore from the kind of experience this produced.

The contemporary English critic John Wain has called the difference between Victorian and Elizabethan theatre a difference between "consumer" and "participation" art. The difference resulted from the physical relationship between the audience and the actor in the two periods, a relationship that determined the kind of communication open to the playwright and the role the drama could play in society. Three basic playhouse shapes have emerged in the history of the theatre: the arena stage, the open stage, and the picture-frame.

**The arena stage.** To the arena, or theatre-in-the-round, belongs the excitement of the circus, the bullring, and such sports as boxing and wrestling. Arena performance was the basis for all early forms of theatre—the Druid ceremonies at Stonehenge, the Tibetan harvest-festival drama, probably early Greek ritual dancing in the *orchestra*, the medieval rounds in 14th-century England and France, the medieval street plays on pageant wagons, the early Nō drama of Japan, the royal theatre of Cambodia. Characteristic of all these theatres is the bringing together of whole communities for a ritual experience; therefore, a sense of ritualistic intimacy and involvement is common to the content of the drama, and only the size of the audience changes the scale of the sung or spoken poetry. Clearly, the idiom of realistic dialogue would have been inappropriate both to the occasion and the manner of such theatre.

**The open stage.** When more narrative forms of action appeared in drama and particular singers or speakers needed to control the attention of their audience by facing them, the open, "thrust," or platform stage, with the audience on three sides of the actor, quickly developed its versatility. Intimate and ritualistic qualities in the drama could be combined with a new focus on the players as individual characters. The open stage and its variants were used by the majority of great national theatres, particularly those of China and Japan, the booths of the Italian commedia, the Elizabethan public and private playhouses, and the Spanish *corrales* (i.e., the areas between town houses) of the Renaissance. While open-stage performance discouraged scenic elaboration, it stressed the actor and his role, his playing to and away from the spectators, with the consequent subtleties of empathy and alienation. It permitted high style in speech and behaviour, yet it could also accommodate moments of the colloquial and the realistic. It encouraged a drama of range and versatility, with rapid changes of mood and great flexibility of tone. It is not surprising that in the 20th century the West has seen a return to the open stage and that recent plays of Brechtian theatre and the theatre of the absurd seem composed for open staging.

**The proscenium stage.** The third basic theatre form is that of the proscenium-arch or picture-frame stage, which reached its highest achievements in the late 19th century. Not until public theatres were roofed, the actors withdrawn into the scene, and the stage artificially illuminated were conditions ripe in Western theatre for a new development of spectacle and illusion. This development had a revolutionary effect upon the literary drama. In the 18th and 19th centuries, plays were shaped into a new structure of acts and scenes, with intermissions to per-

mit scene changes. Only recently has the development of lighting techniques encouraged a return to a more flexible episodic drama. Of more importance, the actor increasingly withdrew into the created illusion of the play, and his character became part of it. In the mid-19th century, when it was possible to dim the house lights, the illusion could be made virtually complete. At its best, stage illusion could produce the delicate naturalism of a Chekhovian family scene, into which the spectator was drawn by understanding, sympathy, and recognition; at its worst, the magic of spectacle and the necessary projection of the speech and acting in the largest picture-frame theatres produced a crude drama of sensation in which literary values had no place.

Audience expectations. It may be that the primary influence upon the conception and creation of a play is that of the audience. An audience allows a play to have only the emotion and meaning it chooses, or else it defends itself either by protest or by a closed mind. From the time the spectator began paying for his playgoing, during the Renaissance, the audience more and more entered into the choice of the drama's subjects and their treatment. This is not to say that the audience was given no consideration earlier; even in medieval plays there were popular non-biblical roles such as Noah's wife, or Mak the sheepthief among the three shepherds, and the antic devils of the Harrowing of Hell in the English mystery cycles. Nor, in later times, did a good playwright always give the audience only what it expected—Shakespeare's *King Lear* (c. 1605), for example, in the view of many the world's greatest play, had its popular elements of folk-tale, intrigue, disguise, madness, clowning, blood, and horror; but each was turned by the playwright to the advantage of his theme.

Any examination of the society an audience represents must illuminate not only the cultural role of its theatre but also the content, genre, and style of its plays. The exceptionally aristocratic composition of the English Restoration audience, for example, illuminates the social game its comedy represented, and the middle class composition of the subsequent Georgian audience sheds light on the moralistic elements of its "sentimental" comedy. Not unrelated is the study of received ideas in the theatre. The widespread knowledge of simple Freudian psychology has undoubtedly granted a contemporary playwright like Tennessee Williams (1911– ) the license to invoke it for character motivation; and Brecht increasingly informed his comedies with Marxist thinking on the assumption that the audiences he wrote for would appreciate his dramatized argument. Things go wrong when the intellectual or religious background of the audience does not permit a shared experience, as when Jean-Paul Sartre (1905– ) could not persuade a predominantly Christian audience with an existentialist explanation for the action of his plays, or when T.S. Eliot (1888–1965) failed to persuade an audience accustomed to the conventions of drawing-room comedy that *The Cocktail Party* (1949) was a possible setting for Christian martyrdom. Good drama persuades before it preaches, but it can only begin where the audience begins.

**Special audiences.** A great variety of drama has been written for special audiences. Plays have been written for children, largely in the 20th century, though Nativity plays have always been associated with children both as performers and as spectators. These plays tend to be fanciful in conception, broad in characterization, and moralistic in intention. Nevertheless, the most famous of children's plays, James Barrie's *Peter Pan* (1904), implied that the young are no fools and celebrated children in their own right. Barrie submerged his point subtly beneath the fantasy, and his play is still regularly performed, while Maurice Maeterlinck's *Blue Bird* (1908) has disappeared from the repertory because of its weighty moral tone.

In the wider field of adult drama, the social class of the audience often accounts for a play's form and style. Court or aristocratic drama is readily distinguished from that of the popular theatre. The veneration in which the Nō drama was held in Japan derived in large part from

Three  
basic  
playhouse  
types

Children's  
drama

the feudal ceremony of its presentation, and its courtly elements ensured its survival for an upper class and intellectual elite. Although much of it derived from the Nō, the flourishing of the Kabuki at the end of the 17th century is related to the rise of a new merchant and middle class audience, which encouraged the development of less esoteric drama. The popular plays of the Elizabethan public theatres, with their broader, more romantic subjects liberally spiced with comedy, are similarly to be contrasted with those of the private theatres. The boys' companies of the private theatres of Elizabethan London played for a better paying and more sophisticated audience, which favoured the satirical or philosophical plays of Thomas Middleton (1570?–1627), John Marston (1576–1634), and George Chapman (1559?–1634). Similarly today, in all Western dramatic media—stage, film, radio, and television—popular and "commercial" forms run alongside more "cultural" and avant-garde forms, so that the drama, which in its origins brought people together, now divides them. Whether the esoteric influences the popular theatre, or vice versa, is not clear, and research remains to be done on whether this dichotomy is good or bad for dramatic literature or the people it is written for.

#### THE RANGE OF DRAMATIC FORMS AND STYLES

Dramatic literature has a remarkable facility in bringing together elements from other performing and nonperforming arts: design and mime, dance and music, poetry and narrative. It may be that the dramatic impulse itself, the desire to recreate a picture of life for others through impersonation, is at the root of all the arts. Certainly, the performing arts continually have need of dramatic literature to support them. A common way of describing an opera, for example, is to say that it is a play set to music. In Wagner the music is continuous; in Verdi the music is broken into songs; in Mozart the songs are separated by recitative, a mixture of speech and song; while operettas and musical comedy consist of speech that breaks into song from time to time. All forms of opera, however, essentially dramatize a plot, even if the plot must be simplified on the operatic stage. This is because, in opera, musical conventions dominate the dramatic conventions, and the spectator who finds that the music spoils the play, or who finds that the play spoils the music, is one who has not accepted the special conventions of opera. Music is drama's natural sister; proof may be seen in the early religious music-drama of the Dionysiac festivals of Greece and the *mystères* of 14th-century France, as well as in the remarkable development of opera in 17th-century Italy spreading to the rest of the world. The librettist who writes the text of an opera, however, must usually subserve the composer, unless he is able to embellish his play with popular lyrics, as John Gay did in *The Beggar's Opera* (1728), or to work in exceptionally close collaboration with the composer, as Brecht did with Kurt Weill for his *Die Dreigroschenoper* (*The Threepenny Opera*, 1928).

Dance, with its modern, sophisticated forms of ballet, has also been traditionally associated with dramatic representation and has similarly changed its purpose from religious to secular. In ballet, the music is usually central, and the performance is conceived visually and aurally; hence, the writer does not play a dominant role. The scenario is prepared for dance and mime by the choreographer. The contemporary Irish writer Samuel Beckett, trying to reduce his dramatic statement to the barest essentials, "composed" two mimes entitled *Act Without Words I* and *II* (1957 and 1966), but this is exceptional.

In motion pictures, the script writer has a more important but still not dominant role. He usually provides a loose outline of dialogue, business, and camera work on which the director, his cameramen, and the cutting editor build the finished product. The director is usually the final artistic authority and the central creative mind in the process, and words are usually subordinate to the dynamic visual imagery. (This subject is developed at length in the article MOTION PICTURES, ART OF.)

The media of radio and television both depend upon

words in their drama to an extent that is not characteristic of the motion picture. Though these mass media have been dominated by commercial interests and other economic factors, they also have developed dramatic forms from the special nature of their medium. The writer of a radio play must acknowledge that the listener cannot see the actors but hears them in conditions of great intimacy. A radio script that stresses the suggestive, imaginative, or poetic quality of words and permits a more than conventional freedom with time and place can produce a truly poetic drama, perhaps making unobtrusive use of earlier devices like the chorus, the narrator, and the soliloquy: the outstanding example of radio drama is *Under Milk Wood* (1953), by the Welsh poet Dylan Thomas.

A similar kind of dramatic writing is the so-called readers' theatre, in which actors read or recite without decor before an audience. (This is not to be confused with "closet drama," often a dramatic poem that assumes dialogue form; e.g., Milton's *Samson Agonistes*, 1671, written without the intention of stage performance.) The essential discipline of the circuit of communication with an audience is what distinguishes drama as a genre, however many forms it has taken in its long history.

**BIBLIOGRAPHY.** ALLARDYCE NICOLL, *World Drama* (1949), offers the best survey of the whole field, but should be supplemented by JOHN GASSNER and EDWARD QUINN, *The Reader's Encyclopaedia of World Drama* (1969); and PHYLLIS HARTNOLL, *The Oxford Companion to the Theatre*, 3rd ed. (1967). The classical texts of dramatic theory and criticism may be found in a collection by B.H. CLARK, *European Theories of the Drama*, rev. ed. (1965), which also contains an extensive bibliography; and a useful commentary on critics writing after 1750 is supplied in RENE WELLEK, *A History of Modern Criticism*, 4 vol. (1955–65). The *Natya Shastra* of BHARATA, the classic source for Indian dramatic theory, was translated by M.M. GHOSH in 1951.

Books of importance in the development of modern theory on drama are: BERNARD BECKERMAN, *Dynamics of Drama* (1970); E.R. BENTLEY, *The Life of the Drama* (1964); KENNETH BURKE, *A Grammar of Motives* (1945); FRANCIS HERGUSON, *The Idea of a Theatre* (1949); S.K. LANGER, *Feeling and Form* (1953); ELDER OLSON, *Tragedy and the Theory of Drama* (1961); RONALD PEACOCK, *The Art of Drama* (1957); and J.L. STYAN, *The Elements of Drama* (1960).

The finest study of the classical drama of Greece is probably H.D.F. KITTO, *Greek Tragedy*, 3rd ed. (1961); and for the medieval drama are recommended: KARL YOUNG, *The Drama of the Medieval Church*, 2 vol. (1933); HARDIN CRAIG, *English Religious Drama of the Middle Ages* (1955); and O. B. HARDISON, *Christian Rite and Christian Drama in the Middle Ages* (1965). Oriental theatre is surveyed in FAUBION BOWERS, *Japanese Theatre* (1952); F.A. LOMBARD, *An Outline History of the Japanese Drama* (1928), which should be read in conjunction with ARTHUR WALEY's classic *The Noh Plays of Japan* (1922); A.C. SCOTT, *The Classical Theatre of China* (1957); A.B. KEITH, *The Sanskrit Drama* (1924); with H.W. WELLS' comparative studies, *The Classical Drama of India* (1963), and *The Classical Drama of the Orient* (1965).

M.C. BRADBROOK, *Themes and Conventions of Elizabethan Tragedy* (1935); and U.M. ELLIS-FERMOR, *Jacobean Drama* (1936), are standard surveys of the English Renaissance drama; and for standard Shakespearean criticism the reader should consult A.M. EASTMAN, *A Short History of Shakespearean Criticism* (1968). The classic source books for the *commedia dell'arte* are P.L. DUCHARTRE, *La Comédie italienne* (Eng. trans., *The Italian Comedy*, 1929, reprinted 1966); and ALLARDYCE NICOLL, *Masks, Mimes and Miracles* (1931). On the French classical drama H. C. LANCASTER, *A History of French Dramatic Literature in the Seventeenth Century*, 9 vol. (1929–42), is standard; but MARTIN TURNELL, *The Classical Moment* (1947), deals more briefly with Corneille, Racine, and Molière. On Restoration comedy J.L. PALMER, *The Comedy of Manners* (1913); and BONAMY DOBREE, *Restoration Comedy* (1924), remain the best.

American drama is surveyed briefly in W.J. MESERVE, *An Outline History of American Drama* (1965); and A.S. DOWNER, *Fifty Years of American Drama, 1900–1950* (1951). U.M. ELLIS-FERMOR, *The Irish Dramatic Movement*, 2nd ed. (1954), is a comprehensive study of the early years at Dublin's Abbey Theatre; and on Western drama after Ibsen the reader should begin by consulting E.R. BENTLEY, *The Playwright as Thinker* (1946); ROBERT BRUSTEIN, *The Theatre of Revolt* (1964); and J.L. STYAN, *The Dark Comedy*, 2nd ed. (1968).

(J.L.S.)

## Dravidian Languages

The Dravidian language family, as known to date, consists of 23 languages spoken by more than 110,000,000 people in South Asia. In terms of population figures the major languages of the family may be listed in the following order: Telugu, 37,600,000; Tamil, 30,560,000; Kannada (Kannāḍa), also called Kanarese, 17,420,000; Malayalam (Malayālam), 17,020,000; Gondi, 1,500,000; Kurukh (Kurukḥ), 1,140,000; and Tulu (Tuḷu), 940,000. The Dravidian languages are spoken in the Republic of India (mainly in its southern, eastern, and central parts), in Sri Lanka (Ceylon), and by settlers in areas of South-eastern Asia, southern and eastern Africa, and elsewhere. Brahui (Brāhui), with 300,000 speakers in Pakistan, is isolated from all of the other members of the family. The four major languages—Telugu, Tamil, Kannada, and Malayalam—possess independent scripts and literary histories dating from the pre-Christian Era. Now recognized by the constitution of India, they form the basis of the linguistic states of Andhra Pradesh (established as the first Indian linguistic state in 1953), Tamil Nadu, Mysore, and Kerala.

Tamil is the language with the greatest geographical extension and the richest and most ancient literature, paralleled in India only by that of Sanskrit. Its phonological and grammatical systems correspond in many points to the ancestral parent language, called Proto-Dravidian.

Nothing definite is known about the origin of the Dravidian family. There are vague indigenous traditions about a migration from the south, from a submerged continent in the Indian Ocean. According to some scholars, Dravidian languages are indigenous to India. In recent years, a hypothesis has been gaining ground about a movement of Dravidian speakers from the northwest to the south and east of the Indian Peninsula, possibly from as far away as Central Asia. Another theory connects the Dravidian speakers with the peoples of the Indus Valley civilization. The Dravidian languages have remained an isolated family until now and have defied all of the attempts to show a connection with the Indo-European tongues, Mitanni, Basque, Sumerian, or Korean. The most promising and plausible hypothesis is that of a linguistic relationship with the Uralic (Hungarian, Finnish) and Altaic (Turkish, Mongol) language groups.

As an independent family, the Dravidian languages were first recognized in 1816 by Francis W. Ellis, a British civil servant. The actual term Dravidian was first employed by Robert A. Caldwell, who introduced the Sanskrit word *drāvida* (which, in a 7th-century text, obviously meant Tamil) into his epoch-making *A Comparative Grammar of the Dravidian or South Indian Family of Languages* (1sted., 1856).

**Languages of the family.** Tamil is spoken by 30,562,698 people (1961) in the state of Tamil Nadu, by another 2,500,000 in Sri Lanka (Ceylon), and in Burma, Malaysia, Indonesia, and Vietnam (about 1,000,000), in East and South Africa (almost 250,000), and by small numbers in British Guiana and on the islands of Fiji, Mauritius, Réunion, Madagascar, Trinidad, and Martinique. The earliest literary monuments of the language belong roughly to the 3rd and 2nd centuries BC. There exist a number of local dialects, the major dialect regions being the northern and eastern areas combined, the western area, the southern area (split into at least four major dialects of Madurai, Tirunelveli, Nanjiland, and Ramnad), and Sri Lanka (Ceylon). Correlated with the social position of the speaker are a number of speech forms; a major division occurs between the Brahmin and the non-Brahmin varieties. In addition, there is a sharp dichotomy between the formal language and informal speech.

Malayalam, closely related to Tamil, is spoken in the state of Kerala by 17,015,782 people. Possessing an independent script, it also has a rich modern literature. There are at least three main regional dialects (North, Central, South) and a number of communal dialects.

In the Nilgiris and adjacent regions, several minor tribes speak the following languages: Kota (862), Toda (765),

Badaga (85,463), Irula (Iruḷa) (4,124). The languages of a number of other tribes may yet be established as independent members of the family (e.g., Kurumba, Paniya).

Kodagu (Kodagu), a non-literary language of a mountainous region called Coorg, has 78,202 speakers.

Kannada (Kanarese), spoken by 17,415,827 people in the state of Mysore, has a dichotomy between educated speech and colloquial Kannada; in the latter at least three social dialects are recognizable—Brahmin, non-Brahmin, and Harijan ("untouchable"). A number of regional dialects (among them, Dharwar, Bangalore, and Mangalore) also exist. Kannada has an orthography of its own and an important ancient and modern literature.

To the south of the Kannada territory, more than 900,000 people speak Tulu (Tuḷu), a South Dravidian language having no developed written literature.

Telugu (37,668,132), the official language of Andhra Pradesh, exhibits a dichotomy between the written and the spoken styles, in addition to a number of sharply distinct local and regional dialects (Telangana, coastal area, Rayalaseema, and a "transitional" zone) and divisions between Brahmin, non-Brahmin, and Harijan speech. The language has its own script, closely akin to that of Kannada, and an important literary tradition.

In the northern parts of Andhra Pradesh, two tribes speak Kolami (46,065 persons) with its dialect Naikri (Naikri), and Naiki (1,000), whereas Parji (94,607) is spoken in Bastar, Madhya Pradesh. In Orissa, Konda (Konda) is spoken by about 12,000 Konda Doras, and about 2,000 Gadbas speak the three closely related dialects of Ollari, Pottangi, and Poya; Pengo (1,254) and Manda (Manda) were discovered only recently, and Naiki of Chānda is also a newly investigated language (since 1961). The Khond tribes of Orissa (600,000) speak two closely related languages, Kui and Kuvi.

In the vast regions of Madhya Pradesh, many groups of Gonds (including about 1,500,000 persons) speak a number of Gondi dialects. Still further to the north, in Bihār, Orissa, and Madhya Pradesh, the Oraon tribe speaks Kurukh (1,132,931), and near the borders of Bihār and West Bengal, 88,645 tribals speak Malto.

The only Dravidian language spoken entirely outside India is Brahui, with about 300,008 speakers in the Quilat, Hairpur, and Hyderābād districts of Pakistan.

Dravidian  
features in  
the  
R̥gveda

**Historical survey of the Dravidian languages.** Although in modern times Dravidian has mainly occupied the southern portion of India, while the Indo-Aryan (Indic) tongues have predominated in north India, nothing definite is known about the ancient domain of the Dravidian parent speech. It is, however, a well-established hypothesis that Dravidian speakers must have been widespread throughout India, including the northwest region. This is clear because a number of features of the Dravidian languages appear in the R̥gveda, the earliest known Indo-Aryan literary work, thus showing that the Dravidian languages must have been present in the area of the Indo-Aryan ones. The Indo-Aryan languages were not, however, originally native to India; they were introduced by Aryan invaders from the north. Several scholars have demonstrated that pre-Indo-Aryan and pre-Dravidian bilingualism in India provided conditions for the far-reaching influence of Dravidian on the Indo-Aryan tongues in the spheres of phonology (*e.g.*, the retroflex consonants, made with the tongue curled upward toward the palate), syntax (*e.g.*, the frequent use of gerunds, which are non-finite verb forms of nominal character, as in "by the falling of the rain"), and vocabulary (a number of Dravidian loanwords apparently appearing in the R̥gveda itself).

Thus a form of Proto-Dravidian, or perhaps Proto-North Dravidian, must have been extensive in north India before the advent of the Aryans. Apart from some islands of Dravidian speech, however, the process of replacement of the Dravidian languages by the Aryan tongues was entirely completed before the beginning of the Christian Era, after a period of bilingualism that must have lasted many centuries. Finally, the almost universal adoption of Indo-Aryan in the north and Dravidian in the south has covered up the original linguistic diversity of India.

The advent of Dravidian speakers in India is shrouded in mystery. There are vague linguistic and cultural ties with the Urals, with the Mediterranean area, and with Iran. It is possible that a Dravidian-speaking people that can be described as dolichocephalic (longheaded from

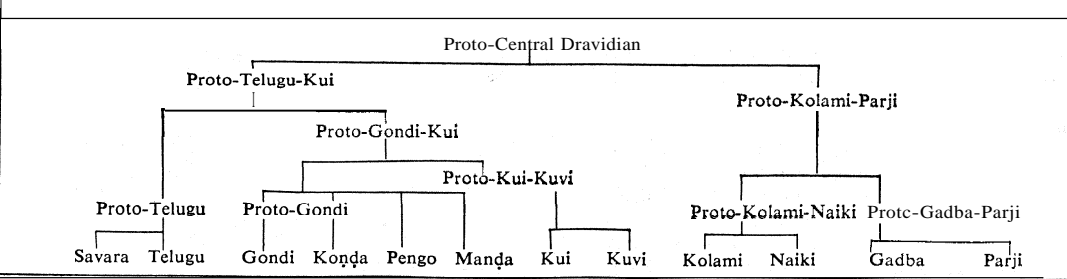

front to back) Mediterraneans mixed with brachycephalic (short-headed from front to back) Armenoids and established themselves in northwest India during the 4th millennium BC. Along their route, these immigrants may have possibly come into an intimate, prolonged contact with the Ural-Altaic speakers, thus explaining the striking affinities between the Dravidian and Ural-Altaic language groups. Between 2000 and 1500 BC, Dravidian speakers moved constantly from the northwest to the southeast of India, and in about 1500 BC three distinct dialect groups probably existed: Proto-North Dravidian, Proto-Central Dravidian, and Proto-South Dravidian. The beginnings of the splits in the parent speech are obviously earlier. It is possible that Proto-Brahui was the first language to split off from Proto-Dravidian, probably during the immigration movement into India sometime in the 4th millennium BC, and that the next subgroup to split off was Proto-Kurukh-Malto, sometime in the 3rd millennium BC (see the family tree diagrams, Tables 1–3).

Compared to the work done on other language families, the progress in comparative Dravidian studies is still meagre. Considerable knowledge has been acquired in comparative phonology (sound systems), but correspondences have been worked out only for the sounds in the roots of words. Very little comparative work has been done on grammatical processes and complete historical grammars of the literary languages are still lacking. Hence the reconstruction of any feature of the Dravidian protolanguage, with the possible exception of some parts of the phonology, must necessarily be very tentative.

The vowel system of Proto-Dravidian consisted of five vowels—*\*i*, *\*u*, *\*e*, *\*o*, *\*a* (an asterisk denotes an unattested, reconstructed, hypothetical form)—each having two quantities, short and long. Relative stability of root vowels seems to have been the rule. The Proto-Dravidian consonant system consisted of obstruents (stops) *\*p*, *\*t*, *\*ṭ*, *\*c*, *\*k*; nasals *\*m*, *\*n*, *\*ṇ*, *\*A*; laterals *\*l*, *\*ḷ*; the flap *\*r*; the voiced retroflex continuant *\*ṛ*; and the semi-vowels *\*y* and *\*v*. The most characteristic feature of the consonantal system was the six positions of articulation for obstruents: labial (with the lips), dental (tongue

Possible

and Ural-  
Altaic  
contact

Table 2: Central Dravidian Subfamily

touching the back of the upper teeth), alveolar (tongue touching the upper gum ridge), retroflex (tip of tongue curled upward toward the palate and back), palatal (body of tongue touching the palate, or roof of the mouth), and velar (back of tongue touching the velum, or soft palate). The retroflex series was very distinctive and important and comprised an obstruant \*ʈ, a nasal \*ɳ, a lateral \*ɭ, and a continuant \*ɹ. No consonant of the alveolar or retroflex series began a word. In the final position all of the consonants occurred, but all of the obstruents were followed by an automatic release sound, the vowel \*-u. Initial consonant clusters did not occur. There was only one series of obstruant phonemes (distinctive sounds); these sounds were voiceless (produced without vibration of the vocal cords) initially and voiced (with vocal cord vibration) between vowels. All Proto-Dravidian roots were monosyllables.

Proto-Dravidian used only suffixes, never prefixes or infixes. Hence, the roots of words always occurred at the beginning. Nouns, verbs, and indeclinable words constituted the original word classes.

During the 1st millennium BC, while Aryanization steadily progressed in north India, the Dravidian-speaking newcomers began to mix with the Negritos and Proto-Australoids in the south; this process of acculturation continued during the period from approximately 1200 to 600 BC. A movement of the Aryans into the south of India began sometime about 1000 BC. Before the 5th century BC, Proto-South Dravidian was probably still one language, with two strongly marked dialects. Within Proto-Central Dravidian, a deep two-way division also occurred, and North Dravidian must have already been split into the Kurukh-Malto and Brahui subgroups (see the family tree diagrams, Tables 1–3).

Table 3: North Dravidian Subfamily

Apart from a possible Dravidian word in the Hebrew text of the Bible (*tukkhīyīm* "peacocks"; cf. Tamil *tōkai* "tail of a peacock"), the Dravidian languages enter history in Sanskrit and Greco-Roman texts. The *Cēras*, a south Indian dynasty, are possibly mentioned in the early Sanskrit text *Aitareya Āraṇyaka*. Kātyāyana, a grammarian of the 4th century BC, mentions the countries of Pāṇḍya (Tamil *pāṇṭiya*), Cola (Tamil *cōla*), and Kerala, or Cēra (Tamil *cēra*); these lands were well known to Kautilya (4th century BC), the author of the earliest treatise on statecraft, and appear in the edicts of the great Buddhist leader Aśoka (3rd century BC). The term *drāvida* is almost certainly a Sanskritization (with an inserted "hypercorrect" *r*) of the earlier Pāli and Prākṛit terms *dāmiḷo*, *damīḷa*, *dāvida*, which must have been derived from the Tamil name of the language, *tamil*. A number of South Dravidian words, almost all of the geographic and dynastic names, occur in such Greco-Roman sources as the *Periplus maris Erythraei* ("Circumnavigation of the Erythraean Sea") of about AD 89 and in the writing of Ptolemaeus of Naukratis of the 2nd century AD; it is also very probable that Western-language terms for rice (compare Italian *riso*, Latin *oryza*, Greek *oryza*) and ginger (compare Italian *zenzero*, German *Zingwer*, Greek *zingiberis*) are cultural loans from Old Tamil *arici* and *iṇci-vēr*, respectively.

Sometime during the reign of Aśoka (3rd century BC), the two South Dravidian languages, Tamil and Kannada, developed into distinct idioms and the two cultures emerged as separate entities; a third major Dravidian linguistic and cultural unit, Telugu, appeared in the Andhra country. In the period from 300 to 100 BC, one of the pre-Tamil dialects (probably that of Madurai) gained

prestige and became the standard literary language (*cen-tamil*), the written form of early Old Tamil, established in poetic texts and in its earliest grammar, *Tolkāppiyam*. At the same time, about 250 BC, the Aśokan Southern Brāhmī script was adapted for Tamil and used in short cave inscriptions by Jain monks during several centuries, dating approximately from the 2nd century BC to the 5th century AD.

The earliest inscriptions in Kannada may be dated at AD 450; Kannada literature begins with Nīpatuṅga's *Kavirājamārga*, about AD 850. The oldest Telugu inscription is from AD 633, and the literature begins with the grammarian Nannaya's 11th-century translation of the Sanskrit classic the *Mahābhārata*. In Malayalam, the earliest writings are from the close of the 9th century, and the first literary text is probably the *Bhāṣākauṭaliyam*, AD 1125–1250.

Since these attested beginnings, the four languages—Tamil, Malayalam, Kannada, and Telugu—have been used continuously in administration and literature up to the present day. In addition to possessing an immense wealth of epigraphic and literary texts, they all developed pronounced features of diglossia, a dichotomy between the standardized, formal language and the informal, colloquial speech, which is divided into regional as well as social dialects. In modern times, all of the four cultivated languages have adapted quickly to new conditions resulting from economic, social, and political changes. All of them are used for basic courses in science and the arts; and new technological terminology is coined, based either on English or Sanskrit models, but often on exclusively indigenous linguistic material (in Tamil).

To date, nothing is known about the history of the non-literary Dravidian languages before their "discovery," which began at the end of the 18th century. The Gonds, however, are mentioned (as Gondaloi) by Ptolemy of Naukratis, writing in the 2nd century AD.

A tendency toward structural and systemic balance and stability is characteristic of the Dravidian group. Nevertheless, there is no doubt about the influence of the other languages of India. Dravidian languages show extensive lexical (vocabulary) borrowing, but only a few traits of structural (either phonological or grammatical) borrowing, from the Indo-Aryan tongues. On the other hand, Indo-Aryan shows rather large-scale structural borrowing from Dravidian, but relatively few loanwords. There is indeed a possibility of Dravidian and Indo-Aryan drawing even closer together in the future; but it is highly doubtful that a new family of languages will develop with the bases of the contributing groups (*i.e.*, Dravidian and Indo-Aryan) completely eliminated through the phenomena of borrowing.

Characteristics of the Dravidian languages. Dravidian languages would probably be called agglutinative in the categorization of the 19th-century philologists. An agglutinative language incorporates separate formal units of distinct meaning into a single word. There are some elements of "internal flexion" (*e.g.*, the alternation of short-long root vowels in derived words), however, as well as regular alternations in vowel and consonant quantities within the root. Relatively low receptivity to change results in a slower rate of change than is found in the Indo-European language family. The degree of phonetic divergence among the Dravidian languages is not very great; hence, etymologies are not too difficult to discover. The territory occupied by Dravidian speakers in India may be characterized as a large dialect area resembling the area of the Romance languages, with numerous boundaries marked by bundles of isoglosses (an isogloss is a boundary line that separates the areas of two differing features of language usage), but also with many isoglosses enclosing more than one language. In any study of Dravidian, therefore, both evolution and diffusion must be taken into account.

Sounds of Dravidian. Compared to the reconstructed system of Proto-Dravidian phonemes (distinctive sounds), the most striking developments in vowels are the gradual elimination of the contrast between *e* and *ē* (long *e*) and *o* and *ō* (long *o*) in Brahui, as a result of the influence of Indo-

Early inscriptions and writings

Agglutinating character of Dravidian

Process of Dravidian acculturation in India

Aryan languages or Iranian or both; the raising of Proto-Dravidian \**e* and \**o* to *i* and *u* and the lowering of these protolanguage sounds in Brahui; and the merger of Proto-Dravidian \**i* and \**u* with \**e* and \**o* in the South Dravidian languages before a consonant plus the vowel *a*. Also noteworthy are the emergence of retroflex vowels (*i.e.*, centralized vowels "coloured" by neighbouring retroflex consonants) in Kodagu and Irula; the nasalization of vowels, as in colloquial Tamil; the loss of vowels in unaccented noninitial syllables in Toda, Kota, some dialects of Kannada, and Tamil, and the resulting consonant clusters (*e.g.*, Kota *anjrčgčgvdk*, "because of the fact that [someone] will cause [someone] to terrify [someone]"). Metathesis (the transposition of sounds, as in "aks" from "ask") and vowel contraction resulted in initial consonant clusters in Telugu and other Central Dravidian languages—*e.g.*, Tamil *koḷu*, but Kui *krđga*, both meaning "fat."

Consonant  
changes

Among the most important consonantal developments are the loss of \**c*-, a typical South Dravidian phenomenon that seems to be still in progress (*e.g.*, Proto-Dravidian \**car*-, but Tamil *ala!* "to burn," and *talal* "to glow"); the velarization of \**c*- to *k*- in North Dravidian when the sound is followed by *ũ* (*e.g.*, Tamil *cuṭu* "be hot," but Malto *kut*- "burn"); the palatalization of Proto-Dravidian \**k*- to *c*- before front vowels in Tamil, Malayalam, and Telugu (*e.g.*, \**ke*- "red," but Tamil *ce*-); and the replacement of \**k*- in North Dravidian by *x* before *g*, *ḡ*, and *ũ* (*e.g.*, Tamil *kal*, but Brahui *xal*, "stone"). The retroflex voiced continuant \**r* has been preserved only in the old stages of the cultivated languages and partly in modern Tamil and Malayalam; elsewhere, it merged with *ḷ*, *d*, and other sounds. Some languages, notably Kannada, developed a secondary *h*-, not inherited from the parent speech (*e.g.*, Tamil *peyar*, Old Kannada *pesar*, but Modern Kannada *hesru*, "name"). According to the Dravidian scholar Bhadriraju Krishnamurti, a laryngeal (or *h*- type of sound) should be reconstructed for some items in Proto-Dravidian.

Problems of accent and intonation still remain to be worked out. Word stress is predictable, always occurring on the radical (initial) syllable and therefore being non-distinctive. The rules of sandhi (change of a sound or sounds as a result of adjacent sounds) are as complicated and delicate as in Sanskrit.

*Grammatical features of Dravidian.* In grammar, the absolutely prevailing process is suffixation, the addition of suffixes. Grammatical functions are, however, also expressed by composition (the compounding of word elements) and by word order. There are no prefixes or infixes. Suffixes agglutinate (are attached to one another); *e.g.*, Tamil *connatileyiruntu* "from what was said" is composed of *col* "say" + *n* "past" + *atu* "3rd person singular neuter" + *il* "locative" + *ḡ* "emphatic" + *y* (an automatic insertion resulting from a sound rule) + *iruntu* "ablative" (*iruntu* comes from *iru* "be" + *nt/ũ* "past").

The major word classes are nouns (substantives, numerals, pronouns), adjectives, verbs, and indeclinables (particles, enclitics, adverbs, interjections, onomatopoeic words, echo words). There are two numbers and four different gender systems, the "original" probably having "male:non-male" in the singular and "person:non-person" in the plural. The pronoun has a category "inclusive:exclusive" in the 1st person plural. A characteristic derivation is that of "pronominalized" or "personal" nouns and adjectives; *e.g.*, Old Tamil *ilai* "youth," *ilai-yam* "young-we," *ilai-y-ar* "young-they." Finite forms of the verb (forms showing person and number) are, ultimately, "pronominalized" verb stems; *e.g.*, Tamil *aṭi-(y)-ēn* ("slave"—1st person singular) "I am a slave"; *nal-(l)-ēn* ("good"—1st person singular) "I am good"; *pd-v-ḡn* ("go"—future—1st person singular) "I shall go." The most characteristic feature of the Dravidian verb is a full-fledged negative system: all of the positive verb forms have their corresponding negative counterparts. Verbs are intransitive, transitive, and causative; there are also active and passive forms. The main (and probably original) dichotomy in tense is *past:non-past*. Present

tense developed later and independently in each language or subgroup.

In a sentence, however complex, only one finite verb occurs, normally at the end, preceded if necessary by a number of gerunds. Gerunds and participles, as well as verb-nouns, play an important role. The determining member always precedes the determined; *e.g.*, Tamil *pon* "gold" + *nakaram* "city" becomes *ponnakaram* "city of gold, golden city." Word order follows certain basic rules but is relatively free.

*Vocabulary.* In vocabulary, different languages were receptive to loanwords in differing degrees. Among the cultivated languages, Tamil has the relatively lowest number of Indo-Aryan loanwords (18–25 percent, according to the style), whereas in Malayalam and Telugu the percentage is much higher. The most important sources of loanwords have been Sanskrit, Pāli, and Prākṛit (with varying impact in different periods); in modern times Urdu, Portuguese, and English have made significant contributions. There was not much lexical borrowing from one Dravidian language into another in historical times. Among all the Dravidian languages, Brahui, in Pakistan, is inevitably the one most influenced by Indo-Aryan and Iranian; in contrast, Toda is probably the one language least influenced by any other idiom. In Tamil, there is currently a very notable and active purifying movement; it aims at removing as many "Sanskritic" (but not English) vocabulary items as possible. Such purism has not yet occurred in any other of the cultivated languages.

*Writing.* Writing was first developed in Tamil Nadu, sometime about 250 BC, when the Aśokan Southern Brāhmī script was adapted for Tamil. The earliest inscriptions in Tamil script proper are the Pallava copper-plates of about AD 550. The Kannada–Telugu script is based on Cālukya (6th century) inscriptions; the Grantha script, used in Tamil Nadu for Sanskrit since the 6th century, was accommodated for Malayalam and Tulu. Apart from these, Tamil has an old cursive script called *Vatṭeḷuttu*, "round script," and Malayalam possesses its own modern cursive form, *Koleḷuttu*, "rod-script."

## Drawing

Drawing as formal artistic creation might be defined as the primarily linear rendition of objects in the visible world, as well as of concepts, thoughts, attitudes, emo-

tions, and fantasies given visual form, of symbols and even of abstract forms. This definition, however, applies to all graphic arts and techniques that are characterized by an emphasis on form or shape rather than mass and colour, as in painting. Drawing as such differs from graphic printing processes in that a direct relationship exists between production and result. Drawing, in short, is the end product of a successive effort applied directly to the carrier, which is usually paper. Whereas a drawing may form the basis for reproduction or copying, it is nonetheless unique by its very nature.

Function  
of drawing  
in the  
visual arts

Although not every art work has been preceded by a drawing in the form of a preliminary sketch, drawing is in effect the basis of all visual arts. Often the drawing is absorbed by the completed work or destroyed in the course of completion. Thus, the usefulness of a ground-plan drawing of a building that is to be erected decreases as the building goes up. Similarly, points and lines marked on a raw stone block represent auxiliary drawings for the sculpture that will be hewn out of the material. Essentially, every painting is built up of lines and pre-sketched in its main contours; only as the work proceeds is it consolidated into coloured surfaces. As shown by an increasing number of findings and investigations, drawings form the material basis of mural, panel, and book paintings. Such preliminary sketches may merely indicate the main contours or may predetermine the final execution down to exact details. They may also be mere probing sketches. Long before the appearance of actual small-scale drawing, this procedure was much used for monumental murals. With sinopia—the preliminary sketch found on a layer of its own on the wall underneath the fresco, or painting on freshly spread, moist plaster—one reaches the point at which a work that merely served as technical preparation becomes a formal drawing expressing an artistic intention.

Not until the late 14th century, however, did drawing come into its own—no longer necessarily subordinate, conceptually or materially, to another art form. Autonomous, or independent, drawings, as the name implies, are themselves the ultimate aim of an artistic effort; therefore, they are usually characterized by a pictorial structure and by precise execution down to details.

Formally, drawing offers the widest possible scope for the expression of artistic intentions. Bodies, space, depth, substantiality, and even motion can be made visible through drawing. Furthermore, because of the immediacy of its statement, drawing expresses the draftsman's personality spontaneously in the flow of the line; it is, in fact, the most personal of all artistic statements. It is thus plausible that the esteem in which drawing was held should have developed parallel to the value placed on individual artistic talent. Ever since the Renaissance, drawing has gradually been losing its anonymous and utilitarian status in the eyes of artists and the public, and its documents have been increasingly valued and collected as evidence of human creativity.

This article will deal with the aesthetic characteristics, the mediums of expression, the subject matter, and the history of drawing.

This article is divided into the following sections:

## I. General considerations

### ELEMENTS AND PRINCIPLES OF DESIGN

**Line and linear techniques.** The principal element of drawing is the line. Through practically the entire development of Western drawing, this figure, essentially abstract, not present in nature, and appearing only as a border setting of bodies, colours, or planes, has been the vehicle of a representational more or less illusionist rendition of objects. Only in very recent times has the line been conceived of as an autonomous element of form, independent of an object to be represented.

Conscious and purposeful drawing represents a considerable mental achievement, for the ability to reduce the spatial objects in the world around one to lines drawn on a plane presupposes a great gift for abstraction. The identification of the motif of a drawing by the viewer is no less an achievement, although it is mastered by practically all human beings. The visual interpretation of a line as a representation of a given object is made possible through certain forms of that line that call forth associations. The angular meeting of two lines, for example, may be considered as representing the borders of a plane; the addition of a third line can suggest the idea of a cubic body. Vaulting lines stand for arches, convergent lines for depth.

With the aid of this modest basic vocabulary, one can distill comprehensible images from a variety of linear phenomena. The simple outline sketch—Greek legend has it that the first "picture" originated from copying the shadows on the sand—represents one of the oldest and most popular possibilities of graphic rendition. After decisively characterizing the form of Egyptian drawing and the archaic art of Greece, the outline sketch became the chief vehicle of artistic communication in late antiquity and the Middle Ages. Used in a variety of ways in the early Renaissance, it became dominant once again in Neoclassicism, as it is, for that matter, in the classicist period of a given artist's total work.

The outline sketch is elaborated into the detailed drawing by means of the line, which differentiates between the plastic and the spatial values of the object. Borders of individual objects, changes in the spatial plane, and varying intensities of colour applied within an outline sketch all tend to enrich and clarify the relationship between the whole and its component parts.

The free beginning, the disappearance, or the interruption of a line provides opportunities for gradually slurring an edge until it becomes a plane, for letting colour

transitions fade away, for having the line vanish in the depth.

The thickening or thinning of a line can also be used to indicate, spatially or by means of colour, a change in the object designated by that line. Even light-and-shadow values may be rendered by differences in stroke strength.

While the chopping up of a line into several brief segments, and, even more, the drawing of individual lines running parallel in one direction, makes the outlined form appear less corporeal and firm, it reproduces the visual impact of the form in a more pictorial manner. Slight shifts in the flow of the line are intended to represent smooth curves and transitions; they also reinforce the effect of light striking a surface and thus give the corporeal appearance. Finally, short, curving segments of a line that do not stand in a clearly angular relationship to one another but are arranged on the sheet in loose formation allow the pictorial and colour component to dominate, as in the work of the 16th-century Italian artist Jacopo Tintoretto. An extreme case is the complete dissolution of the linear stroke into dots and spots, as, for example, in the drawings of the 19th-century pointillist painter Georges Seurat.

A mere combination of these varied shapes of the line,

without reference to the mediums in which the lines are drawn, provides the artist with a plethora of subjective opportunities for the expression both of general stylistic traits and of personal characteristics. An arrangement of forceful, mainly straight strokes in accentuated, sharp angles lends the drawing an austere character emphasizing dramatic and expressive traits. This method of drawing, in fact, is characteristic of stylistic epochs and artistic regions (not to mention individual artists) that prefer these qualities: in the rather sober city of Florence, in German Expressionism, where it is used to convey mood, but also in the drawings of Rembrandt and Vincent van Gogh. Soft lines, on the other hand, running in **drawn-out**, smoothly rounded forms and stressing graphic regularity above any statement of content, constitute the formal equivalent to elegant, courtly, and lyric qualities of expression. Accordingly, they are often found in drawings of the Soft style; in the early Renaissance, particularly in the work of artists from the Italian province of Umbria and in young Raphael's sketches; in the work of Nazarenes, a 19th-century group of Romantic painters whose subjects were **mainly religious**; in the **Jugendstil**, a late-19th- and early-20th-century German decorative style parallel to Art Nouveau in its organic foliate forms, sinuous lines, and non-geometric curves; and in a very pure form in **one of** the classic draftsmen, the 19th-century French painter Jean-Auguste-Dominique Ingres. A markedly even-stroke texture, with waxing and waning strokes in regular proportions and evenly distributed within the page, brings drawing close to calligraphic writing and is found in all stylistic epochs that value ornamentation.

The technique of hatching gives the line **an** additional potential for the clarification of plastic relationships and of light phenomena. In hatching, parallel, short, equidistant, more or less straight lines create static and tectonic (structural) values by marking individual body planes. Gently curved hatching stresses the roundness of the body and can also accentuate, as tone value, shaded parts of the representation.

Cross-hatching, in which two layers of hatching intersect at right angles, reinforces the body-and-shadow effect. Known since the days of Michelangelo and **Dürer** in the 15th and 16th centuries, this artistic technique is often used with slanted or even curved hachures for the linear rendition of rounded parts. In rigorously monotone drawings, this method is the most suitable for the depiction of spherical bodies. The human body, with its highly articulated surface, can be modelled in this fashion very clearly and precisely. For 17th- and 18th-cen-

tury engravers, this process became the most important means of drawing. All of these different possibilities of linear rendition can be achieved with pen and crayon as well as with the brush.

**Plane techniques.** Linear techniques of drawing are supplemented by plane methods, which can also be carried out with crayon. For example, evenly applied dotting, which is better done with soft mediums (see *Surfaces, mediums, and techniques* below), results in an areal effect in uniform tone. Various values of the chiaroscuro (pictorial representation in terms of light and shade without regard to colour) scale can also be rendered by means of dry or moist rubbing. Pulverized drawing materials that are rubbed into the drawing surface result in evenly toned areas that serve both as a closed foundation for linear drawing and as indication of colour values for individual sections.

More significant for plane phenomena, however, is brushwork, which, to be sure, can adopt all linear drawing methods but the particular strength of which lies in stroke width and tone intensity, a medium that allows for extensive differentiation in colour tone and value. Emphases created by the repeated application of the same tone provide illusionistic indentations that can be conceived of spatially and corporeally. Colour differences result from the use of various mediums. Brushwork also lends itself to spatial and plastic representation, just as it can constitute an autonomous value in nonrepresentational drawings.

All of these effects of monochrome drawing are accentuated with the use of varicoloured mediums of a basic material; for example, coloured chalks, drawing inks, or watercolour. While these mediums enrich the art of drawing, they do not widen its basic range.

**The drawing surface.** To these graphic elements must be added another phenomenon the formal significance of which is restricted to drawing: the effect of the unmarked drawing surface, usually paper. Almost all studies (drawings of details), many autonomous sheets, most portrait drawings, as well as figure compositions, still lifes, and even landscapes stand free on the sheet instead of being closed off with a frame-line. Thus, the empty surface, suggesting by itself a spatial background to the drawing on it, contributes actively to the artistic effect.

Even within line composition, the surface left blank fulfills an essential role as a representational value defined by the drawn statements surrounding it as body of a given substantiality or space of a given expanse. Among the details conveyed by the empty space may be the planes of a face, the smooth width of a garment, the mass of a figure or object, the substance the borders and nuances of which are indicated by the drawing. Even the space around individual objects, the spatial distance between them and their environment, the width of a river and the depth of a landscape may be merely signalled by the drawing and filled by the void.

This void can itself become the dominant form enclosed by lines or contours—for example, in decorative sketches and in many ornamental drawings that make use of the negative form, an effect attainable also by tinting the blank planes.

**Relationship between drawing and other art forms.** The bond between drawing and other art forms is of course very close, because the preliminary sketch was for a long time the chief purpose of the drawing. A state of mutual dependence exists in particular between painting and drawing, above all, in the case of sketches and studies for the composition of a picture. The relationship is closest with preliminary sketches of the same size as the original, the so-called cartoons whose contours were pressed through or perforated for dyeing with charcoal dust. Once transferred to the painting surface, the sketch had served its purpose.

On autonomous sheets, too, the close connection between drawing and painting is evidenced by the stylistic features that are common to both. Drawing and painting agree in many details of content and form. Measurements; proportions of figures; relationship of figure to surrounding space; the distribution of the theme within

the composition according to static order, symmetry, and equilibrium of the masses or according to dynamic contrasts, eccentric vanishing points, and overaccentuation of individual elements; rhythmic order in separate pictorial units in contrast to continuous flow of lines—all of these formal criteria apply to both art forms. The uniform stylistic character shared by drawing and painting is often less severely expressed in the former because of the spontaneous flow of the unfettered artist's stroke, or "handwriting," and of the struggle for form as recorded in the pentimenti (indications in the drawing that the artist had changed his mind and drawn over his original formulation). Furthermore drawing can stimulate certain aspects of movement more easily than painting can through the rhythmic repetition of a contour or the blended rubbing of a sharp borderline.

Still closer, perhaps, is the bond between drawing and engraving, which works with the same artistic means, with monochrome linearity as its main formal element and with various tone and plane methods closely related to those of drawing.

Drawing is more independent than sculpture because sculpture uses a three-dimensional model. As a result, sculptors' drawings can always claim a greater degree of autonomy. (For the special position of the architectural sketch, see *Subject matter of drawing* below.)

#### SURFACES, MEDIUMS, AND TECHNIQUES

**Types of ground.** One can draw on practically anything that has a plane surface (it does not have to be level); for example, papyrus and parchment, cloth, wood, metals, ceramics, and even walls, glass, and sand. (With some of these, to be sure, another dimension is introduced through indentations that give the visual effect of lines.) Ever since the 15th century, however, paper has been by far the most popular ground.

The technique of paper manufacturing, introduced from East Asia by the Arabs, has remained virtually unchanged for the past 2,000 years. A fibrous pulp of mulberry bark, hemp, bast, and linen rags is drained, pressed, and dried in fiat molds. The introduction of wood pulp in the mid-19th century, which enabled manufacturers to satisfy the enormously increased demand for bulk paper, did not affect art paper because paper of large wood content yellows quickly and is therefore ill-suited for art drawing. The essential preparation of the paper to give it a smooth and even surface for writing or drawing was once done by rubbing it with bone meal, gypsum chalk, or zinc and titanium white in a very thin solution of glue and gum arabic. The proper priming, achieved through repeated rubbing and polishing, was of the utmost importance, especially for metalpoint drawings. If such preparation is too weak, the paper accepts the stroke badly; if it is too strong, the coating cracks and chips under the pressure of the hand. Since the early 15th century, however, the sheets have been given the desired smooth and nonabsorbent consistency by dipping them in a glue or alum bath. The addition of glue also made it possible to impart to the pulp paper a quality that permitted pen drawings. Pigments, too, could of course be added to the pulp, and the so-called natural papers—chiefly blue and called Venetian papers after the centre of the retail trade in this commodity—became more and more popular. While the 17th century liked half tints of blue, grey, brown, and green, the 18th preferred warm colours such as ivory and beige, along with blue. Since the 18th century, paper has been manufactured in all conceivable colours and half tones.

The range of quality has also greatly increased since the end of the 18th century to give more painstakingly produced drawing papers. Even in earlier times, the absorbent Japan paper made of mulberry bark enjoyed great popularity. Handmade paper, stronger and free of wood, with an irregular edge, has remained to this day a favourite surface for drawings. Vellum, delicate and without veins, resembles parchment in its smooth surface. Modern watercolour paper is a pure linen paper glued in bulk and absolutely free of fat and alum; its two surfaces are of different grain. For pastel drawings, a firm, slight-

ly rough surface is indicated, whereas pen drawings are best done on a very smooth paper.

Granulated and softer drawing tools, such as charcoal, chalk, and graphite are not as dependent on a particular type of paper; but, because of their slight adhesiveness, they often require a stronger bond with the foundation as well as some form of surface protection. This process of fixing was formerly done through repeated varnishing with gum-arabic solution and even with glue or egg-white emulsion. Modern siccatives (drying substances) inhibit discoloration but cannot prevent the living surface from appearing sealed, as it were, under a skin. In pastels especially, the manifold prismatic effects of finely powdered coloured crayons are thus lost, and the bright and airy surface is turned into an amorphous, heavy layer. Pastels, which brush off easily, are therefore best preserved under glass.

**Tools and techniques.** Such varied tools as slate pencils, charcoal, metal styli, and chalks may be used for drawing as well as all writing utensils, including pens, pencils, and brushes; indeed, even chisels and diamonds are used for drawing. Dry drawing tools differ in effectiveness from liquid ones because it is not irrelevant from the artistic point of view whether one uses a self-drawing medium that permits an evenly flowing line dependent only on hand pressure or a transferring tool that must be put down periodically and refilled with resultant differences in the strength and concentration of the line. Modern drawing mediums that combine both possibilities, such as fountain pens, ball-point pens, and felt pencils, are recent inventions.

No less varied than the nature and composition of these drawing mediums is their aesthetic effect. It would nevertheless be wrong to systematize the art of drawing on the basis of the techniques applied; not only does almost every technique have several applications but it can also be combined with other techniques, and the draftsman's temperament inevitably plays a role as well. Even if certain techniques predominate in certain periods, the selection of drawing mediums depends on the intended effect and not vice versa. Artists have always been able to attain the desired effect with a variety of techniques. Dry mediums, for example, are predestined for clear lines, liquid ones for plane application. Yet extremely fine strokes can also be made by brush, and broad fields can be marked in with pencil or crayon. Some mediums, including charcoal, one of the oldest, if not the oldest of all, allow both extremes.

**Charcoal.** In every hearth or fireplace, partially consumed pieces of wood remain that can be used as a convenient tool for drawing. Evidence of charcoal sketches for mural, panel, and even miniature paintings can still occasionally be seen under the pigment. Drawing charcoal produced from wood that is as homogeneous as possible gives a porous and not very adhesive stroke. The pointed charcoal pencil permits hair-thin lines; if used broadside on the surface, it creates evenly toned planes. Rubbing and pulverizing the charcoal line results in dimmed intermediate shades and delicate transitions. Because of its slight adhesiveness, charcoal is eminently suited to corrective sketching; but if the drawing is to be preserved, it must be protected by a fixative.

As a medium for quick, probing sketches and practice in studying models, charcoal was once much used in all academies and workshops. The rapid notation of difficult poses, such as Tintoretto demanded of his models, could be done quickly and easily with the adaptable charcoal pencil. While some of these sheets were deemed worthy of preservation, hundreds have surely been lost.

Charcoal has often been used for portrait drawings to preserve for the eventual painting pictorial tints that were already present in the preliminary sketch. When destined to be autonomous portraits, charcoal drawings are executed in detail; with their sharp accents and delicate modelling, such portraits cover the whole range of the medium. In "Portrait of a Lady," by the 19th century French painter Edouard Manet, the grain of the wood in the chair, the fur trimming on the dress, the compactness of the coiffure, and the softness of the flesh are all ren-

dered in the same material: charcoal. Popular as that material was for studies and sketches, it has been used for independent drawings destined for preservation by only a few artists; for example, the 17th-century Dutch painter Paulus Potter. It is somewhat more frequent among the great draftsmen of the 19th and 20th centuries, such as Edgar Degas, Henri de Toulouse-Lautrec, Kathe Kollwitz, and Ernst Barlach.

Oiled charcoal, with the charcoal pencils dipped in linseed oil, provides better adhesion and a deeper black. Used in the 16th century by Tintoretto, this technique was applied above all by the Dutch draftsmen of the 17th century in order to set deep-black accents. The advantage of better adhesion in the indentations of the paper in contrast to dry charcoal, which sticks to the elevations, has to be paid for, however, by "incurability"; i.e., correction cannot be made. In addition, charcoal crayons that have been deeply dipped in oil show a brownish streak left by the oil alongside the lines.

**Chalks.** The chalks, which resemble charcoal pencils in outward appearance, are an equally important drawing medium. If charcoal was primarily a medium for quick sketching that could be corrected and for the search for artistic form, chalk drawing, which can also fulfill all of these functions, has steadily gained in importance as an autonomous vehicle of expression. Since the end of the 15th century, stone chalk, as found in nature, has become increasingly more significant in art drawing. As a basic material, alumina chalk has various degrees of hardness, so that the stroke varies from slightly granular to homogeneously dense and smooth.

The attempt to produce a crayon or pencil of the greatest possible uniformity has led to the production of special chalks for drawing; that is, chalks, which, after being pulverized, washed, and molded into convenient sticks, allow a softer and more regular stroke and are also free of sandy particles. The admixture of pigments (carbons in the case of black chalks) creates various tints from a rich black to a brownish gray; compared to the much-used black chalk, the brown variety is of little significance. White chalk, also found in nature, is rarely employed as an independent medium for drawing, although it is frequently used in combination with other mediums in order to achieve reflections of light as individual accents of plastic modelling.

Beginning with the 15th century, chalk has been used

"Head of Girl" (study for "The Virgin of the Rocks," 1483), silverpoint on light brown paper by Leonardo da Vinci. In the Biblioteca Reale, Turin, Italy. 18.2 X 15.9 cm.

Pen and ink, chalk, silverpoint, and wash drawings

"An Island in the Lagoon," pen, brown ink, and carbon ink wash over ruled pencil lines by Canaletto (1697–1768). In the Ashmolean Museum, Oxford, England. 18.3 X 27.8 cm.

Study probably for "L'Indifferent," black, red, and white chalk on yellowish-gray paper by Jean-Antoine Watteau (1684–1721). In the Museum Boymans-van Beuningen, Rotterdam. 27.2 X 19 cm.

"Madonna with Many Animals," pen, ink, and watercolour by Albrecht Durer, c. 1503. In the Albertina, Vienna. 32.1 X 24.3 cm.

"Le Château Noir," pencil and watercolour by Paul Cézanne, c. 1895–1900. In the Museum Boymans-van Beuningen, Rotterdam. 36 × 52.6 cm.

**Crayon, pencil, sepia, and pastel drawings**

"The Dancers," pastel on paper by Edgar Degas, 1899. In the Toledo Museum of Art, Ohio. 62 × 64.5 cm.

"Trees and a Stretch of Water on the Stour," pencil and sepia wash by John Constable (1776–1837). In the Victoria and Albert Museum, London. 16.2 × 20.3 cm.

"Two Women III," crayon on paper by Willem de Kooning, 1952. In the Allen Memorial Art Museum, Oberlin College, Ohio. 37.5 × 47 cm.

increasingly for studies and sketches. Its suitability for drawing exact lines of any given width and also for laying on finely shaded tints makes it particularly appropriate for modelling studies. Accents that stress plastic phenomena are applied by varying the pressure of the hand. Characteristic details in portrait drawings in particular can be brought out in this manner. Pictorial values as well as light and shadow effects can be rendered with chalk without losing their firm, plastic form. For the same reason, chalk is also most valuable in sketching out paintings and indicating their values.

All of these qualities explain why chalk is such a good medium for autonomous drawings. Indeed, there is scarcely a draftsman who has not worked in chalk, often in combination with other mediums. Aside from portrait drawings done all over the world, landscapes have formed the main theme of chalk drawings, especially with the Dutch, in whose art landscape drawings have played a large role. Ever since the invention of artificial chalk made of lampblack (a fine, bulky, dull-black soot deposited in incomplete combustion of carbonaceous materials), which possesses a precisely measurable consistency—an invention ascribed to Leonardo da Vinci—the pictorial qualities of chalk drawing have been fully utilized. Chalks range from those that are dry and charcoal-like to the fatty ones used by lithographers.

Another very important drawing pencil is similarly a chalk product: the red pencil, or sanguine, which contains ferric oxide, which occurs in nature in shadings from dark brown to strong red and can also be manufactured from the same aluminum-oxide base with ferric oxide or rust added. Besides the stronger pictorial effect possible because of its chromatic value, sanguine also possesses a greater suppleness and solubility in water. Thus, a homogeneous plane can be created through moist rubbing, a compact stroke through liquid linear application, a very delicate tone through light wiping. Although this oxide was used for red tints in prehistoric painting, sanguine does not seem to have acquired artistic dignity until the 15th century, when it became customary to fix drawings by painting them over with a gum solution, for sanguine has no more adhesiveness than charcoal. In the 15th century, sanguine was a popular drawing medium because of its wealth of pictorial possibilities. Those inclined to be colorists—such as the portraitists Jean Clouet and Hans Holbein, the Flemish painters around Peter Paul Rubens, and, above all, the French artists of the 18th century—particularly favoured it. The possibilities of sanguine range from suggestive forms with markedly plastic values to a very pictorial, soft rendition of visual surface stimuli.

A combination of various chalks offers still richer coloristic possibilities. Black chalk and sanguine have been widely used since the 16th century to achieve colour differentiation between flesh tones, hair, and the material of garments. The combination of black and white chalk serves plastic modelling, as does that of the softer sanguine with white chalk; in the former case, the accentuation rests with the black, in the latter, with the more suggestive delineation in white.

A decidedly coloristic method lies in the combination of various chalk colours with one another and with tinted paper. Such pictorially executed sheets, called *à deux crayons* (with two colours) and *à trois crayons* (with three colours), respectively, were especially popular in 17th- and 18th-century France. Antoine Watteau reached a previously unheard of harmony of different chalks on natural paper. With the three colours, Nicolas Lancret, Jean-Btienne Liotard, Jacques-André Portail, François Boucher—to name but a few such artists—achieved sensitive drawings that are very appealing coloristically.

An additional colour refinement is made possible with pastel crayons. An ample selection of dry colour pigments in pastel crayons, prepared with a minimum of agglutinants and compounded with different shades of white for the articulation of tints, is commercially available. The colours can be laid on in linear technique directly with the crayons, but an area application made with a piece of soft suede or directly, with the fingers, is

more frequent. Although this technique was known to the Accademia degli Incamminati (to the painter Guido Reni, for example) as early as the 17th century, it did not reach its flowering until the 18th century, especially in France (with Jean-Marc Nattier and Jean-Baptiste-Siméon Chardin) and in Venice (with Rosalba Carriera). Pastel chalks are particularly favoured for portraits; their effect approximates that of colour-and-area painting rather than line drawing.

In the 19th and 20th centuries, Degas reverted to a stronger accentuation of the delineatory aspects of drawing. With intermediate varnishes he achieved an overlay drawing with different colours and thus an increased emphasis on individual strokes. This technique, fundamentally different from the older one, was imitated with minor variations by Odilon Redon, Gustave Moreau, Jean-Edouard Vuillard, Pierre Bonnard, and others. It has also been borrowed by such Expressionist artists as Edvard Munch and Ernst Ludwig Kirchner.

Modern grease chalks offer a chromatic scale of similar range. Developed originally for such technical purposes as the lettering of very smooth surfaces, such as metal or glass, they can be applied in the same flat manner as pastels, although with the opposite aesthetic effect: that of compact colours. It was the 20th-century English sculptor Henry Moore who first and convincingly exploited the feasibility of continuing, with other mediums, such as pen or watercolour, work on the firm surface that had been led out with grease chalks.

**Metalpoints.** Metalpoints have been used for writing and delineation ever since the scriptoria of antiquity. It required little imagination to employ them also in drawing. The most frequently used material was soft lead, which on a smooth surface comes out pale gray, not very strong in colour, and easily erasable but very suitable for preliminary sketches. Aside from lead, tin and copper were also used, as well as sundry lead-and-pewter alloys. The 15th-century Venetian painter Jacopo Bellini's book of sketches in London with leadpoint drawings on tinted paper, is a particularly valuable example of this technique, even if individual portions and, indeed, entire pages that had become effected were drawn over long ago. One can see little more than the traces left by the pencil because, as in many other metalpoint drawings, the sketches were redrawn in another medium. Botticelli, for example, sketched with a leadpoint the outline of his illustrations to Dante's *Divine Comedy*, retracing them afterward with the pen. Metalpoints were used into the 18th century for perspectivist constructions and auxiliary delineation, especially in architectural drawings.

More suited to permanent drawing is the silverpoint, which requires special preparation of the foundation and, once applied, cannot be corrected. Its stroke, also pale gray and mostly oxidized by now into brown, adheres unerasably. Silverpoint drawings accordingly require a clearer concept of form and a steady hand because corrections remain visible. Because too much pressure can bring about cracks in the foundation, the strokes must be even; emphases, modelling, and light phenomena must be rendered either by means of dense hachures, repetitions, and blanks or else supplemented by other mediums. Despite these difficulties, silverpoint was much used in the 15th and 16th centuries. Dürer's notebook on a journey to Holland shows landscapes, portraits, and various objects that interested him drawn in this demanding technique. Silverpoint was much in demand for portrait drawings from the 15th into the 17th century; revived in the 18th-century Romantic era, it is still occasionally used by modern artists.

**Graphite point.** Toward the end of the 16th century, a new drawing medium was introduced and soon completely displaced metalpoint in sketching and preliminary drawing: the graphite point. Also called Spanish lead after its chief place of origin, this drawing medium was quickly and widely adopted; but because of its soft and smeary consistency it was used for autonomous drawings only by some Dutch painters, and even they employed it mostly in conjunction with other points. (It might be added that the graphite point was originally taken for a

metal because its texture shines metallically in slanting light.) The lead pencil, or more properly *crayons Conté*, became established in art drawing after Nicolas-Jacques Conté invented, around 1790, a manufacturing process similar to that used in the production of artificial chalk. Purified and washed, graphite could henceforth be made with varying admixtures of clay and in any desired degree of hardness. The hard points, with their durable, clear, and thin stroke layers, were especially suited to the purposes of Neoclassicist and Romantic draftsmen. The Germans working in Rome, in particular, took advantage of the chance to sketch rapidly and to reproduce, in one and the same medium, subtle differentiations as well as clear proportions of plasticity and light. Among the most masterful pencil artists of all was Ingres, who pre-sketched systematically in pencil the well-thought-out structure of his paintings.

The more pictorially inclined artists of the late 19th century, such as Ferdinand Delacroix, preferred softer pencils in order to throw into plastic relief certain areas within the drawing. Seurat, on the other hand, reached back to graphite in his drawings from the concert cafés, among them "Au concert européen" (Museum of Modern Art, New York) in which he translated the *pointillistic* technique (applying dots of colour to a surface so that from a distance they blend together) into the monochrome element of drawing. Pencil frottage (rubbing made on paper laid over a rough surface), first executed by the Surrealist artist Max Ernst, represents a marginal kind of drawing.

*Coloured crayons.* Coloured crayons, in circulation since the later 19th century, offer all the possibilities of black graphite points; and, in combinations, they attain a stronger colour value than chalks because they do not merge with one another. Every line preserves its original and characteristic colour, a form of independence that Gustav Klimt and Picasso exploited to the full.

*Incised drawing.* A role apart is that played by incised drawings. Their pronounced linearity gives them the visual appearance of other drawings; materially, however, they represent the opposite principle, that of subtracting from a surface rather than adding to it. Incised drawings

are among the oldest documents of human activity. In primitive African cultures, the methods and forms of prehistoric bone and rock drawings have survived into the present. In a decorative and conceivably also symbolic form, incised decorations on pottery have existed for thousands of years; insofar as the comparison is valid, they correspond in every formal respect to applied drawings of the same period. A formal equivalent may also be observed in later times: in the decorative details of implements, especially metal—from the drawings on Greek mirrors, through the jewelry made at the end of the Roman Empire, to the scenes on medieval weapons and, above all, on Renaissance dress armour. More often than not these are drawings that follow certain models rather than free drawings in the sense of sketches.

Logically, one would also have to consider all *niello* work under the heading of drawing, because the picture in this case is cut out of the metal and filled with a deep black-coloured paste so that it appears to the eye as a linear projection on a plane. In like manner, work with the graver or burin (cutting tools) and with the etching needle on the engraving plate may be considered to parallel in its execution that gradual effort applied directly to the carrier that was defined earlier as the art of drawing. The difference lies in the fact that this work is not a goal in itself but the prerequisite for a printing process that is intended to be repetitive.

*Brush, pen, and dyestuffs.* Of the many possibilities of transferring liquid dyestuffs onto a plane, two have become particularly significant for art drawing: brush and pen. To be sure, finger painting, as found in prehistoric cave paintings, has occasionally been practiced since the late Renaissance and increasingly so in more recent times. For drawing as such, however, the method is irrelevant. Similarly, the use of pieces of fur, frayed pieces of wood, bundles of straw, and the like is more significant as a first step toward the camel's-hair brush than as indication that these objects were ever drawing mediums in their own right. Although it is antedated by the brush, which in some cultures (East Asia, for example) has remained in continued use, the pen has been the favorite writing and drawing tool ever since classical antiquity.

"The Prophet Jonah Before the Walls of Nineveh," by Rembrandt, reed pen in bistre with wash, c. 1654–55. In the Albertina, Vienna. 21.7 X 17.3 cm.

#### The reed pen

The principle of transferring dyestuffs with the pen has remained virtually unchanged for thousands of years. The capillary effect of the split tip, cut at a slant, applies the drawing fluid to the surface (parchment, papyrus, and, since the late Middle Ages, almost exclusively paper) in amounts varying with the saturation of the pen and the pressure exerted by the drawing hand. The oldest form is that of the reed pen; cut from papyrus plants, sedge, or bamboo, it stores a reservoir of fluid in its hollow interior. Its stroke—characteristically powerful, hard, and occasionally forked as a result of stronger pressure being applied to the split tip—became a popular medium of artistic expression only with the rise of a subjective view of the artist's personality during the Renaissance. Rembrandt made superb use of the strong, plastic accents of the reed pen, supplementing it as a rule with other pens or brushes. Beginning in the 19th century with the Dutch artist van Gogh, pure reed-pen drawings with a certain forcefulness of expression have been created by all artists. Expressionists such as George Grosz used the reed pen frequently.

If the selection of the reed pen already implies a formal statement of sorts, that of the quill pen opens up a far wider range of possibilities. Ever since the rise of drawing in Western art—that is, since the late Middle Ages—the quill has been the most frequently used instrument for applying liquid mediums to the drawing surface. The importance accorded to this tool is attested by the detailed instructions in painters' manuals about the fashioning of the pen from wing shafts of geese, swans, and even ravens. The supple tip of the quill, available in varying strengths, permits a relatively wide scale of individual strokes—from soft, thin lines, such as those used in preliminary sketches for illustrations in illuminated books, through waxing and waning lines that allow differentiation within the stroke, to energetic, broad lines. It was only when metal pens began to be made of high-grade steel and in different strengths that they became a drawing implement able to satisfy the demands made by the individual artist's hand.

Although all dyestuffs of low viscosity lend themselves to pen drawing, the various inks are most often employed. The manufacture of gallnut ink had been known from the medieval scriptoria, copying rooms set apart for scribes in monasteries. An extract of gallnuts mixed with

iron vitriol and thickened with gum-arabic solution produces a writing fluid that comes from the pen black, with a strong hint of purple violet, and dries almost black. In the course of time it turns a darkish brown, so that the writing fluid in old manuscripts and drawings cannot always be identified by the colour alone. In contrast to other brown writing fluids, the more strongly coloured parts of gallnut ink remain markedly darker; and because inks of especially great vitriol content decompose the paper, the drawing, particularly in its more coloured portions, tends to shine through on the reverse side of the sheet. Only industrially produced chemical inks possess the necessary ion balance to forestall this undesirable effect.

Another ink, one that seems to have found no favour as a writing fluid but has nonetheless had a certain popularity in drawing, is bistre, an easily dissolved, light-to-dark-brown transparent pigment obtained from the soot of the lampblack that coats wood-burning chimneys. Its shade depends both on the concentration and on the kind of wood from which it is derived, hardwoods (especially oaks) producing a darker shade than conifers, such as pine. During the pictorially oriented Baroque period, in the 17th and early 18th centuries the warm tone that can be thinned at will made bistre a popular medium with which to supplement the planes of a pen drawing.

Also derived from a carbon base is India ink, made from the soot of exceptionally hard woods, such as olive or grape vines, or from the fatty lampblack of the oil flame, with gum-arabic mixed in as a binding agent. This deep-black, thick fluid preserves its dark tone for a long time and can be thinned with water until it becomes a light gray. Pressed into sticks or bars, it was sold under the name of Chinese ink or India ink. This writing fluid, known already in Egypt and used to this day in China and India, has been manufactured in Europe since the 15th century. Favoured in particular by German and Dutch draftsmen because of its strong colour, it lent itself above all to drawing on tinted paper. Since the 19th century, India ink has been the most popular drawing ink for pen drawings, replacing all other dyestuffs in technical sketches. Only very recently have writing inks gained some significance in art drawing—in connection with the practical fountain pen.

Chinese  
or India  
ink

For a relatively short time, a dyestuff of animal origin, sepia, obtained from the pigment of the cuttlefish, was used for drawing. Known ever since Roman times, it did not come into more general use until the 18th century. Compared to yellowish bistre, it has a cooler and darker tone, and is brown with a trace of violet. Until the 18th century, it was employed by such amateur painters as the German poet Johann Wolfgang von Goethe because of its effectiveness in depth; as a primary pigment, however, it has been completely replaced by industrially manufactured watercolours.

Other dyestuffs are of only minor importance compared with these inks, which are primarily used for pen drawings. Minium (red lead) was used in the medieval scriptoria for the decoration of initial letters and also in illustrated pen drawings. Chinese white is easier to apply with a pointed brush because of its thickness; other pigments, among them indigo and green copper sulphate, are rarely found in drawings. For them, too, the brush is a better tool than the pen. The systematically produced watercolours of various shades are almost wholly restricted to technical drawings.

In combination with written texts, pen drawings are among the oldest artistic documents. Already in classical times, texts were illustrated with firm contours and sparse interior details. During the Middle Ages, marginal drawings and book illustrations were time and again pre-sketched, if not definitively executed, with the pen. In book painting, decidedly delineatory styles developed in which the brush was also employed in the manner of a pen drawing: for example, in the Carolingian school of Reims, which produced the Utrecht Psalter in the 9th century, and also in southern Germany, where a separate illustrative form with line drawings was widespread with the *Biblia Pauperum* ("Poor People's Bibles," biblical picture books used to instruct large numbers of people

in the Christian faith). The thin-lined outline sketch is also characteristic of the earliest individual drawings of the late Middle Ages and early Renaissance. Sketches after ancient sculptures or after nature as well as compositions dealing with familiar motifs form the main themes of these drawings. Such sheets were primarily used as models for paintings; gathered in sketchbooks, they were often handed on from one generation to the next. The practical usefulness of these drawings is attested by the supplements added to them by younger artists and by the fact that many metalpoint drawings that had become hard to decipher were redrawn with the pen, as shown by the sketchbooks of the 15th-century Italian artist Antonio Pisanello, now broken up and preserved in several different collections.

In the 16th century, the artistic range of the pen drawing reached an individual articulation that it hardly ever attained again. Every artist was free to exploit with the pen the formal possibilities that corresponded to his talents. Thus Leonardo used a precise stroke for his scientific drawings; Raphael produced relaxed sketches, in which he probed for forms and variations of form; Michelangelo drew with short strokes reminiscent of chisel work; Titian contrasted light and dark by means of hachures laid broadly over the completed figures. Among the Northerners, Dürer mastered all the possibilities of pen drawing, from quick notation to the painstakingly executed autonomous drawing, ranging from a purely graphic and delineatory technique to a spatial and plastic modelling one; it is no wonder that he stimulated so many other artists. The subjective attitude of the later 16th century is often expressed more clearly in Mannerist drawings—characterized by spacial incongruity and excessive elongation of the human figures, which are as revelatory of the artist's personality as handwriting—than it is in completed works of painting and sculpture. A special form of exact drawing is found in models for

engravings; some of these were directly mounted on the wood block; some anticipate the style of the copperplate engraving in the pen-drawing stage, with waxing and waning lines, delicate stroke layers, and cross-hatching for spatial and plastic effects.

In the 17th century, the pen drawing took second place to combined techniques, especially wash, a sweep or splash of colour, applied with the brush. An open style of drawing that merely hints at contours, along with contrasting thin and powerful strokes, endowed the line itself with expressive qualities. In his numerous drawings, Rembrandt in particular achieved an exceedingly subtle plastic characterization and even light values through the differentiation of stroke layers and the combination of various pens and brushes.

Additional techniques came to the fore in the 18th century, with the pen sketch providing the scaffold for the drawing that was carried out in a pictorial style. Only decorative sketches and practical studies were laid out more often as linear drawings.

The closed, thin-contour drawing regained its importance with Neoclassicism at the end of the 18th century. The Nazarenes (the nickname of the Lucas Brotherhood—later Guild of St. Luke, who lived in monastic style) and Romantics consciously referred to the early-Renaissance manner of drawing, modelling with thin lines. With closed contours, carefully set hair-and-shadow strokes, and precise parallel hachures, they attained plastic values by purely graphic means.

This technique was again followed by a more pictorially oriented phase, culminating in the late 19th century in the recognition of drawing as the most immediate and personal expression of the artist's hand. The pure pen drawing took its place by the side of other highly esteemed art forms. The English Art Nouveau artist Aubrey Beardsley at the end of the 19th century applied the direct black-white contrast to planes, while in the 20th

century the French masters Henri Matisse and Picasso reduced the object to a mere line that makes no claim to corporeal illusion. A large number of illustrators, as well as the artists who draw the comic strips, prefer the clear pen stroke. In the Russian artist Wassily Kandinsky's nonrepresentational compositions, finally, the independence of the line as an autonomous formal value became a new theme in drawing. In the hair-thin automatist seismograms (so-called because of their resemblance to the records of earthquakes) of the 20th-century German artist Wols (Alfred Otto Wolfgang Schulze), which are sensitive to the slightest stirring of the hand, this theme leads to a new dimension transcending all traditional concepts of a representational art of drawing.

The use of a brush in drawing considerably antedates that of the pen; in some cultures, notably in East Asia, the brush is still the most popular writing tool. Although it is best suited to the flat application of pigments—in other words, to painting—its use in a clearly delineatory function, with the line dominating and (a crucial property of brush drawing) in monochrome fashion, can be traced back to prehistoric times.

All of the above-mentioned drawing inks have been used as dyes in brush drawings, often with one and the same pigment employed in combined pen-and-brush work. Still greater differentiation in tone is often obtained through concentrated or thinned mediums and with the addition of supplementary ones. To the latter belong chiefly distemper, a paint in which the pigments are mixed with an emulsion of egg or size or both, and watercolours, which can be used along with bistre and drawing ink. Even oils can sometimes be used for individual effects in drawing, as in the works of the 17th-century Flemish painter Jacob Jordaens.

Sinopia, the preliminary sketch for a monumental wall painting, was done with the brush and has all the characteristics of a preparatory, form-probing drawing. The sketch was carried out directly on the appropriate spot and covered over with a thin layer of plaster, on which the pictorial representation was then painted.

The brush drawing differs from the pen drawing by its greater variation in stroke width, and by the stroke itself, which sets in more smoothly and is altogether less severely bordered. Early brush drawings nonetheless show a striking connection with the technique of the pen drawing. The early examples of the 15th century completely follow the flow of contemporaneous pen drawings. Leonardo's or Diirer's pen drawings, with their short, waxing and waning stroke layers, refine the system of pen drawing; many 16th-century artists used a comparable technique. The brush drawing for chiaroscuro sheets on tinted paper was popular because Chinese white, the

main vehicle of delineation in this method, is more easily applied with the brush than the pen and because the intended pictorial effect is more easily attained, thanks to the possibility of changing abruptly to a plane representation.

Such representations are particularly distinctive as done by Vittore Carpaccio and Palma il Giovane in Venice and in a Mannerist spotting technique used by Parmigianino. In the 16th century, the brush nevertheless played a greater role as a supporting than as independently form-giving instrument. Pure brush drawings were rare even in the 17th century, although the brush played a major role in landscapes, in which, by tinting of varying intensity, it ideally fulfilled the need to provide for all desired degrees of spatial depth and strength of lighting. Some Dutchmen, such as Adriaen Brouwer, Adriaen van Ostade, and Jan Steen, transcended the limits of drawing in the narrower meaning of the term by doing brushwork limited to a few tones within a monochrome scale, giving the impression of a pictorial water-colour.

Although the coloristically inclined 18th century was little interested in the restriction to a few shadings within one colour value, Jean-Honoré Fragonard raised this technique to perfection, with all its possibilities of sharply accented contours, soft delineation, delicate tones, and deep shadows. The brush drawings of the Spanish painter Francisco Goya must also be counted among the

"Three Men Digging," by Francisco de Goya (1746-1828), brush drawing in sepia. In the Metropolitan Museum of Art, New York. 21 × 14 cm.

great achievements of this technique. In his strong plastic effects, the English painter George Romney made the most of the contrast between the white foundation and the broad brushstrokes tinted in varying intensities. Other English artists, among them Alexander Cozens, John Constable, and J.M.W. Turner, took advantage of the delicately graded pictorial possibilities for their landscape studies.

In the 19th century, the French artists Théodore Géricault, Eugène Delacroix, and Constantin Guys still followed the character of the brush drawing, even though it was already being replaced by the variegated water-colour and gouache painting, a method of painting with opaque colours that have been ground in water and mingled with a preparation of gum. In modern drawing, the brush has regained some importance as an effective medium for contrasting planes and as carrier of the

theme; in this, the dry brush has proven itself a useful tool for the creation of a granular surface structure.

The combination of various techniques plays a greater role in drawing than in all other art forms. Yet it is necessary, in the numerous drawings in which two or more mediums are involved, to distinguish between those in which the mediums were changed in the course of artistic genesis and those in which an artistic effect based on a combination of mediums was intended from the beginning.

In the first case, one is confronted with a preliminary sketch, as it were, of the eventual drawing: the basic structure with some variations is tried out in charcoal, chalk, metalpoint, pencil, or some other (preferably dry and easily corrected) material and then carried out in a stronger and more durable medium. Most pen drawings are thus superimposed on a preliminary sketch. The different materials actually represent two separate stages of the same artistic process.

More relevant artistically is the planned combination of different techniques that are meant to complement each other. The most significant combination from the stylistic point of view is that of pen and brush, with the pen delineating the contours that denote the object and the brush providing spatial and plastic as well as pictorial—that is, colour—values. The simplest combined form is manuscript illumination, where the delineated close contours are filled in with colour. The drawing may actually be improved if this is done by a hand other than the draftsman's or at a later time.

More important is brushwork that supplements linear drawing, in which entire segments may be given over to one technique or the other; for example, the considerable use of white (which is hard to apply with the pen) in drawings on tinted paper. In similar complementary fashion the brush may be used for plastic modelling as a way of highlighting, that is indicating the spots that receive the greatest illumination. The technique of combined pen-and-brush drawing was favored by the draftsmen of Germany and the Netherlands, especially in the circle around Diirer and the south German Danube School. Shadows, too, can be inserted in a drawing with dark paint. The illusion of depth can also be achieved with white and dark colours in a pure chalk technique.

In contrast to these methods, which still belong to a linear system of drawing, is the flat differentiation of individual segments of a work in (usually) the same medium: wash. Various bodies and objects are evenly tinted with the brush within or along the drawn contours. Planes are thus contrasted with lines, enhancing the illusionary effect of plasticity, space, and light and shadow. This modelling wash has been used again and again since the 16th century, sometimes in combination with charcoal, chalk, or pencil drawings. A further refinement, used particularly in landscape drawings, is wash in varying intensities; additional shadings in the sense of atmospheric phenomena, such as striking light and haze merging into fog and cloud, can be rendered through thinning of the colour or repeated covering over a particular spot. A chromatic element entered drawing with the introduction of diluted indigo, known in the Netherlands from the East India trade; it is not tied to objects but used in spatial and illusionist fashion, by Paul Brill and Hans Bol in the 16th and 17th centuries, for example. The mutual supplementation and correlation of pen and brush in the wash technique was developed most broadly and consistently in the 17th century, in which the scaffold, so to speak, of the pen drawing became lighter and more open, and brushwork integrated corporeal and spatial zones. The transition from one technique to the other—from wash pen drawings to brush drawings with pen accents—took place without a break. Claude Lorrain and Nicolas Poussin in 16th- and 17th-century France are major representatives of the latter technique, and Rembrandt once again utilized all its possibilities to the full.

Whereas this method served—within the general stylistic intentions of the 17th century—primarily to elucidate spatial and corporeal proportions, the artists of the 18th

century employed it to probe this situation visually with the aid of light. The unmarked area, the spot left empty, has as much representational meaning as the pen contours, the lighter or darker brush accent, and the tinted area.

The art of omission plays a still greater role, if possible, in the later 19th century and in the 20th. Paul Cézanne's late sheets, with their sparse use of the pencil and the carefully measured out colour nuances, may be considered the epitome of this technique. As the colouring becomes increasingly varied through the use of watercolours to supplement a pen or metalpoint drawing, one leaves the concept of drawing in the strict sense of the term. According to the quality and quantity of the mediums employed, one then speaks of "drawings with watercolour," "watercoloured drawings," and "watercolours on preliminary drawings." The predominant stroke character, rather than the fact that paper is the carrier, is the chief feature when deciding whether or not the work may legitimately be called a drawing.

The combination of dry and fluid drawing mediums provides a genuine surface contrast that may be exploited for sensuous differentiation. Here again a distinction must be made between various ways of applying the identical medium—for example, charcoal and charcoal dust in a water solution or, more frequently, sanguine and sanguine rubbed in with a wet brush—and the stronger contrast brought about by the use of altogether different mediums. Chalk drawings are frequently washed with bistre or watercolour, after the principle of the washed pen drawing. Stronger contrasts, however, can be obtained if the differing techniques are employed graphically, as the Flemish draftsmen of the 17th century liked to do. The Chinese ink wash of chalk drawings also contributes to the illusion of spatial depth. Along with such Dutch painters as Jan van Goyen and members of the family van de Velde, Claude Lorrain achieved great mastery in this technique. The differentiated treatment of the foreground with pen and brush and the background with chalk renders spatial depth plausible and plastic. In modern art, the use of different mediums—whether for plastic differentiation, such as Henry Moore carried out with unequalled mastery in his "Shelter Drawings," or only for the purpose of con-

trasting varied surface stimuli of nonrepresentational compositions, as well as the enrichment with colours and even with collage elements (the addition of paper, metal, or other actual objects) broadens the concept of the drawing so that it becomes an autonomous picture the mixed technique of which transcends the borderline between drawing and painting.

**Mechanical devices.** Mechanical aids are far less important for art drawing than for any other art form. Many draftsmen reject them altogether as unartistic and inimical to the creative aspect of drawing.

Apart from the crucial importance that mechanical aids have had and continue to have for all kinds of construction diagrams, plans, and other applied drawings, some mechanical aids have been used in varying but significant measure for artistic drawings. The ruler, triangle, and compass as basic geometric instruments have played a major role especially in periods in which artists created in a consciously constructionist and perspectivist manner. Marks for perspective constructions may be seen in many drawings of early and High Renaissance vintage.

For perspectively correct rendition, the graticulate frame, marked off in squares to facilitate proportionate enlargement or reduction, allowed the object to be drawn to be viewed in line with a screen on the drawing surface. Fixed points can be marked with relative ease on the resultant system of coordinates. For portrait drawings the glass board used into the 19th century, had contours and important interior reference points marked on it with grease crayons or soap sticks, so that they could be transferred onto paper by tracing or direct copying. Both processes are frequently used for preliminary sketches for engravings to be duplicated, as is the screened transmission of a preliminary sketch onto the engraving plate or, magnifying, the painting surface. In such cases the screen lies over the preparatory drawing.

Mirrors and mirror arrangements with reducing convex mirrors or concave lenses were likewise used (especially in the 17th and 18th centuries) as drawing aids in the preparation of reproductions. Even when it was a matter of the most exact rendition of topographical views, such apparatus, as well as the camera obscura (a darkened enclosure having an aperture usually provided with a lens through which light from external objects enters to form an image on the opposite surface), were frequently employed. In a darkened room the desired section is reflected through a lens onto a slanting mirror and from that inverse image is reflected again onto the horizontally positioned drawing surface. Lateral correction can be obtained by means of a second mirror.

Unless the proportions do not allow it, true-to-scale reducing or enlarging can also be carried out with the aid of the tracing instrument called the pantograph. When copying, the crayon or pencil inserted in the unequally long feet of the device reproduces the desired contours on the selected scale.

Most of these aids were thus used in normal studio practice and for the preparation of certain applied drawings. Equally practical, but useful only for closely circumscribed tasks, were elliptic compasses, curved rulers, and stencils, particularly for ornamental and decorative purposes. Only a few present-day artists use stencils or simple blocks with a given shape in larger scale composition, in order to obtain the effect of repetition, often in an arbitrary use, in "alienating" technique and colour.

Mechanically produced drawings such as typewriter sketches, computer drawings, and oscillograms, all of which can bring forth unusual and attractive results, nevertheless do not belong to the topic because they lack the immediate creativity of the art drawing.

#### APPLIED DRAWINGS

Applied and technical drawings differ in principle from art drawings in that they record unequivocally an objective set of facts and on the whole disregard aesthetic considerations. The contrast to the art drawing is sharpest in the case of technical project drawings, the purpose of which is to convey not so much visual plausibility as to give exact information that makes possible the realiza-

tion of an idea. Such plans for buildings, machines, and technical systems are not instantly readable because of the orthogonal (statically independent) projection, the division into separate planes of projection, and the use of symbols. Prepared as a rule with such technical aids as ruler and compass, they represent a specialized language of their own, which must be learned. For topographic (detailed delineation of the features of a place) and cartographic (map-making) drawings, too, a special terminology has developed that above all systematizes spatial representations, making them intelligible to the expert with the aid of emblems and symbols.

Equally far removed from any claim to artistic standing are most illustrations serving scientific purposes, the aim of which is to record as objectively as possible the characteristic and typical features of a given phenomenon. The systematic drawings, used especially in the natural sciences to explain a system or a function, resemble plans; descriptive and naturalistic illustrations, on the other hand, approach the illusionistic plausibility of visual experience and can attain an essentially artistic character. A good many artists have drawn scientific illustrations, and their works—the botanical and zoological drawings of the Swiss Merian family in the 17th and 18th centuries, for example—are today more esteemed for their artistic than for their documentary value.

Of a similarly ambivalent nature is the illustrative drawing that perhaps does not go beyond a simple pictorial rendition of a literary description but because of its specific formal execution may still satisfy the highest artistic demands. Great artists have again and again illustrated Bibles, prayerbooks, novels, and literature of all kinds. Some of the famous examples are Botticelli's illustrations for Dante's *Divine Comedy* and Dürer's marginal illustrations for the emperor Maximilian's prayerbook. Some artists have distinguished themselves more as illustrators than as autonomous draftsmen, as for example the 18th-century German engraver Daniel Chodowiecki, the 19th-century caricaturist Honoré Daumier, the 19th-century satiric artist Wilhelm Busch, and the 20th-century Austrian illustrator Alfred Kubin.

Clearly connected with illustrative drawing is caricature, which, by formally overemphasizing the characteristic traits of a person or situation, creates a suggestive picture that—precisely because of its distortion—engraves itself on the viewer's mind. This special kind of drawing was done by such great artists as Leonardo, Diirer, and the 17th-century artist Gian Lorenzo Bernini and by draftsmen who, often for purposes of social criticism, have devoted themselves wholly to caricaturing, such as the 18th-century Italian Pier Leone Ghezzi, the 19th-century Frenchman Grandville (professional name of Jean-Ignace-Isidore Gérard), and Daumier.

From such overdrawn types developed continuous picture stories that could dispense to a considerable extent with the explanatory text. Modern cartoons are based on these picture stories. Through the formally identical treatment of peculiar types, these drawings acquire an element of consecutiveness that, by telling a continuing story, adds a temporal dimension to two-dimensional drawing. This element is strongest in trick drawings that fix on paper, in brief segments of movement, invented creatures and phenomena that lack all logical plausibility; a rapid sequence of images (leafing through the pages, seeing it projected on the screen) turns the whole into apparent motion. The artistic achievement, if any, lies in the original invention; its actual realization is predetermined and sometimes carried out by a large and specialized staff of collaborators, often with the aid of stencils and traced designs. Moreover, since the final result is partially determined by the mechanical multiplication, an essential criterion of drawing—the unity of work and result—does not apply.

#### SUBJECT MATTER OF DRAWING

Anything in the visible or imagined universe may be the theme of a drawing. In practice, however, by far the greatest number of art drawings in the Western world deal with the human figure. This situation springs from

Mechanically produced drawings

Modern cartoons

the close bond between drawing and painting: in sketches, studies, and compositions, drawing prepared the way for painting by providing preliminary clarification and some formal predetermination of the artist's concept of a given work. Many drawings now highly regarded as independent works were originally "bound," or "latent," in that they served the ends of painting or sculpture. Yet, so rounded, self-contained, and aesthetically satisfying are these drawings that their erstwhile role as handmaidens to the other pictorial arts can be reconstructed only from knowledge of the completed work, not from the drawing itself. This situation is especially true of a pictorial theme that acquired, at a relatively early stage, an autonomous rank in drawing itself: the portrait.

**Portraits.** Drawn 15th-century portraits—by Pisanello or Jan van Eyck, for example—may be considered completed pictorial works in their concentration, execution, and distribution of space. The clear, delicately delineated representation follows every detail of the surface, striving for realism. The profile, rich in detail, is preferred; resembling relief, it is akin to the medallion. Next in prominence to the pure profile, the three-quarter profile, with its more spatial effect, came to the fore, to remain for centuries the classic portrait stance.

The close relationship to painting applies to practically all portrait drawings of the 15th century. Even so forceful a work as Dürer's drawing of the emperor Maximilian originated as a portrait study for a painting. At the same time, however, some of Dürer's portrait drawings clearly embody the final stage of an artistic enterprise, an ambivalence that can also be observed in other 16th-century portraitists. The works of Jean and François Clouet in France and of the younger Hans Holbein in Switzerland and even more markedly in England in the same century bestowed an autonomy on portrait drawing especially when a drawing is completed in chalk of various colours. The choice of the softer medium, the contouring, which for all its exactitude is less severely self-contained, and the more delicate interior drawing with plane elements gives these drawings a livelier, more personal character and accentuates once more their proximity to painting.

In polychromatic chalk technique and pastel, portrait drawing maintained its independence into the 19th century. In the 18th century, Quentin de La Tour, François

Boucher, and Jean-Baptiste Chardin—all of these artists from France—were among its chief practitioners, and even Ingres, living in the 19th century, still used its technique. In pastel painting, the portrait outweighed all other subjects.

In the choice of pose, type, and execution, portrait painting, like other art forms, is influenced by the general stylistic features of an epoch. Thus, the extreme pictorial attitude of the late Baroque and Rococo was followed by a severer conception during Neoclassicism, which preferred monochrome techniques and cultivated as well the special form of the silhouette, a profile contour drawing with the area filled in in black. Unmistakably indebted to their 15th-century predecessors, the creators of portrait drawings of the early 19th century aimed once more at the exact rendition of detail and plastic effects gained through the most carefully chosen graphic mediums: the thin, hard pencil was their favorite instrument, and the silverpoint, too, was rediscovered by the Romantics.

More interested in the psychological aspects of portraiture, late 19th- and 20th-century draftsmen prefer the softer crayons that readily follow every artistic impulse. The seizing of characteristic elements and an adequate plane rendition weigh more heavily with them than realistic detail. Mood elements, intellectual tension, and personal engagement are typical features of the modern portrait and thus also of modern portrait drawing, an art that continues to document the artist's personal craftsmanship beyond the characteristics of various techniques.

**Landscapes.** As early as the 15th century, landscape drawings, too, attained enough autonomy so that it is hard to distinguish between the finished study for the background of a particular painting and an independent, self-contained sketched landscape. Already in Jacopo Bellini's 15th-century sketchbooks (preserved in albums in the British Museum and the Louvre), there is an intimate connection between nature study and pictorial structure; in Titian's studio in the 16th century, landscape sketches must have been displayed as suggestions for pictorial backgrounds.

But it was Dürer who developed landscape as a recollected image and autonomous work of art, in short, as a theme of its own without reference to other works. His watercolours above all but also the drawings of his two Italian journeys, of the surroundings of Nurnberg and of the journey to the Netherlands, represent the earliest

pure landscape drawings. Centuries had to pass before such drawings occurred again in this absolute formulation.

Landscape elements were also very significant in 16th-century German and Dutch drawings and illustrations. The figurative representation, still extant in most cases, is formally quite integrated into the romantic forest-and-meadow landscape, particularly in the works of the Danube School—Albrecht Altdorfer and Wolf Huber, for example. More frequently than in other schools, one finds here carefully executed nature views. In the Netherlands, Pieter Bruegel drew topographical views as well as free landscape compositions, in both cases as autonomous works.

### 17th-century landscape drawing

In the 17th century, the nature study and the landscape drawing that grew out of it reached a new high. The landscape drawings of the Accademia degli Incamminati (those of Domenichino, for example) combined classical and mythological themes with heroic landscapes. The Frenchman Claude Lorrain, living in Rome, frequently worked under the open sky, creating landscape drawings with a hitherto unattained atmospheric quality. This type of cultivated and idealized landscape, depicted also by Poussin and other Northerners residing in Rome (they were called Dutch Romanists), is in contrast with the unheroic, close-to-nature concept of landscape held primarily by the Netherlanders. All landscape painters—a specialty that was strongly represented in the artistically specialized Low Countries—also created independent landscape drawings (Jan van Goyen and Jacob van Ruisdael and his uncle and cousin, for example), with Rembrandt again occupying a special position: capturing the characteristics of a region often with only a few strokes, he enhanced them in such manner that they acquire monumental expressive power even in the smallest format. In 18th-century Italy, the topographically faithful landscape drawing gained in importance with the advent of the *vedutisti*, the purveyors of "views," forming a group by themselves (among them, Giambattista Piranesi and Canaletto [Giovanni Antonio Canal]) and often working with such optical aids as the graticulate frame and camera obscura. Landscape drawings of greater artistic freedom, as well as imaginary

landscapes, were done most successfully by some French artists, among them Hubert Robert; pictorially and atmospherically, these themes reached a second flowering in the brush-drawn landscapes of such English artists as Turner and Alexander Cozens, whose influence extends well into the 20th century.

Given their strong interest in delineation, the 18th-century draftsmen of Neoclassicism and, even more, of Romanticism observed nature with topographical accuracy. As a new "discovery," the romantically and heroically exaggerated Alpine world now took its place in the artist's mind alongside the arcadian view of the Italian landscape.

Landscape drawings and even more, watercolours, formed an inexhaustible theme in the 19th century. The French artist Jean-Baptiste-Camille Corot and, toward the end of the century, Cézanne and van Gogh, were among the chief creators of landscape drawings. While landscapes form part of the work of many 20th-century draftsmen, the genre as such takes second place to general problems of form, in which the subject is merely treated as starting point.

**Figure compositions and still lifes.** Compared to the main themes of autonomous drawing—portraiture and landscape—all others are of lesser importance. Figure compositions depend greatly on the painting of their time and are often directly connected with it. There were, to be sure, artists who dealt in their drawings with the themes of monumental painting, such as the 17th-century engraver and etcher Raymond de La Fage; in general, however, the artistic goal of figure composition is the picture, with the drawing representing but a useful aid and a way station. Genre scenes, especially popular in the 17th-century Low Countries (as done by Adriaen Brouwer, Adriaen von Ostade, and Jan Steen, for example) and in 18th-century France and England, did attain some independent standing. In the 19th century, too, there were drawings that told stories of everyday life; often illustrative in character, they may be called "small pictures," not only on account of the frequently multicoloured format but also in their artistic execution.

Still lifes can also lay claim to being autonomous drawings, especially the representations of flowers, such as those of the Dutch artist Jan van Huysum, which have been popular ever since the 17th century. Here, again, it is true that a well-designed arrangement transforms an

immediate nature study into a pictorial composition. In some of these compositions the similarity to painting is very strong; the pastels of the 19th- and 20th-century artist Odilon Redon, for instance, or the work of the 20th-century German Expressionist Emil Nolde, with its chromatic intensity, transcend altogether the dividing line between drawing and painting. In still lifes, as in landscapes, autonomous principles of form are more important to modern artists than the factual statement.

**Fanciful and nonrepresentational drawings.** Drawings with imaginary and fanciful themes are more independent of external reality. Dream apparitions, metamorphoses, and the entwining of separate levels and regions of reality have been traditional themes in drawing. Consider the late 15th-century phantasmagoric works of Hieronymus Bosch as an early example. Or there are allegorical peasant scenes by the 16th-century Flemish artist Pieter Bruegel along with the carnival etchings of the 17th-century French artist Jacques Callot. Other

artists whose works illustrate what can be done with drawing outside of landscape and portraiture are: the 18th-century Italian engraver Giambattista Piranesi, the 18th- and 19th-century Anglo-Swiss artist Henry Fuseli, the 19th-century English illustrator Walter Crane, the 19th-century French symbolist artist Gustav Moreau, and the Surrealists of the 20th century.

Nonrepresentational art, with its reduction of the basic elements of drawing—point, line, plane—to pure form, offered new challenges to drawing. Through renunciation of associative corporeal and spatial relationships, the unfolding of the actual dimensions of drawing and the structure of the various mediums acquire new significance. The graphic qualities of the line in the plane, the unmarked area had already been emphasized in earlier times—for example, in the *groteschi* of Raphael in the 16th century (the fanciful or fantastic representations of human and animal forms often combined with each other and interwoven with representations of fo-

Nonrepresentational art

liage, flowers, fruit, or the like) and in calligraphic, exercises such as *moresques* (strongly stylized linear ornament, based on leaves and blossoms)—but mostly as printing or engraving models for the most disparate decorative tasks (interior decoration, furniture, utensils, jewelry, weapons, and the like).

**Artistic architectural drawings.** There is one field in which drawing fulfills a distinct function: artistic architectural drawings are a final product in their form and quality as drawings, differing from the impersonal, exact plans and designs by precisely the same "handwriting" character that typifies art drawings. In many cases, no actual execution of these plans was envisaged; since the early Renaissance, such ideal plans have been drawn to symbolize, in execution and accessories, an abstract content. Despite the often considerable exactitude with which the plans are drawn, the personal statement predominates in the flow of the line. This personal note clearly identifies the drawings of such artists and architects as Albrecht Altdorfer, Leonardo, Michelangelo, Bernini, Francesco Borromini, and Piranesi. Also distinct from the ground-plan type of architectural drawing are the art drawings of autonomous character created by such 20th-century architects as Erich Mendelsohn and Le Corbusier.

## 11. History of drawing

### WESTERN

As an artistic endeavour, drawing is almost as old as mankind. In an instrumental, subordinate role, it developed along with the other arts in antiquity and the Middle Ages. Whether preliminary sketches for mosaics and murals or architectural drawings and designs for statues and reliefs within the variegated artistic production of the Gothic medieval building and artistic workshop, drawing as a nonautonomous auxiliary skill was subordinate to the other arts. Only in a very limited sense can one speak of centres of drawing in the early and High Middle Ages; that is, the scriptoria of the monasteries of Corbie and Reims in France, as well as those of Canterbury and Winchester in England, and also a few places in southern Germany, where various strongly delineatory (graphically illustrated) styles of book illumination were cultivated.

**14th, 15th, and 16th centuries.** In the West, the history of drawing as independent artistic document began toward the end of the 14th century. If its development was independent, however, it was not insular. Just as the greatest draftsmen have been for the most part also distinguished painters, illustrators, sculptors, or archi-

ects, so the centres and the high points of drawing have generally coincided with the leading localities and the major epochs of the other arts. Moreover, the same stylistic phenomena have been expressed in drawing as in other art forms. Indeed, drawing shares with other art forms the characteristics of individual style, period style, and regional features. Drawing differs, however, in that it interprets and renders these characteristics in terms of its own unique mediums.

Drawing became an independent art form in northern Italy, at first quite within the framework of ordinary studio activity. But with nature studies, copies of antiquities, and drafts in the various sketchbooks (those of Giovannino de'Grassi, Antonio Pisanello, and Jacopo Bellini, for example), the tradition of the Bauhiitten studio workshop changed to individual work: the place of "exempla," models, reproduced in formalized fashion was now being taken by subjectively probing and partially creative drawings. In the early 15th century the international Soft Style of the period still largely predominated over the draftsman's individual "handwriting." At mid-century, however, the differentiation of drawing style according to region and the artist's personality set in. Essential criteria, destined to remain characteristic for generations, begin to strike the eye.

In drawing produced north of the Alps, the characteristic features lie in the tendency to pictorial compactness and precise execution of detail. Many painters produced individual drawings, but the most notable draftsmen are the otherwise unidentified 15th-century German Master of the Housebook and his contemporary Martin Schongauer. Both of these artists were also major copperplate engravers, so that it is not always easy to determine whether the work is a preliminary sketch or an independent drawing.

In Italian Renaissance drawings, of which there are a

Drawing as an independent art form

great many, the diverging stylistic features of the various artistic regions were particularly evident. What they had in common was the overwhelming importance of the sketch and the study, in contrast to the far rarer finished drawings. The formal and thematic connection with painting is very close even when it was not a question of preliminary drawings. The draftsmen of Venice and northern Italy preferred an open form with loose and interrupted delineation in order to achieve even in drawing the pictorial effect that corresponded to their painters' imagination.

In central Italy, on the other hand, and especially in Florence, it was the clear contour that predominated, the closed and firmly circumscribed form, the static and plastic character. Corresponding to the functional purpose of drawing, the individual artists' studios (which, as was the case with the Medicis' Academy of St. Mark, also had to engage in general educational and humanistic investigations) formed the most significant centres of art drawing. In these large studios, drawing served not only for the probing realization of creative ideas, it was not only study and mediator between the conception and the master's finished work; it functioned also as teaching aid for the assistants who worked with the master and as a vehicle for the formation and preservation of an individual workshop tradition. Although Leonardo's scientific interests were expressed in a large number of drawings, his ideal concept of the human figure is much more frequently preserved in the drawings of his collaborators and successors than in his own. Raphael and Michelangelo were also outstanding draftsmen. Each of them used drawing in order to allow his thoughts about individual works to mature; each had a highly personal drawing style, the one with a soft and rounded stroke, the other with a sculptor's intermittent and powerful stroke. Probably a great deal of drawing was done in Raphael's studio, especially if only for the preparation of the engravings after Raphael's compositions. From Michelangelo's hand came the first so-called connoisseur drawings that are esteemed as a personal document. They are the precursors of the collector's drawings that began in the later 16th century (autonomous works, destined for collections).

Northern  
European  
drawing

North of the Alps the autonomy of drawing was championed in the first instance by Diirer, an indefatigable draftsman who mastered all techniques and exercised an enduring and widespread influence. The delineator-constituent clearly predominates even in his paintings. This corresponds to the general stylistic character of 16th-century German art, within which Matthias Grinewald, with his freer, broader, and therefore more pictorial style of drawing, and the painters of the Danube school, with their ornamentalizing and agitated stroke, represent significant exceptions. In their metamorphosing of the perceived reality into drawings, the landscapes of Altdorfer and Wolf Huber in particular are astonishing documents of a feeling for nature that might almost be called Romantic.

Soberer, incredibly compact in their pictorial concept and yet akin to the Renaissance in their objective viewing, were the portrait drawings of Hans Holbein, the Younger, whose sojourns in 16th-century England proved stimulating to other artists as well. Similar, if less personal than Holbein because of the stricter linearity of their work, were the drawings of the French portraitists Jean and François Clouet. In the Low Countries, where they were combined with the idealized image of Italy (as in the drawings of Lucas van Leyden), Diirer's methods gained lasting popularity in the landscape drawings and studies "after life" by Pieter Bruegel the Elder.

Drawing acquired a pivotal significance in the period of Mannerism (c. 1525–1600), both as a document of artistic invention and as a means of its realization. Jacopo Pontormo in Florence, Parmigianino in northern Italy, and Tintoretto in Venice used point and pen as essential and spontaneous vehicles of expression. Their drawings were clearly related to their painting, both in content and in the graphic method of sensitive contouring and daringly drawn foreshortening.

**17th, 18th, and 19th centuries.** In the early 17th century, Jacques Callot rose to prominence in French art: gifted as a draftsman above all, he recorded with the pen his clever inventions and great picture stories, primarily in bold abbreviations.

The importance of drawing for an artist's growth and the widening of his horizon is attested also by the work of Peter Paul Rubens, whose studies and sketches make up an integral part of his creative achievement. In order to disseminate his pictorial themes and concept of form, he maintained his own school for draftsmen and engravers. Among the circle of Flemings around him, Jacob Jordaens and Sir Anthony Van Dyck are notable as draftsmen with a style of their own.

Hercules Seghers was among the most fascinating artists of the 17th century, a creator of drawn and etched landscapes that he continued to rework while experimenting with printing processes. From the point of view of technique and form, he was important for the greatest artist of Holland, Rembrandt. Seghers combined great inventiveness, especially in his interpretations of Old Testament motifs, and broad mastery of all the techniques of drawing. In his studio, too, drawing was emphasized as a teaching aid and a means of formal experimentation.

Most Dutch painters of the 17th century, such as the van de Velde family, Brouwer, van Ostade, Pieter Saenredam, and Paulus Potter, were also industrious draftsmen who recorded their special thematic concerns in drawings that were largely completed. Beyond serving as preparation for paintings, these were regarded as autonomous works representing the final stage of the creative process.

In 17th-century Italy, drawing by way of artistic practice and experimentation became established in the academies, especially in Bologna. More significant, however, was the continuing development of landscape drawing, as initiated by the brothers Agostino and Annibale Carracci and articulated further by Domenichino and Salvator Rosa. The Frenchman Claude Lorrain so developed the landscape drawing of the Roman countryside that it became almost a genre of its own; in his works, which were often intended for sale, nature study and an idealized pictorial concept are uniquely merged. In detailed studies directly before the object, he achieved a timeless validity. Like Lorrain, Poussin also drew under the open sky. Using various techniques, he combined realistic experiences and humanistic concepts in idealizing compositions the figures and scenes of which are harmoniously integrated into a spacious landscape. This open-air painting and drawing was practiced also by some other artists who spent a considerable time in Rome—the Dutch artists Jan Asselijn, Nicolaes Berchem, Karel Dujardin, and Adam Pijnacker, for example. For most southern European artists of the 17th century, however, drawing was a mere stage in the creation of a painting.

17th-  
century  
Italian  
landscape  
drawing

Antoine Watteau, too, did drawings to "keep his hand in" for his painting, although he did so with an independence that led him far beyond the immediate occasion. Most figures in the paintings from various periods of his career were based on earlier drawings. In the grand scale of his form and the attention paid to pictorial elements, he carried on in the manner of Rubens, combining it with the light esprit of the 18th century. The leading position of French art in the first half of that century was confirmed by the achievements of Boucher, Fragonard, Hubert Robert, and Gabriel de Saint-Aubin, whose drawings include figure studies, genre-like works, and landscapes.

In contrast to the French draftsmen who brought about a flowering of the *à trois crayons* method on tinted paper, some artists created similar landscapes with pen and brush but with greater objective abbreviation. Mention must here be made of Venice, with the Giovanni Battista Tiepolo family, whose expansively conceived pen drawings, washed with a broad brush, call forth the kind of luminaristic effect that Francesco Guardi also used for landscape studies and imaginary scenes. These had been preceded by Canaletto's views of Venice, composed more

severely as far as tectonic (constructional) detail is concerned but nonetheless the first examples of this form of the landscape capriccio, or fantasy. The architect Giambattista Piranesi made his name primarily as a draftsman who recorded views of Rome; above all, in his drawings of architecture and eerie vaults ("Carceri"), he left behind a body of work of great intellectual and formal forcefulness.

The Spanish painter Goya, at the very end of the 18th and in the beginning of the 19th century, was in advance of his time in the way in which he handled his themes. Forming an odd contrast to the court-painter's pictures, his brush-and-sanguine drawings are rather more closely tied to his cycles of etchings. He combined the luminaristic effects of Tiepolo's drawings, with the dramatic impact of a Rembrandt chiaroscuro.

Also at the turn of the 19th century is an artist whose main work was that of a draftsman: the English caricaturist and social satirist Thomas Rowlandson, who produced colourful and distinctive watercolours. The late 18th and, even more, the early 19th century produced a drawing style that, in accordance with both the Neoclassical and the Romantic ideal, emphasized once more the linear element. In Ingres, idealistic Neoclassicism found an exemplary expression of strict linearity, and the pencil drawing became a downright classical form. The Nazarenes and Romantics in Rome and the Alpine region (Joseph Anton Koch, the brothers Friedrich and Ferdinand Olivier and Julius Schnorr von Carolsfeld) as well as those in north Germany (Philipp Otto Runge and Caspar David Friedrich) were more lyrical but equally rigorous in the use of the hardpoint; after a long time, they were the first northern artists to have made a significant contribution to the history of drawing. Among 19th-century artists, the emphasis on delineation was characteristic also of Moritz von Schwind in Germany and John Millais in England. (In the Neoclassical phase of the 20th century it was renewed, in a more open and "handwriting" fashion, by Thomas Eakins in the United States as well as by Picasso, Matisse, and Amedeo Modigliani in France.) The drawings of Delacroix, while preserving plastic qualities, show a broader stroke and are thus more pictorial. Daumier, active in all mediums primarily as a draftsman, utilized pictorial chiaroscuro effects in forcible statements of social criticism.

France continued to be a leading centre of the art of drawing, a form that was given a very personal note in each case in the works of Degas, Toulouse-Lautrec, van

Gogh, and Cézanne. The line—the common point of departure for all of the above-mentioned artists—did not disappear until Seurat's plane shading, done in the pointillist manner.

**Modern.** Except for a few stylistic currents such as Tachisme (paintings consisting of irregular blobs of colour), drawing is represented in the work of practically all 20th-century artists; it is as international as modern art itself. As the other arts have become nonrepresentational, thus attaining autonomy and formal independence in relation to external reality, drawing is more than ever considered an autonomous work of art, independent of the other arts; and the sketch, study, and project—that is, the drawing as a stage in the genesis of works of sculpture, painting, and architecture—have greatly diminished in importance. Some schools and individual artists as well have concentrated on drawing and in very individualistic ways. The German Expressionists, for instance, developed especially emphatic forms of drawing with powerful delineation and forcible and hyperbolic formal description; notable examples are the works of Ernst Barlach, Kathe Kollwitz, Alfred Kubin, Ernest Ludwig Kirchner, Karl Schmidt-Rottluff, Max Beckmann, and George Grosz. In the artists' group *Der Blaue Reiter* (The Blue Rider), Wassily Kandinsky was foremost in laying the groundwork for a new evaluation of the nonrepresentational line. Paul Klee's lyrically sensitive drawings, carried out in a pen technique of unheard-of sublimity, represent a high point of modern drawing. In France, drawing plays a major role, especially in the work of the painters of the École de Paris (School of Paris), such as Pierre Soulages and Hans Hartung, who consider the line, the framework of lines, and the network of lines, as primary manifestations of form. Wols (Alfred Otto Wolfgang Schulze) and also the English artist Graham Sutherland may actually be called spiritual draftsmen who put their faith in the magic of the line. Finally, drawing occupies a considerable place in the work (including all its variants of style and form) of Picasso, once again a man who knew how to make use of its manifold technical possibilities. One is surely justified in calling him the greatest draftsman of the 20th century and one of the greatest in the history of drawing.

millennium BC; but the earliest pictorial work is in lacquer or on bronze vessels, contemporaneous with Alexander the Great (ruled 336–323 BC). It relies on contour and silhouette, with men and animals depicted in horizontal registers (levels, one above the other) reminiscent of Egyptian and Mediterranean work. The extent of any mutual influence between East and West cannot yet be determined. Under the Later Han dynasty (AD 23–220) wall paintings, linear in character, were produced in fresco (wet plaster) and secco (dry). Only in the Northern Wei (386–534) and T'ang (618–907) dynasties did the true character of Chinese drawing on silk or paper emerge. In the 7th century, the characteristic albums (*ts'e-yeh*) of drawings appear.

No distinction was made between drawing and painting because all Chinese pictorial art was fundamentally graphic. The artist worked with the fine point of the brush on paper or silk laid horizontally on a table. Work in pure outline was called *pai-miao*; ink applied in splashes, *p'o-rno*. Colour was used sparingly or not at all. The final work was not made direct from nature.

Hindu and Buddhist paintings at Ajantā in India and also in Ceylon reveal the essential quality in all Indian art: emphasis on a flowing, rhythmic contour to express movement and gesture. Drawings on palm leaf of the 11th century are similarly based on the use of line to depict mythological scenes.

The 14th century saw the manufacture of paper, introduced from China, permitting the production of the vertical book. Despite the Muslim prohibition of human representation, books illustrated with drawings, sometimes with flat decorative colour, were produced at the Persian and Mughal courts but not for public display. The use of a precise and expressive line constituted the basis for Persian and Indian (both Mughal and Rājput) miniature paintings, which show people in landscape or in relation to buildings.

Japanese art tended to follow that of China until the early 19th century, when the popular colour print was introduced. In the graceful feminine gestures of Utamarō's work, the Oriental love of the flowing contour is manifest, allowing his line to vary in width and density. Hokusai's drawings of social life in a humorous, almost grotesque vein, invariably reveal his complete command of the expressive line. (Ed.)

**BIBLIOGRAPHY.** JOSEPH MEDER, *Die Handzeichnung*, 2nd ed. (1923), a voluminous book with instructively selected illustrations, remains the basic work on the history and techniques of drawing. Another treatment of the subject, more concise in every respect, is HEINRICH LEPORINI, *Die Künstlerzeichnung*, 2nd ed. (1955). ARTHUR E. POPHAM published an

introduction to drawing in *A Handbook to the Drawings and Watercolours in the Department of Prints and Drawings of the British Museum* (1939), based on the ample materials held by the British Museum. CHARLES DE TOLNAY in *History and Technique of Old Master Drawings* (1943); and JAMES WATROUS in *The Craft of Old Master Drawings* (1957), deal, from different points of view, with the history and techniques of the old masters; while HERIBERT HUTTER in *Die Handzeichnung* (1966; Eng. trans., *Drawing: History and Technique*, 1968), stresses the artistic function of drawing and includes modern works. DANIEL M. MENDELWITZ, *Drawing* (1966), provides a historical résumé, with reference to the artistic elements and technical means of drawing; in the supplement *A Study Guide* (1967), he offers practical instructions for drawing techniques and their application, as does R. BEVERLY HALE in *Drawing Lessons from the Great Masters* (1964). JAKOB ROSENBERG illustrates the possibilities of drawing in *Great Draughtsmen from Pisanello to Picasso* (1959), with samples from the works of eight great artists. *Great Drawings of All Time*, ed. by IRA MOSKOWITZ, 4 vol. (1962), contains a summary with comments by leading authorities. M.W. EVANS, *Medieval Drawings* (1969), is useful for the early history of the art of drawing; PAUL J. SACHS, *Modern Prints and Drawings: A Guide to a Better Understanding of Modern Draughtsmanship* (1954), for the most recent developments. H. BOECKHOFF and F. WINTER, *Das grosse Buch der Graphik* (1968), gives the history of the 24 best-known collections, with comments by the various curators and the basic catalog of each collection. The number of detailed investigations in regard to individual countries, periods, and artists is too large to be listed in this bibliography. LUIGI GRASSI, *Storia del disegno* (1947), is very valuable for the role of drawing with the historical theories of art, including the elucidation of the original sources for further study. Unsurpassed in method and fundamental for an intensive study of this subtle theme is BERNHARD DEGENHART'S essay "Zur Graphologie der Handzeichnung," in *Jahrbuch der Hertziana*, vol. 1 (1937).

(H.R.H.)

## Dreams

The mysterious quality of dreams may be appreciated in part from the attitudes they have evoked during human history. While any effort toward classification must be subject to inadequacies, beliefs about dreams fall into various classifications depending on whether dreams are believed to be reflections of reality, sources of divination, curative experiences, waking states, or evidence of unconscious activity (the so-called Freudian dream).

### DIVERSE VIEWS ON THE NATURE OF DREAMS

**Dreams as reflecting reality.** Contemporary philosophers continue to argue about the differences between reality and dreams. English philosopher Bertrand Russell (1872–1970) wrote "it is obviously possible that what

we call waking life may be only an unusual and persistent nightmare" and further stated that "I do not believe that I am now dreaming but I cannot prove I am not." Philosophers generally try to resolve the question by saying that so-called waking experience seems vivid and coherent. As French philosopher René Descartes (1596–1650) put it: "... memory can never connect our dreams one with the other or with the whole course of our lives as it unites events which happen to us while we are awake"; or, as Russell stated succinctly: "Certain uniformities are observed in waking life, while dreams seem quite erratic."

Members of many cultures have variously coped with this dilemma; for example, among the Eskimo of Hudson Bay and the Patani Malay people, it is believed that during sleep one's "soul" leaves his body to live in a special dreamworld. Believers often consider it dangerous to wake someone lest his "soul" be lost. On these grounds the Tajal people of Luzon, for example, severely punish for awakening a sleeping person. In other cultures, dream events are held to be identical with reality; thus a Macusi Indian of Guyana is reported to have become enraged at the European leader of an expedition when he dreamed that the leader had made him haul a canoe up dangerous cataracts. He awoke exhausted and could not be persuaded that the dream was not real. There is a tradition in Borneo that if a man dreams that his wife is an adulteress, her father must take her back. A Zulu man is said to have broken off a friendship after dreaming that the friend meant him harm. A Paraguayan Indian, reportedly having dreamed a missionary shot at him, attempted to kill the missionary.

In other instances, dream events are believed to demand fulfillment. Jesuit priests in the 1700s reported that among Iroquois Indians it was obligatory to carry out dreams as soon as possible; one Indian was said to have dreamed that ten friends dove into a hole in the ice of a lake and came up through another. When told of the dream, the friends duly enacted their roles in it, but unfortunately, only nine of them succeeded. After dreaming of something valuable, Kurdish people were immediately expected to take it, by force if necessary. Among some natives of Kamchatka a man need only dream of a girl's favour for her to owe him her sexual favours.

Such interpretations in which the dream is given a status of reality need not imply that the two are indistinguishable. In some instances, the dream may be differentiated from reality, but dreams are accorded a superior status to the banal activities of wakefulness.

**Dreams as a source of divination.** There is an ancient belief that dreams predict the future; the Chester Beatty Papyrus is a record of Egyptian dream interpretations dating from the 12th dynasty (1991–1786 BC). In the Iliad, a character named Agamemnon is visited in dream by a messenger of the god Zeus to prescribe his future actions. From India, a document called the Atharvaveda, attributed to the 5th century BC, contains a chapter on dream omens. A Babylonian dream guide was discovered in the ruins of the city of Nineveh among tablets from the library of the emperor Ashurbanipal (668–627 BC). The Old Testament is rife with prophetic dreams, those of the pharaohs and of Joseph and Jacob being particularly striking. Among pre-Islamic peoples dream divination so heavily influenced daily life that the practice was formally forbidden by Muhammad (c. 570?–632), founder of the Muslim religion.

Ancient and religious literatures express most confidence about so-called message dreams. Characteristically, a god or some other respected figure appears to the dreamer (typically a king, a hero, or a priest) in time of crisis and states a message. Such reports are found on ancient Sumerian and Egyptian monuments; frequent examples appear in the Old and New Testaments. Joseph Smith (1805–1844), the founder of the Mormon religion, said that an angel had directed him to the location of buried golden tablets that described American Indians as descendants of the tribes of Israel.

Not all dream prophecies are so readily accepted. In

the epic Odyssey, for example, dreams are classed as false ("passing through the gate of Ivory") and as true ("passing the Gate of Horn"). Furthermore, prophetic meaning may be attributed to dream symbolism. In the Bible, Joseph interpreted sheaves of grain and the moon and stars as symbols of himself and of his brethren. In general, the social status of dream interpreters varies; in cultures for which dreams loom important, their interpretation frequently is a specialized occupation of such people as priests, elders, or medicine men.

Perhaps the most famous dream interpretation book is that of the Greek geographer, Artemidorus (c. 2nd century AD) and is called *Oneirocritica* (from the Greek *oneiros*, "a dream"). Dream books remain widely available today. They continue to enjoy profitable sales in Europe, Asia, the Americas, Africa, and elsewhere among people who follow them in affairs of the heart, in gambling, and in matters of health and work.

**Dreams as curative.** So-called prophetic dreams in the Middle-Eastern cultures of antiquity often were combined with other means of prophecy, such as animal sacrifice, and with efforts to heal the sick. In classical Greece, dreams became directly associated with healing; ailing people came to dream in oracular temples where priests and priestesses advised about the cures dreams were held to provide. Similar practices, known as dream incubation, are recorded for Babylon and Egypt. In a widespread cult, suffering petitioners came to at least 600 temples of the Greek god of medicine to perform rites or sacrifices in efforts to dream appropriately, sleeping in wait of the appearance of the god or his emissary to deliver a cure. Many stone monuments placed at the entrances of the temples survive to record dream cures.

**Dreams as extensions of the waking state.** Even in early human history dreams also were interpreted as reflections of waking experiences and of emotional needs. Aristotle (384–322 BC), despite his contemporaries who practiced divination and incubation, in his work *Parva naturalia* attributed dreams to sensory impressions from "external objects . . . pauses within the body . . . eddies . . . of sensory movement often remaining like they were when they first started, but often too broken into other forms by collision with obstacles." In anticipation of psychoanalyst Sigmund Freud (1859–1939), Aristotle wrote that sensory function is reduced in sleep, favouring the susceptibility of dreams to emotional subjective distortions.

In spite of Aristotle's unusually modern views and even after a devastating attack by the Roman statesman Marcus Tullius Cicero (106–43 BC) on dream divination (*De divinatione*), views that dreams have supernatural attributes persisted vigorously until the 1850s and the classical work of French physician Alfred Maury, who studied more than 3,000 reported recollections of dreams. Maury concluded that dreams arose from external stimuli, instantaneously accompanying such impressions. He wrote that part of his bed once fell on the back of his neck and woke him, leaving the memory of dreaming that he had been brought before a French revolutionary tribunal, questioned, condemned, led to the scaffold, bound by the executioner and that the guillotine blade fell.

The English poet Coleridge reported that he had written "Kubla Khan" as the result of creative thinking in a dream. Having fallen asleep while reading about that Mongol conqueror, he woke to write down a fully developed poem he seemed to have composed while dreaming. Novelist Robert Louis Stevenson said that much of his writing was developed by "little people" in his dreams, and specifically cited the story of Dr. Jekyll and Mr. Hyde in this context. A German chemist, F.A. Kekulé von Stradonitz, attributed his interpretation of the ring structure of the benzene molecule to his dream of a snake with a tail in its mouth. Otto Loewi, a German physiologist, attributed to a dream inspiration for an experiment with a frog's nerve that helped him win the Nobel Prize. In all of these cases the dreamers reported having

Dreams in the Bible

Creative dreaming

thought about the same topics over considerable periods while they were awake.

**Psychoanalytic interpretations.** Among Freud's earliest writings was *The Interpretation of Dreams* (1899). His insistence that dreams are "the royal road to the unconscious" continued from it down to his last published statement on dreams, printed about a year before he died. Freud held that dreams reflect waking experience; he offered a theoretical explanation for their bizarre nature, invented a system for their interpretation, and elaborated on their curative potential.

Freud theorized that thinking during sleep tends to be primitive and regressive and that the effects of forgetting (repression) are reduced. Repressed wishes, particularly those associated with sex and hostility, were said to be released in dreams when the inhibitory demands of wakefulness diminished. The content of the dream was said to derive from such stimuli as urinary pressure in the bladder, traces of experiences from the previous day (day residues), and from associated infantile memories. The specific dream details were called their manifest content; the presumably repressed wishes being expressed were called the latent content. Freud suggested that the dreamer kept himself from waking and avoided unpleasant awareness of repressed wishes by disguising them as bizarre manifest content in an effort called dreamwork. He held that impulses one fails to satisfy when awake are expressed in dreams as sensory images and scenes. In dreaming, Freud believed:

All of the linguistic instruments . . . of subtle thought are dropped . . . and abstract terms are taken back to the concrete . . . The copious employment of symbols . . . for representing certain objects and processes is in harmony (with) the regression of the mental apparatus and the demands of censorship.

It was theorized that one aspect of manifest content could come to represent a number of latent elements (and vice versa) through a process called condensation. Further displacement of emotional attitudes toward one object or person theoretically could be displaced in dreaming to another object or person or not appear in the dream at all. Freud further observed a process called secondary elaboration which occurs when people wake and try to remember dreams. They may recall inaccurately in a process of elaboration and rationalization and provide "the dream, a smooth facade, (or by omission) display rents and cracks." This waking activity he called secondary revision.

In seeking the latent meaning of a dream, Freud advised the individual to associate freely about it. From listening to the associations, the analyst was supposed to determine what the dream represented, in part through an understanding of the personal needs of the dreamer.

#### EFFORTS TO STUDY DREAMING

**Dream reports.** Though each person seems to know his own private dreams, the manner in which people dream obviously defies direct observation. It has been said that each dream "is a personal document, a letter to oneself" and must be inferred from the observable behaviour of people. Furthermore, observational methods and purposes clearly affect conclusions to be drawn about the inferred dreams. Reports of dreams collected from people after morning awakenings at home tend to exhibit more content of an overt sexual and emotional nature than do those from laboratory subjects. Such experiences as dreaming in colour seldom are spontaneously mentioned but often emerge under careful questioning. Reports of morning dreams are typically more rich and complex than those collected early at night. Immediate recall differs from what is reported after longer periods of wakefulness; psychoanalysts seem to elicit more recollections of overt sexual dreams than do laboratory investigators. In spite of these complications, there have been substantial efforts to describe the general characteristics of what people say they have dreamed.

The reported length of dreams varies widely between

and within individuals (and by inference, so does the length of the presumed dreams themselves). Spontaneously reported dreams among laboratory subjects are typically short; about 90 percent of these reports are less than 150 words long, although some may exceed 1,000. With additional probing, about a third of such reports are longer than 300 words.

Some investigators have been surprised by repeated findings that suggest dreams may be less fantastic or bizarre than generally supposed. In the language of modern art, one investigator stated that visual dreams are typically faithful to reality (representational) with little, if any, abstractionist or surrealistic dreaming. Any variations from the representational, in terms of fuzziness or simplification of imagery, were characterized as impressionistic. Except for those that are very short, dreams are reported to take place in ordinary physical settings, about half of them seeming quite familiar to the dreamer; only rarely is the setting said to be exotic or peculiar.

Apparently dreams are quite egocentric, the dreamer perceiving himself as a participant, though the presence of others is typically recalled. Seldom does the person remember an empty, unpopulated dreamworld, and individuals seem to dream roughly two-thirds of the time about people they know. Usually they are close acquaintances; family members are mentioned in about 20 percent of dream reports. Recollections of notables or weird representations of people are generally rare.

The typical report is of visual imagery; indeed, in its absence, the person may say only that he had been thinking rather than "dreaming" while asleep. Rare statements about dreams dominated by auditory experience commonly are made with claims of actually having been awake. It is unusual, however, to hear of dreams without some auditory characteristics.

One typically is told of bland dreams; when there are emotional overtones, they tend to be unpleasant about 65 percent of the time. Fear and anxiety are most commonly mentioned, followed by anger; pleasant feelings are most often those of friendliness. Reports of overtly erotic dreams, particularly among those gathered in laboratories, are infrequent.

Despite their generally representational nature, dreams seem somehow odd or strange. Perhaps this is related to discontinuities in time and purpose. One suddenly may dream of himself in a familiar auditorium viewing a fencing match rather than hearing a lecture and abruptly in the "next scene" walking beside a swimming pool. Or an individual may have the experience of lying in a hallway listening to two people standing by an elevator; he may be looking at a bleeding hand and walk across an empty room to a liquor cabinet to find a roll of adhesive tape. These sudden transitions contribute to the dreamer's feeling of strangeness, and this is enhanced by his waking statements that the bulk of his dreams cannot be clearly recalled, giving them a dim, mysterious quality.

**Physiological dream research.** A new era of dream research began in 1953 with the discovery that rapid eye movements during sleep seem often to signal that a person is dreaming. In that year it was observed that, about an hour or so after falling asleep, laboratory subjects are apt to experience a burst of rapid eye movement (REM) under their closed lids, a change in brain waves detected by an electroencephalograph as an electrical pattern resembling that of an alert waking person, and an increased rate of breathing. Such episodes, typically lasting five–ten minutes, are followed by a period of relative quiescence and then commonly by another appearance of REM and associated responses; the cycle usually repeats three or four times a night. In 1953 it was discovered that when subjects were awakened during REM, they reported vivid dreams 20 out of 27 times; when roused during non-REM sleep, they recalled dreams in only four of 23 instances. Subsequent systematic study confirmed this relationship among REM, activated brain waves (EEG), and dream recall. Several thousand experimental studies utilizing these observable indices of dreaming have since been conducted.

Length of  
dream  
reports

Dream-  
work

Rapid eye  
movement

A major finding is that the usual report of a vivid, visual dream is primarily associated with REM and activated EEG. On being aroused while exhibiting these signs, people recall dreams with visual imagery about 80 percent of the time. When awakened in the absence of them, however, people still report some kind of dream activity, though only about 30 to 50 percent of the time; and in such cases they are apt to remember their dreams as being relatively "thoughtlike," realistic, and as resembling the experiences of wakefulness.

The combined duration of the REM-EEG condition (sometimes called the D-state) takes up about 25 percent of the normal sleep period in young human adults. D-state occurs episodically in bursts throughout the night, ordinarily first appearing about 100 minutes after sleep begins and lasting for approximately ten minutes. This tends to be followed by successive episodes every 90–100 minutes through the night, each successive episode being longer than the preceding one. Young adults rarely show D-state during less than 18 percent or more than 30 percent of the sleep period. Newborn infants, however, show about 50 percent D-state. This declines until, by age 10, the D-state stabilizes at about 25 percent of total sleeping time, remaining at this level until people reach their 60s. There is tentative evidence of some slight decrease in the duration of D-state sleep among very elderly persons.

D-state sleep has been reported for all mammals studied; it has been observed, for example, among monkeys, dogs, cats, rats, elephants, shrews, and opossums; these signs also have been reported in some birds and reptiles.

Surgical destruction of selected brain structures among laboratory animals has clearly demonstrated that the D-state depends on an area within the brain stem known as the pontine tegmentum. Evidence indicates that D-state sleep is associated with a mechanism involving a bodily chemical called norepinephrine; other stages of sleep seem to involve another chemical (serotonin) in the brain. Among other physiological changes found intimately related to D-state sleep are increased variability in breathing and heart rate, relaxation of skeletal muscles (in lower animals), and, in humans, reduction of electrical activity in muscles near the base of the tongue and penile erections or increase in vaginal blood flow.

When people are chronically deprived of the opportunity to manifest D-state activity (by awakening them whenever there is EEG evidence of dreaming), it appears increasingly difficult to prevent them from dreaming. On recovery nights (after such deprivation) when the subject can sleep without interruption, there is a substantial increase in the number of reports of dreaming. This rebound effect continues in some degree on subsequent recovery nights, depending on how badly the person has been deprived.

During D-states in the last 6% to 7% hours of sleep people are likely to wake by themselves about 40 percent of the time. This figure is about the same as that for dream recall, people saying they had a dream the previous night about 35 percent of the time (roughly once every three or four nights). Evidence concerning the amount and kind of dreaming also depends on how rapidly one is roused and on the intensity of his effort to recall. Some people recall dreams more often than the average, while others rarely report them. While these two groups of people show little difference in amount of D-state sleep, evidence suggests that nonrecall reflects a general tendency on the part of the individual to repress or to deny his experiences.

The psychoanalytic literature is rich with reports indicating that what one dreams about reflects his needs and his immediate and remote past experience. Nevertheless, when someone in D-state sleep is stimulated (*e.g.*, by spoken word or by drops of water on his skin), the chances that he will say he has dreamed about the stimulus, or anything similar, are quite low. Studies in which people have watched vivid movies before falling asleep also indicate some possibilities of influencing dreams but again clearly emphasize the limitations of

such influences. Highly suggestible people seem likely to dream as they are told to do while under hypnosis, but the influence of direct suggestion during ordinary wakefulness seems quite limited.

Variations within the usual range of about 18 to 30 percent of D-state sleep apparently are unrelated to differences in the amount or content of dreaming. The amount of D-state further seems generally independent of wide variations in the daily activities or personality characteristics of different people; groups of scientists, athletes, housewives, and artists, for example, cannot be reliably distinguished from each other in terms of D-state activity. Such disorders as schizophrenia and mental retardation appear to have no clearly discernible effect on the amount of time sufferers spend in REM-activated EEG sleep.

Although there are exceptions, most stimulant drugs (*e.g.*, amphetamines) and depressants (*e.g.*, barbiturates and alcohol) effectively tend to reduce D-state activity. When these drugs are taken in doses ordinarily prescribed by physicians, reduction may amount to 50 percent. Withdrawal of such drugs typically results in a dramatic increase (rebound), the person showing considerably more REM-EEG symptoms than he did before being dosed.

#### DREAMLIKE ACTIVITIES

Related states of awareness may be distinguished from the dream experiences typically reported; these include dreamlike states experienced as one falls asleep and as he awakens, respectively called hypnagogic and hypnopompic reveries. During sleep itself there are nightmares, observable signs of sexual activity (*e.g.*, nocturnal emissions of sperm), and sleepwalking. Even people who ostensibly are awake may show evidence of such related phenomena as hallucinating, trance behaviour, delirium, and reactions to drugs (see HALLUCINOGEN).

Rapid eye movement is not characteristic of sleep onset; nevertheless, as individuals drift (as inferred from EEG activity) from wakefulness through drowsiness into sleep, they report dreamlike hypnagogic experiences about 90 percent of the time on being awakened. Most of these experiences (about 80 percent) are said to be visual. If dreaming is defined as at least partly hallucinatory and somewhat dramatic, then awakening from drowsiness or at the onset of sleep yields recall of experiences that may be classified as dreams for about 75 percent of the occasions. These "dreamlets" seem to differ from dream-associated REM sleep in being less emotional (neither pleasant nor unpleasant), more transient, and less elaborate. Such hypnagogic experiences apparently tend to incorporate abstract thinking and recall of recent events (day residues) and to be quite typical of falling asleep. Systematic studies remain to be made of the hypnopompic reveries commonly reported mornings before full arousal, but it seems likely that they include recollections of the night's dreams, or represent one's drifting back into transient REM sleep.

Extreme behavioural manifestations during sleep—night terrors, nightmares, sleepwalking, enuresis (bed-wetting)—all have been found generally unrelated to ordinary dreaming. Night terrors (*pavor nocturnus*) are characterized by abrupt awakening, sometimes with a scream; a sleeping child may sit up in bed, apparently terror stricken, with wide-open eyes, and often with frozen posturing that may last several minutes. Afterward there typically is no recollection of dreamlike experience. Observed in about 2 or 3 percent of children, roughly half of the attacks of night terror occur between the ages of four and seven; about 10 percent of them are seen among youngsters as old as 12 to 14 years. Nightmares typically seem to be followed by awakening with feelings of suffocation and helplessness and expressions of threateningly fearful thinking. Evidence of nightmares is observed for 5 to 10 percent of children, primarily about eight to ten years of age. As early as 1897 it was reported that night terrors could be induced by rousing soundly sleeping children and suggesting dire events (*e.g.*, that the house is on fire). Later it was found that signs of spontaneously

Effects  
of drugs

Night-  
mares

Signs of  
dreaming  
among  
non-  
humans

generated night terrors and nightmares are related to abrupt awakening from deep sleep that experimentally appears dreamless. This suggests that the vividly reported fears well may be produced by emotional disturbances that first occur on awakening.

Sleepwalking, observed in about 1 percent of children, predominantly appears between ages 11 and 14. Apparently sleeping individuals rise and walk from their beds, eyes open, usually avoiding obstacles, and expressing no recollection of the episode when they wake. Studies of EEG data indicate that sleepwalking occurs only in deep sleep when dreams seem essentially absent; the behaviour remains to be reported for REM sleep.

Enuresis, or bed-wetting, occurs in about one-fourth of children over age four. These episodes seem not to be associated with REM as much as they do with deep sleep in the absence of D-state signs.

Nocturnal emission of sperm remains to be described in terms of any distinguishing EEG pattern; such events are quite rarely observed among sleeping laboratory subjects. Among a large sample of males who were interviewed about their sexual behaviour about 85 percent reported having experienced emissions at some time in their lives, typical frequency during the teens and 20s being about once a month. Of the females interviewed 37 percent reported erotic dreams, sometimes with orgasm, averaging about three to four times a year. Most often, however, openly sexual dreams are said not to be accompanied by orgasm in either sex. Males not infrequently could recall no dreams associated with emission, although most implicated erotic dreaming.

Dreamlike experiences induced as trances, deliriums, or hallucinatory behaviour by drugs seems attributable to lowered efficiency of the central nervous system in processing sensory stimuli from the external environment. The result seems to be that one's physiological activities begin to escape environmental constraint to the point that internalized, uncritical thinking and perceiving prevail.

As noted, since antiquity dreams have been viewed as a source of divination, as a form of reality, as a curative force, and as an extension or adjunct of the waking state. Psychoanalytic theorists stress the individual meaningfulness of dreams and their relation to personal hopes and fears. Contemporary research focusses on efforts to discover and describe unique, complex biochemical and neurophysiological bases of dreaming. Among the plethora of theories ranging from those that assert dreaming to be awareness of a god's voice to those that reduce the dream to physical activity in the nervous system, no single, encompassing theory seems yet to be available (see also SLEEP).

**BIBLIOGRAPHY.** SIGMUND FREUD, *Die Traumdeutung* (1900; Eng. trans., *The Interpretation of Dreams*, 1953), Freud's classical theory of dream interpretation, also found in *An Outline of Psychoanalysis*, trans. by JAMES STRACHEY (1949); G.E. VON GRÜNEBAUM and R. CAILLOIS (eds.), *The Dream and Human Societies* (1966), a scholarly work on the place of dreams in a wide variety of cultures, with a chapter on dream research; R.M. JONES, *The New Psychology of Dreaming* (1970), an attempt to coordinate experimental findings on dreams with classical theories; EDWIN DIAMOND, *The Science of Dreams* (1962), a book, written for the layman, that serves as a bridge between early ideas about dreams and subsequent experimental work; DAVID FOULKES, *The Psychology of Sleep* (1966), a work primarily about the experimental analysis of dreams, written at a level comprehensible to the layman; H.A. WITKIN and H.B. LEWIS (eds.), *Experimental Studies of Dreaming* (1967), a collection of papers on dream research with particular emphasis on such psychological variables as pre-sleep experiences and aspects of dream recall; ERNEST HARTMANN, *The Biology of Dreaming* (1967), a technical work emphasizing biological and physiological bases. Additional relevant material may be found in W.B. WEBB, *Sleep: An Experimental Approach* (1968).

(W.B.W.)

## Dreiser, Theodore

It was as the author of the then "shocking" novel *Sister Carrie* that Theodore Dreiser, in 1900, made his entrance

on the American literary stage and was received so coldly that he fled it for 11 years. Although his life was devoted also to magazine editing and writing, philosophical inquiry, poetry, and social protest, it was as novelist that he showed his real genius at the same time that he highlighted the slow relaxation of American mores. The man rejected in 1900 for violating literary proprieties was acclaimed as a master in 1925 for *An American Tragedy*. That the latter was accepted was because the public, not Dreiser, had changed.

Born on August 27, 1871, in Terre Haute, Indiana, a member of a family of 12 who often lived in appalling poverty, Dreiser was so offended by his German-born father's narrow Catholicism that he later abandoned and denounced the church. His gentle, illiterate, Ohio-born mother was the parent he always remembered with love. Educated in several Indiana towns where the harried family moved in hope of betterment, he managed to complete one year at the University of Indiana with the aid of a teacher who saw promise in him. Thereafter, he wandered into journalism in Chicago, St. Louis, and Pittsburgh before reaching New York in 1894. There, aided by his then prosperous older brother Paul Dresser, a popular composer ("On the Banks of the Wabash"), he became a writer of magazine articles. He was tall and hulking, with a peasant crudity that could also be charming—a thinker influenced by T.H. Huxley, Herbert Spencer, and Darwin, believing man a product of continuing evolution that he was helpless to alter. His marriage in 1898 to Sara White, whom he had met in St. Louis, soon encountered difficulties because of his roving affections and moody temperament.

*Sister Carrie* sold only 456 copies. Although it was praised by the young novelist Frank Norris, and in England by Arnold Bennett and H.G. Wells, its quick death sent Dreiser into emotional prostration during which he all but lost his sanity and came near starving in a Brooklyn slum. He was saved by the kindly Paul, who had been searching for him. The novel's impropriety lay less in the immorality of the heroine than in her "common" origin and the fact that she was not punished for her transgressions. Based largely on Dreiser's family recollections, including an adventure of one of his sisters, *Sister Carrie* depicted crises and intimacies of folk life not yet welcomed in print, revolutionary in the realistic detail and profound human sympathy that shone through Dreiser's awkward writing style.

Taking refuge in editorial work, he became, in 1907, the well-paid editor in chief of the housewife-oriented Butterick magazines, which embraced the very taboos that had smothered his novel. Here—not without some wry humour over the literary pruderies his job compelled him to observe—he dealt with contributors including H.L. Mencken, who became his friend and critic. Forced out in 1910 because of a "scandalous" infatuation for the daughter of an assistant editor, he finished his second novel, *Jennie Gerhardt* (1911), which was lauded by Mencken and fared well enough to encourage him. His fascination with the machinations of the unscrupulous and successful emerged in *The Financier* (1912) and *The Titan* (1914), both patterned after the adventures of the railway magnate Charles T. Yerkes.

The door to acceptance, opening a crack, was slammed in his face in 1916 when *The "Genius"* (published the year before), largely a literary reconstruction of his own artistic and romantic travail, was suppressed by the New York Society for the Suppression of Vice. Though Mencken joined him loyally in a long campaign against such censorship, Dreiser was forced again to resort to magazine writing for subsistence. Separated from his wife, he lived thriftily in New York's Greenwich Village, then a haven for the avant-garde in literature, art, and politics. There he was known for his superstitions and his affairs with women as well as his resentment of a society that rejected honest writing. Among his friends were other rebels, including the poet Edgar Lee Masters and the writers Floyd Dell, Sherwood Anderson, George Jean Nathan, and the Powys brothers, Llewellyn and John C. He had published the autobiographical *A Traveler* at

*Sister  
Carrie*

An  
American  
Tragedy

*Forty* (1913) after a trip to Europe, *A Hoosier Holiday* (1916) after a motor journey to his native state, and *Plays of the Natural and Supernatural* (1916). None of these books was very profitable. Nor did he prosper with the tragic drama *The Hand of the Potter* (published 1918), *Free*, a collection of short stories (1918), the taken-from-life sketches of *Twelve Men* (1919), the philosophically unorthodox *Hey Rub-a-Dub-Dub* (1920), the autobiographical *A Book About Myself* (1922), a portion of which was to appear as *Newspaper Days* in 1931, or the descriptive *Color of a Great City* (1923). His prospects seemed bleak in 1925 when he published *An American Tragedy*, his first novel in ten years, based on a famous murder case in New York state.

This story of a young man trying to escape poverty who is driven to murder by social forces he cannot resist was an immediate critical and popular success. It was dramatized on Broadway and sold to Hollywood for a film, bringing Dreiser the acclaim and wealth that had for so long been denied him. Joseph Wood Krutch, a well-known critic, called it "the greatest American novel of our generation." Critics formerly hostile to Dreiser even agreed that it rose above his well-known difficulties with syntax and diction. As Sherwood Anderson wrote, urging Americans to read it,

Find out, once and for all, the difference between a human flesh and blood, male man, full of real tenderness for life, and the smarties, the word slingers, the clever fellows . . . of the writing world.

Dreiser quit the Village, took an elegant apartment and a country place, bought gaudy clothing, and became the darling of literary intellectuals of that bull-market time. His visit to Russia, where he saw little hope for social improvement because his mechanistic philosophy ruled out such hope, resulted in the skeptical *Dreiser Looks at Russia* (1928). His evident borrowings from Dorothy Thompson's book about Russia caused him to quarrel with her husband, Sinclair Lewis. His *Chains* (1927) and *A Gallery of Women* (1929) comprised short stories and sketches written earlier. Indeed, his greatest literary days were over. He communed with scientists, hoping to find explanations for eternal mysteries he felt religion evaded. Never divorced, he had lived since 1920 with the beautiful and admiring Helen Richardson, a second cousin, who endured his other affairs as a necessity of his genius—emotional stimulants he felt he needed to bring out his best writing. His income was reduced by the 1929 market crash and the depression that followed it, forcing him to scale down his luxurious mode of life. His book of poems, *Moods, Cadenced and Declaimed* (1926), had a sale of 922 copies, and the autobiographical *Dawn* of the same year sold not much better. No slave to consistency or academic logic, he began to see possibilities for good in the Communism he had recently rebuffed as well as in other plans for social amelioration. He was angered by American joblessness and privation alongside opulence. Unreasonable though he could be at times toward individuals, he had endless sympathy for society's underdogs. He threw himself into social protest despite its obvious conflict with his determinist philosophy, giving so much time and effort to insurgent causes that two long-planned novels, *The Bulwark* and *The Stoic*, were put aside and his writing in general suffered. The literary hero of the '20s became the tough-talking radical reformer of the '30s. He was so independent of the "party line" that the American Communist Party utilized his prestige for years before it would admit him to membership under the careful auspices of more conformist members. Soviet Russia later rewarded him with \$34,600 in royalties for Russian sales of his works.

In 1939 he and Helen moved to Hollywood, where he squeezed a living out of the capitalist system he had come to despise, in part by sales of his earlier works to the films. He published occasional pamphlets criticizing government inadequacies and mailed them out at his own expense. His *America Is Worth Saving* (1941) was little more than an expanded pamphlet against capitalism. Earlier friendships—even the one with his longtime

crony, Mencken—dwindled, and although he established new ones, his California life was a break with the past. He married the adoring and neglected Helen secretly in 1944 after the death of his first wife—a triumph for her although his stormy infidelities continued. His last novels, the long-delayed *The Bulwark* (1946) and *The Stoic* (1947) suffered from his haste and fatigue.

Although his brief popular vogue had passed when he died on December 28, 1945, at his home in Hollywood, he had won a unique place in literature through a sincerity, power, and compassion so striking as to render less important his failings in technique and polish. *Sister Carrie* and *An American Tragedy* are enduringly great folk novels as well as literary landmarks. His autobiographical works combine with his letters and other writings to reveal a rebellious life composing a drama of its own in its intense activities and involvement, his efforts to solve cosmic mysteries along with earthly political inequities, his belief in tea-leaf readers and Ouija boards existing without conflict with his excursions into pure science, his frank sensuality, his violence and unreason sometimes balanced by geniality and tenderness. His works have been widely translated, with large editions in Russia; critical interest in him still persists.

#### MAJOR WORKS

FICTION: *Sister Carrie* (1900); *Jennie Gerhardt* (1911); *The Financier* (1912); *The Titan* (1914); *The "Genius"* (1915); *Free, and Other Stories* (1918), including "The Lost Phoebe" and "The Second Choice"; *An American Tragedy* (1925); *Chains* (1927); *The Bulwark* (1946); *The Stoic* (1947).

OTHER WORKS: *A Traveler at Forty* (1913); *A Hoosier Holiday* (1916); *Plays of the Natural and Supernatural* (1916); *The Hand of the Potter* (published 1918), a play; *Twelve Men* (published 1919), biographical sketches; *Hey Rub-a-Dub-Dub: A Book of Essays and Philosophy* (1920); *A Book About Myself* (1922); *The Color of a Great City* (1923); *Moods, Cadenced and Declaimed* (1926; as *Moods, Philosophical and Emotional, Cadenced and Declaimed*, 1935), verse; *Dreiser Looks at Russia* (1928); *A Gallery of Women* (1929); *My City* (1929); *Epitaph* (1930); *Dawn* (1931); *Tragic America* (1932); *America Is Worth Saving* (1941).

**BIBLIOGRAPHY.** The bulk of Dreiser's colourfully voluminous letters and papers are at the University of Pennsylvania Library, Philadelphia. W.A. SWANBERG, *Dreiser* (1965), an exhaustive biography, avoids literary criticism. ROBERT H. ELIAS, *Theodore Dreiser: Apostle of Nature* (1949), illuminates Dreiser's philosophy and in the emended reissue (1970), contains a valuable survey of research and criticism. F.O. MATTHIESSEN, *Theodore Dreiser* (1951), is primarily criticism; while *The Stature of Theodore Dreiser*, ed. by ALFRED KAZIN and CHARLES SHAPIRO (1955), is an anthology ranging from reminiscence to criticism and contains the best general bibliography yet available. HELEN RICHARDSON DREISER, *My Life with Dreiser* (1951), is her candid account of their difficult relationship; the *Letters of Theodore Dreiser*, 3 vol., ed. by R.H. ELIAS (1959), is a rich selection. A balanced critical biography is PHILIP L. GERBER, *Theodore Dreiser* (1964); RICHARD LEHAN, *Theodore Dreiser: His World and His Novels* (1969), stresses the writer against his background. *Two Dreisers* by ELLEN MOERS (1969), combines biography and criticism in an intensive study concentrating on *Sister Carrie* and *An American Tragedy*.

(W.A.S.)

#### Dress

The varieties of dress (from the French *dresser*, "to set out, to arrange") worn by human beings, now and in the past, are so numerous that it is not possible to deal with all of them. Thus, this article does not consider national or regional costumes of the various peasant peoples of Europe or other parts of the world or the garb of modern primitive peoples of Africa, the Americas, and Asia. It deals chiefly with three main aspects of the subject of dress: (1) the ancient Mediterranean world; (2) western Europe (chiefly England and France), considered as standard for Europe and America, from the Middle Ages to contemporary times; and (3) East and South Asia.

Clothes and fire presumably were discovered in Paleolithic times, and both were important in extending the range of human habitation. It is possible only to guess at

Assess-  
ment

Decline as  
a writer

Paleolithic  
origins

the nature of clothes worn at a time so remote. Some authorities believe that Heidelberg man may have used his powerful jaws for chewing leather (as the Eskimo does today) and so have made it pliable enough for use as clothing. Neanderthal man certainly had tools, some of them strongly suggesting the instruments used by tanners; Neanderthal woman stayed at home while the man went hunting, and it is thought that it was at this time that a differentiation arose between male and female dress. In a cave of Cro-Magnon time, at Cavillon in France, a hairpin was found in such a position near a body as to leave no doubt as to its use. Other objects resembled toggles, or double buttons, and there were also bracelets and leg ornaments. Caverns in the Dordogne have yielded bone pendants and collars of ivory, shells, stags' teeth, and fish vertebrae. Mural paintings in a rock shelter at Cogull in the Spanish province of Lérida (Figure 1), show people clothed in what seem to be skin garments somewhat resembling those of the modern Eskimo. Skin garments cannot be made without needles, and specimens of these have been found in large numbers in Magdalenian burials.

From *Historia del Arte*; photograph, E.D.I. Studio, Barcelona, Spain

Figure 1: Paleolithic women wearing fur skirts. Detail of a reproduction of a mural painting in the rock shelter at Cogull, Lérida, Spain, possibly 8000 BC. In the Museo Arqueológico, Barcelona, Spain.

The theory of one scholar is that there are strong reasons for believing that the use of fundamental garment forms of a rudimentary perfection dates from the Magdalenian. A simple tunic, the ancestor of a long line of similar pieces, the skirt and kilt (or divided coverings for the legs), the mantle, or cape (precursor of the coat), as well as moccasins or boots, are among the probabilities. If this is the case, the fundamental forms of European clothing were established at this remote period and hardly changed in essentials until the middle of the 14th century AD.

Neolithic garments

Neolithic man made use of wool and flax fibres for clothing manufacture. Decorated spindle whorls found, for example, in the Grotte du Pontal, Hérault, indicate that the vital discovery of thread had been made, and fragments of both plaited and woven cloth have been found at Robenhausen in Switzerland and elsewhere. Dyes were used, the colours being the primaries—red (obtained from hematite), yellow (from the yellow weed *Reseda luteola*), and blue (from danewort).

Primitive man not only dyed his few clothes but also painted his body; and body markings, by painting, tattooing, or scarification, served to promote vanity, denote prestige, attract the opposite sex, indicate clan membership, and frighten the enemy, and they were probably not differentiated in his mind from garments. (Ja.L.)

## I. Western dress

### ANCIENT EGYPT

Modern knowledge of ancient Egyptian dress derives for the most part from ancient paintings and sculpture, since very few garments have been preserved. It is necessary to remember, therefore, that artists were very much bound by tradition and, further, that modes of representation lagged behind actual changes of fashion.

Practically the only fabric that has been preserved is linen, found in graves of the Neolithic period long before the Dynastic period. The Egyptians themselves realized that flax culture was very old and believed that the gods were clothed in linen before they made their first appearance on Earth. Wool seems scarcely ever to have been used, and silk and cotton were unknown. The Egyptians had not learned to use the mordants required to dye linen successfully and, as their clothing was frequently washed, only white was really practical. Nonetheless, yellow, blue, green, and red garments were worn on occasion. Costumes made of materials with coloured patterns are represented; but whether the material was linen, and if so how these patterns were applied and how often such garments actually appeared in real life, is uncertain. Tapestry weaving was known but was extremely rare, tapestries and embroideries apparently occurring only in garments belonging to the king and to members of his family and, indeed, being treated as heirlooms. To make up for the lack of colour, the material of the dress might be elaborately pleated or arranged in a mass of fine folds; bright ribbons might be tied around the waist and hair, and those who could afford to do so wore brilliantly coloured jewelry, often combined with garlands and wreaths of flowers.

As is usually the case, new fashions originated among the rich; the general tendency was toward greater and greater elaboration in both costume and accessories.

The first clothing worn by men was a narrow band around the waist to which pendants were attached, the whole arrangement being both amuletic and decorative. The loincloth and kilt were later developments of this. The characteristic masculine garment throughout the Dynastic period was a white linen kilt, a rectangular piece of cloth wrapped around the body and tied in front. The length, fullness, and method of adjustment varied with the date and the social position of the wearer. In the earlier Old Kingdom the kilt was usually short and draped smoothly around the hips. Often one or both of its lower corners were rounded; sometimes it was pleated or partially pleated and later it might be stiffened to project in front (Figure 2). In the Middle Kingdom there was a fashion for long kilts, sometimes reaching from waist to ankles, sometimes hanging from the armpits, with no belt or other interruption at the waist. In the late 18th dynasty, a double kilt appeared, long and full, with the upper one doubled and gathered in front. Fullness was always concentrated in front; and all garments—both men's and women's—were adjusted so as to fit the figure smoothly behind (Figure 3). A triangular loincloth sometimes, perhaps usually, was worn under the kilt.

Men's clothing

Although the upper part of the body was often left bare or covered with a shawl, shirts were worn during all periods. They are first represented in art, however, in the 18th dynasty. The shirt, like the kilt, was made of a rectangular piece of linen, the material being folded and sewn up the sides, with openings left for the arms and a hole cut at the fold for the head. Several shirts have been preserved with long, tight sleeves sewn into the armholes. The richly furnished intact tomb of the architect Kha of the 18th dynasty (the contents of which are in the Museo Egizio, Turin) contained a pile of about 50 loincloths,

## Women's clothing

many kilts 20 to 23 inches (50 to 58 centimetres) wide to about 67 inches (170 centimetres) long, seven sets of loin-cloths and kilts tied up together, and a pile of shirts of both light summer and heavy winter weight.

The earliest representations of women show them either nude or clad in tightly fitting white linen skirts down to the ankles. The characteristic woman's garment in the Old Kingdom was a long, tight slip held up by suspenders over the shoulders (Figure 2). During the Middle King-

dom and early 18th dynasty, artists copied Old Kingdom representations closely; and it is not possible to ascertain when the draped robe, which first appeared in pictures after the first half of the 18th dynasty, actually came into fashion (Figure 3). These robes were unshaped, each consisting of a length of material wound around the body, brought up over one or both shoulders, and tied at the breast. There were numerous ways of arranging the drapery; most commonly, the right arm was left free. Some pictorial representations seem to indicate a tight garment under the robe, but probably the artist was only trying to represent the first twist of the cloth, strained over the body so that folds or pleats were smoothed out. Men are also represented wearing the draped robe in the later New Kingdom.

Women, like men, wore heavy mantles for warmth. Examples survive of materials with a self-pattern on the right side that appears on the reverse as a thick, warm tufting. In the privacy of their homes most women may have gone about without clothing, as did their maids, who are often so represented.

Children are invariably shown naked, their heads shaved except for the "lock of youth" that hangs down one side. Still, a few children's shirts—smaller models of their parents'—have been preserved.

Sandals of woven rushes or of leather were worn on occasion by men, women, and children; but probably the Egyptians usually went barefoot, as, indeed, they still do in rural districts.

The clothing described above was for the most part that of the official class. The king himself is shown either in the severely simple short kilt of the Old Kingdom or in contemporary costume, with decorations peculiar to himself—an elaborately worked jacket, a jewelled belt and apron, and a variety of crowns or royal headdresses. At the other end of the social scale were the labourers and

workers in the fields, who went nude or perhaps wore a belt or loincloth of linen or leather.

Heavy wigs or a padding of false hair, worn by both men and women, are known from an early period. They served not only as an adornment but also to protect the wearer's head from the burning rays of the sun, thus in a way acting as hats. Semicircular kerchiefs, tied by the corners at the nape of the neck under the hair, were sometimes worn to protect the wig on a dusty day. Wigs were dressed in many different ways, each characteristic of a given period; generally speaking, the hair became longer and the arrangement of curls and braids—set with beeswax—more complicated as time went on.

The earliest records indicate that the Egyptians grew hair on their chins. They frizzed, dyed, or hennaed this beard and sometimes plaited it with interwoven gold thread. Later, a metal false beard, or postiche, which was a sign of sovereignty, was worn by queens as well as kings. This was held in place by a ribbon tied over the head and attached to a gold chin strap, a fashion existing from about 3000 BC to 1580 BC.

Cosmetics, like wigs, served a practical as well as an ornamental purpose. During the Predynastic period, men as well as women applied a line of green paint around the eyes, which helped to absorb some of the sun's glare. In dynastic times the colour of paint used was a dark gray. Red ochre seems to have been used to colour the cheeks and henna the palms, nails, and, in the late period at least, the hair. (Ed.)

#### MESOPOTAMIA

Simplicity characterized Mesopotamian clothing in the periods of that civilization's greatest flowering. Garments typically consisted of a rectangular piece of loosely woven wool, bleached or dyed red or blue. Linen was employed to a lesser extent, its use increasing in the 1st millennium BC. The warp formed a straight fringe along the short sides, sometimes knotted into tassels. The weft could be made to stick out in loops, forming a wavy fringe on the long sides. Red and blue garments had white fringes, and white garments often had coloured fringes. As Mesopotamian art suppresses most folds, the rendering of the borders is the best clue to the draping of the garment. Men normally draped their clothes counterclockwise, women clockwise. Since manual labour and warfare require freedom of movement, the long garments denote leisure and peaceful pursuits. In the earliest periods, clothes were discarded during the performance of feats of strength or service in the temple.

Wigs worn by men and women

Typical Mesopotamian garments

**Protoliterate and Early Dynastic periods.** During the Protoliterate period (c. 3400–c. 2900 BC) men of rank wore an ankle-length skirt, the rectangular cloth wrapped so that the visible short side was in front.

During the Early Dynastic period (c. 2900–2334 BC) the cloth was wrapped as before; but the short side was behind the left hip, where the ends of the belt or the cloth itself were knotted. A fringe of long weft loops encircled the skirt below. In the later part of the period, a luxury version had rows of loops all over (Figure 4).

Figure 4: Sumerian votive figures from the Square Temple of Abu at Tall al-Asmar, wearing Mesopotamian dress. (Left) Male wearing skirt with long weft loops encircling the bottom, c. 2600 BC. In the Metropolitan Museum of Art, New York. (Right) Female draped in cloth placed over the left shoulder and then passed under the right arm, c. 2900 BC. In the Iraq Museum, Baghdad.

Women wore a similar but larger cloth. With one short side it was placed over the left shoulder, then it was passed under the right armpit and again over the left shoulder, from where the other side hung down to the ankles, covering the left arm except for the hand. A hidden pin or stitching may have held the two layers of material together on the left breast (Figure 4).

**Akkadian, Neo-Sumerian, and Old Babylonian periods.** Men of rank now also wore a full-sized cloth (at least 100 by 50 inches [250 by 125 centimetres]), placed with the centre of one short side on the left lower arm (which had to be kept horizontal), wrapped around the back, under the right armpit and over the left arm and shoulder, thus giving freedom of movement to the legs and right arm. The other short side curved up the back. One corner was either tucked under the right armpit or brought forward over the right shoulder. When the cloth grew even longer, it was wrapped around twice, ending over the left arm. Exceptionally, the cloth might be wound clockwise, the first turn forming a skirt and the second brought over the left shoulder with the same result of disengaging the right arm while enveloping the left.

The beret, worn by rulers in the north in the Early Dynastic period, was current in the Akkadian period. Thereafter a turban, sometimes covered with curls as if made of fur, was the royal headgear.

For women, an arrangement covering both shoulders, not unknown before, now became common. The centre of one long side was placed across the bosom. Both short sides were passed under the armpits, crossed in the back

and brought forward over the shoulders and upper arms, so that two points hung down in front. The hair might be enveloped in a cloth held in place by a headband.

**Kassite period.** Mountaineers from the border of Iran who ruled Babylonia during this time (c. 1595–c. 1157 BC) introduced heavy, richly decorated clothes and soft shoes.

**Assyrian period.** The basic garment of the Assyrians was the rectangular tunic. The slits for neck and arms often had embroidered borders, and tassels sometimes appeared around the bottom. Depending on the freedom of movement desired, tunics were ankle length or knee length, girt with a cummerbund over which a narrow belt might be worn. Sandals were the common footgear (Figure 5).

Over the tunic, the king threw a long shawl, draped like the traditional garment but, being narrower than the latter, covering the right side only from the waist down. For the lesser members of the court the width of the shawl decreased, becoming a mere sash. The king also wore a headband with rosettes, either separately or over a pointed cap similar to a fez.

Figure 5: Assyrian king (possibly Ashurnasirpal II), with an elaborately dressed beard, wearing sandals and a full-length tunic decorated with embroidery and tassels, amber figurine, 9th century BC. In the Museum of Fine Arts, Boston.

Assyrian women wore a sleeved tunic and a large shawl, wrapped so as to cover both shoulders.

The Babylonians also wore sleeved and belted tunics, drawn smooth in front so that the folds of the material were concentrated in the back of the garment. Diagonal shoulder bands may denote rank. The royal headdress (generalized in Persian times) took the shape of a pointed cap with a streamer. (M.N.v.L.)

The Assyrians (like the ancient Persians) devoted great care to oiling and dressing their beards, using tongs or curling irons to create elaborate ringlets and frizzles, in a tiered effect. Assyrians resorted to a black dye for eyebrows, hair, and beard, whereas the Persians used henna, which produced an orange-red colour, a style that existed from 1900 BC. Gold dust, gold thread, and scented yellow starch were sometimes used in the hair and beard for festive occasions. (W.J.Tu.)

#### PERSIAN, ARAB, AND OTTOMAN EMPIRES (TO MODERN TIMES)

The primitive costume of the Persians was made of animal skins, for wool was little known before the time of

Garments  
of men of  
rank

Importance of  
beards

Cyrus and cotton and silk were not known at all. The costume was in the form of a coat and breeches; and this, with minor modifications, has lasted until modern times. With growing prosperity, the Persians began to make both coat and trousers of coloured cloth. They wore at first a conical leather hat, which was exchanged for a time for the Phrygian cornet (Figure 6). The conical

Figure 6: Achaemenid Persian man wearing a coat, trousers, and a Phrygian cornet. Silver statue, c. 559–330 BC. In the Vorderasiatisches Museum, East Berlin.  
By courtesy of Vorderasiatisches Museum, Berlin

cap was sometimes circled by bands of cloth, in which perhaps may be seen one of the origins of the turban. A relief found in the ruins of the palace of Persepolis shows various figures bringing presents, clad in a mixture of Persian and Hebrew modes (the Hebrew dress was longer than the Persian and, in the Semitic tradition, without trousers). There is hardly any trace in ancient Persian monuments of the dress of women.

Scythians and Parthians wore trousers with coats that were open at the front and crossed with a belt to keep them in place. The coats of the women were longer but otherwise similar, except that the belt was sometimes replaced by a long piece of cloth wound around the hips and knotted in front.

**7th century.** Arab conquest in the 7th century AD brought modifications. Arab costume itself has been singularly unchanging, as can be seen from occasional representations in monuments of ancient Assyria and Egypt. The Arabs' earliest garments seem to have been a piece of cloth wrapped around the body below the armpits and a long, full shirt with or without sleeves. The descendant of this latter garment is the garb of many modern Egyptians. The Arabs wore over it a mantle of coarse wool or of camel's hair in the shape of a sack open at the bottom, with holes for arms and head. This is the *aba* mentioned in the Bible as the costume of the Hebrew prophets. It was usually cream coloured with wide vertical stripes of black, white, brown, and blue. The head-dress was a small piece of cloth wound round the head or folded in a triangle and kept in place by a ribbon tied in a knot at the front or a cord, plain or ornamented, encircling the crown. This is the *ḥā'ik*, the characteristic Arab headdress even of the 20th century. Under it is

worn a felt cap (or several felt caps one over the other) coloured red, white, or brown.

No representation is known of the early dress of Arab women, but it probably resembled closely the dress of men and has continued to do so. The shirt, or chemise, reaching to the ground and very wide, was open over the chest but buttoned at the neck. A scarf was worn around the waist. The mantle consisted of a large rectangle of woolen cloth, black or blue with yellow or red stripes. It was sometimes worn over the head on top of a small fichu (triangular scarf) wound around the crown. The usual veil is a band of black crepe or white muslin, sometimes long enough to reach the feet, kept in place by two ribbons attached to a circlet around the head and often ornamented with pearls or coins.

**11th century.** The great Turkish migration of the 11th century brought some changes to both Arab and Persian costume. The Persian costume at this time consisted of a shirt, a caftan (a Turkish word describing a kind of long coat open at the front, with short sleeves, and sometimes edged with fur), and a cloak. The cap of lambskin in the form of a truncated cone, introduced by the Turks, is still worn in Persia. A cap of similar form but red in colour and made of felt, the *fez*, became the characteristic headgear of Turks until abolished by Kemal Atatürk in 1925.

Characteristically, the Persian trousers were baggy and gathered in at the ankles. Slippers were made of leather and had turned-up points. Kurds, Afghans, Georgians, and Armenians long preserved these modes, which are by no means extinct.

**16th century.** Documentation increases during the 16th century, when Europe became conscious of the Turkish threat, and there was a growing interest in exotic dress. The costume worn by Persian women—and still surviving—consisted of a white cotton chemise with long sleeves; long woolen stockings; woolen embroidered slippers; wide trousers of dyed cotton, tied around the ankles and hanging in folds; an underwaistcoat with long sleeves open to the elbow and a short-sleeved overwaistcoat; a small cap; and a shawl tied around the waist. A veil of white muslin was either wound around the head or suspended just below the eyes. Out of doors, women threw over their shoulders a piece of cloth that covered them completely.

Men's dress at this period, at least among the upper classes, consisted of trousers at first extremely ample (still worn among the Kurds) but gradually growing tighter. The chemise, or shirt, often striped and patterned, worn outside the trousers and falling sometimes to the knees and sometimes to half-calf, was provided with long sleeves. The caftan was buttoned across the chest and closed by means of a scarf (Figure 7). Its long skirts were sometimes turned back and attached to the belt. An outer garment as long as the caftan and always more ample was of a different colour. In the 20th century the overmantle was provided with long wide sleeves, sometimes slit. A very ancient garment, long retained, was the *'abā*, a kind of long cloak, originally made of camel hide, thrown over the shoulders. Sometimes it had a single wide sleeve, a peculiarity preserved by the modern Kurds.

The waistcoat, dating from the end of the 16th century, was generally of red or blue cloth with braid of a contrasting colour and adorned with small buttons sewed very close together. Over this was sometimes worn a short coat, rather like an Eton jacket, similarly ornamented. Red leather slippers were worn by all except clergy and magistrates, who wore blue.

The original headgear of the Turks was probably a round Tatar cap edged with fur, but after the capture of Constantinople the sultan imitated the Prophet Muhammad by surrounding his cap with a large amount of white muslin wound around and around. It was at this period that the turban became usual among the Turks. Functionaries were compelled to wear it in a form determined by their rank. The costume of the lower classes consisted simply of trousers and a cloak of hide or cloth.

Women's costume was hardly to be distinguished from

Persian dress

The caftan and *'abā*

Turkish headgear

Modifications brought about by the Arab conquest

Figure 7: Persian prince wearing a caftan buttoned across the chest and closed with a scarf. "Prince Muhammad Beg of Georgia," watercolour on paper by Rezā 'Abbāsī, Isfahan, early 17th century. In the Islamisches Museum Berlin, East Berlin. By courtesy of the Islamisches Museum Berlin

that of men except that the trousers continued to be more ample. The chemise, made of white muslin and falling to mid-thigh, was décolleté and had no sleeves or very short ones. The dress was open in front and reached the ground. Veils of black horsehair or white muslin were attached to the headdress, a small cap that was often ornamented with precious stones. The hair was worn either loose and flowing or in plaits encased in a kind of cloth tube.

**20th century.** In the second half of the 20th century, the visitor to Near Eastern countries finds little enough of the traditional costumes described. After the foundation of the Turkish republic there was a progressive invasion of European influences, particularly in Turkey itself. Men largely adopted some form of European dress, the women less so, except in Egypt. Wealthy Egyptian women obtained their clothes from the best couture houses of Paris; and even peasant women, if they had not abandoned the veil, wore one of net that hardly concealed the features. On the other hand, the black horsehair veil still worn by the women of Damascus and Baghdad makes it difficult for an observer to decide whether the wearer is coming or going.

The typical Turkish fez is still worn by men in Egypt, the rest of the costume being altogether European. This was the rule among the Turks in the days of the last sultans, who themselves wore frock coats with Turkish headgear. Indeed, the process of Europeanizing had begun in the middle of the 19th century. In 1873 the Imperial Ottoman Commission for the Universal Exhibition of Vienna sponsored an elaborate work containing photographs of men and women in all parts of the Turkish empire, and the pages of this volume reveal clearly not only the variety of costume in the different regions but also the layers of influence out of which they had been built up. In what was then the *vilâyet* of Baghdad, men are shown dressed in the pure Arab mode, while the women wear a recognizably Persian costume. The peasant of the neighbourhood of Jerusalem wears a long white cotton shirt, with a broad leather belt, and over it a garment resembling a Western academic gown, with broad black and white stripes; his fez is wound around with white muslin. A Christian artisan in the region east of the Jordan River

wears over his long open shirt, the jubbah, a long, sleeved garment resembling a Western mackintosh. A peasant woman of Damascus is seen covered with jewelry "like an Assyrian idol of which her costume conserves the archaic form." A peasant woman of Lebanon, on the other hand, wears garments of biblical simplicity. The clothes of a woman of Beirut are plainly *à la française*. A Kurdish soldier has a turban like that of the Afghans. In Istanbul the same bewildering variety is apparent. The old-fashioned bourgeois is still clad in the costume of his ancestors; the young government employee wears black trousers and a frock coat—there was nothing Oriental about his garb except the fez. Between these two extremes could be found every combination and permutation possible. Especially after World War II the process of Europeanization was greatly speeded up. (Ja.L.)

#### THE AEGEAN

Clothing worn by the Cretans in the 3rd and 2nd millennia BC and by the Mycenaeans in the second half of the 2nd millennium was very different from Oriental as well as from later Greek costume. Early in the 3rd millennium in Crete, men wore a short loincloth attached to a tight, broad belt (Figure 8, right). A relief vase from the early 2nd millennium shows a prince wearing long hair, uncovered, and an officer wearing a helmet. From Late Minoan times, a life-size stucco relief showing a king and a wall painting showing young men carrying precious gifts indicate that elaborate loincloths, with woven patterns and embroidered borders and adorned in front with tassels, were worn. Similar are the costumes of envoys from Crete pictured in Egyptian tombs.

On the mainland, in Mycenae, Tiryns, and Sparta, where the Cretan civilization was accepted and imitated in the second half of the 2nd millennium, men wore short tunics with long sleeves for war and the hunt, a helmet with boars' teeth, high sandals, and leggings. The figure of a musician carved on the sarcophagus of Ayia Triádha in Crete (c. 1400 BC) shows that this tunic was adopted there from the Mycenaeans; the lyre player wears a long, sleeveless tunic with a stripe running around the shoulders and down to a decorative border. The priests who bring offerings wear fur skirts.

The costume of Cretan noblewomen is much more complicated, reflecting the luxurious living and gay spirit of court life. A lady of the 3rd millennium wore a bell-skirted dress, the sleeveless bodice of which exposed the breasts and stood away from the nape of the neck. Her cap was high and turbanlike. In the Middle and Late Minoan periods this dress became a tailored, well-fitted, elegant robe. The temple repository in Knossos shows priestesses with bell-shaped skirts made of small strips sewn horizontally together or of different-coloured flounces falling one over another (Figure 8, left). An apron, similar to the loincloth of the men, hangs from a broad, tight belt. The jacket is open in front, but the breasts are covered by a diaphanous vest. Narrow sleeves cover the upper arms. The headdress is a high turban or a crown.

When Cretan civilization was taken over by the mainland, women accepted this rich dress and made it even richer. The best example is provided by the figures of women from a fresco at Tiryns; their dress exhibits flounces (strips of material attached to the garment at their upper edges), some smooth, others with scale and half-moon patterns in different colours; the jacket has borders of flower petals. The hair is elaborately bound up with ribbons and rings, with rows of small curls before and behind the headband, a chignon on the crown of the head from which a ponytail falls, and four long strands falling down the back (Figure 8, left). When women went to the hunt, as shown in another fresco from Tiryns, they wore a simple tunic like that of the men, except that it had short sleeves and no belt. In bull games women wore the apronlike loincloth and high sandals of the men. On the Late Minoan sarcophagus of Ayia Triádha, the priestess, like the priest, wears a skirt made of fur.

In the shaft tombs of Mycenae many golden diadems,

breastplates, and buttons have been found, the last used perhaps as jewelry or sewn on dresses as ornaments.

#### GREECE AND ROME

**Greece.** The clothing of the Greeks, like their civilization, changed with the three periods of their history: the Archaic (c. 750–c. 500 BC), the Classical (c. 500–323 BC), and the Hellenistic (323–30 BC). In the Archaic period the dress was influenced by the Near East; in the Classical period it was original and harmonious; in the Hellenistic period it was luxurious.

In the Archaic period, overall patterns, as well as figured representations, ornamented fabrics. In the Classical period, patterns were restricted to borders and central stripes. Priestesses wore only white, but other women used many different colours. In the Hellenistic period these became more brilliant, and many mixed colours, particularly violet, were used. Servants and artisans wore dark dresses.

The main dress of Greek men and women in all periods was a linen (later sometimes woollen) shirt, the *chiton*. Homer mentions the garment often, terming it radiant white and long. Ionian men wore it with a train, and a long *chiton* was worn by all men in the Archaic period, later only by elderly men, priests, and charioteers (Figure 9, left). After the Persian war, young men wore a short, narrow version. In its simplest form, the *chiton* was made of two panels of linen cloth seamed up the sides and across the top, with openings left for the head and arms. Actors and priests (for example, the priest of Athena on the central slab of the east frieze of the Parthenon) wore sleeved *chitons*.

The *chiton* worn by women was much wider than that of men (sometimes as wide as the woman's measurement from fingertip to fingertip, with the arms outstretched). Hence the openings for the arms were left at the top, rather than on the sides; in adjusting the garment the wearer brought the two edges together at the shoulder and fastened them with a brooch or brooches along the

upper arms. The waist was gathered in with a girdle, the extra length (the garment was about a foot longer than the wearer was tall) making a *kolpos*, or pouch, well illustrated by the caryatids (columns in the form of female figures) of the Erechtheum.

Artisans, warriors, and slaves wore a short *chiton*, often with the right shoulder left free.

A garment worn exclusively by women, in the early Archaic and later again in the Classical period, was the *peplos*, a large rectangular piece of wool folded vertically and worn with an overfold at the top in several different ways (Figure 9, right). Every four years the young girls of the best families of Athens, under the guidance of the priestess, wove a new *peplos* for the cult statue of Athena Polias, the city goddess.

Athletic Spartan girls and other young girls wore the *peplos* without a belt and with one side left open so that the leg showed. In most cases, however, a belt was worn, either around the waist or, in the Hellenistic period, much higher, just below the bust. If the overfold of material at the top was long, the belt was laid over it; and it is seen thus in many statues of Athena. If the overfold was short, the belt was placed below it and a pouch made of the excess length. For young girls both overfold and pouch were long, so that the dress could easily be lengthened for the growing girl by shortening overfold, or pouch, or both. When *peplos* and *chiton* were worn together, the *peplos* served as the overdress.

The *peplos* and the *chiton* became more and more similar in form with the passage of time. Sometimes the *peplos* was worn without an overfold; sometimes the *chiton* was worn with one—an example of the latter is that worn by the caryatids of the Erechtheum. In the Hellenistic period very costly materials—cotton and silk, in addition to thin linen and wool—were used. A heavy woollen *chiton* (*peronātris*) was fixed on the shoulders with clasps (*peronē*).

The *peplos*, being merely a rectangular piece of material, could also be used as a mantle (*himation*). As such,

The peplos

### The *himation* and *chlamys*

in the Archaic period, it was laid symmetrically over both shoulders and the ends were allowed to hang down in front. In the Classical period it was commonly draped in such a way that a long end hung down from the left shoulder in front; the *himation* then was carried back over the left shoulder, across the back, across the right shoulder or hip to the front, across the body, and again thrown back over the left shoulder, arm, or hip (Figure 10, left). Women draped the *himation* over their heads when walking outside the house, as did both men and women in mourning. The many possibilities for style of draping were used by sculptors to reflect the character of the wearer of the *himation*.

A smaller mantle, the *chlamys*, worn by men only, was draped around the upper body and fastened with a brooch on the right shoulder, leaving the right arm free (Figure 10, right). The four corners hung freely on the right side. The two lower ones were rounded during the Hellenistic period.

Men and women generally wore sandals, the soles of which were fastened by leather thongs crossed in various ways and bound above the ankle. Men also on occasion wore high leather boots, and women sometimes wore soft closed shoes. Women's shoes became very luxurious in the Hellenistic period. White and red were preferred colours.

### Hair styles and beard;

In the Archaic period men wore beards, which were often curled into ringlets with tongs, and long hair. After the Persian Wars they cut their hair short; and in the Hellenistic period they shaved their beards on the order of Alexander the Great, who feared the beards might serve as handles to the enemy. Women often wore their hair parted in the centre and bound up in various ways

with ribbons, diadems, and scarves; chignons and loose back hair were common. Little girls wore braids and twisted locks. In the Hellenistic period the so-called melon coiffure, with many partings, like the rind of a melon, was fashionable for women and children. (M.B.)

**Etruria.** Whatever the origin of the Etruscans, the people of the region now called Tuscany developed their civilization in the so-called orientalizing period in close contact with Greek and Near Eastern culture. Some differences were due to the great wealth their mineral deposits brought them, although their clothes conformed in general to the Greek fashion of the period. Athletes and young men wore short pants (*perizoma*); older men wore a long *chiton* covered by the heavy woollen *chlaina*, which was pinned at the shoulder by a brooch, or fibula. There was a short *chiton*, although this was worn less frequently than in Greece or in the East, and a three-quarter length *chiton*, more Oriental than Greek. Men wore their hair bobbed, as in Greece. Women also wore a long *chiton*, with a peculiarly Etruscan mantle hanging straight down the back. Long back braids, known elsewhere in the Mediterranean in Late Mycenaean and

orientalizing times, were typically Etruscan. Hats included the simple *pileus*, as in Greece, the *petasos*, and pointed Oriental models. Judging from the rich gold jewelry found in tombs, their taste ran to luxurious necklaces, earrings, bracelets, fibulae, and pectorals.

Around the middle of the 6th century many elements were adopted from the Greeks of Asia Minor (Ionia), probably often by way of Greek colonies in southern Italy and Sicily. The thin linen Ionian tunic (possibly an Etruscan word) or *chiton* replaced the earlier woollen, straight *chiton*, although the *peplos* with overfold was

never adopted in Etruria. Pointed shoes became the rage, for men as well as women, from c. 550 to 475 BC. The typical hair style for women was the high chignon, or *tutulus*, often covered by a veil, or the Greek kerchief, or *mitra*. Men wore their hair long. Mantles for women remained rectangular, though they were not worn in the contemporary Greek fashion. Men adopted a rounded mantle, the *tebenna*, the forerunner of the later Roman toga. The short version, worn by the Etruscans in Rome at the time of the last Tarquin, was what the Romans later called the *trabea* and adopted as ritual religious dress. Roman ritual costume preserved many fashions of this period (*tutulus*, or *sex crines*, *calcei*, *toga praetexta*, *bullae*), much as modern church vestments preserve the dress of the Middle Ages. From c. 450 to 300 BC Etruscan dress conformed more closely to Greek dress, although some typically Etruscan elements remained, such as the rounded mantle for the men and a special *chiton* for women. By the Hellenistic period, Etruria had been conquered by the Romans. Etruscans wore the standard Hellenistic fashions, except for the *tebenna*. The longer model was worn by the Romans as the toga, symbol of Roman or Italian citizenship. (L.B.W.)

**Rome.** After the Tarquins were driven out and the Etruscans defeated and brought under the supremacy of Rome in the 4th century BC, the Romans kept the Etruscan dress, at least for their priests (Figure 11, left). After the conquest of Magna Graecia, however, in the 3rd century, Roman women adopted the *chiton* (Latin *tunica*) with a high belt and *himation* (*palla*). Men also began to wear the *himation* (*pallium*). Nevertheless, the Romans had a number of original forms of dress. The most characteristic feature of Roman dress is its sharp differentiation by social and professional classes.

The tunic, a shirt corresponding to the Greek *chiton*, was introduced to Italy by the Etruscans (Figure 11, left). It consisted of two pieces of linen sewn up the side and across the top, with holes left for the head and arms. Plebeians, herdsmen, and slaves wore narrow tunics of coarse linen in dark colours; patricians wore fine white wool. For children, the tunic was made wide, with large sleeves. The tunic *angusticlavia*, or tunic with narrow

stripes, was worn by children of patricians until 16, when they received a pure white tunic (*tunica pura*). Magistrates and knights wore the *tunica angusticlavia*, senators and other high officers, the *tunica laticlavia* (with broad stripes). Women's tunics had a broad central stripe down the front. At funerals and other rites and by brides, the tunic was worn ungirt (*tunica recta*).

In later times the sleeves were woven in one piece with the body of the tunic, and the decoration became variegated, particularly for children (Figure 11, right). In the 2nd century AD the sleeves became very wide, the stripes often being repeated on them; this garment was the *dalmatica*, fabricated of white Dalmatian wool. It was later taken over as a Christian liturgical vestment.

The distinctive Roman mantle, the toga, originally Etruscan (Figure 12, top), was worn during the early period by both men and women of all classes. Gradually, it was abandoned by women, then by labouring people, then by the main body of patricians. Throughout the history of the empire, however, it remained the state dress, the garment of the emperor and of high officials of the state. Colour and purple border were rigidly prescribed for most wearers, and the style of draping became extremely complicated—so complicated that rich men had special slaves whose chief duty was handling the toga (Figure 12, bottom). For triumphs and, later, for consuls, the toga was embroidered (*toga picta*). Candidates for office wore an all-white toga *candida*.

Footwear was differentiated according to classes. Women wore closed shoes in white, red, green, or yellow. Men wore sandals, those of the patricians being red with a moon-shaped ornament on the back. Senators wore brown shoes with four black leather straps wound around the leg up to the middle of the calf and tied in two knots. Consuls wore white shoes. Soldiers wore heavy boots with toes free. (M.Bi.)

In Rome, wigs came into use in the early days of the empire. They were also known to the Carthaginians; indeed, the Greek historian Polybius said that Hannibal used wigs as a means of disguise. Juvenal relates that the empress Messalina assumed a yellow wig, a badge of prostitution, for her visits to brothels. Later, the fashion-

able ladies of Rome almost universally used hairpieces, and references in the writings of Ovid and Martial indicate that the golden hair imported from Germany was most favoured. Men also occasionally wore wigs for disguise or, like the emperor Otho, to conceal baldness. Women continued to have wigs of different colours as part of their ordinary wardrobe; Faustina, wife of Marcus Aurelius, is said to have had several hundred. Some portrait busts—for example, that of Plautilla in the Louvre—had removable hair, so that by changing the wig a statue would never be unfashionable.

The Romans frowned on the curled beards of the Greeks, considering them effeminate, and preferred a trim, well-groomed shape. The use of the razor was encouraged in 6th-century BC Rome in an effort toward hygienic reform, but shaving did not become general until about 454 BC, when a group of Greek Sicilian barbers came to the mainland from Sicily. Barbershops were situated on the main streets but were patronized only by those who could not afford slaves. The Roman general Scipio Africanus, according to the scholar Pliny the Elder, was the first Roman to shave daily. Philosophers, however, retained their beards. A beard at this time also signified mourning.

(M.B.)

#### EUROPE THROUGH THE 18TH CENTURY

**Middle Ages.** In the early Middle Ages the clothes of both men and women in western Europe showed very little change from those of five centuries before, when Gaulish and Germanic costume had been assimilated by

that of Rome, toga abandoned, and trousers—usually loose and cross-gartered—added. Short tunics, sometimes two at once, often made of undyed woollen cloth, were worn by men almost universally. Shoes were simple moccasins, often made of untanned leather. An ample cloak completed the outfit. Such a costume remained that of men of the lower classes for many centuries. Women wore a kirtle, a rather long, shapeless dress concealing the lines of the figure. The sleeves were long and wide, and beneath them could be seen the tight-fitting sleeves of an underbodice. There was very little decoration, and colours were simple—mainly earth colours and vegetable dyes. The hair was entirely concealed by a veil.

Feudal lords returning from the Crusades introduced Oriental luxuries such as silks and damasks (see below *Non-Western dress: China*). Trousers were replaced by close-fitting hose, revealed by a tunic that at first reached to the knees and later to the ankles. The long, full gown had tight, embroidered or jewelled sleeves; and around the hips was a decorated belt from which hung a pouch, a sword, and a dagger. There was also a straight over-mantle fastened around the neck by a cord, chain, or jewelled clasp. Improvements in weaving and dyeing made possible a wider range of colours, and the garments of both sexes began to be trimmed with fur. The typical male headgear consisted of a hood framing the face and forming part of a short cape over the shoulders. The hood was sometimes lengthened at the back to form a point or even a long tail known as a liripipe.

The shaping of garments to the body, for both men and

Appearance of "fashion" in the mid-14th century

women, began at the end of the 13th century; and by the middle of the 14th something that can be recognized as "fashion" appeared (Figure 13). Men wore a gipon, a kind of short tunic, tight-fitting and buttoned down the front; the sleeves were very tight and long enough to cover the knuckles, the neck was round and low. When the gipon was worn without an overgarment called a cotehardie (a close-fitting, long-sleeved tunic long enough to cover the buttocks), it was belted around the hips. Tight hose were revealed, the two legs often of different colours. The upper garments were sometimes similarly of divided colour and adorned with heraldic emblems; for at this period both men and women often wore their coats of arms on their own persons. Shoes, long and pointed, were known as crackowes after the Polish city of Cracow (Krakow); it is thought that the marriage of Richard II of England to Anne of Bohemia (Poland at

that time being part of the kingdom of Bohemia) was responsible for this fashion. Gloves, at first worn by kings and bishops as a status symbol, were worn universally among the upper classes in the 14th century.

A characteristic male overgarment from 1380 to 1450 was the houppelande, later called the gown. It fitted the upper part of the body closely but fell below the waist in folds; it was belted around the hips. The neck had a high, upright collar, the edge of which was often "dagged," or cut in fancy shapes. The hood also was dagged; and between 1390 and 1410 a peculiar mode arose of inserting the head into the face opening, winding the folds around like a turban, and binding them in place with the liripepe. The dagged edge thus formed a kind of cockscomb. Hats were also worn with a plume attached by means of a jewelled brooch.

Women continued to wear the kirtle but, like men's clothes, more closely fitted and now décolleté. Sleeves were extremely tight, with many buttons. The cotehardie worn by women had long sleeves sometimes reaching to the ground. Over it, women wore a sideless surcoat, consisting of a front and back descending to below the waist, which remained fashionable for more than a century. In headdresses there was increasing elaboration. Older women continued to wear the veil and the wimple, a piece of cloth covering the chin; but court ladies adopted a kind of circular arch of ridged or pleated linen. Another fashion was to frame the face by means of two pillar-shaped structures of net enclosing the side hair.

After 1400, men were clean-shaven; they were, indeed, almost compelled to be so because of the introduction of a helmet with a chinpiece instead of the cowl of mail usual in the preceding century. They also cut their hair short; and after 1410 the "bowl crop," which looked as if the hair had been cut around a bowl, was usual.

About 1420 the gipon, now called a doublet, began to develop a collar. The cotehardie worn over it was very short at the beginning of the century, but knee length from about 1410 to 1450. The houppelande, or gown, showed considerable variation in the shape of the sleeves. The belt was now usually worn at the waist instead of around the hips. Materials were richer, and there was an increasing use of fur trim. Hose now began to be joined together like modern theatrical tights and were attached to the lower edge of the doublet by "points," or strings. The hood became rare except among the peasantry, the usual form of headgear being the chaperon, a kind of ready-made turban. There was an increasing use of hats, some of them resembling the top hats of a later age. Women's headgear assumed fantastic shapes; the hennin, or steeple headdress (a cone with a veil attached at the top), for example, was fashionable in France and Flanders between 1460 and 1480 (though it never became popular in England). There was also a turban for women and a so-called butterfly headdress of transparent gauze raised above the head by means of long pins.

In the second half of the 15th century men wore, under a very short doublet, a kind of padded waistcoat, known

Increasing use of hats

confusingly as a petticoat. The shoulders of the doublet were puffed and padded. A tall brimless hat, like a Turkish fez, was worn. For women, the sideless surcoat was replaced by the gown, often with a very deep décolletage. Skirts were very long, often with a train (Figure 14).

**16th century.** The characteristic English fashions of the 16th century were beginning to appear at the time of the accession of Henry VII in 1485. For women, the butterfly headdress was replaced by a low hood lined with fabric of a contrasting colour and turned back in a broad fold. When this was stiffened in the shape of a flat arch it developed into the "Tudor" headdress.

Men were still clean-shaven but wore their hair long. Hats were sometimes adorned with large feathers. Long, pointed shoes gave place to extremely broad shoes. Sleeves, sometimes detachable, also became noticeably wider. They were nearly always puffed and slashed, a curious fashion supposed to have been derived from the costume of German mercenaries. The doublet was longer, reaching almost to the knees, but parted in the front to reveal the codpiece, a pouch at the crotch of the breeches. Under the doublet, men wore a waistcoat, over it, a jerkin or jacket, and over that, a sleeveless and heavily furred gown. All prosperous men wore a gold chain; and this, together with the sleeveless furred gown, has survived as the traditional dress of English mayors. The hat was generally small and worn over one ear. After 1530 it was the fashion to cut the hair short and wear a full beard (Figure 15).

Women wore the kirtle and over it the gown, tight-fitting to the waist and falling in ample folds to the ground. Toward the end of Henry VIII's reign the gown was given a curious bell-shaped sleeve, narrow at the shoulder and opening out to an enormous fur cuff. Trains became shorter after 1530 and 10 years later disappeared entirely. The neck of the gown was cut low and square, revealing the neck of the kirtle and, below that, the top of the chemise.

The English hood, or Tudor arch headdress, was gradually replaced by the French hood, which was smaller and worn farther back on the head, exposing the hair above the forehead.

The German influence that had been dominant in the first half of the century gave place about 1550 to Spanish. The new effect was narrower, tighter, and more formal. The doublet had a narrower sleeve, and its skirts shrank almost to the waist. Puffed trunk hose, frequently slashed in contrasting colours, covered the hips and thighs. The characteristic cloak was short, reaching only to the hips, and about 1560 it was the fashion to wear it attached to one shoulder only.

The most striking characteristic of both men's and women's costume in the second half of the 16th century was the ruff, a frill of folded linen, worn around the neck, that gradually grew larger and larger. It was at first supported by wires, but the invention of starching made these unnecessary. Women's ruffs were worn above or divided in front to show the décolletage. Sometimes worn with the ruff was the rebato, a wired collar edged

with lace and standing up behind the head in the shape of wings. This is the style familiar from portraits of Queen Elizabeth I (Figure 16). Much jewelry was worn by men, chiefly in the form of gems sewn onto the doublet. Women wore stomachers (a jewelled garment worn over chest and stomach) as well as necklaces and ropes of pearls.

Women's skirts grew wider and wider and were kept distended by a roll farthingale (a padded roll worn around the hips) or by a wheel farthingale, which made its wearer look as if she were standing in a large drum. The dresses, however, were sometimes sufficiently short to show the clocked (with the sides ornamented with woven or embroidered decoration) and molded stockings made possible by the invention of the stocking frame. In the last quarter of the century, women wore their hair turned back from the forehead over a pad or a wire known as a palisado. Men generally wore their hair short, and beards were almost universal: pointed, forked, or spade-shaped, sometimes even dyed crimson. Many men adopted the curious fashion of wearing an earring in one ear. The flat caps that had been worn in the first half of the century were replaced among the fashionable by hats of various kinds. Apprentices and others of low degree were ordered to wear woollen caps, but the law was ineffective and was repealed in 1597. Women wore hats only for riding or travelling.

**17th century.** The modes of the 16th century continued almost unchanged until after the death of Queen Elizabeth I and even during the early years of the reign of James I. The change came about in 1610 with the disappearance of trunk hose and the vogue for longer and tighter breeches. Tall hats ornamented with feathers gave place to low-crowned, wide-brimmed hats. Instead of shoes, there were wide boots reaching to the knee and turned down or half-length boots with wide tops. Ruffs were replaced by wide collars falling over the shoulders and edged with lace. This became the characteristic Van Dyck collar of the Cavaliers; in a plainer form it was worn by the Roundheads also. Women's neckwear showed the same transition, although sometimes the ruff and falling collar were worn together. Women began to wear a square piece of material pinned around the back of the head known as a head roll. The bodice was now short-waisted, with a round instead of a square décolletage, often laced up the front with a ribbon. The sleeves were wide and sometimes puffed and slashed. The skirt, instead of being distended over a farthingale, was now bunched up to reveal a petticoat (Figure 17). Among the men, long hair showed Royalist and short hair Puritan sympathies.

The Puritans' costume was similar to that worn by their Dutch contemporaries; the Cavalier costume was essentially French. The Restoration of Charles II was a real victory for French over English fashion. The doublet had become so short that the shirt was revealed between it and the breeches, and its sleeves also were very short, reaching just to the elbow. The breeches, loose at the knee like very wide shorts, were called Rhinegraves. Every item of clothing was lavishly decorated with ribbons. The falling collar had become a kind of bib edged with lace (Figure 17).

Then, in 1666, there was a complete revolution in masculine attire. The diarist Samuel Pepys records: "This day the King begins to put on his vest . . . being a long cassock close to the body of black cloth . . . and a coat over it." The other great diarist of the period, John Evelyn, calls it "a comely dress after the Persian mode." The new costume, which by 1670 was firmly established in both England and France, consisted of a long coat with wide, turned-back sleeves and a row of buttons down the front. Some of these were left unbuttoned to reveal a garment almost identical but without sleeves. Neither coat nor waistcoat (as the undergarment was to be called) was provided with collar or rever (portions of a garment turned back to reveal the reverse side), but a cravat of lace or muslin, sometimes with a bow, was worn. Breeches were tight-fitting; and the stockings, gartered below the knee, were pulled up over them. The out-

fit was completed by a hat that had already begun to be cocked but had not yet become a tricorne, or three-cornered hat (Figure 18, top).

From Versailles, where Louis XIV began to wear a wig in the late 17th century, the fashion spread throughout Europe (Figure 18, top). After the Restoration in England, under Charles II, the wearing of the peruke became general. Samuel Pepys records that he parted with his own hair and "paid £3 for a periwig of human hair," and on going to church found that "it did not prove so strange as I was afraid it would."

There was not much change in women's dress during the first 20 years of the reign of Charles II, though women's garments gradually became stiffer and more formal. They aimed at an effect of height; and this tendency culminated in the last decade of the 17th century in the fontange, or topknot, a high lace cap supported on a wire frame.

**18th century.** Men's dress remained static for almost the whole of the 18th century, the typical costume consisting of a long square-tailed coat, embroidered waistcoat, tight knee breeches, and clump-heeled, square-toed shoes. The three-cornered hat was universal (Figure 18, bottom and 20). Under Queen Anne the wig attained its maximum development, covering the back and shoulders and floating down over the chest. Many varieties were perfected, the cheaper versions being of horsehair. (Smaller, less pretentious wigs, custom-ordered from London, were also worn in the American colonies.) Women, in general, did not wear wigs but had their own hair, sometimes with the addition of false hair, elaborately dressed and powdered.

As the century progressed, the wig and hat grew smaller. The fashion of powdering the hair gave a touch of artificiality and served to distinguish the upper from the lower classes. The waistcoat also grew gradually smaller until it assumed something like its 20th-century form. But there was no real change in essentials until the eve of the French Revolution.

Women's dress was not so constant. Shortly after the death of Queen Anne in 1714, the farthingale returned under another name and in a rather different form, known at first as the hoop skirt and later under the French name of punier, or pannier. By 1730 it had become a general European fashion. Panniers were structures of osier reeds or whalebone, rather like a country-

woman's basket, worn on the hips so that the skirt was extended sideways and not all the way around. The extreme width even had an effect on the architecture of the period—for example, the curved balusters of staircases, especially constructed to allow for the passage of women's voluminous skirts. The hair, however, was now dressed close to the head, the towering fontange having been completely abandoned.

"Watteau gown"

A charming fashion of the first quarter of the century was the *sacque*, or "Watteau gown," a loose gown, worn over a tight bodice, with long, vertical pleats falling from the shoulders to the ground (Figure 18, bottom). At first it was a *négligé*, but by the 1730s it had become the accepted *robe à la française*, or French dress. As dresses grew less formal, the materials of which they were made became lighter; heavy brocades gave place to flowered taffetas and damasks, and even to delicate lawns and dimities. Men's coats, plain and dun coloured at the beginning of the century, began to be embroidered all over

or made of patterned velvet. The shirt ended in a frill of lace at the wrist and throat. The silk stockings, now usually white, were no longer rolled over the knees. The three-cornered hat became much smaller, and it was sometimes carried under the arm so as not to disturb the position of the wig.

In women's dress, in 1750, there was a striking decrease in the size of hoops. The triangular-shaped bodice, long and with a tight waist, was cut very low in a square décolletage. The bodice was sometimes laced across the front with ribbons, the corset thus not being a separate garment but forming part of the dress (Figure 19). In cold weather small capes and even large cloaks were worn. Muffs were a popular accessory with both men and women, some of them large enough to hold a small lap dog.

In the 1770s women's hair began to rise, and the general effect was again one of height rather than width. The shape of dresses began to be modified, the side panniers replaced by a pad worn at the back, giving the appearance of a bustle.

The 1790s saw a fundamental change in both men's and women's costume, essentially a change from court to country modes. Instead of the tricorne, men began to wear a hat which, with its narrow brim and high crown, is the obvious ancestor of the top hat. Embroidery disappeared from men's coats, and the skirts were cut away in front. What resulted was a hunting or riding costume. Boots were substituted for pumps, and swords ceased to be carried. Men began to wear their own hair instead of wigs, and toward the end of the century they gave up the use of powder (Figure 20, top).

Women's clothes showed a new simplicity based upon what were supposed to be classical modes. About 1795 the waist became extremely high and remained so for a quarter of a century (Figure 20, bottom). The materials used were very plain and thin; in France transparent fabrics were occasionally worn. High-heeled shoes were replaced by heelless slippers; and caps were discarded in favour of bandeaux, or narrow bands for the hair. From 1794 to 1797 there was a fashion for wearing two or three large ostrich plumes in the hair; and this fashion, slightly modified, persisted in court dress into the 20th century. Dresses were so scanty that cashmere shawls and wraps of various kinds came into fashion as well

## COLONIAL AMERICA

**Early period.** The settlers of the New World brought with them habits and ideas concerning dress that were characteristic of their places of origin. Basically, however, the dress of the American colonists was completely under English influence. Historical events of 17th-century England had their influence on costume; and plain dress and rich dress became, in effect, the respective symbols of Puritan and Cavalier. Many Virginia colonists leaned toward the Cavaliers; Puritan ideas prevailed in Massachusetts. Virginia dress, though it differed little in design from that of New England, was in general more costly. The Puritans omitted such extravagances as fine brocades, rich laces, ribbons, and feathers; the change to simpler dress that had begun before their departure for America continued.

Probably the greatest change in clothing in America, as opposed to Europe, took place in everyday working costume, the Americans wearing heavier and warmer clothing made of stronger and stouter materials. The distinguishing characteristic of all clothes listed in the inventories of the colonization companies is their wearing quality, and the terms "heavy cloth" and "strong durable stuff" are often encountered. Men and boys wore comfortable, durable jackets and breeches, for example, made from deerskin and buckskin tanned to the consistency of fine chamois with the use of animal brains, a process the colonists had learned from the Indians.

Men wore breeches full at the waist and knee; the *mandilion*, a loose cloak, often lined with fabric of a different colour; doublet and jerkin, somewhat similar garments resembling a jacket, often sleeveless when designed to be worn over another garment; the cassock, similar to doublet and jerkin but longer; and the buffcoat, a strong coat of buff leather, with or without sleeves, tied by a wide sash around the waist. The doublet was especially important, worn by both men and women and by children, its high, tight collar often surmounted by a stiff linen collar or band. It was made of two thicknesses of cloth and welted at the armhole, the welt, or wing, being a piece of cloth set over the armhole where body and sleeves met. The everyday dress of women was a short gown of durable material, with a full skirt over a homespun petticoat, covered by a long apron of white linen. The more stylish dress was longer and made of finer material. It often had the *virago* sleeve—full at elbow and shoulder and drawn in at intervals by strings of narrow ribbon—that appears in most 17th-century portraits of American women and children.

Slashed clothing was fashionable, as in England; in the openings made by the slashes could be seen rich materials. In 1634, however, the general court of Massachusetts forbade men and women to make or buy clothes with more than one slash in each sleeve and another in the back. The starched ruff of the early 17th century gave way to a falling band, the common form of which was a broad, plain, linen collar. Both men and women wore this collar and plain linen turnback cuffs.

Stockings were either knitted or cut from woven cloth and sewn to fit the leg. They were attached to men's breeches by points, or strings, which were also used to secure other garments; later, sashlike garters replaced points. Both men and women wore stout leather shoes with medium heels. Men also wore French falls, a buff leather boot with a high top wide enough to be crushed down. After 1660 the jackboot, a shiny black leather boot large enough to pull over shoe or slipper, replaced the French falls; oxfords of black leather were worn by school children.

Both men and women wore a steeple hat of felt or the more expensive beaver. Men also wore the *montero* cap, which had a flap that could be turned down, and the *Monmouth* cap, a kind of stocking cap. Women of all ages wore a French hood, especially in winter, when it was made of heavy cloth or fur-lined; this hood, tied loosely under the chin, is seen in many portraits of the time. Sometimes the steeple hat was worn on top of the hood.

As colonial wealth increased, so did refinements in

Difference between American and European clothing

as the spencer, a short tailless coat with tight-fitting sleeves.

These modes, both masculine and feminine, had been anticipated by children's clothes a generation before. It was not until the middle of the 18th century that there were any special clothes for children, who were dressed as replicas of their elders except that boys wore their own hair instead of wigs. Like adults, they had full-skirted coats, tricorne hats, and lace ruffles; little girls wore long dresses and were tightly laced, even from infancy. Jean-Jacques Rousseau's theories of education induced many upper class parents to clothe their children more sensibly. By the 1770s, boys were wearing soft shirts and comfortable trousers, and girls loose white dresses with a hint of the high waist. (Ja.L.)

Special clothes for children

clothing. Many portraits of American women in the last half of the 17th century show costume as stylish as that worn in England. The skirt of the woman's gown was gathered to the bodice and hung full to the floor or was open in front to show the petticoat; sometimes the sides were caught together in the back. This increasing back fullness developed into the bustle, which lasted until about 1711, when the hoop came in. Small, elegant aprons became fashionable.

In the 1660s, as in France and England, the doublet, jerkin, and cassock were gradually transformed into the coat, which became the general style of man's attire. In the last quarter of the 17th century, the characteristic men's clothing of the 18th took shape: the periwig, the tricornered hat, the ruffle of lace or sheer linen at throat and wrists, the long waistcoat, the skirted coat with wide, turnback cuffs, tight breeches, sash garters, and buckled shoes.

The rise of  
"fashion"

**18th century.** Fashion was a noticeable element in the first half of the 18th century in America. No laws restricted fine dress in this prosperous period, and merchant ships brought to all the seaport towns elegant fabrics as well as other luxuries. Dresses and suits of homespun, stout shoes, and durable cloaks were worn as before; but those who could afford to do so had stylish dress. There was no waste of fabric, however. The cherished brocade dress, the fine suit, and embroidered waistcoat were often bequeathed by will to the second and even the third generation. There were no fashion plates (illustrations of clothing styles), but jointed dolls dressed in the latest styles were sent at regular intervals from London to the American colonies.

The most fashionable woman's dress during most of the 18th century was the *sacque*, or "Watteau gown" (see above Europe: 18th century), whose ample folds displayed to full advantage the costly material of which it was often made. The commonest woman's dress, however, one worn with variations both before and after the *sacque*, was a dress with a long-waisted, pointed bodice, a full skirt, a rather low, rounded or square neck, and a close-fitting sleeve with a ruffle at the elbow (Figure 19). Stays, or corsets, were a necessary article of dress at the time.

The woman's dress shoe was a brocade slipper with a French heel and usually a buckle. Often the pattern, or overshoe, worn to shield the slipper, was made of the same material. As in the 17th century, cloaks were worn extensively, called by such names as *pompadors*, *roque-laures*, *capuchins*, and *cardinals*. The cardinal, as the name suggests, was a hooded scarlet cloak and was worn during the entire century.

Women's  
headgear

Women's hoods, which previously had been made ordinarily of black silk or heavy cloth, now came in fine fabrics and gay colours. The calash, a great bonnet that resembled the extension top of a *calèche*, or French carriage, was worn with a high, pompadour style of hairdress. This head covering, usually of thin silk, with whalebone or rattan run at two- to three-inch (five- to eight-centimetre) intervals through shirrings, could be pulled over the face or pushed back. The *mobcap*, a huge white lace or lawn cap with deep-hanging frills, was also worn. Gypsy hats and the skimming-dish hat, or skimmer, both of leghorn straw, were worn after 1750.

From 1770 to 1780 the polonaise gown was popular. The bodice was fitted as before; but the full skirt was curved away from the front and caught up on either side at the back so that it fell in three large loops, showing an elaborately quilted or embroidered petticoat. A long apron of sheer, embroidered linen was worn with the open-front gowns of this period. Gold beads and fans for women and snuffboxes for men were important accessories.

Little had happened to the costume worn by men at the close of the 17th century except for a shortening of the waistcoat, a decrease in the size of the turnback cuffs and the wig, and the replacement of the cravat by the stock, which fastened at the back so that the frilled edge of the shirt could be seen at the open front of the waistcoat (Figure 21).

Figure 21: Eighteenth-century American man wearing a wig, ruffle of sheer linen at throat and wrists, long waistcoat, skirted coat with turn-back cuffs, tight breeches, and stockings "Portrait of Theodore Atkinson, Jr.," oil painting by John Singleton Copley, 1757. In the Museum of Art, Rhode Island School of Design, Providence.

After 1760, breeches were fastened at the knee with buttons and a small buckle; and the front of the coat, which was developing a collar, was cut away at the sides. Unpowdered, natural hair became popular for both men and women. (A.W.M.)

#### EUROPE AND AMERICA, 19TH AND 20TH CENTURIES

**Early 19th century.** The dress of the Regency dandy was a smartened version of European late 18th-century country clothes. Beau Brummell, whose clothes were copied by the Prince Regent himself, was so concerned with fit that he had his coat made by one tailor, his waistcoat by another, and his breeches by a third. The neckcloth was so elaborate and voluminous that Brummell's valet sometimes spent a whole morning getting it to sit properly. It was at this period (c. 1811–20) that English modes for men became everywhere accepted as correct, even in Napoleonic France (the top hat, for example, became almost universal).

The  
Regency  
dandy

France continued, however, to dictate women's fashions, except for an interlude between 1802 and 1814, when communication was difficult and English dresses diverged noticeably from those worn in Paris. After the abdication of Napoleon in 1814, however, English women's clothing immediately reverted to Parisian styles. The French waist was still high, but the skirt had become wider at the hem and was rather heavily decorated at the lower edge to make it stand out. The invention of the fashion plate meant that fashions now filtered down the social scale more quickly. The only real change in men's dress after 1814 was that trousers began increasingly to replace breeches; in summer they were usually made of white duck.

In 1820 women's waistlines resumed their normal position, becoming steadily tighter and tighter. Skirts continued to expand, sometimes weighted at the lower edge with a band of fur. Colour came back again after a long eclipse, and there was a vogue for tartans. A little puffed and sometimes slashed sleeve began about 1825 to be worn with another transparent sleeve over it. When this was made opaque, the sleeve assumed the leg-of-mutton shape so characteristic of the period. After 1830, while skirts grew shorter, sleeves became enormous. Hats were also extremely large and ornamented with flowers and ribbons.

Women's  
dress

**Victorian age.** With the accession of Queen Victoria in 1837 these romantic modes began to be modified. The wide sleeves disappeared or, rather, the bulge was placed farther down the arm. Large hats, indeed hats of any kind except turbans, were abandoned in favour of the poke bonnet. Shawls were universally worn. The general effect was subdued and modest. On the other hand, evening dresses developed a wide décolletage that exposed the shoulders; this early Victorian style, which would have been thought extremely improper in the 18th century, was accepted without question.

The increasing amplitude of skirts in the early 1850s caused a revival of the 18th-century hoop in an improved form—the crinoline, a stiff fabric made of horsehair and linen thread (Figure 22, left). This item was soon replaced by a series of flexible hoops, sometimes forming a separate structure and sometimes sewn into the petticoat.

Men's clothes at this period had a somewhat sombre look. The top hat had become the shiny silk hat, usually black. The clothes, except for a surviving fancy waistcoat, were also black, although shepherd's plaid trousers were occasionally worn. The cutaway coat was now worn as evening dress only (Figure 22, right). High neckcloths had been abandoned for collars and ties not very different from those worn in the 20th century.

The crinoline reached its largest dimension about 1860. After that it began to slip to the back and was indeed no more than a half crinoline. Then, about 1869, it was replaced by the bustle, although hoops were sometimes still employed (Figure 22, right). Hats, worn tilted over the forehead, replaced bonnets. In men's clothes there was a steady evolution toward less formal modes, a short black coat sometimes replacing the frock coat or morning coat. The bowler hat, invented in the 1850s for country wear, began to be worn in town. The suit, with coat and trousers made of the same material, was worn by younger men.

As the 1870s progressed, the bustle was gradually reduced until it was no more than a fullness at the bottom of the skirt. Almost all dresses had long trains, even the street dresses of fashionable women. In 1880 the fullness of the skirt disappeared for a brief period; dresses were not only smooth over the hips but fairly narrow around the hem. The waist was very tight and the general effect was of a corset worn outside the dress. The bodice was high-necked and very closely fitted. By 1884, however, the bustle was back again in a slightly different form,

stretching straight out at the back like a shelf. Hats were small, perched squarely on top of the head.

Not all of the women of the 1880s, however, wore these fashionable clothes. Followers of the Aesthetic Movement in England wore looser garments—though the waists were still tight—with enormous sleeves supposed to resemble those worn by women in early Florentine paintings. The humorous journals of the period made great play with the contrast between fashionable and Aesthetic modes.

For men, the 1880s provided a certain relief from formality by the invention of various kinds of sports clothes. Men took to knickerbockers and tweed jackets, straw hats and "deerstalkers" like that immortalized by Sherlock Holmes. Women also wore straw hats and bodices of naval cut to match the double-breasted "reefers" of the men. In the 1890s women began to wear knickerbockers for cycling, a real revolution in female attire. They also thought it necessary for this purpose to adopt men's stiff collars and trilby hats (Figure 23, top).

In 1890 sleeves rose to a point on the shoulders, and this feature expanded until it produced the characteristic balloon sleeves of the middle of the decade, familiar from the drawings of Aubrey Beardsley and the posters of Toulouse-Lautrec. Muffs, almost universally worn, were so small that they could be carried on one forearm, the other hand being perpetually occupied in lifting the dress. In evening dress, décolletage, which had been modest in the 1870s and 1880s, became more daring.

Children's clothes were less sensible and comfortable than they had been 50 to 60 years before. What had started in the 1820s as rational dress for boys had been formalized into the rigid discomfort of the Eton suit with its stiff white collar. Fortunate boys were dressed in sailor suits and unfortunate ones as "Little Lord Fauntleroy," in velvet suits with lace collars and cuffs and with the hair dressed long in curls. Little girls were dressed in elaborate and easily soiled garments with much lace. Their skirts were shorter than those of adult women, but the waists were nearly as tight.

As the century drew to a close, the wide sleeve slipped and became a bulge over the forearm, facilitating the wearing of the short capes then fashionable. A prodigious quantity of lace was worn, at the wrists or in the form of a frilled shirt front attached to the bodice. For informal wear, blouses had become popular, these too adorned with frills of lace.

Men's daytime clothes had divided into formal and informal wear. Formal wear consisted of a long frock coat with silk lapels, white or gray waistcoat, striped trousers, an all-the-way-round stiff white collar and a silk (top)

**Invention  
of men's  
sports  
clothes**

Crinolines  
and bustles

hat. Informal wear consisted of a checked suit or knickerbockers and a Norfolk jacket, and a straw hat. Cloth caps also were worn. Even with this costume, however, it was usual to wear a stiff collar. Men's evening dress had also divided into a formal tail coat and an informal dinner jacket, a stiff shirt being worn with both.

Beards  
and  
moustaches

From about 1840 to 1870, side whiskers attained a longer, more luxuriant growth and were sometimes referred to as "mutton chops" or "Piccadilly weepers." In the United States they were called "dundrearys" after Lord Dundreary, a character in the play *Our American Cousin*. The name "burnsides," or "sideburns," came from the name of a U.S. Civil War general, Ambrose Burnside. The "imperial," a pointed tuft of whiskers on the chin, was named in honour of Napoleon III. Long side whiskers merging into a moustache became known as the "Franz Josef" in honour of the Emperor of Austria. In the 1880s the trend was toward the clean-shaven, although beards and moustaches were retained by older and professional men. In the British Army the "walrus" moustache became popular; it was forbidden to shave the upper lip. In the U.S., a moustache that curled upward at the ends, called a "handle bar," found great favour. Professional men favoured the pointed Vandyke beard. Eventually, whiskers became a distinguishing mark of butlers and footmen, who wore them in the 20th century.

**Early 20th century.** The first decade of the 20th century showed comparatively little change in the essential lines of feminine costume. The mature type of women was admired: tall, small-waisted, heavy-bosomed, and with a peculiar stance—the S-shaped look, resulting from what was strangely known as the "health" corset, a corset boned in such a way as to throw the hips back and the bosom forward. The effect was accentuated by the Russian blouse and cascades of lace descending from the bust. Never since the days of William III had so much lace been worn. Lace collars and collarettes, lace sleeves, lace plastrons (trimming on the bodice), lace overbodies, and lace petticoats, only to be glimpsed occasionally, but requiring the finest workmanship—there was hardly any part of women's dress that was not adorned with this expensive form of decoration. Real lace in such quantities being unobtainable and machine-made lace somewhat despised, a compromise was discovered in Irish crochet, for which there was a considerable vogue, especially in 1907. Skirts were long and sweeping, with a curious resemblance to the dominant line of *art nouveau* furniture. The hair was piled high on the head, and a flat pancake hat projected forward as if to balance the trailing skirts (Figure 23, bottom).

Introduc-  
tion of  
pajamas

A revolution in nightwear took place in the early years of the century. For 300 years or more, women had worn in bed a long smock and men a longer version of the day shirt. Pajamas now began to take their place. They are thought to have originated in India (*pājāma* in Hindi means "drawers") and, once introduced into the West, became steadily more popular not only for men but also for women.

In 1908 a slight modification began to be discernible in women's clothes. The bust was no longer thrust quite so far forward as before; the exaggerated overlap of the blouse was abandoned, and skirts became a little narrower at the hem, though they still trailed on the ground and had to be gathered up in the hand when crossing a wet or muddy street. The change resulted, in part, from the coming of what was called the empire gown, though it did not resemble very closely the high-waisted dress of a century before. Its effect was to make the figure appear tubular; by 1910 the process was complete. At the same time hats became extremely wide and the wide skirt was replaced by a very narrow one.

The  
hobble  
skirt

The hobble skirt of 1911, one of the strangest garments ever worn by women, shackled the legs so completely that walking was almost impossible. The feminine silhouette, as so often, resembled a triangle, but a triangle standing on its apex. With the enormous hats went very large muffs; and the handbag reappeared, since it was impossible for such narrow skirts to contain pockets. In

the draped effect of evening dresses there is a curious Orientalism, due in part to Paul Poiret, the most fashionable dressmaker of the period, and in part to the immense success of the Russian ballet. For day wear the tailor-made, or suit, was very popular. Fashionable trimming consisted of buttons sewn in the most unlikely places all over the costume.

A kind of tunic overskirt made its appearance in 1912, and by early 1914 had become the feature of dress upon which the attention of designers was concentrated (Figure 24). It was to provide the jumping-off stage for the development of the next mode, which involved a fundamental change in the neckline. The new fashion was known as the V-neck and was considered by many to be dangerous to both health and morals. Men's clothes remained extremely formal.

The outbreak of World War I in 1914 did not bring

Figure 24: "Afternoon Dress with Hoop Tunic," by Bernard Boutet de Monvel, 1914. In the collection of François Boucher, Paris.

about any immediate change in women's dress; but about the middle of 1915 the narrow underskirt was abandoned and a lampshade tunic became the whole dress. This skirt reached to mid-calf, revealing high laced boots. Hats were now small and were usually trimmed with a vertical feather. The shortish skirts and high boots remained in fashion with only slight modification until the end of 1918.

**Post-World War I.** By 1921, the skirt fullness of the war period had disappeared, and waists had disappeared with it. The general effect was tubular, the corset having been completely abandoned. The extremely low waist was indicated only by the lower edge of the now inevitable jumper. Hair was bobbed, but the close-fitting, bell-shaped cloche hat had not yet appeared. Hoop skirts, or panniers, made a brief appearance in 1923 but did not long affect the prevailing trend. It was not until 1925 that the extremely short skirt made its appearance. With

it were worn silk stockings in various shades of flesh pink, a startling innovation.

Skirts became even shorter in 1927, when it was impossible for a woman to sit down without showing her knees (Figure 25, left). The short skirt lasted for day wear until 1930, but evening dresses, by careful degrees—tails, trains, sidepieces, and transparent hems—became long again. In 1930 day skirts suddenly lengthened to mid-calf or lower and the waistline moved back to its normal position. There was a temporary vogue for large sleeves, not, as in 1830 and 1895, to decrease the apparent size of the waist, but to make the hips look smaller. The emphasis throughout the 1930s was on slim hips and backless dresses, and sometimes the whole outfit looked as if it had been designed to be seen from the rear. The shoulders were heavily padded to make them look square. The long reign of the cloche hat came to an end, to be replaced by a variety of very small hats that were worn perched forward over one eye (Figure 25, centre).

Men's clothes showed a steady movement toward more informality. The frock coat disappeared altogether, and the morning coat and silk hat were worn only on ceremonial occasions. Wide trousers known as "Oxford bags" came in 1924, and trousers remained wide until the end of the 1930s. Soft collars replaced the stiff white linen variety; and for golf and other sports men wore baggy knickerbockers known as knickers or plus fours, often with a gaily coloured sweater.

Women's sports clothes became more and more scanty, and it became usual to play tennis in shorts or very short skirts, without stockings. Swimsuits were extremely scanty.

Two marked general tendencies may be noted: the disappearance of class distinction in women's day clothes and a marked divergence between day clothes and evening clothes. Many women were now engaged in some kind of work away from home during the day, and there was evolved for this purpose a kind of working uniform, consisting of the tailor-made, or suit. Trousers, in the form of slacks, were increasingly worn for sports but not yet for shopping. On the other hand, even girls in the lower income groups assumed for evening some kind of "glamour" dress, a dress based ultimately on what had been seen in motion pictures. This influence tended to inhibit change over the years, since as much as two years might elapse between the shooting of a film and its gen-

eral release. The "glamour" toilettes of the 1930s are therefore curiously static and tend to have the appearance of fancy dress.

**World War II.** Just before World War II there was an attempt on the part of dress designers to bring back the boned corset. Fashion commentators spoke of "the figure of eight which the new clothes demand; so get it, by hook, by crook, or by corset." Apart from this trend, there was a wild variety of styles, especially in evening dress. There were hooped skirts and hobble skirts (a kind of throwback to the fashions immediately preceding World War I) and even harem skirts. But these developments were cut short by the war.

By the summer of 1939, day skirts were almost as short as they had been in the late 1920s. Shoes were very square-toed with low heels. When war came, the little hats that had served for a decade were often replaced by head scarves and, in wet weather, by plastic hoods. Housewives as well as factory workers took to slacks, thereby making stockings unnecessary. Even with skirts, many women began to go about with bare legs, on which stockings were sometimes painted with a line drawn down the back to simulate the still obligatory seam. Clothes rationing was introduced in Britain in June 1941, and for the rest of the war fashion may be said to have ceased to exist in that country. In the United States, rationing of clothing worked little hardship, but restrictions on uses of fabrics (leading to the virtual disappearance of silk and nylon) affected clothing. The daytime silhouette for women continued to be broad-shouldered and short-skirted. The short dress for evening reappeared. The hair was worn upswept in the back, with a high pompadour in front, or else hanging loosely to the shoulders or below.

**Post-World War II.** When communication with France was restored in 1945, there was a cry that "fashion is going feminine," but in fact there was at first very little change. Day dresses had more rounded shoulders and a slightly smaller waist; evening dresses sought to revive the modes of 1939. Then in the spring of 1947 Christian Dior launched a "New Look" from Paris (Figure 25, right). The shoulders were narrow, there was a new emphasis on the bust, and the skirt was much lengthened and had a wide, billowing hem. Hats, after their wartime eclipse, returned to popularity, with much experiment in form and colour. Brims, in general, were large and flaring or small and turned back against the crown.

The "New Look"

A popular development in postwar fashions was the late-afternoon cocktail dress, which by means of a minor adjustment, such as discarding a bolero, could be made to serve as an evening dress also. There was a certain revival of such Victorian modes as the crinoline for formal occasions. It was as if women were unconsciously striving to return to a more settled age. There was a marked emphasis on the bosom, the desired effect sometimes obtained by means of a padded or inflated brassiere. Soon, however, the "New Look" gave place to what seemed like a revival of the modes of the 1920s, with the straight lines and displaced waists of typical postcrisis periods. Dior brought out an H-line and then an A-line, and it seemed as if the designers were unable to decide whether to echo the fashions of 1800 or those of 1925. By the early 1960s, they appeared to have made up their minds — fashionable dress resembling very closely that of the '20s, with a lowered waist and very high hemline. Shoes were excessively pointed, with stiletto heels. In the servantless postwar world, women often wore slacks for housework and shopping; in some communities long shorts (Bermudas or Jamaicas) replaced slacks; and culottes, or divided skirts, reappeared.

Men's clothes after the war showed a curious reversion, not to Victorian but to Edwardian modes: tighter trousers, coats buttoned higher, and the revived bowler hat. There was a passing craze for fancy waistcoats. Slacks, sport shirt (worn without a tie), and a jacket resembling battle dress, together with a variety of sweaters (jerseys in Great Britain), became ordinary wear for many young men. In the evening the tailcoat almost entirely disappeared, but the dinner jacket maintained its popularity.

Revival of the Edwardian look for men

(Ja.L.)

The fashion revolution that began on London's Carnaby Street in 1957 with the introduction of the "Mod" look led to the permissive, youth-oriented, and anti-establishment fashions of the 1960s, when styles never moved so swiftly, had so many contradictions, or displayed such variety. If the result was easily natural, individual, and unrestrained, it was acceptable. A preference for making your own fashion became current and a taste for ethnic, nostalgic, erotic, or "far out" effects were "in." This was the era of the erratic hemline (mini, midi, and maxi); pants suits, hot pants, and short shorts; boots and platform shoes; and flared or bell bottom trousers. Borrowing freely from the opposite sex, unisex fashions came into vogue by the end of the 1960s. Women often

adopted such masculine attire as military surplus and work clothes and the stylish male had long hair, carried a pocketbook, wore jewelry, and used a wide variety of cosmetics. By the early 1970s, however, there was a return to traditional elegance and classical styling. The layered look (adding garment to garment) was popular and fashion design was often inspired by the styles of the 1930s and the early 1940s. (Ed.)

## II. Non-Western dress

Western-style clothes, which many persons prefer to wear during business hours, are now a common sight in many of the large cities of eastern and southern Asia; but they do not dominate the scene and are usually exchanged for traditional dress when the day's work is done. In Korea and especially in Japan, traditional styles of dress reflect marked Chinese influence, though both countries developed characteristic styles of their own. In like manner, modes of dress in the Indian subcontinent have been a source of inspiration to some of the countries of South-east Asia and of the East Indian archipelago.

### EAST ASIA

**China.** More than 2,000 years before the beginning of the Christian era, the Chinese discovered the marvellous properties of silk and shortly thereafter invented looms equipped with devices that enabled them to weave patterned silks rapidly enough to satisfy the demand for them by luxury-loving Chinese society. Thus, centuries before Chinese silks began to be shipped westward and still more centuries before the West learned the secret of sericulture, the people of China had already established ultrarefined standards of elegance in matters of dress.

The earliest period of Chinese history for which reliable visual evidence of clothing styles is obtainable is the Han dynasty (206 BC–AD 220). Han bas-reliefs and scenes painted in colour on tiles and lacquers show men and women dressed in wide-sleeved kimono-style garments which, girdled at the waist, fall in voluminous folds around their feet. This p'ao-style robe continued to be worn in China until the end of the Ming dynasty (1644). The graceful dignity of post-Han p'ao is revealed in Chinese figural paintings of the 8th to 13th centuries AD (Figure 28) and also in the modern kimono of Japanese women; for this Chinese style, introduced into Japan in

the 8th century, has been little changed in the country of its adoption during the intervening centuries. Even today the kimono continues to be worn and is commercially very successful.

The Chinese records indicate that at least as early as the T'ang period (618–907) certain designs, colours, and accessories were used to distinguish the ranks of Imperial, noble, and official families; but the earliest visual evidence of these emblematic distinctions in dress is to be found in Ming portraits. In some of these, emperors are portrayed in voluminous dark-coloured p'ao on which the 12 Imperial symbols, which from time immemorial had been designated as Imperial insignia, are displayed. Other Ming portraits show officials clothed in red p'ao that have large bird or animal squares (called "mandarin squares," or p'u-fang) on the breast, specific bird and animal emblems to designate each of the nine ranks of civil and military officials having been adopted by the Ming in 1391.

When the Manchus overthrew the Ming in 1644 and established the Ch'ing dynasty, it was decreed that new styles of dress should replace the voluminous p'ao costume. The most formal of the robes introduced by the Manchus was the ch'ao-fu, designed to be worn only at great state sacrifices and at the most important court functions. Men's ch'ao-fu had a kimono-style upper body with long, close-fitting sleeves that terminated in the "horse-hoof" cuff introduced by the Manchus, and a closely fitted neckband over which was worn a detached collar distinguished by winglike tips that extended over the shoulders. Below, attached to a set-in waistband, was a full, pleated or gathered skirt. Precisely stipulated colours and pattern arrangements of five-clawed dragons and clouds, waves and mountains were specified for the ch'ao-fu of emperors, princes, nobles, and officials; the bright yellow of the emperor's robe and the 12 Imperial

symbols emblazoned on it clearly established his lofty rank. All other ranks wore "stone blue" *ch'ao-fu* decorated in accordance with prescribed rules about the number, type, and arrangement of dragon motifs.

Among women, only those of very high rank were permitted to wear *ch'ao-fu*. Women's robes were less commodious than the men's and were cut in long, straight lines with no break at the waist. The narrow sleeves with horse-hoof cuffs of these *ch'ao-fu* robes and the arrangement of their dragon, cloud, mountain, and wave patterns were essentially the same as those of the so-called dragon robes discussed below. They were clearly differentiated from the dragon robes, however, by their cape-like collars and by flaring set-on epaulets which, gradually narrowed, were carried down under the arms. Stole-like vests, always worn over women's *ch'ao-fu*, were also a distinguishing feature of this costume. The colour of the empress's *ch'ao-fu* was bright yellow, related shades being worn by princesses and wives of princes.

*Chi-fu*, or "dragon robes" (*lung-p'ao*) as they were usually called, were designed for regular court wear by men and women of Imperial, noble, and official rank (Figure 29). The *chi-fu* was a straight, kimono-sleeved robe with a closely fitted neckband that continued across the breast and down to the underarm closing on the right side, the long tubular sleeves terminating in horse-hoof cuffs. The skirt of the *chi-fu* cleared the ground to permit easy walking and in men's garments was slit front and back as well as at the sides to facilitate riding; the extra slits were the only feature that distinguished the *chi-fu* of men below the rank of emperor from those of their wives. All *chi-fu* were elaborately patterned with specified arrangements of dragons, clouds, mountains, and waves, to which were added auspicious and Buddhist or Taoist motifs. Distinctions in rank were indicated by the colours of the robes and by slight variations in the basic patterns; but, because of the large number of personages who wore *chi-fu*, these distinctions were not always easily recognizable. Emperors' *chi-fu*, either yellow or blue, were always distinguished by the 12 Imperial symbols; but they have also been found on a number of empresses' robes (which have identifying dragon sleeve bands), even though the Ch'ing regulations did not pre-

scribe them for wear by the empress. A large number of *chi-fu*, including those worn by emperors and empresses, were acquired by Western museums after 1912, when the overthrow of the Manchu regime and the establishment of the Chinese republic did away with the official hierarchies of Imperial China; these provide a rich but complicated field of study.

The *p'u-fu*, a three-quarter-length coat worn by men and women over their *ch'ao-fu* and *chi-fu*, became an important adjunct of Ch'ing dynasty dress because it proclaimed the wearer's exact rank at a glance, for it was made of plain purplish-black silk on which his insignia was emblazoned in bright colours and gold. The specially designated *kun-fu* of the emperor and the *p'u-fu* of his family were distinguished by specific numbers and arrangement of five-clawed dragon medallions; the *p'u-fu* of nobles had squares enclosing four-clawed dragons or other mythical beasts; and civil and military officials each had their appropriate *p'u-fang*.

The informal Manchu *ch'ang-fu*, a plain long robe, was worn by all classes from the emperor down, though Chinese women also continued to wear their Ming-style costumes, which consisted of a three-quarter-length jacket and pleated skirt. Men's *ch'ang-fu*, cut in the style of the *chi-fu*, usually were made of monochrome patterned damask or gauze; women's *ch'ang-fu* had wide, loose sleeves finished off with especially designed sleevebands and gay woven or embroidered patterns. Modern traditional Chinese dress developed directly out of these *ch'ang-fu* styles. Men's robes underwent very little change. Women first narrowed the *ch'ang-fu*, then cut the sleeves off at the shoulders, and finally shortened the skirt and slit it up the sides to form the sheath style.

**Japan.** The earliest representations of dress styles in Japan are in 3rd- to 5th-century-AD clay grave figures, a

few of which show men and women wearing meticulously detailed two-piece costumes, consisting of crossed-front jackets that flare out over the hips, the men's worn over full trousers, which, banded above the knees, hang straight and loose beneath; women's jackets are worn over pleated skirts (Figure 30).

Two-piece costumes appear to have been worn regularly during the 7th and 8th centuries, the jackets of this period being called *kinu*, the men's trousers, *hakama*, and the women's skirts, *mo*. It is known, however, that during

the Nara period (710–784) Japanese court circles adopted Chinese court dress, the most characteristic feature of which was the long kimono-style p'ao garment; thus, it must be supposed that the *kinu*, *hakama*, and *mo* were the accoutrements of middle and lower class society, though these garments may also have been adapted for wear under the p'ao. It is clear that emblematic colours and patterns as well as the p'ao style were borrowed from China because modern court dress in Japan, which has been little changed since the 12th century, has many purely Chinese characteristics.

The most important court costumes of Japan are the *sokutai* of the emperor and the *jūni-hitoe* of the empress, which are worn only at coronations and at very important ceremonial functions. (Similar costumes are worn by the crown prince, by princes and princesses of the blood, by high officials, and by ladies-in-waiting.) The voluminous outer robe (*ho*) of the emperor's *sokutai* is cut in the style of the Chinese p'ao but is given a distinctively Japanese look by being tucked up at the waist so that the skirt ends midway between the knees and the floor. This *ho* robe is yellow (the colour worn only by emperors and their families in China), and it is patterned with *hōō* birds and *kilin* (japanized versions of the mythical Chinese *feng-huang* and *ch'i-lin*). The outer and most important of three kimonos worn under the *ho* is the *shitagasane*, which has an elongated back panel that forms a 12-foot (four-metre) train. The *shitagasane* is made of white damask, as the the baggy white trousers (*ueno-hakama*) that are a characteristic feature of the *sokutai* costume. Both of these garments and a cap-shaped headdress (*kammuri*) of black lacquered silk, with an upright pennon, decorated with the Imperial chrysanthemum crest, are purely Japanese in style; but the ivory tablet (*shaku*) carried by the emperor when wearing the *sokutai* was undoubtedly inspired by tablets of jade that Chinese emperors carried as symbols of their Imperial power.

The outermost garment of the empress' *jūni-hitoe* costume is a wide-sleeved jacket (*karaginu*) that reaches only to the waist and has a pattern of *hōō* bird medallions brocaded in colours of the empress' choice. Attached to the waist at the back of the *karaginu* is a long, pleated train (*rno*) of sheer, white silk decorated with a painted design. The outer kimono (*uwagi*) is very large to accommodate the many layers of kimono worn under it, the abnormally long skirt swirling out fanwise around the wearer's feet. This, too, is made of rich brocade, its design and colours being a matter of personal taste. Under the *uwagi* is a plain purple kimono and under that a robe

known as the *itsutsu-ginu*, which has multiple bands of coloured silks (usually five) attached at the edges of the sleeves, at the neckline, and at the hem, giving the appearance of several robes worn one over another. No special interest attaches to the *hitoe* kimono worn under the *itsutsu-ginu* or to the *kosode* worn next to the body, but the divided skirt (*naga-bakama*) that completes the costume is an extremely picturesque garment. Made of stiff, red cloth and fastened high up under the breasts, the *naga-bakama* covers the feet in front and is carried out in a train in back. Worn with the *jūni-hitoe* is an elaborate coiffure known as *suberakashi*; and, affixed directly over the forehead, are special hair ornaments consisting of a lacquered, gold-sprinkled comb surmounted by a gold lacquered chrysanthemum crest.

Other types of dress formalized in the 12th century were the *noshi* (courtiers' everyday costumes) and the *kariginu*, worn for hunting. Both of these garments were voluminous hip-length jackets worn with baggy trousers tied at the ankles. At this time also it became necessary to devise special costumes for the newly formed samurai caste. The *hitatare*, the formal court robe of samurai, and the *suo*, a crested linen robe designed for everyday wear, though more closely related in style to the Chinese p'ao than the *noshi* and *kariginu*, were characterized by V-shaped necklines accentuated by inner-robe neckbands of white. Several centuries later the samurai adopted the *kamishimo*, a striking jumperlike garment, with extended shoulders and pleated skirt-trousers, which was worn over the *hitatare*. This costume probably inspired a later fashion of wearing skirt-trousers (*hakama*) over a full-length black kimono which, together with the short black *haori* coat, is today the approved formal attire for Japanese men (Figure 31).

The basic kimono style adopted by Japanese women during the Nara period has remained amazingly close to that of the p'ao robes worn by the women of T'ang China. The kimono is usually thought of as a Japanese invention, and it was in fact the master designers and dyers of Japan who, in the 17th and 18th centuries, evolved styles of decoration that have made it the most beautiful garment in the world (Figure 32). The practice of wearing short-sleeved kimono (*kosode*) as outer garments and belting them in with narrow sashes (*obi*) originated during the Muromachi period (Ashikaga shogunate; 1338–1573), when samurai women began to wear a voluminous outer kimono (*uchikake*) as a kind of mantle. Eventually, the *kosode* came to be worn only by married women, the long-sleeved *furisode* being reserved

The most important court costumes

Other types of 12th-century formalized dress

for young unmarried girls. The wide *obi*, which is today the most elegant feature of the Japanese costume, was not adopted until the early 18th century; and it was at this time also that women first began to wear the short *haori* coat, which has come to be an important feature of Japanese women's dress.

The *yukata*, which is worn by both men and women, is a cotton kimono with stencil-dyed patterns (usually done in shades of indigo) that were originally designed for wear in the home after a bath. Because it has become accepted practice to wear *yukata* on the street on warm summer evenings, the cottons designed for them have become increasingly handsome.

**Korea.** Some of the basic elements of modern traditional dress in Korea, the *chōgori* (jacket), *paji* (trousers), and *turumagi* (overcoat), were probably worn at a very early date, but the characteristic two-piece costume of today did not begin to evolve until the period of the Three Kingdoms (c. 57 BC–AD 668). During the early part of this period both men and women wore tight, waist-length jackets and short, tight trousers; and it is believed that the Koreans' traditional fondness for white clothing dates from this period (Figure 33).

Korean records state that special costumes for court wear modelled after those of T'ang China were adopted during the reign of Kim Ch'unch'u in the 7th century; but Chinese influence on Korean dress at this period is verifiable only in changes that occurred in the everyday costumes of the nobility. Noblewomen formerly had worn tight trousers and jackets (which continued to be worn by the poorer classes); now they began to appear in wide-sleeved, hip-length jackets, belted at the waist, and in full-length skirt-trousers. The corresponding dress for noblemen was a narrower, tunic-style jacket, cuffed at the wrists, belted, and worn with roomy trousers bound in at the ankles. The most striking evidence of Chinese influence at this time is to be seen in the style of the *turumagi* overcoat worn by noblemen, pictured in fresco paintings as a voluminous full-length garment made almost exactly like the *p'ao* robe of T'ang China. One-piece robes were never worn in Korea until the late 13th century, when the court was forced to adopt Mongol dress; after Mongol domination ended in 1364, Koreans wore the one-piece robe only at wedding ceremonies.

In the 15th century, Korean women began to wear pleated skirts (*ch'ima*) and longer *chōgori* (jackets), a style undoubtedly introduced from China. Noblewomen wore full-length *ch'ima* to indicate their social standing and began gradually to shorten the *chōgori* until eventually it attained its present length, just covering the breast. This style made it necessary to reduce the fullness of the skirt somewhat in order to make it possible to extend it almost up to the armpits, which remains the fashion (Figure 33).

The adoption of Chinese-style *p'u-fang* (mandarin squares) as emblems of rank for civil and military officials (who wore them on their *turumagi*, or overcoats) appears to have been the only notable example of Chinese influence on men's dress at this period. Otherwise, few changes were made until 1894, when class distinctions were relaxed by government decree. It was at this time that the *turumagi* was shortened and narrowed to its present form.

The most picturesque costume of modern Korea is that of men of leisure, *yangban*, who are past 60 years of age. The *yangban* wear white almost exclusively, their costumes consisting of full trousers tied at the ankles with ribbons, over which is worn a short *chōgori* and a fitted vest and, over all, a loose *turumagi*, which falls just below the knees and is tied at the breast. The patriarchal appearance of the *yangban* (who is usually bearded) is accentuated by a black horsehair hat, its flat brim and high crown giving him somewhat the appearance of an American colonial Pilgrim Father (Figure 33). Younger men wear a similar costume (though not the hat) in gray, light blue, or light brown.

Women's costumes feature a bolero-style white *chōgori*, finished off at the neck by a figured band or ribbon that ties from left to right, and high-waisted *ch'ima*, which, in formal costumes, is a full, billowing garment made of beautifully patterned silk.

#### SOUTH ASIA

The Hindu population of South Asia comprises about 2,000 castes whose members wear clothes and ornaments that clearly indicate their caste. The subject of dress, therefore, cannot be dealt with satisfactorily in a few paragraphs. Some of the principal features of upper class Hindu and Muslim dress and the history of their development can, however, be sketched briefly.

The ancient origin of two of the most characteristic garments of modern India, the dhoti worn by men and the sari worn by women, is verifiable in sculptured re-

The dhoti and sari

Figure 34: South Asian dress.

lief's dating back as far as the 2nd century BC. In these and in slightly later reliefs, both men and women are pictured wearing a long piece of cloth wrapped around the hips and drawn between the legs in such a fashion that it forms a series of folds down the front. The upper bodies of both men and women were unclothed, though women wore a narrow cloth girdle around the waist. Men are pictured wearing large turbans, women with head scarves that fall to the hips. Women also wore a great amount of jewelry—bracelets, anklets, and girdles—men's ornaments consisting solely of bracelets.

No major change in costume appears to have been made until the 12th century, when the Muslims conquered north and central India. In this part of the subcontinent, radical new dress styles were adopted to conform with Muslim practice, which required that the body be covered as completely as possible. Men's costumes thereafter consisted of the *jāmāh*, a long-sleeved coat that reached to the knees or below and was belted in with a sash, and wide trousers known as *isār* (Figure 34, right). These garments and the *farjī*, a long, gownlike coat with short sleeves, which was worn by priests, scholars, and high officials, were made of cotton or wool, silk being forbidden to men by the Qur'ān. Somewhat modified, these traditional styles continue to be worn by upper class men of Pakistan and Bangladesh.

Women's garments, dictated by the Muslim conquerors, consisted of wide-topped trousers snugly fitted around the calves of the legs, a long shirtlike garment, and a short, fitted outer jacket. Silk was not forbidden to women; and highborn women, forced to spend their lives in seclusion, devoted a great deal of time and money to their costumes. The Mughal emperor Akbar's Rājput wives, inspired by the profusion of luxurious fabrics available in India, designed a graceful new style of dress, which Muslim women adopted forthwith. This costume consisted of an open-front pleated skirt, or *ghāghrā*, worn with a long apronlike panel over the front opening, and a short-sleeved, breast-length jacket called a *coli* (Figure 34, left). The *ghāghrā* and *coli* continue to be basic elements of Muslim women's dress, the loose front panel having been replaced by the traditional sari, which is worn as an overgarment, one end draped around the hips, the other carried up over the shoulder or head.

Dress in southern India was little affected by Muslim rule in the north. The dhoti continued to be worn by

most Hindu men (it is forbidden to some castes) and the sari by women. Some additions to these traditional costumes have been adopted. On formal and semiformal occasions many Hindu men wear a long, full-skirted, white cotton coat, which reaches to the knees and buttons down the front from top to bottom, over jodhpur-style white trousers; and most Hindu women wear a short coli-style jacket under a sari or a loose waist-length bodice. (Pa.S.)

## Driesch, Hans Adolf Eduard

Through his many and varied pioneering experiments in embryology, Hans Driesch exerted an uncommon influence on biology. Possessed of a philosophical cast of mind, he worked in experimental embryology as a gifted amateur for over 20 years before becoming a professor. As soon as he assumed this position he became a systematic philosopher rather than a scientist, devoting himself fully to systematic philosophy. His inability to interpret his experimental results in strictly scientific terms led him into vitalism—the concept that the processes of life cannot be explained only by the laws of physics and chemistry—for which he was the last great spokesman.

By courtesy of the Ruprecht-Karl-Universität,  
Heidelberg, West Germany

Driesch.

Driesch was born at Bad Kreuznach, a German spa, on October 28, 1867. For his early education, his father, a well-to-do gold merchant in Hamburg, sent him to a prominent humanistic gymnasium that had been founded by a friend of Martin Luther. Driesch's interest in zoology was aroused while he was still a child by the unusual live animals his mother kept in their home.

Following the prevailing custom in Germany, Driesch attended several universities (at Hamburg, Freiburg, and Jena); he studied zoology and also chemistry and physics, which were not usual topics of study at that time for zoologists. He did his doctoral work at Jena under Ernst Heinrich Haeckel, whose main interest was in phylogeny, a special branch of evolutionary theory. But Driesch's own work took a different direction. His doctoral dissertation in 1887 dealt with factors controlling the growth of colonial hydroids.

For the next ten years Driesch travelled extensively; he also experimented during this period with marine eggs, frequently at the international Zoological Station in Naples. In 1891 he separated the first two cells formed

by a dividing sea urchin egg and discovered that each would form a whole lama. A similar experiment had been performed on the frog's egg by Wilhelm Roux in 1888, but with quite different results; each of the first two cells formed only half an embryo, and Roux concluded that the parts of an organism are determined at the two-cell stage. Driesch, however, concluded that the fate of a cell is not determined at the two-cell stage, but by its position in the whole organism. He published his first wholly theoretical monograph that year and, in 1892, speculated that vitalistic interpretations of biological data might be reasonable. His experimental results gave strong impetus to the then new science of experimental embryology.

Driesch made many other less well known but equally important contributions to embryology. He produced a giant larva by fusing two embryos. By compressing dividing eggs he caused an abnormal distribution of nuclei, thereby proving that the nuclei are all equivalent; this experiment was an important forerunner of modern genetics. He recognized that nuclei and cytoplasm interact and postulated that the nucleus exerts its influence on the cytoplasm by means of ferments, or enzymes. In 1896 he shook sea urchin larvae to displace their skeleton-forming cells and observed the displaced cells return to their original positions. This experiment was the first demonstration of embryonic induction—that is, the interaction between two embryonic parts resulting in differentiation that would not have occurred otherwise—the theoretical aspects of which he had speculated upon in a monograph published in 1894.

By 1895 Driesch was a convinced vitalist. He felt himself driven to this position by his inability to interpret his cell-separation experiments in mechanistic terms; he could not envisage a machine that could divide into two identical machines. Driesch applied the Aristotelian term *entelechy* to denote a vital agent that could regulate organic development. Although such an agent could not be explained by physical science, he believed that its actions were related to the activity of enzymes, which he recognized as important in development.

In 1899 Driesch married Margarete Reifferscheidt, by whom he had two children, Kurt and Ingeborg, both of whom became musicians. Settling in Heidelberg, he continued to perform embryological experiments until 1909, when he was at last habilitated—the procedure then required to enter the German university hierarchy—in natural philosophy. As a member of the faculty of natural sciences, he held successive professorships of philosophy at Heidelberg beginning in 1912 and transferred to Cologne in 1919 and to Leipzig in 1921. As a philosopher, he was strongly influenced by Immanuel Kant, and metaphysics was one of his specialties; logic was another. Perhaps because of his leanings toward vitalism, he also became interested in parapsychology.

Driesch's work was of immediate importance in stimulating the progress of experimental embryology. His experimental and theoretical studies—widely disseminated in his own time though now forgotten—on embryonic induction, enzyme action, and nuclear and cytoplasmic interaction led to work that continues today, but in a less vitalistic framework. In 1935 Driesch was forced into early retirement by the Nazis, but he continued to write until his death in Leipzig on April 16, 1941.

**BIBLIOGRAPHY.** MARGARETE DRIESCH, "Das Leben von Hans Driesch," in ALOYS WENZL (ed.), *Hans Driesch, Persönlichkeit und Bedeutung für Biologie und Philosophie von heute . . .* (1951), includes a bibliography of articles and monographs; CURT HERBST, "Hans Driesch als experimenteller und theoretischer Biologe," *Arch. EntwMech. Org.*, 141:111-153 (1941-42), analyzes his scientific work. JANE OPPENHEIMER, "Hans Driesch," *Dictionary of Scientific Biography*, vol. 4, pp. 186189 (1971), is the only biography available in English. The best known of Driesch's many books on embryology and on philosophy is *Science and Philosophy of the Organism*, 2 vol. (1908; 2nd ed., 1929). Driesch's posthumous autobiography is *Lebenserinnerungen. Aufzeichnungen eines Forschers und Denkers in entscheidender Zeit* (1951).

## Drug and Drug Action

Drugs, chemical substances that affect the functions of living things, are used in treating, preventing, and diagnosing diseases. Numerous other definitions of the word drug exist; in the popular sense, the term drug refers mainly to substances that affect psychological or behavioral functions or lead to varying degrees of dependence or addiction. Pharmacology, the science of drugs, deals with all aspects of drug action and can be considered a part of biology and an important basic medical science. The experimental study of drugs and drug action dates from the mid-19th century, and a German pharmacologist, Oswald Schmiedeberg, has been called the father of pharmacology.

The most important source of drugs today is chemical synthesis. The increase in the manufacture of drugs has resulted in the development of 25,000 or more drugs and drug products. Numerous drugs of natural origin also are available; these are obtained from plants, animals, minerals, bacteria, and fungi. In most instances, however, either an active principle is purified from a natural substance or some chemical modification is introduced. Drugs of natural origin include the antibiotics, which are derived from the growth media of bacteria or fungi (*e.g.*, the penicillins, streptomycin), and the immunizing agents (*e.g.*, vaccines, antitoxins, antiserums), whose exact chemical nature has not yet been established. Drugs produced by numerous pharmaceutical businesses throughout the world are prescribed by physicians or purchased without prescriptions (the so-called patent medicines or over-the-counter drugs).

Many drugs are potentially dangerous chemicals that can cause serious, sometimes fatal, poisoning if used incorrectly; governments of various countries, therefore, have established certain legal requirements concerning drug use. In the United States, for example, control of drugs is based on laws enacted under the Federal Food, Drug, and Cosmetic Act, which are enforced by the U.S. Food and Drug Administration (FDA). The purposes of governmental regulations include the protection of the drug user against the potential hazards of drugs and against fraud. The United States Pharmacopeia (USP), the National Formulary (NF), and the *Pharmacopoeia Internationalis* are examples of official publications that provide names, chemical and physical properties, and other information concerning drugs.

Associated with the benefits that have resulted from modern drug development has been an increase in medical and nonmedical uses and abuses of drugs. Most hospital patients, for example, receive four or five drugs during a hospital stay, and large quantities of drugs also are used by private physicians and by individuals for self-medication. Widespread abuse of drugs has been reflected by an increase in the occurrence of drug toxicity, also referred to as iatrogenic disease. Increased consumption of psychoactive drugs and narcotics (see below Drugs that produce stupor and narcosis) has resulted in a drug cult or drug culture.

### GENERAL ASPECTS OF DRUG ACTION

**Chemical structure and drug receptor interactions.** The primary basis of drug action is an interaction between a drug molecule and some specific cellular component, which is called a receptor or receptive substance. Functional changes produced by a drug on various organs (*e.g.*, heart, lung, kidney) are termed effects. In contrast, the basic interactions between a drug molecule and a receptor are referred to as the action or mechanism of action of a drug. The mechanism by which a drug influences a cellular process to cause a functional change in an organ has not yet been established for all drugs. Most drugs are selective in their activity; *i.e.*, a main action may be associated with some primary effect. Such selectivity provides a convenient basis for the classification of drugs; *e.g.*, certain drugs affect the central nervous system (CNS), or the heart, or the blood vessels. This selectivity, however, is relative, since no drug exerts only a

single action. Although the exact nature of the receptor is not yet known for many drugs, evidence exists that receptors may be associated with specific enzymes (*i.e.*, organic catalysts) in cell cytoplasm or membranes, or with other molecules found in the cell.

Drug-receptor interactions involve two distinct processes: affinity is a term applied to the specific localization of a drug at its binding sites in a receptor; intrinsic activity, or efficacy, is the specific functional change that results from the binding of a drug. The degree of receptor binding, however, is not always a criterion of the degree of efficacy because drugs also may be bound nonspecifically in body tissues (*e.g.*, plasma proteins) without inducing any pharmacological effects. The magnitude of the action of a drug also is proportional to the concentration of a drug at a receptor; *i.e.*, intensity of drug action increases with increasing drug dosage. This graded response, which has been attributed to the occupation of increasing numbers of receptors by increasing numbers of drug molecules, is referred to as receptor occupancy.

Changes in the chemical structure of a drug can modify its actions. The relationship between chemical structure and drug action, referred to as a structure-activity relationship (abbreviated SAR), has been extensively studied. Among numerous groups of drugs, chemical modification of a parent drug molecule has been widely used in studying drug receptor interactions and in attempting to develop new drugs. General similarities in actions and effects of several chemically derived classes of drugs, or cogeners (*e.g.*, barbiturates, sulfonamides), are known. On the other hand, it is not always possible to predict the results of chemical modifications; *e.g.*, one type of chemical change, acetylation, of the parent molecule of morphine leads to increased efficacy, but substitution of a methyl group in the morphine molecule leads to formation of nalorphine, a potent morphine antagonist.

Evidence also exists that drug-receptor interaction depends on the three-dimensional structure of a drug molecule. One isomer (*i.e.*, structural arrangement) of norepinephrine, for example, induces significantly more intense physiological activity than another; this is the case also with the effects of the isomers of amphetamine on the central nervous system. These structure-activity relationships may be the result of fundamental differences in intramolecular forces and the three-dimensional structure of a drug molecule.

**Mechanisms of drug action.** In attempts to establish mechanisms of drug-receptor interactions, the nature of the effects of drugs that have opposite actions (*i.e.*, drug antagonists) have been extensively studied. Drugs that combine with receptors and initiate action have both affinity and efficacy (or intrinsic activity); these drugs are called agonists. Drugs that react with receptors but show no efficacy are called antagonists. An agonist usually cannot combine with receptors that have been blocked by an antagonist; this is termed receptor blockade. In some types of drug antagonism, however, an increase in the amount of an agonist can overcome a blockade induced by an antagonist. Known as competitive antagonism, this phenomenon may be the result of competition between the two drugs for specific receptor sites. On the other hand, in noncompetitive antagonism the receptor blockade induced by an antagonist is not affected regardless of the amount of agonist added. It has been suggested that, in this case, agonist and antagonist may act at different binding sites on the same receptor.

It has been observed that the relationships between agonist and antagonist obey the law of chemical kinetics or law of mass action, in that the velocity of the reactions between agonist and antagonist at a receptor site is directly proportional to the quantities of the reacting substances. Most drug-receptor interactions also have been shown to behave in a manner similar to the interactions between enzymes and specific tissue chemicals usually referred to as substrates, in which reversible enzyme-substrate complexes are formed. Drug-receptor interactions, therefore, have been described as a lock and key relationship between drug molecules and receptors. The

Affinity  
and  
efficacy

Figure 1: (A) Representation of the active centre of a cholinesterase enzyme molecule and its interaction with acetylcholine. G represents an electron-rich centre. (B) Hypothetical complex between acetylcholine and its receptor.

Adapted from A. Goldstein, L. Aronow, and S.M. Kalman, *Principles of Drug Action: The Basis of Pharmacology* (1968); Hoeber Medical Division, Harper & Row

specificity of drug action among chemically related drugs apparently depends on the degree of fit between a drug and its receptor molecules; an optimal **fit** would correspond to maximal specificity of drug action.

Figure 1 illustrates the concept of drug and receptor interactions. Figure 1A shows the molecular fit involved in interactions between a drug, acetylcholine, which acts as a substrate, and the enzyme cholinesterase (with specific anionic and esteratic binding sites within the structure of the molecule), which acts as a protein receptor for the acetylcholine molecule. Figure 1B illustrates the complex acetylcholine might possibly form with a hypothetical receptor. The fit between acetylcholine and its receptor at the two binding sites suggests ionic bonding (*i.e.*, attraction between oppositely charged particles, positive attracted to negative). On the other hand, in other types of drug-receptor interactions, more stable binding may occur between drug and receptor and involve covalent bonds, in which two atoms share a pair of negatively charged particles, or hydrogen bonds. The administration of an antagonist drug also may cause changes in the shape of a protein receptor; such conformational changes in protein structure could partially or completely prevent the actions of a specific agonist by changing the positions of the binding sites so that chemical interaction would no longer be possible.

Although the fundamental mechanisms of drug-receptor interactions are not yet known with certainty, it is known that the mechanism of action of some types of drugs is related to special physical or chemical properties. Magnesium sulfate, for example, is poorly absorbed in the large intestine, and the retention of water that results there causes the cathartic action of the salt; the antidotal action of dimercaprol (British Anti-Lewisite; BAL) in mercury poisoning is due to the affinity of mercury ions for certain chemical groups on the BAL molecule that complex with mercury, thus making it inactive. Alterations in control mechanisms involved in transmission of nerve impulses and in the permeability of the cell membrane to various substances also are involved in some types of drug actions. Nonspecific interferences in cell functions caused by the properties of some drugs (*e.g.*, the general anesthetics) also can reversibly interfere with the normal functions of brain cells.

Quantitative evaluation of drug responses and efficacy. The intensity of the effects of a drug depends on the dose, or quantity of the drug used. Although drug responses may be increased or decreased by numerous factors (see below Factors modifying *drug* responses), dose-effect relationships can be determined for any drug by plotting the dose of the drug against the intensity or magnitude of the effects observed under controlled experimental conditions. Although the relationship between dose and effect varies considerably among different types of drugs, generally, when increasing doses of a drug are plotted against the intensity of the effects produced, an S-shaped curve is obtained. Drugs with similar actions have similar types of curves.

If the amount of one drug required to produce a given response is smaller than the quantity of another drug re-

quired to produce an equal effect, the former is said to be more potent than the latter; conversely, if the quantity of one drug required to produce an effect is larger than the quantity of another drug required to produce the same effect, the former is less potent than the latter. The term potency, therefore, refers only to comparative drug quantities; potency alone is not a criterion of the efficacy of a drug. The relative degree of drug effectiveness can be determined experimentally from dose-effect curves. The slope of the curve, which indicates the rate of increase in response with increasing doses of a drug, also provides some indication of its margin of safety (see below *Drug interactions and drug toxicity*). In the quantitative assessment of drug action, the use of dose-effect curves is indispensable.

As a result of hereditary variability, individuals differ in their response to the same dose of a drug. For exact comparisons of the relationships between drug efficacy and drug toxicity, therefore, a dose-percent curve, in which the dose of the drug is plotted against the percent response, is used. The dose required to produce a specific response in 50 percent of individuals tested is called the median effective dose and is abbreviated ED<sub>50</sub>. In comparative toxicity tests with animals, death is the end point, and the dose required to cause death in 50 percent of the animals is termed the median lethal dose (abbreviated LD<sub>50</sub>). For an experimental evaluation of the margin of safety of a drug, therefore, the ratio between the median toxic dose and the median effective dose (LD<sub>50</sub>/ED<sub>50</sub>), referred to as the therapeutic index of a drug, is widely used to predict the safety range of a drug for therapeutic use.

In the case of drugs that contain unknown quantities of active principles or mixtures of active principles, chemical analysis is not used to determine activity; instead, quantitative evaluation of activity is performed by biological assay or bioassay methods. These methods involve comparing dose-effect curves of a preparation of the unknown with dose-effect curves of an official reference standard of the same drug; *e.g.*, pituitary extract or insulin, supplied by either the World Health Organization or the government of the country involved. In order to achieve uniformity in such drug preparations, evaluation of the preparations is carried out in laboratory tests involving animals.

Factors modifying drug responses. Both the quality and the quantity of the effects of a drug can be influenced by numerous factors. These factors include those concerned with the drug itself; *i.e.*, dose, route of administration, frequency of administration, absorption, distribution in the body, metabolism, and rate of excretion. Other factors are concerned with features of the experimental animal, or patient, to whom the drug is given; *i.e.*, age, weight, sex, hereditary factors, physiological variability, and associated disease states.

Influences and bias on the part of patient and physician can significantly modify drug responses, thus interfering with the interpretation of the therapeutic efficacy of a drug. In order to avoid such complications, test responses to new drugs require the use of a dummy preparation or

substitute drug, referred to as a placebo, which consists of an inactive constituent (e.g., lactose, glucose) in place of the active drug. In addition, so-called blind or double blind procedures are employed. In blind tests a patient does not know if he is given a placebo or the real drug; in double blind tests neither the patient nor the physician knows if the real drug or a placebo is being tested.

Variation in drug responses due to excessive natural sensitivity to a drug is termed idiosyncrasy; decreased natural sensitivity is termed resistance. Repeated use of certain drugs (e.g., morphine) can lead to acquired resistance, or tolerance, in which higher and higher doses are required to produce the same quantitative response. An acute form of tolerance occurs with some drugs tested by repetition at short intervals; this tolerance is referred to as tachyphylaxis. Repeated use of a drug can also lead to drug dependence (i.e., if the drug is not available, an individual shows abnormal emotional symptoms) or to drug addiction, which is a more intense form of dependence associated with both physical and psychological distress.

#### Drug combinations

Another important factor that can modify drug responses is drug combinations. The use of fixed dose combinations of drugs may be dangerous because individuals vary in their susceptibility to different drugs. In some cases, however, drugs may be legitimately combined in order either to improve their therapeutic efficiency or to lessen any toxic or adverse effects associated with high doses of either drug used alone.

Drug interactions and drug toxicity. When two or more drugs are combined, the resultant effects of either drug may be either increased, decreased, neutralized, or antagonized. When the combined effects of two drugs equal the expected sum of the individual effects, the response is termed summation. The combined effects may, however, be additive; i.e., not equal to the expected sum of the two effects. When combined responses to two drugs exceed the sum of the expected effects of the individual agents, the enhanced response is termed synergism or potentiation.

No drug is entirely nontoxic; therefore, caution is a prerequisite to drug use. Drug toxicity may involve the development of effects that range from trivial or mild to serious or fatal. Apart from their primary effect, unavoidable side effects may also develop from secondary or associated effects that result from use of a particular drug. Toxic reactions to a drug, often the result of drug allergy, or hypersensitivity, may be associated with skin rashes, high fever (called drug fever), and damage to white or red blood cells. Allergy is often an unpredictable feature of the use of new drugs; there is, as yet, no satisfactory experimental procedure for evaluating this type of potential drug toxicity. Drug allergy primarily involves immunological (i.e., antigen-antibody) reactions. Drug toxicity may increase in the presence of liver or kidney disease, due to impairment in the detoxification or excretion of drugs. The use of drugs during pregnancy requires special precautions in view of possible damaging effects to the fetus; for example, development of fetal abnormalities (teratogenic effects) were observed with the drug thalidomide. Drug toxicity is also a problem in infants and children because drug detoxifying enzymes are not completely developed in the young.

#### THE FATE OF DRUGS IN THE BODY

General characteristics. In order to exert its action, a drug must reach its receptor, or target, site in an adequate quantity. The amount of a drug that reaches a receptor site depends on the dose given and the route of administration used (e.g., oral, injection, etc.). Most drugs are carried to tissues or organs of the body in the plasma of the blood stream, ultimately crossing the walls of very small blood vessels, called capillaries, to reach their target sites. Variable amounts of different drugs, however, may be combined (i.e., bound) reversibly with protein molecules in the plasma; some drugs also are stored in different body tissues in a free or bound form. Drugs may also be modified chemically in the body through the com-

plex series of events known as metabolism. Finally, both the residue of the unaltered drug and the products, called metabolites, of its metabolism are eliminated from the body by excretion, mainly through the kidneys. The ultimate fate of a drug in the body is dependent, however, on its inherent physical and chemical properties and on various factors related to its administration, distribution, storage, metabolism, and elimination.

Figure 2 is a schematic illustration of the general fate (i.e., absorption, distribution, and excretion) of drugs. Plasma, body fluids, and cells are separated by cellular components known as membranes (vertical broken lines in Figure 2), the living barriers through which a drug must pass during its absorption, distribution, and excretion. Although the exact nature of biological membranes has not yet been clearly established, there is evidence that all cell membranes are similar in structure and consist of double layers of lipid (fat) molecules with layers of protein molecules on the inner and outer surfaces of the membrane. Openings, referred to as "pores," may exist at intervals in cell membranes; in addition, normal cell membranes are selective with respect to the passage of certain charged atoms through them. The outer layers of cell membranes contain enzymes that are important in transferring substances through the membranes; these enzymes may be affected by certain drugs.

Importance of membranes

Figure 2: Absorption, distribution, and excretion of drugs

The passage of a drug through cell membranes is achieved by two general mechanisms, namely, passive transfer and active transport. Passive transfer involves simple, or passive, diffusion of a drug through a membrane by physical processes; that is, the rate of passage is directly proportional to the amount of a drug on each side of the membrane. Passive diffusion can occur in either direction across a membrane (inward or outward), and small molecules cross membranes at a faster rate than do large ones. The rate of diffusion also depends on the relative ease with which the drug dissolves in oil or water and the ratio of ionized, or charged, to un-ionized molecules of the drug in solution. Since most drugs are either weak organic acids or bases, their degree of ionization depends on the hydrogen ion concentration (or pH) of fluids on either side of the cell membrane. Because an un-ionized drug dissolves more readily in lipids than does an ionized one, and because membranes contain lipids, most drugs diffuse through membranes in the un-ionized form. The rate of diffusion of a drug is influenced by changing the hydrogen ion concentration (pH) at the cell membranes. On the other hand, a water-soluble ionized drug generally is poorly absorbed; i.e., it does not cross the membrane barrier with ease.

The active transport of drugs is an energy-dependent process in which drugs can cross membranes against concentration gradients. Active transport is specific and depends on the three-dimensional structure of a drug. Active transport of drugs can be blocked specifically by chemicals whose structure is closely related to that of the drug, by drugs that affect receptors, or, nonspecifically, by drugs that interfere with energy production in cells. Although the complex biochemical processes involved in active transport have not yet been established with certainty, the fate of a drug in the body depends both on its chemical and physical properties and on the special characteristics of passive and active transport involved at the cell membranes through which the drug must pass.

Administration and distribution. Drugs are administered by two general methods, enteral and parenteral. Enteral (i.e., involving the alimentary canal) methods of drug administration include oral (swallowing the drug), sublingual (placing the drug under the tongue), and rectal

Enteral and parenteral administration

(placing the drug in the lower section of the intestinal canal or rectum). Parenteral (*i.e.*, involving channels outside the alimentary canal) methods of drug administration include intravenous (direct injection into a vein), subcutaneous (injection under the skin), intramuscular (injection into muscles), and inhalation (through the lungs). The rate of absorption into the blood following drug administration by any route depends on the physical and chemical properties of the drug itself. After oral administration, absorption of a drug into the bloodstream occurs in the stomach and the intestines; although enteral absorption usually involves passive transfer through membranes, special active transport mechanisms may be involved with some substances (*e.g.*, glucose absorption from the intestines). In the intravenous route of drug administration, the effects of a drug may become evident within seconds; this may be especially valuable for emergency treatment. Rapid intravenous injections, however, may involve serious circulatory and respiratory complications. After subcutaneous or intramuscular injections, the tissue distribution of a drug whose absorption involves passive transfer also depends on the local blood supply. Inhalation is used with gases, and passage of the gas into the blood occurs rapidly by passive transfer through the epithelial cell layer of the lungs.

In blood plasma (see Figure 2), drugs are found either free in solution or bound to the plasma. The ultimate distribution of a drug to the tissues depends on the degree of binding of a drug to the plasma. Transfer of a drug through the walls of blood vessels is rapid and occurs by passive transfer. The supply of most drugs to tissues, therefore, is limited by the rate of blood flow rather than by diffusion through blood capillaries, with the exception of supply to the tissues of the central nervous system. In this case, the blood-brain barrier appears to permit selectively the passage of drugs into the brain.

**Metabolism.** After its distribution to tissues, a drug may undergo various chemical transformations in the body. These changes result in the formation of some new chemical, or metabolite, which usually is less active than the original drug. In some cases, however, the metabolite may be more active than the original form of the drug; some drugs, in fact, require metabolic transformation for their action. The metabolites of most drugs are more water soluble than the original drug and, therefore, can be excreted more easily in urine than can the drug itself.

The metabolism of drugs is catalyzed by enzymes found in a subcellular network in the liver known as the endoplasmic reticulum. The amount of drug-metabolizing enzymes in the liver varies among individuals of the same species and in different species. These differences also correlate with variations in the duration of action of the same drug in different individuals and species. Individual variability in rates of drug metabolism may also contribute to differences in individual susceptibility. Hereditary defects in some enzymes (*e.g.*, plasma cholinesterase) are responsible for increased sensitivity of some individuals to certain substances. Liver enzymes are not present in newborn children and appear very slowly during early childhood. This lack of enzymes may be responsible for the increased sensitivity and toxicity of drugs in infants and young children.

The metabolism of a specific drug may be blocked or enhanced by other drugs that affect liver enzymes, which are not drug specific; the effects of a specific drug may be altered, therefore, if drug combinations are used. Inhibition of the action of metabolizing enzymes (*e.g.*, monoamine oxidase) of one drug by another may cause serious drug reactions, even death; monoamine oxidase, for example, is involved in the metabolism of several classes of drugs. On the other hand, repeated administration of drugs that are inactivated by liver enzymes may induce an increase in enzyme synthesis; therefore, certain drugs may stimulate their own metabolism, and prolonged administration may result in a progressive decrease in the effectiveness of a drug. In addition, increased enzyme activity induced by one drug can cause enhanced destruction of other drugs normally metabolized by the same en-

zyme. The induction of liver enzymes by one drug, therefore, can render other drugs less effective.

**Elimination.** Elimination of drugs from the body is mainly by excretion through the kidneys. Some drugs also may be eliminated through the liver into the intestines; in such cases, however, reabsorption from the intestines and subsequent kidney excretion may occur. Gaseous drugs are eliminated mainly through the lungs, although small quantities of these drugs may occur in sweat, saliva, and milk. Drugs are excreted through the kidneys in their unchanged form or as metabolites and may be ionized or un-ionized; the rate of drug excretion through the kidneys is dependent on all of these factors. During renal excretion, passive transfer of the drug occurs first through the membranes of kidney structures called glomeruli. The rate of membrane transfer depends primarily on the quantity of drug in the blood; however, the amount of a drug that is bound (to plasma) may interfere with its rate of passage through the glomerular membranes. Drugs are excreted from the kidney tubules both by passive transfer and by specific active transport mechanisms. The rate of drug excretion may be modified by changes in the hydrogen ion concentration (pH) in the kidney tubules.

Absorption, distribution, metabolism, and excretion influence the rate of disappearance of a drug from the bloodstream and are significant in predicting the duration of action of a drug. After a single dose of a drug, its concentration in the blood rapidly attains a maximum, then progressively declines with time. The overall rate of disappearance of a drug from the blood, defined as the time required to produce a 50 percent decrease in the concentration of the drug in the blood, is referred to as the biological half-life or  $t_{1/2}$  of the drug. If the blood concentration of a drug declines rapidly (*i.e.*, the drug has a short biological half-life), it must be administered at shorter intervals than a drug whose blood concentration declines slowly. The frequency of administration and the dose required to achieve prolonged and effective blood levels often can be deduced from the biological half-life of a drug. Absorption, storage, metabolism, and excretion of a specific drug, however, complicate the relationship between dose and blood concentration.

#### ACTIONS OF VARIOUS CLASSES OF DRUGS ON MAJOR PHYSIOLOGICAL SYSTEMS

**Cardiovascular system.** Drugs affecting the cardiovascular system, or cardiovascular drugs, include several drug classes. Cardiac glycosides, or the digitalis group (*e.g.*, digitalis leaves, digoxin, digitoxin, ouabain), increase the force of heart muscle contractions and slow the rate of the heartbeat. Increased contractility, a direct action of these drugs on the heart muscle, may be caused by an increased calcium-ion effect that is concerned with the processes of muscle excitation and contraction, or by inhibition of the enzyme adenosine triphosphatase, which affects the transport of sodium ions and potassium ions through membranes. Irregular heart contractions, which also may occur with digitalis, presumably are caused by decreased intracellular concentrations of potassium ions; slowing of the rate of the heartbeat, however, is an indirect effect involving nerves that innervate the heart. Digitalis also causes nausea and vomiting as a result of stimulation of a specific region of the central nervous system. The digitalis group of drugs is used to treat chronic heart failure; as heart function improves, tissue swelling is reduced, and urine output is increased.

Anti-arrhythmic drugs (*e.g.*, quinidine, procaine amide), cardiac depressants used to treat heart irregularities, depress excitability of the heart, prolong the normal recovery time between contractions of the heart, and slow the rate of conduction of nerve impulses through the heart. These direct actions on heart tissues may involve changes in the ability of the membrane to permit passage of certain ions. Other anti-arrhythmic drugs belong to various drug groups; *e.g.*, lidocaine is a local anesthetic, propranolol is a blocking agent, and diphenylhydantoin is an anticonvulsant.

Importance of the kidney

Liver enzymes

Drugs that affect the heart

Anti-anginal drugs (*e.g.*, glyceryltrinitrate, other nitrates and nitrites referred to as "the nitrites") are used for relief of chest pain in coronary heart disease, angina pectoris. These drugs act by relaxing the coronary blood vessel, as well as others, so that coronary blood flow increases and blood pressure falls. In high doses, anti-anginal drugs also depress heart muscle contractions and decrease the heart rate. The mechanism of anti-anginal action has not yet been established with certainty but is probably indirect, either an improvement in the oxygen supply to the heart or a reduction in the oxygen required by the heart to meet its work demands.

Drugs that affect the blood include anti-anemia agents (*e.g.*, ferrous salts, vitamin B<sub>12</sub>, folic acid), anticoagulants (*e.g.*, heparin, dicumarol), and coagulants (*e.g.*, vitamin K, menadione). Ferrous salts act by supplying iron to iron-deficient individuals; vitamin B<sub>12</sub> and folic acid are used to treat deficiency diseases (*e.g.*, pernicious anemia) and to promote red blood cell formation in bone marrow. Anticoagulants, which prevent clotting and depress protein synthesis in the liver, probably act by forming inactive complexes with special blood-clotting factors. Coagulants supply vitamin K and are useful in controlling excessive bleeding (see CARDIOVASCULAR SYSTEM DISEASES AND DISORDERS).

Smooth and skeletal muscle systems. Several groups of drugs affect smooth muscle structures and skeletal muscle. Uterine muscle stimulants (*e.g.*, ergot, ergot alkaloids such as ergotamine and ergonovine, oxytocin) selectively increase force and rate of the contractions of uterine muscles by exerting a direct action. General smooth muscle stimulants (*e.g.*, histamine, serotonin, angiotensin, vasopressin) are all naturally occurring tissue substances that cause contractions of all smooth muscles (*e.g.*, in arterioles, intestines, bronchioles, uterus). Angiotensin, the most potent vasoconstrictor known, produces an intense and sustained increase in blood pressure. Vasopressin, a potent drug, causes constriction of the coronary blood vessel and deleterious effects on the heart in high doses.

General smooth muscle depressants include caffeine, aminophylline, papaverine, and bradykinin; all cause expansion of small blood vessels, called arterioles, and a fall in blood pressure, which is the depressor effect. Bradykinin produces an increase in the permeability of blood vessels to various substances, as does histamine, and stimulates pain receptors in the skin. Smooth muscle stimulants and depressants both exert direct actions on smooth muscle, probably by altering membrane permeability, although the mechanism of their action has not yet been established with certainty.

Skeletal neuromuscular blocking agents, or curare-like drugs, include two main groups. The drugs tubocurarine and gallamine are called competitive blockers; succinylcholine and decamethonium are referred to as depolarizing blockers. These drugs are used to increase muscle relaxation and to overcome skeletal muscle spasms during general anesthesia. All curare-like drugs cause weakness, relaxation, and, ultimately, temporary paralysis of all skeletal muscles. Tubocurarine and related competitive blocking drugs act at receptors on neuromuscular junctions by competing with acetylcholine, a chemical involved in the transmission of nerve impulses, thus blocking its action; the effects of these drugs are antagonized by neostigmine and other drugs. Succinylcholine and decamethonium, the depolarizing blocking drugs, cause a persistent depolarization, or leakage of charge, of muscle membranes; this is responsible for the blocking actions of these drugs, since the membrane can no longer transmit impulses. Depressants of the central nervous system (*e.g.*, minor tranquilizers) also interrupt nerve impulse transmission and thus can cause skeletal muscle relaxation (see MUSCLE DISEASES).

Central nervous system. Anesthetics. Drugs affecting the central nervous system (CNS) comprise several large groups of drugs. In the first group are drugs that prevent the perception of inflicted pain; these drugs, called anesthetics, are used to prevent pain during surgery. Two

types of anesthetics are inhalation anesthetics (*e.g.*, ether, nitrous oxide, cyclopropane) and intravenous anesthetics (*e.g.*, thiopental sodium). General anesthetics cause rapid partial loss of consciousness and of pain sensation; other effects may include varying degrees of euphoria, excitement, or struggling. Excitatory effects caused by anesthetics are the results of a reduction in the activity of the brainstem and removal of normal inhibitions. Surgical anesthesia results in complete loss of consciousness, analgesia, loss of spinal cord functions, cessation of cell movements, and muscular relaxation; respiration and circulation, however, are maintained. Characteristic changes in the electrical activity of the brain also occur. General anesthetics, whose action involves sequential reduction in the activity of certain regions of the brain and the spinal cord, are soluble in lipids and relatively insoluble in water. Lipid solubility generally correlates with potency; *i.e.*, the more lipid-soluble an anesthetic, the more potent it is.

A group of agents known as local anesthetics (*e.g.*, procaine, lidocaine) also are used to prevent the pain of minor surgery (*e.g.*, the extraction of a tooth). Injected locally, these anesthetics cause local nerve blockage. Sensations of pain and temperature and pressure changes are blocked progressively. The actions of local anesthetics depend on the diffusion of molecules into nerve cell membranes and subsequent interference of membrane function (see ANESTHETIC).

Analgesics. Pain-reducing drugs known as analgesics affect the central nervous system. There are two types of analgesics, nonnarcotic analgesics (*e.g.*, acetylsalicylic acid or aspirin, related synthetic agents) and narcotic analgesics, whose use may lead to dependence or addiction. Nonnarcotic analgesics relieve mild pains (*e.g.*, headache pain, rheumatic, joint, or muscle pains), reduce body temperature in fevers, relieve inflammatory pain, and increase uric acid excretion without depressing the CNS. Nonnarcotic analgesics, however, are ineffective in alleviating severe pain caused by injury or diseases in the chest or abdomen. The mechanism of their analgesic action has not yet been established with certainty but may be an effect on the CNS (see ANALGESIC). The narcotic analgesics produce drowsiness and an increased state of well-being (euphoria) or anxiety (dysphoria); relief of pain is followed by sleep. Narcotic analgesics also may elevate the threshold at which pain is perceived, depress psychological responses associated with pain, depress coughing and breathing, and cause nausea, vomiting, narrowing of the pupils of the eyes, increased spinal reflexes, constipation, and contraction of smooth muscles. Narcotic analgesics, therefore, cause both depression and stimulation of brain functions (see below Drugs that produce stupor and narcosis).

Tranquillizers and antidepressants. Drugs that stabilize behaviour and reduce anxiety are of two types. Major tranquilizers (*e.g.*, chlorpromazine, reserpine) and minor tranquilizers (*e.g.*, meprobamate, chlordiazepoxide) constitute one type; antidepressants (*e.g.*, imipramine, monoamine oxidase inhibitors) make up the second type. Both major and minor tranquilizers have a calming effect, reduce aggression, and produce withdrawal and drowsiness, but not sleep; these effects are associated with changes in numerous physiological systems. The major tranquilizers are used to treat psychoses (*e.g.*, schizophrenia); the minor ones are used as anti-anxiety drugs. Antidepressant drugs increase mental alertness and elevate mood. The main action of both tranquilizers and antidepressants is a selective depression or stimulation of important functions in the midbrain (see TRANQUILLIZER).

Sedatives and hypnotics. Drugs that quiet a patient or induce sleep are called sedative-hypnotic drugs. They include barbiturates (*i.e.*, derivatives of barbituric acid such as barbital, phenobarbital, amobarbital, secobarbital, pentobarbital) and nonbarbiturates (*e.g.*, chloral hydrate, paraldehyde, inorganic bromides, glutethimide, methypylon). At one dose level, these drugs calm a patient and relieve tension and anxiety; this is called a

Local  
anesthetics

Drugs that  
affect  
muscles

Barbitu-  
rates

sedative effect. In higher doses, however, this group of drugs produces sleep; this is called a hypnotic effect. The effects of sedative-hypnotic drugs result from a decrease in certain brain functions equivalent to those that occur during normal sleep; excessive doses lead, however, to general anesthesia, and death may result from respiratory failure (see **SEDATIVE-HYPNOTIC DRUGS**).

Drugs that produce *stupor* and narcosis. This group of drugs causes drug dependence; *i.e.*, a state of psychological and/or physical dependency, manifested either by the desire or compulsion to take a drug following its periodic or continued use. Drugs that produce dependence include both CNS depressants (*e.g.*, opiate narcotics, barbiturates, nonbarbiturate sedative-hypnotic drugs, minor tranquilizers, ethyl alcohol) and CNS stimulants (*e.g.*, cocaine, amphetamines, cannabis, mescaline, caffeine, nicotine). The characteristic feature of drug dependence is the development of withdrawal symptoms if use of the drug is discontinued (see **NARCOTIC; DRUG PROBLEMS**).

Drugs that stimulate consciousness. The drugs that excite or stimulate consciousness are of two types. Adrenergic CNS stimulants, so-called because they stimulate the secretion of an adrenalin-like substance at certain nerve endings, include amphetamines and related compounds. General CNS stimulants, also called convulsants (*e.g.*, strychnine, pentylentetrazol, picrotoxin), can antagonize excessive CNS depression (see **STIMULANT**).

**Hallucinogens.** Drugs that profoundly alter mental and psychological functions are known as hallucinogens or psychotomimetic or psychedelic drugs. Included in this group are LSD (lysergic acid diethylamide), cannabis, tetrahydrocannabinol (THC), mescaline, psilocybin, and various tryptamine derivatives. LSD, which has been studied most extensively, causes variable psychotic-like mental aberrations, delusions, and hallucinations but has only minimal adrenergic-like effects. Cannabis is a mild intoxicant in low doses, and mescaline has been used in religious ceremonies (see **HALLUCINOGEN**).

**Autonomic nervous system.** Drugs that affect the autonomic nervous system, which consists of the parasympathetic nervous system and the sympathetic nervous system, can be separated into five groups. Cholinergic drugs (*e.g.*, acetylcholine, muscarine, methacholine, pilocarpine) resemble acetylcholine in their physiological action in that they excite receptors sensitive to acetylcholine at nerve endings; on the other hand, anticholinesterase drugs (*e.g.*, neostigmine, physostigmine) inhibit the reaction in which acetylcholine is broken down at nerve endings. This group of drugs slows the rate of the heartbeat, relaxes vascular smooth muscles, contracts smooth muscles in the intestinal tract, eyes, and lungs, and increases glandular secretions (*e.g.*, sweat, saliva) by directly or indirectly exciting receptors at certain nerve endings. Cholinergic blocking drugs (*e.g.*, atropine, hyoscine or scopolamine, homatropine, various antihistamines, and tranquilizers) cause decreased glandular secretions, decreased muscle contractions in the intestinal tract, eyes, and lungs, constriction of blood vessels, and blockage of skeletal muscle functions by blocking the action of acetylcholine at nerve endings. Adrenergic or sympathomimetic drugs (*e.g.*, levarterenol or norepinephrine, epinephrine or adrenaline, isoproterenol) may act directly at adrenergic receptors or indirectly, either by stimulating the release of the physiological adrenergic mediators epinephrine and norepinephrine or by inhibiting the enzymes involved in their metabolism. The effects of these drugs include an increase in heart rate, contractions and dilation of bronchioles in the lungs, constriction of blood vessels of the skin, mucous membranes, lungs, and brain, and an increase in glandular secretions. Adrenergic-blocking drugs include dibenamine, phenoxybenzamine, phentolamine, ergot alkaloids, dichloroisoproterenol, and propranolol. Indirect blocking agents (*e.g.*, reserpine, guanethidine, monoamine oxidase inhibitors) decrease the functions of the sympathetic nervous system by interfering with storage, binding, release, or metabolism of norepinephrine and epinephrine. Such in-

terference blocks the receptors of the sympathetic nervous system. Ganglionic drugs affect both sympathetic and parasympathetic nerves and therefore cause numerous adverse side effects (see **NERVOUS SYSTEM DISEASES**).

**Eyes.** Drugs that affect pupillary size and visual accommodation are cholinergic, cholinergic-blocking, and adrenergic agents, which exert local actions on the eyes. Cholinergic drugs and the anticholinesterases cause the following: pupillary constriction due to contraction of circular muscle fibres in the iris, spasm of accommodation resulting from contraction of a ciliary muscle, and increased outflow of fluid from the eye. Cholinergic-blocking agents cause expansion of the pupils by inhibiting circular muscle fibres in the iris, and paralysis of accommodation by relaxing ciliary muscles. Adrenergic or sympathomimetic agents such as epinephrine cause constriction of blood vessels around the eyes, thus reducing reddening of the eyes; these agents cause expansion of the pupils by stimulating contraction of certain muscle fibres of the iris (see **EYE DISEASES AND VISUAL DISORDERS**).

**Excretory system.** Drugs that affect the excretory system include diuretics (*e.g.*, chlorothiazide, hydrochlorothiazide, mersalyl), which increase both sodium-ion excretion and water excretion by the kidneys. The diuretics act directly in inhibiting reabsorption of sodium ions and chlorine ions in the kidney tubules. Other diuretics act in different ways. Acetazolamide, for example, increases hydrogen-ion concentration in the kidney tubules by inhibiting an enzyme important in the formation of uric acid. Ammonium chloride and other acid-forming diuretics excreted in urine increase acidity in the tubules; osmotic agents (*e.g.*, mannitol) act after excretion of urine to increase the passage of water into the tubules. Antidiuretics (*e.g.*, vasopressin) decrease urine excretion; by increasing the permeability of the tubule membranes, reabsorption of water is increased. The uricosurics, or gout remedies, may act by increasing the removal of uric acid from blood or by inhibiting an enzyme involved in the normal synthesis of uric acid (see **EXCRETORY SYSTEM DISEASES**).

**Digestive system.** Drugs that affect the digestive system are of several types. One type acts on glandular secretion in the stomach; for example, antacids such as sodium bicarbonate, magnesium oxide, and aluminum oxide neutralize excess acid in the stomach. In the liver and biliary tract, bile salts increase bile secretion. Emetic drugs (*e.g.*, strong salt solutions, apomorphine) induce vomiting, act to stop irritation of the stomach, or affect a specific region of the brain. Anti-emetic drugs (*e.g.*, chlorpromazine, anticholinergic and antihistamine drugs) may depress functions of the CNS. Purgatives (*e.g.*, bulk laxatives such as agar and bran) absorb water to increase the bulk of the intestinal contents. Saline laxatives (*e.g.*, sodium sulfate, magnesium sulfate, magnesium oxide), on the other hand, contain poorly-absorbed ions that increase the amount of water retained in the intestines, thus causing reflex intestinal motility or peristalsis (see **DIGESTIVE SYSTEM DISEASES**).

**Reproductive system.** Sex hormones include estrogens and progesterones, the female sex hormones, and androgens, the male sex hormones. Estrogens (*e.g.*, estradiol, estrone, ethinyl estradiol, diethylstilbestrol) and progesterone (*e.g.*, progesterone, hydroxyprogesterone, norethindrone, norethynodrel) are used to treat hormone deficiencies. The purpose of oral contraceptive drugs used by women is the prevention of the release of the egg by suppression of the activity of certain hormones secreted by the pituitary gland. A variety of combinations of progesterone-like drugs (*e.g.*, norethynodrel) and of estrogens (*e.g.*, ethinylestradiol) is used in oral contraceptives. The androgens (*e.g.*, testosterone, methyl testosterone) are responsible for the development of male sex characteristics (see **REPRODUCTIVE SYSTEM DISEASES**).

**Histamine response system.** The drugs that affect the action of histamine are called antihistamines. Many are synthetic agents (*e.g.*, diphenhydramine, tripeleminamine, pyrilamine, chlorpheniramine, promethazine). Although

Epinephrine and norepinephrine

Anti-histamines

they are effective in antagonizing the effects of histamine on smooth muscle contractions, blood capillary permeability, and salivary secretion, antihistamines are ineffective in stopping the increased gastric secretion caused by histamine and are not effective in relieving bronchial asthma. Antihistamines do provide some protection, however, from allergy and anaphylaxis, both of which are hypersensitivity reactions. The exact functions of histamine are not yet established. Other histamine-like substances (*e.g.*, serotonin, bradykinin) also are involved in histamine responses, and some antihistamines also show, for example, antiserotonin activity. The antihistamines act as competitive antagonists of histamine; that is, they compete with histamine for specific receptors. This competition, however, does not occur at all histamine receptor sites (see HISTAMINE AND ANTIHISTAMINES).

**Immune response system.** Drugs affecting the immune response system are called immunosuppressive drugs. Purine analogs (*e.g.*, 6-mercaptopurine, azathioprine) depress the formation of bone marrow, destroy the mucosal lining and blood capillaries of the gastrointestinal tract, and may interfere with nucleic acid synthesis in cells. Corticosteroids (*e.g.*, hydrocortisone, cortisone, prednisone) also exert numerous actions. Antilymphocytic serum (ALS) can also suppress the immune response system. The exact mechanism by which this group of drugs acts is not yet known with certainty, but they do increase the opportunities for viral invasion of tissues (see IMMUNITY).

#### ACTIONS OF VARIOUS CLASSES OF DRUGS AGAINST INVADING PATHOGENS

The primary objective of chemotherapy (*i.e.*, the treatment of disease with chemicals) is to develop chemicals that act selectively against disease-producing microorganisms (*i.e.*, pathogens) without affecting the diseased host. The actions of a drug on a pathogen may be determined either by establishing the minimal effective concentration of an agent against a specific pathogen or by establishing the ratio (called the chemotherapeutic coefficient) between the dose of a substance that effectively destroys a pathogen and the dose that is toxic to an experimental host that has the disease.

Drugs that affect pathogenic bacteria, termed antimicrobial agents, include the antibiotics, which are substances produced by living organisms such as molds and bacteria, and the synthetic chemotherapeutic agents (*e.g.*, sulfonamides). These drugs may exert bacteriostatic action (*i.e.*, inhibit the growth of bacteria) or bacteriocidal action (*i.e.*, kill bacteria). Differences in susceptibility may allow one bacterial species to resist certain concentrations of a drug that would kill another; the first species thus has natural resistance to the drug and may multiply to produce resistant pathogens (*e.g.*, penicillin-resistant bacteria). Drugs that exert a bacteriostatic action may cause a temporary inhibition of bacterial growth, but natural defense mechanisms of a diseased host may be necessary to destroy the organisms. If the defense mechanisms fail and pathogens survive and multiply, they will have acquired resistance to a specific drug or to a group of drugs (called cross resistance).

**Antibiotics.** An important group of antibiotics is the penicillins, which includes natural penicillins (*e.g.*, penicillin G, obtained from the growth medium of certain molds), derived or semisynthetic penicillins (*e.g.*, penicillin V, obtained by chemical modification of the growth medium of certain molds), and synthetic penicillins (*e.g.*, cloxacillin, ampicillin, carbenicillin). Penicillin substitutes include cephalosporins, erythromycins, and lincomycin. Other antibiotics include the tetracyclines (*e.g.*, chlortetracycline, oxytetracycline, tetracycline), chloramphenicol, and streptomycin.

The antibiotics are effective against various species of bacteria, and each antibiotic group has a more or less characteristic antimicrobial spectrum; *i.e.*, the penicillins are effective against specific types of microorganisms that may not be affected by other groups of antibiotics. The mechanism of action of the penicillins involves an

interference with a constituent of the bacterial cell wall, which protects the bacterial membrane. If a bacterial cell wall is damaged by a penicillin, the resulting injury to the membrane causes death. Certain bacteria, however, rapidly acquire resistance to the penicillins by synthesizing enzymes that destroy penicillin molecules. Derived and synthetic penicillins are less easily destroyed by these enzymes than are natural penicillins. Penicillin-resistant bacteria are a problem because they retain the ability to cause disease.

Penicillins cause little damage to the cells of host tissues and, therefore, have an extremely high chemotherapeutic coefficient. A disadvantage of natural penicillins (in addition to bacterial resistance) is hypersensitivity (*i.e.*, allergic reactions) that may occur in individuals receiving them; sometimes these reactions result in death. Semisynthetic and synthetic penicillins, however, are less likely to cause severe allergic reactions.

Some antibiotics (*e.g.*, polymyxins, nystatin, amphotericin) act directly on the cell membrane to destroy it. The tetracyclines, chloramphenicol, and streptomycins are effective against many bacteria, certain viruses, and some protozoans. These agents, generally referred to as broad spectrum antibiotics, exert a bacteriostatic action that prevents the multiplication of an invading bacterial species by interfering with various aspects of the process of protein synthesis (see ANTIBIOTIC).

**Synthetic chemotherapeutic agents.** The sulfonamides include a large number of chemically related synthetic agents (*e.g.*, sulfadiazine, sulfamethoxypyridazine, succinylsulfathiazole, sulfisomidine) with a wide spectrum of antimicrobial activity; they exert both bacteriostatic and bacteriocidal actions and are used mainly to treat urinary infections. Sulfonamides prevent the synthesis of an important metabolite, folic acid, in certain bacteria; *i.e.*, sulfonamides act as antimetabolites. Since sulfonamides do not interfere with bacterial utilization of folic acid, bacteria that can accumulate folic acid from their environment are not affected. In addition, use of sulfonamides may cause hypersensitivity reactions involving the skin and the bone marrow.

Numerous other synthetic chemicals are used in the chemotherapy of bacterial infections (*e.g.*, paraaminosalicylic acid and isoniazid in tuberculosis), protozoal infections (*e.g.*, quinine and chloroquine in malaria), and metazoal infections (*e.g.*, piperazine in roundworm infestations [see CHEMOTHERAPEUTIC DRUGS]).

#### ACTIONS OF VARIOUS CLASSES OF DRUGS AGAINST CANCER CELLS

Adequate evidence for specific biological distinctions between cancer cells and normal cells has not yet been established with certainty. Although cancer cells show a rapid rate of growth, some normal tissues (*e.g.*, the intestinal mucosa and bone marrow) also have remarkably rapid growth rates; cancer cells, however, also have a higher than normal content of nucleic acids. There are seven main classes of drugs that act against cancer cells. Alkylating agents contain alkyl radicals that attach themselves to the molecules of proteins, nucleic acids, and amino acids in cells. Among the alkylating agents are the nitrogen mustards (*e.g.*, mechlorethamine, chlorambucil, cyclophosphamide), the ethylenimines (*e.g.*, thio-TEPA, triethylenemelamine), and the alkyl sulfonates (*e.g.*, busulfan). All of them block the synthesis of deoxyribonucleic acid (DNA), the hereditary material of the cell. Antimetabolites such as methotrexate and 5-fluorouracil act by interfering with the synthesis of certain chemicals and enzymes necessary to form nucleic acids. Anti-tumour antibiotics (*e.g.*, actinomycin D, mithramycin, mitomycin C) also block nucleic acid synthesis. Radioactive isotopes of iodine, gold, and phosphorus produce destructive effect on tissues and may also induce bone marrow damage. Hormones also may induce tumour regression in some cases. Alkaloids (*e.g.*, vinblastine, vincristine) stop cell division and induce other cellular changes, especially in the bone marrow and hair follicles. Miscellaneous agents (*e.g.*, urethan, colchicine) also influence cell division

in various ways. Most drugs employed in cancer chemotherapy lead to immunosuppression (see above *Chemotherapy*) and reduce antibody reactions associated with tissue transplantations, both with respect to the responses of the host against the graft and vice versa. The therapeutic value of such agents is limited by their toxic actions on cells (see CANCER).

## Drug Problems

For thousands of years people have experimented with a variety of naturally occurring substances that act on human nervous tissues: alcohol to intoxicate a weary mind, belladonna to calm an angry intestine or to poison an adversary, opium to overcome worry and strain. The relief of pain, in particular, is an ancient aim of mankind, and various narcotic and sleep-producing agents were probably used by primitive people. But for many there is another kind of pain—the pain of existing—and since ancient times people have been trying to expand their vision, enhance their appreciation of the world, change their mood, alter their inner existence, or stupefy their awareness with such drugs as alcohol, opium, and cannabis. It is written in Genesis (9:20) that Noah planted a vineyard, "and he drank of the wine, and became drunk, and lay uncovered in his tent." Alcohol has been used in many cultures and has been worshipped as a god. Opium has also been used extensively, at least since the time of ancient Greece. Homer tells how some of Odysseus' crew succumbed to forgetfulness in the land of the lotus-eaters, and the ancient Vedic philosophers of India spoke of soma, a mysterious and probably mythical plant. Coca, coffee, and tobacco have also played their parts in history.

## I. Characteristics of drug use and abuse

### THE FUNCTIONS OF PSYCHOTROPIC DRUGS

To consider drugs only as medicinal agents or to insist that drugs be confined to prescribed medical practice is to fail to understand human nature. The remarks of the American sociologist Bernard Barber are poignant in this regard:

Not only can nearly anything be called a "drug," but things so called turn out to have an enormous variety of psychological and social functions—not only religious and therapeutic and "addictive," but political and aesthetic and ideological and aphrodisiac and so on. Indeed, this has been the case since the beginning of human society. It seems that always and everywhere drugs have been involved in just about every psychological and social function there is, just as they are involved in every physiological function.

The enhancement of aesthetic experience is regarded by many as a noble pursuit of human beings. Although there is no general agreement on either the nature or the substance of aesthetics, certain kinds of experiences have been highly valued for their aesthetic quality. To Schopenhauer (*The World as Will and Representation*), contemplation was the one requisite of aesthetic experience; a kind of contemplation that enables one to become so absorbed in the quality of what is being presented to the senses that the "Will" becomes still and all needs of the body silent. Many drugs reportedly foster this kind of Nirvana and are often used by people in an attempt to achieve it. For Nietzsche (*Birth of Tragedy*), humans are able to lose their futile individuality in the mystic ecstasy of universal life under the Dionysian spell of music, rhythm, and dance. The American Indians with their peyote and jazz musicians with their marijuana discovered this kind of Dionysian ecstasy without any formal knowledge of aesthetics.

Love is a highly valued human emotion. Thus, it is not surprising that there has been a great deal of preoccupation with the feeling of love and with those conditions believed to enhance the attainment of love. Little is actually known concerning the aphrodisiac action of certain foods and drugs, but for many years both have been associated in people's minds with the increased capacity for love. Although the physiological effects may be doubtful, the ultimate effect in terms of one's feeling of love is probably a potent incentive for the repetition of the experience and for those conditions that are believed to have produced the experience. Hallucinogenic substances such as LSD are believed by many people to induce a feeling of love. But what the drug user regards as love and what those people around him regard as love in terms of the customary visible signs and proofs often do not coincide. Even so, it is plausible that the dissipation of tensions, the blurring of the sense of competition, and the subsidence of hostility and overt acts of aggression—all have their concomitant effect on the balance between the positive and negative forces within the individual, and, if nothing else, the ability of drugs to remove some of the hindrances to loving is valued by the user.

Native societies of the Western Hemisphere have utilized, apparently for thousands of years, plants containing hallucinogenic substances. The sacred mushrooms of Mexico were called "God's flesh" by the Aztecs. During the 19th century the Mescalero Apaches of the southwestern United States practiced a peyote rite that was adopted by many of the Plains tribes. Psychedelic drugs have the unusual ability to evoke at least one kind of a mystical-religious experience, and a positive change in religious feelings is commonly found in studies of the use of these drugs. Whether they are also capable of producing religious lives is an open question. Their supporters argue that the drugs appear to enhance personal security and that from self-trust may spring trust of others and

Aesthetic and hallucinogenic functions

that this may be the psychological soil for trust in God. In the words of Aldous Huxley (*The Doors of Perception*): "When, for whatever reason, men and women fail to transcend themselves by means of worship, good works and spiritual exercise, they are apt to resort to religion's chemical surrogates" (see also PHARMACOLOGICAL CULTS).

Stress-reducing and supportive functions

William James (*The Varieties of Religious Experience*) observed at the turn of the century that "Our normal waking consciousness, rational consciousness as we call it, is but one special type of consciousness, whilst all about it, parted from it by the filmiest of screens, there lie potential forms of consciousness entirely different." Some people deliberately seek this other consciousness through the use of drugs; others come upon them by accident while on drugs. Only certain people ever have such a consciousness-expanding (psychedelic) experience in its fullest meaning, and the question of its value to the individual must be entirely subjective. For many people, the search for the psychedelic experience is less a noble aim and more the simple need of a psychic jolt or lift. Man is a paradox of sorts. Although he goes to great lengths to produce order and stability in his life, he also goes to great lengths to disrupt his sense of equanimity, sometimes briefly, sometimes for extended periods of time. It has been asserted that there are moments in everyone's life when uncertainty and a lack of structure are a source of threat and discomfort, and moments when things are so structured and certain that unexpectedness can be a welcome relief. Whatever the reason, people everywhere and throughout history have deliberately disrupted their own consciousness, the functioning of their own ego. Alcohol is and has been a favourite tool for this purpose. With the rediscovery of some old drugs and the discovery of some new ones, man now has a wider variety of means for achieving this end.

Many persons face situations with which, for one reason or another, they cannot cope successfully, and in the pressure of which they cannot function effectively. Either the stresses are greater than usual or the individual's adaptive abilities are less than sufficient. In either instance, there are a variety of tranquillizing and energizing drugs that can provide psychological support. This is not chemotherapy in its more ideal sense, but it does enable large numbers of persons to face problems that they might not have otherwise been able to face. Some situations or stresses are beyond the control of the individual, and some individuals simply find themselves far more human and productive with drugs than without drugs. An enormous amount of drug support goes on by way of such familiar home remedies as the aspirin bottle, the luncheon cocktail, and the customary evening drink without anyone calling it that. There is no clear dividing line between drug support and drug therapy. It is all therapy of sorts, but deliberate drug manipulation is a cut different from drug buffering, and much of the psychological support function is just that—taking the "raw edge" off of stress and stabilizing responses.

Therapeutic functions

The therapeutic use of drugs is so obvious as to require little explanation. Many of the chemical agents that affect living protoplasm are not capable of acting on the brain, but some of those that do are important in medical therapeutics. Examples are alcohol, the general anesthetics, the analgesic (pain-killing) opiates, and the hypnotics, which produce sleep—all classified as central-nervous-system depressants. Certain other drugs, such as strychnine, nicotine, picrotoxin, caffeine, cocaine, and the amphetamines, stimulate the nervous system. Most drugs truly useful in the treatment of mental illness, however, were unknown to science until the middle of the 20th century. With the discovery of reserpine and chlorpromazine, some of the major forms of mental illness, especially the schizophrenias, became amenable to chemotherapeutic treatment. These tranquillizing drugs seem to reduce the incidence of certain kinds of behaviour, particularly hyperactivity and agitation. A second group of drugs has achieved popularity in the management of milder psychiatric conditions, particularly those in which patients manifest anxi-

ety. This group includes drugs that have a mild calming or sedative effect and that are also useful in inducing sleep. Not all drugs in psychiatric use have a tranquillizing action. The management of depression requires a different pharmacological effect, and the drugs of choice have been described as being euphorizing, mood-elevating, or antidepressant, depending on their particularly pharmacological properties. There are also drugs useful in overactive states such as epilepsy and Parkinsonism. The so-called psychedelic drugs also may have therapeutic uses.

Drugs have other functions that are not so intimately related to individual use. Several important early studies in physiology were directed toward understanding the site and mode of action of some of these agents. Such studies have proved indispensable to the understanding of basic physiology, and drugs continue to be a powerful research tool of the physiologist. The ability of drugs to alter mental processes and behaviour affords the scientist the unique opportunity to manipulate mental states or behaviour in a controlled fashion. The use of LSD to investigate psychosis and the use of scopolamine to study the retention of learning are examples. The use of drugs as potential instruments of chemical and biological warfare has received wide public attention and scorn. The political use of drugs is a frightening possibility. Whether as a "truth serum," a "brainwashing" technique, a way of destroying certain stable elements of culture, or a way of reducing entire societies to a tranquil slavery, this aspect of drug use should be viewed with alarm because all such uses are obviously possible.

#### THE NATURE OF DRUG ADDICTION AND DEPENDENCE

If opium were the only drug of abuse, and the only kind of abuse were one of habitual, compulsive use, discussion of addiction might be a simple matter. But opium is not the only drug of abuse, and there are probably as many kinds of abuse as there are drugs to abuse, or, indeed, as maybe there are persons who abuse. Various substances are used in so many different ways by so many different people for so many different purposes that no one view or one definition could possibly embrace all the medical, psychiatric, psychological, sociological, cultural, economic, religious, ethical, and legal considerations that have an important bearing on addiction. Prejudice and ignorance have led to the labelling of all use of **nonsanctioned** drugs as addiction and of all drugs, when misused, as narcotics. The continued practice of treating addiction as a single entity is dictated by custom and law, not by the facts of addiction.

The tradition of equating drug abuse with narcotic addiction originally had some basis in fact. Until recent times, questions of addiction centred on the misuse of opiates, the various concoctions prepared from powdered opium. Then various alkaloids of opium, such as morphine and heroin, were isolated and introduced into use. Being the more active principles of opium, their addictions were simply more severe. More recently, new drugs such as methadone and demarol were synthesized but their effects were still sufficiently similar to those of opium and its derivatives to be included in the older concept of addiction. With the introduction of various barbiturates in the form of sedatives and sleeping pills, the homogeneity of addictions began to break down. Then came various tranquillizers, stimulants, new and old hallucinogens, and the various combinations of each. At this point, the unitary consideration of addiction became untenable. Legal attempts at control often forced the inclusion of some nonaddicting drugs into old, established categories—such as the practice of calling marijuana a narcotic. Problems also arose in attempting to broaden addiction to include habituation and, finally, drug dependence. Unitary conceptions cannot embrace the diverse and heterogeneous drugs currently in use.

**Popular misconceptions.** The bewilderment that the public manifests whenever a serious attempt is made to differentiate states of addiction or degrees of abuse probably stems from two all-too-common misconceptions

Confusion of drug abuse and narcotic addiction

concerning drug addiction. The first involves the stereotype that a drug user is a socially unacceptable criminal. The carry-over of this conception from olden times is easy to understand but not very easy to accept today. Ironically, the so-called dope fiend, if indeed one does exist, is likely to be a person who is not using an opiate. The depressant action of opium and its derivatives is simply not consistent with the stereotype. The second misconception involves the naïve belief that there is something magically *druglike* about a drug, which makes a drug a drug. Many substances are capable of acting on a biological system, and whether a particular substance comes to be considered a drug depends, in large measure, upon whether it is capable of eliciting a "druglike" effect that is valued by the user. There is nothing intrinsic to the substances themselves that sets one active substance apart from other active substances; its attribute as a drug is imparted to it by use. Caffeine, nicotine, and alcohol are clearly drugs, and the habitual, excessive use of coffee, tobacco, or an alcoholic drink is clearly drug dependence if not addiction. The same could be extended to cover tea, chocolates, or powdered sugar, if society wished to use and consider them that way. The task of defining addiction, then, is the task of being able to distinguish between opium and powdered sugar while at the same time being able to embrace the fact that both can be subject to abuse. This requires a frame of reference that recognizes that almost any substance can be considered a drug, that almost any drug is capable of abuse, that one kind of abuse may differ appreciably from another kind of abuse, and that the effect valued by the user will differ from one individual to the next for a particular drug, or from one drug to the next drug for a particular individual. This kind of reference would still leave unanswered various questions of availability, public sanction, and other considerations that lead people to value and abuse one kind of effect rather than another at a particular moment in history, but it does at least acknowledge that drug addiction is not a unitary condition.

**Physiological effects of addiction.** Certain physiological effects are so closely associated with the heavy use of opium and its derivatives that they have come to be considered characteristic of addictions in general. Some understanding of these physiological effects is necessary in order to appreciate the difficulties that are encountered in trying to include all drugs under a unitary definition that takes as its model opium. **Tolerance** is a physiological phenomenon that requires the individual to use more and more of the drug in repeated efforts to achieve the same effect. At a cellular level this is characterized by a diminishing response to a foreign substance (drug) as a result of adaptation. Although opiates are the prototype, a wide variety of drugs elicit the phenomenon of tolerance, and drugs vary greatly in their ability to develop tolerance. Opium derivatives rapidly produce a high level of tolerance; alcohol and the barbiturates a very low level of tolerance. Tolerance is characteristic for morphine and heroin and, consequently, is considered a cardinal characteristic of narcotic addiction. In the first stage of tolerance, the duration of the effects shrinks, requiring the individual to take the drug either more often or in greater amounts to achieve the effect desired. This stage is soon followed by a loss of effects, both desired and undesired. Each new level quickly reduces effects until the individual arrives at a very high level of drug with a correspondingly high level of tolerance. Man can become almost completely tolerant to 5,000 milligrams of morphine per day, even though a "normal," clinically effective dosage for the relief of pain would fall in the 5 to 20 milligram range. An addict can achieve a daily level that is nearly 200 times the dose that would be dangerous for a normal, pain-free adult.

Tolerance for a drug may be completely independent of the drug's ability to produce **physical dependence**. There is no wholly acceptable explanation for physical dependence. It is thought to be associated with central-nervous-system depressants, although the distinction between depressants and stimulants is not as clear as it was once

thought to be. Physical dependence manifests itself by the signs and symptoms of abstinence when the drug is withdrawn. All levels of the central nervous system appear to be involved, but a classic feature of physical dependence is the "abstinence" or "withdrawal" syndrome. If the addict is abruptly deprived of a drug upon which the body has physical dependence, there will ensue a set of reactions, the intensity of which will depend on the amount and length of time that the drug has been used. If the addiction is to morphine or heroin, the reaction will begin within a few hours of the last dose and will reach its peak in one to two days. Initially, there is yawning, tears, a running nose, and perspiration. The addict lapses into a restless, fitful sleep and, upon awakening, experiences a contraction of pupils, gooseflesh, hot and cold flashes, severe leg pains, generalized body aches and constant movement. The addict then experiences severe insomnia, nausea, vomiting, and diarrhea. At this time he has a fever, mild high blood pressure, loss of appetite, dehydration, and a considerable loss of body weight. These symptoms continue through the third day and then decline over the period of the next week. There are variations in the withdrawal reaction for other drugs; in the case of the barbiturates, minor tranquilizers, and alcohol, withdrawal may be more dangerous and severe. During withdrawal, drug tolerance is lost rapidly. The withdrawal syndrome may be terminated at any time by an appropriate dose of the addicting drug.

**Addiction, habituation, and dependence.** The traditional distinction between "addiction" and "habituation" centres on the ability of a drug to produce tolerance and physical dependence. The opiates clearly possess the potential to massively challenge the body's resources, and, if so challenged, the body will make the corresponding biochemical, physiological, and psychological readjustment to the stress. At this point, the cellular response has so altered itself as to require the continued presence of the foreign substance (drug) to maintain normal function. When the substance is abruptly withdrawn or blocked, the cellular response becomes abnormal for a time until a new readjustment is made. The key to this kind of conception is the massive challenge that requires radical adaptation. Some drugs challenge easily, but it is not so much whether a drug can challenge easily as it is whether the drug was actually taken in such a way as to present the challenge. Drugs such as caffeine, nicotine, bromide, the salicylates, cocaine, amphetamine and other stimulants, certain tranquilizers and sedatives are normally not taken in sufficient amounts to present the challenge. They typically but not necessarily induce a strong need or craving emotionally or psychologically without producing the physical dependence that is associated with "hard" addiction. Consequently, their propensity for potential danger is judged to be less, so that continued use would lead one to expect habituation but not addiction. The key word here is *expect*. These drugs, in fact, are used excessively on occasion and, when so used, do produce tolerance and withdrawal signs. Morphine, heroin, other synthetic opiates, and to a lesser extent codeine, alcohol, and the barbiturates, all carry a high propensity for potential danger in that all are easily capable of presenting a bodily challenge. Consequently, they are judged to be addicting under *continued* use. The ultimate effect of a particular drug, in any *event*, depends as much or more on the setting, the expectation of the user, his personality, and the social forces that play upon him, as it does on the pharmacological properties of the drug itself.

Enormous difficulties have been encountered in trying to apply these definitions of **addiction** and **habituation** because of the wide variations in the pattern of use. (The one common denominator in drug use is variability.) As a result, in 1964 the World Health Organization recommended a new standard that replaces both the term drug addiction and the term drug habituation with the term drug dependence. Drug dependence is defined as a state arising from the repeated administration of a drug on a periodic or continual basis. Its characteristics will vary with the agent involved, and this must be made clear by

Distinctions between addiction and habituation

Characteristics of the development of tolerance

Physical dependence

Drug  
depend-  
ence

designating drug dependence as being of a particular type—that is, drug dependence of morphine type, of cannabis type, of barbiturate type, and so forth. As an example, drug dependence of a cannabis (marijuana) type is described as a state involving repeated administration, either periodic or continual. Its characteristics include (1) a desire or need for repetition of the drug for its subjective effects and the feeling of enhancement of one's capabilities that it effects, (2) little or no tendency to increase the dose since there is little or no tolerance development, (3) a psychic dependence on the effects of the drug related to subjective and individual appreciation of those effects, and (4) absence of physical dependence so that there is no definite and characteristic abstinence syndrome when the drug is discontinued.

Considerations of tolerance and physical dependence are not prominent in this new definition, although they are still conspicuously present. Instead, the emphasis tends to be shifted in the direction of the psychological or psychiatric makeup of the individual and the pattern of use of the individual and his subculture. Several considerations are involved here. There is the concept of psychological reliance in terms of both a sense of well-being and a permanent or semipermanent pattern of behaviour. There is also the concept of gratification by chemical means that has been substituted for other means of gratification. In brief, the drug has been substituted for adaptive behaviour. Terms such as hunger, need, craving, emotional dependence, habituation or psychological dependence tend to connote a reliance on a drug as a substitute gratification in the place of adaptive behaviour.

Psychological dependence. Several explanations have been advanced to account for the psychological dependence on drugs, but as there is no one entity called addiction, so there is no one picture of the drug user. The great majority of addicts display "defects" in personality. Several legitimate motives of man can be fulfilled by the use of drugs. There is the relief of anxiety, the seeking of elation, the avoidance of depression, and the relief of pain. For these purposes, the several potent drugs are equivalent, but they do differ in the complications that ensue. Should the user develop physical dependence, euphoric effects become difficult to attain, and the continued use of the drug is apt to be aimed primarily at preventing withdrawal symptoms.

It has been suggested that drug use can represent a primitive search for euphoria, an expression of prohibited infantile cravings, or the release of hostility and of contempt; the measure of self-destruction that follows can constitute punishment and the act of expiation. This type of psychodynamic explanation assumes that the individual is predisposed to this type of psychological adjustment prior to any actual experience with drugs. It has also been suggested that the type of drug used will be strongly influenced by the individual's characteristic way of relating to the world. The detached type of person might be expected to choose the "hard" narcotics to facilitate indifference and withdrawal from the world. Passive and ambivalent types might be expected to select sedatives to assure a serene dependency. Passive types of persons who value independence might be expected to enlarge their world without social involvement through the use of hallucinogenic drugs, whereas the dependent type of person who is geared to activity might seek stimulants. Various types of persons might experiment with drugs simply in order to play along with the group that uses drugs; such group identification may be joined with youthful rebellion against society as a whole. Obviously, the above descriptions are highly speculative because of the paucity of controlled clinical studies. The quest of the addict may be the quest to feel full, sexually satisfied, without aggressive strivings, and free of pain and anxiety. Utopia would be to feel normal, and this is about the best that the narcotic addict can achieve by way of drugs.

Although many societies associate addiction with criminality, most civilized countries regard addiction as a medical problem to be dealt with in appropriate therapeutic

ways. Furthermore, narcotics fulfill several socially useful functions in those countries that do not prohibit or necessarily censure the possession of narcotics. An old League of Nations report said: "The social and hygienic conditions under which a great part of the working classes in the Far East live are of so low a standard that these classes of people strive to find some form of diversion permitting them to forget at least for some moments the hardships of life." In addition to relieving mental or physical pain, opiates have been used medicinally in tropical countries where large segments of the population suffer from dysentery and fever.

#### HISTORY OF DRUG CONTROL

The first major national efforts to control the distribution of narcotic and other dangerous drugs were the efforts of the Chinese in the 19th century. Commerce in poppy (opium) and coca leaf (cocaine) developed on an organized basis during the 1700s. The Manchus of China attempted to discourage opium importation and use, but the English East India Company, which maintained an official monopoly over British trade in China, was engaged in the profitable export of opium from India to China. This monopoly of the China trade was eventually abolished in 1839–42, and friction increased between the British and the Chinese over the importation of opium. Foreign merchants, including those from France and the United States, were bringing in ever-increasing quantities of opium. Finally, the Manchu government required all foreign merchants to surrender their stocks of opium for destruction. The British objected, and the Opium War (1839–42) between the Chinese and the British followed. The Chinese lost and were forced into a series of treaties with England and other countries that took advantage of the British victory. In 1858, the importation of opium into China was legalized by the Treaty of Tientsin, which fixed a tariff rate for opium importation. Further difficulties followed. An illegal opium trade carried on by smugglers in south China encouraged gangsterism and piracy, and the activity eventually became linked with powerful secret societies in the south of China.

International controls. Throughout the 1800s, the Chinese government regarded opium as an important moral and economic question, but obviously China needed international help. In 1909, U.S. President Theodore Roosevelt proposed an international investigation of the opium problem, and a meeting of 13 nations held in Shanghai in the same year resulted in recommendations that formed the basis of the first opium convention at The Hague in 1912. Ratification of the Hague Convention occurred during the meetings of 1913 and 1914. Although further regulatory activity was suspended during World War I, ratification of the Versailles peace treaties of 1919–20 also constituted a ratification of the Hague Convention of 1912. The League of Nations was then given responsibility to supervise agreements with regard to the traffic in opium and other dangerous drugs. A further important development in drug control was the convention of 1925, which placed further restrictions on the production and manufacture of narcotics. Six more international conventions and agreements were concluded between 1912 and 1936.

Under a Protocol on Narcotic Drugs of December 1946 the functions of the League of Nations and of the Office International d'Hygiène Publique were transferred to the United Nations and to the World Health Organization. In 1948 a protocol extended the control system to synthetic and natural drugs outside the scope of the earlier conventions. In 1953 a further protocol was adopted to limit and regulate the cultivation of the poppy plant and the production of, or international and wholesale trade in, and use of opium. Before the protocol became operative in 1963 the international control organs found a need for codifying and strengthening the existing treaties, and a Single Convention on Narcotic Drugs was drawn up in New York in 1961. This Convention drew into one comprehensive control regime all the earlier agreements, limited the use of coca leaves and cannabis

use

to medical and scientific needs, and paved the way for the International Narcotics Control Board. The Convention came into force in 1964, and the new board began duty in 1968.

**National controls.** The United States is perhaps the nation most preoccupied with drug control, and it is largely the "Americanized" countries that have made narcotics regulation a matter of public policy with the consequent network of laws, criminal detection agencies, and derived social effects. The principal U.S. legislation has been the Harrison Narcotics Act of 1914, the Opium Poppy Control Act of 1942, and the Narcotic Drug Control Act of 1956; the Drug Abuse Control Amendment of 1965 added controls over depressant, stimulant, and hallucinogenic drugs not covered under the other narcotic control acts. Manufacturers and distributors are required to register with the U.S. Food and Drug Administration, retail dealers are required to keep inventories, and physicians are required to limit the period of prescription and the number of refills permitted. Heroin manufacture was prohibited in the United States in 1924, and by 1956 all heroin legally held in the United States was surrendered to the government. The legal use of heroin is practically nonexistent today anywhere in the world—largely because of the action of the League of Nations.

Great Britain controls the manufacture, distribution, and sale of narcotics through the Dangerous Drug Act of 1920. The British system, however, is based on a public policy position different from that of the United States, and narcotic addiction has remained a minor social problem. In 1967, England placed the prescription of narcotics under the control of the National Health Service and its associated clinics. Canada and Japan attempt to control narcotics in much the same manner as the United States with much the same consequence in terms of high rates of addiction. Opium traffic appears to still flourish in Asia, but the East has officially gone through a period of regulation, governmental monopoly over cultivation, and finally prohibition of use.

**Extent of contemporary drug abuse.** Complete and reliable data on the extent of drug abuse in recent years is simply not available. To specify the size and extent of the drug problem, accurate information as to manufacture, distribution, and sale of drugs would be needed. Complete evaluation would also require knowledge of the incidence of habituation and addiction in the general population, the number of persons admitted to hospitals because of drug intoxication, and the number of arrests for drug sales that do not conform to the law. This kind of determination is not possible under existing laws even for the legitimate sources of drugs. Unfortunately, much of the drug traffic is from uncontrolled, illicit sources, and here there is an almost total absence of reliable information. Black market diversion of drugs may occur at any point from the manufacture of basic chemicals used to synthesize the drugs, through the process of actually preparing the drug, to the distribution of the final drug form, to the retail drug store, or even the physician. This is a complex chain involving chemical brokers, exporters, and dealers in addition to those who have more direct involvement with the drug process. Finally, there is the problem of currentness. Time is involved in reporting at each level of information, and the final data may be no more recent than three to five years, and a basic source or reference work may contain figures that have suffered a decade of delay from the actual occurrence of the drug abuse. Drug abuse patterns change over a relatively short time. In the 1960s, the youthful drug abuser tended to use a drug that increased the level of consciousness. In contrast, it had been only a short time earlier that youthful drug abuse involved only the hypnotics and alcohol, which depress consciousness and blunt experience.

The U.S. Federal Bureau of Narcotics maintains a register of so-called active addicts who in the early 1970s numbered approximately 60,000 persons; the actual number of narcotic addicts in the United States was probably closer to 120,000 persons. England has about 400 addicts

but this number has been steadily growing as a result of an influx of narcotic addicts from Canada. With the exception of Germany, other European countries have no more than a few hundred narcotic addicts each. West Germany has close to 5,000 addicts. Canada has from 3,000 to 3,500 addicts. In the Middle and Far East, the highest rates are found in Egypt, India, and Iran, with lesser rates for Borneo, Burma, China, Japan, and Korea. Opium cultivation has been declining in each of the last several years and is found chiefly in Asia. In 1965, India (55.8 percent), the U.S.S.R. (25.8 percent), and Turkey (17.7 percent) accounted for almost the total output of opium as reported to the United Nations. Bolivia and Peru are the chief producers of coca leaf (for cocaine).

The extent of problems involving other drugs can only be guessed from certain superficial indicators. By 1966, for example, approximately 8,000,000,000 amphetamine tablets were being produced yearly in the United States. This would give each adult and child 35 doses of a five-milligram tablet each year. It is probable that about half the production is diverted into illegal channels, and that 90 percent of the illegal traffic emanates from restaurants, truck stops, gasoline stations, and bars. The barbiturate figures are older (1957), but production was estimated to be 864,000 pounds or 26 doses of 100 milligrams for each adult and child yearly. Barbiturates are the leading mode of suicide in the U.S., accounting for over 3,000 deaths each year. A 1967 report to the U.S. president on medical care prices indicated that retail sales of sedatives and tranquilizers had increased 535 percent between the years 1953 and 1965. Marijuana and the hallucinogens are illegal, and no good data are available.

## II. The varieties of psychotropic drugs

### OPIMUM, MORPHINE, HEROIN, AND RELATED SYNTHETICS

The opiates are unrivalled in their ability to relieve pain. Opium is the dried milky exudate obtained from the unripe seed pods of the poppy plant (*Papaver somniferum*), which grows naturally throughout most of Asia Minor. Of the 20 or more alkaloids found in opium, only a few are pharmacologically active. The important constituents of opium are morphine (10%), papaverine (1%), codeine (0.5%), and thebaine (0.2%). (Papaverine is pharmacologically distinct from the narcotic agents and is essentially devoid of effects on the central nervous system.) In 1803, a young German apothecary's assistant named Sertürner isolated crystalline morphine as the active analgesic principle of opium. Codeine is considerably less potent (1/6) and is obtained from morphine. **Diacetylmorphine**—or heroin—was developed from morphine by the Bayer Company of Germany in 1898 and is five to ten times as potent as morphine itself. Opiates are not medically ideal. Tolerance is developed quite rapidly and completely in the more important members of the group, morphine and heroin, and they are highly addictive. In addition, they produce respiratory depression and frequently cause nausea and emesis. As a result, there has been a constant search for synthetic substitutes: meperidine (Demerol), first synthesized in Germany in 1939, is a significant addition to the group of analgesics, being one-tenth as potent as morphine; alphaprodine (Nisentil) is one-fifth as potent as morphine but is rapid-acting; methadone, synthesized in Germany during World War II, is comparable to morphine in potency; levorphanol (Levo-Dromoran) is an important synthetic with five times the potency of morphine. These synthetics exhibit a more favourable tolerance factor than the more potent of the opiates, but they fall short of an ideal analgesic in being addictive. Of this entire series, codeine has the least addiction potential and heroin has the greatest (see also NARCOTIC).

**History.** The narcotic and sleep-producing qualities of the poppy have been known to man throughout recorded history. Sumerian records from the time of Mesopotamia (5000 to 4000 BC) refer to the poppy, and medicinal reference to opium is contained in Assyrian medical tablets. Homer's writings indicate Greek usage at least by 900

use

BC; **Hippocrates** (c. 400 BC) made extensive use of medicinal herbs including opium. The Romans probably learned of opium during their conquest of the eastern Mediterranean; **Galen** (AD 130–200) was an enthusiastic advocate of the virtues of opium, and his books became the supreme authority for hundreds of years. The art of medicinals was preserved by the **Islamic** civilization following the decline of the Roman Empire; opium was introduced by the Arabs to Persia, China, and India. **Paracelsus** (1493–1541), professor at the University of Basle, introduced laudanum, the modern tincture of opium. **Le Mort**, a professor of chemistry at the University of Leyden (1702–18), discovered paregoric for the control of diarrhea by combining camphor with tincture of opium.

There is no adequate comprehensive history of the addictive aspects of opium use in spite of the fact that it has been known since antiquity. Because there were few alternative therapeutics or pain-killers until the 19th century, opium was somewhat of a medical panacea. Thus, although at least one account in 1701, by a London physician named Jones, spoke of an excessive use of opium, there appears to have been no real history of concern until recent times, and opiates were easily available in the West in the 19th century, for instance, in a variety of patent medicines. Physicians prescribed them freely, they were easy to obtain without prescription, and they were used by all social classes. At one time, the extensive use of these medicines for various gynecological difficulties probably accounted for the high addiction rate among women (three times the rate among men). Today, in the United States, only one addict out of six is a woman. The invention of the hypodermic needle in the mid-19th century and its subsequent use to administer opiates during wartime produced large numbers of addicted soldiers (about 400,000 during the U.S. Civil War alone); it was thought mistakenly that if opiates were administered by vein, no hunger or addiction would develop, since the narcotic did not reach the stomach. Toward the end of the 19th century, various "undesirables" such as gamblers and prostitutes began to be associated with the use of opiates, and narcotics became identified more with the so-called criminal element than with medical therapy. By the turn of the 20th century, narcotic use had become a worldwide problem, and various national and international regulatory bodies sought to control traffic in opium from the Near and Far East.

In the 20th century, until recently, narcotic use was largely associated with metropolitan slums, principally among poor and culturally deprived. Currently, narcotic use has begun to spread to middle class youth, and, interestingly, there is evidence that the middle class is now beginning to look at narcotic addiction as a mental health problem. When it was confined to the slums, it was considered a police problem.

**Physiological effects.** The various opiates and related synthetics all produce about the same physiological effects. All are qualitatively similar to morphine in action and differ from each other mainly in degree. The most long-lasting and conspicuous physiological responses are obtained from the central nervous system and the smooth muscle of the gastrointestinal tract. These effects, while restricted, are complex and vary with the dosage and the route of administration (intravenous, subcutaneous, oral). Both depressant and stimulant effects are elicited. The depressant action involves the cerebral cortex, with a consequent narcosis, general depression, and reduction in pain perception; it also involves the hypothalamus and brain stem, inducing sedation, the medulla, with associated effects on respiration, the cough reflex, and the vomiting centre (late effect). The stimulant action involves the spinal cord and its reflexes, the vomiting centre (early effect), the tenth cranial nerve with a consequent slowing of the heart, and the third cranial nerve resulting in pupil constriction. Associated effects of these various actions include nausea, vomiting, constipation, itchiness of the facial region, yawning, sweating, flushing of skin, a warm sensation in the stomach, fall in body temperature, diminished respiration, and heaviness in the limbs.

The most outstanding effect of the opiates is one of analgesia. All types of pain perception are affected, but the best analgesic response is obtained in relieving dull pain. The analgesic effects increase with increasing doses until a limit is reached beyond which no further improvement is obtained. This point may fall just short of complete relief.

Depression of cortical function results in a euphoric response involving a reduction of fear and apprehension, a lessening of inhibitions, an expansion of ego, and an elevation of mood that combine to enhance the general sense of well-being. Occasionally in pain-free individuals, the opposite effect, dysphoria, occurs and there is anxiety, fear, and some depression. In addition to analgesia and associated euphoria, there is drowsiness, mental and physical impairment, a clouding of consciousness, poor concentration and attention, reduced hunger or sex drives, and sometimes apathy.

Apart from their addiction liability, respiratory depression leading to respiratory failure and death is the chief hazard of these drugs. All of the more potent opiates and synthetics produce rapid tolerance, and tolerance to one member of this group always is associated with tolerance to the other members of the group (cross-tolerance). The more potent members of the group have a very great addiction liability with the associated physical dependence and abstinence syndrome.

**Types of users.** There is no single narcotic addict personality type: addiction is not a unitary phenomenon occurring in a single type. The great variation in addiction rates and classes of addicts in various countries caution against placing too great an emphasis on personality variables as major causative factors. Even within the United States, there is great danger in generalizing from the cases of the patients found at the public health service hospitals in Lexington, Kentucky, and in Fort Worth, Texas. These inmates are a highly select group of adults who have spent previous time in correctional institutions. They are not representative of the adolescent addict or the adult addict who has not had continual difficulty with the law. The United States has recently experienced a new type of slum-dwelling addict who is a member of a closely knit adolescent gang. This subculture is highly tolerant of drug abuse, and the members have ready access to narcotic drugs. They do not actively seek the opportunity to try heroin; neither are they deliberately "hooked" on heroin by adult drug peddlers. They are initiated to narcotic use by friends, gang members, or neighbourhood acquaintances, and the opportunity for such use is almost always casual but ever present. This "kicks" user is apt to abandon narcotics when gang membership is abandoned. The chronic user is more likely to be the immature adolescent at the periphery of gang activities who uses narcotics for their adjustive value in terms of his deep-seated personality problems. He does not abandon drug use for the more conventional pursuits when he enters adulthood. Instead, old ties are severed; interest in previous friendships is withdrawn; athletic and scholastic strivings are abandoned; competitive, sexual, and aggressive behaviour becomes markedly reduced, and he retreats further into his drug-induced state. Identification is now with the addict group: a special culture with a special language. The addict's world revolves around obtaining drugs.

**Means of administration and their effects.** Most persistent users follow a classic progression from sniffing (similar to the oral route), to "skin popping" (subcutaneous route), to "mainlining" (intravenous route)—each step bringing more intense experience, a higher addiction liability. With mainlining, the initial "thrill" is more immediate. Within seconds, a warm, glowing sensation spreads over the body, most intense in the stomach and intestines, comparable to sexual release. This intense "rush" is then followed by a deep sense of relaxation and contentment. The user is "high" and momentarily free. It is this initial state of intense pleasure that presumably brings the novice to repeat the experience, and it is this mode of administration that hastens him on the way to

Opiates as analgesics and depressants

20th-century patterns of use

Emotional and physical feelings of heroin use

drug tolerance and physical dependence. Soon he finds that the effects are not quite there. Instead, his body is beginning to experience new miseries. At this juncture, he "shoots" to avoid discomfort. The euphoria is gone. He now spends every waking moment in obtaining further supplies to prevent the inevitable withdrawal symptoms should he fail. Habits are expensive. If indigent, the addict must spend all his time "hustling" for drugs—which means that he must steal and dispose of \$50,000 worth of goods to support a habit that may cost \$10,000 a year or raise money by other means such as prostitution, procuring, or small-time narcotics peddling. An addict is judged by his success in supporting his habit. The addict always faces the danger of withdrawal, the danger of arrest, the danger of loss of available supply, the danger of infection, of collapsed veins, or of death from overdosage. Very few individuals are still addicted by the age of 40. They have either died, somehow freed themselves from their addiction, or sought treatment.

**Therapy.** Drug dependence can be viewed as an ethical problem: Is it right and permissible to need a narcotic agent? How one answers this question dictates the position one will take in regard to addiction therapy. In general, the addict can be given his drug, he can be placed on a substitute drug, or drugs can be barred from him. Narcotic maintenance, which gives the addict his drug, is the system employed in the management of opiate dependence in England. Methadone treatment is a drug substitution therapy that replaces opiate addiction with methadone addiction in order that the addict might become a socially useful citizen. Synanon, a therapeutic community movement involving an intensive program of family-like resocialization, is an approach with total abstinence as its goal. Psychological approaches to total abstinence through re-education involve psychotherapy, hypnosis, and various conditioning techniques that attempt to attach unpleasant or aversive associations to the thoughts and actions accompanying drug use. Each of these approaches has had successes and has limitations.

Great Britain began to control the use of narcotics in 1950 but, unlike the United States, has embraced the principle of drug maintenance. Supporters of the approach have insisted that, at least until recently, narcotic addiction in Great Britain remained a very minor problem because addiction is considered an illness rather than a crime. (In recent years, however, addiction has apparently become more widespread, for uncertain reasons.) The British physician was earlier allowed to prescribe maintenance doses of a narcotic if, in his professional judgment, the addict was unable to lead a useful life without the drug. But in 1967 the British government took the right to prescribe for maintenance addiction away from the general practitioner and placed it in the hands of drug-treatment clinics. Although some addicts must obtain legal supplies from the clinic, others are allowed to obtain supplies from a neighbourhood pharmacy and medicate themselves. These clinics also provide social and re-educative services such as psychotherapy for the addict. The general experience among these clinics has been that a large proportion of the addicts are becoming productive, socially useful members of the community.

There are two major drawbacks to the maintenance use of narcotic drugs such as employed by the British. Both the physical and the social health of the user remains unsatisfactory. A high incidence of hepatitis, bacterial endocarditis, abscesses, and, on occasion, fatal overdosage accompanies the self-administration of opiates. Socially, the addict on self-administration also tends to remain less productive than his peers—the reason apparently being that the individual on narcotic maintenance is still very preoccupied with certain aspects of narcotic use. Narcotic addiction is a two-faceted problem: the yearning for the "high" and the felt sense of not being physiologically normal. The addict on narcotic maintenance often attempts to obtain or retain both drug effects: frequent intravenous use prevents the feeling of drug hunger and maximizes his attempt to experience euphoria.

Methadone therapy aims to block the abnormal reactions associated with narcotic addiction while permitting the addict to live a normal, useful life as a fully participating member of the community. Methadone provides a "narcotic blockade" in that it is possible to increase methadone medication to a point at which large oral doses will induce a state of cross-tolerance in which the euphoric effects of other narcotics cannot be felt even in very high doses. Additionally methadone has the ability to allay the feeling of not being right physically, which the addict finds he can correct only by repeated narcotic use. Methadone treatment, then, rests on these two pharmacological actions: the blockade of euphoric effects and the relief of "narcotic hunger." Methadone is not successful in every case (10–15% failure), but results, to date, have been dramatic. In a 1970 study conducted in New York City on 2,862 addicts who entered a treatment program, 2,279 remained in the program, and none returned to daily use of heroin. The majority either accepted employment or started school, and previous patterns of antisocial behaviour were either eliminated or significantly reduced. Methadone is a drug of addiction in its own right, but it does not have some of the more serious undesirable consequences associated with heroin.

Synanon is a social movement founded in 1958 by Charles Dederich to teach self-reliance and promote personal growth. Dederich is a former alcoholic who brought certain principles that he had found helpful in Alcoholics Anonymous to the treatment of drug addiction. This is a type of moral therapy that has produced encouraging results. As a social climate, Synanon combines certain elements of the autocratic family with the kind of structure one might find in a primitive tribe. The individual is expected to perform tasks as part of the group. His peers who have preceded him in the Synanon experience have a certain status of "elders," and there is a group leader who has the characteristics of the "head" of the household or tribal chief. The central figures in this simulated family structure attempt to teach values and enhance the spiritual aspects of the individual. Emphasis is directed toward the offending behaviour, which is the use of drugs, and there is a rigid requirement that there be total abstinence from addictive substances. The "synanon" per se is a form of group therapy conducted by a recovered drug addict who relies heavily on his own experiences in his work with the newcomer to the group. Initially, he is authoritarian and will employ ridicule and hostile attacks. There is also a technique that places the addict in a position in which he must accept vigorous, rough feedback on his own behaviour. Generally, however, the setting is supportive and permissive. The addict is judged in terms of present behaviour, not past. The basic philosophy is to regard him as a rational person. At no time is addiction viewed as a sickness.

In such countries as the United States, where the addict is treated as a criminal, physicians are prevented from administering opiates for the maintenance of addiction. Acceptable treatment includes enforced institutionalization for about four months, strict regulation against ambulatory care until the person is drug free, and the total prohibition of self-administration of drugs even under a physician's care. Estimates of cures based upon decades of these government-regulated procedures range from 1 to 15 percent.

#### HALLUCINOGENIC DRUGS

It is difficult to find a suitable generic name for a class of drugs having as many diverse effects as have been reported for "hallucinogens." Abnormal behaviour as profound as the swings in mood, disturbances in thinking, perceptual distortions, delusions, and feelings of strangeness that sometimes occur with these drugs is usually indicative of a major mental disorder; consequently these substances are often called psychotomimetic to indicate that their effects mimic the symptoms of a naturally occurring psychosis. There are indeed points of similarity between the drug states and the natural psychoses, but there are also many dissimilarities—so many as to make

Methadone therapy

Synanon

Narcotic maintenance

Problems of terminology and definition in hallucinogens

the resemblance quite superficial. Such substances as the bromides, heavy metals, belladonna alkaloids, and intoxicants can, however, cause abnormal behaviour to a degree sometimes described as psychotic, and if the list is extended to include the drugs being discussed here, then the objection—that the term psychotomimetic should refer only to the mimicking of a natural psychosis—is no longer valid. Taking this point of view, some investigators prefer the term psychogenic ("psychosis causing"). One of the most conspicuous features of this kind of drug experience is the occurrence of the distinctive change in perception called hallucination. For this reason the term hallucinogenic is sometimes used. Most people are aware, however, even while under the influence of the drug, that their unusual perceptions have no basis in reality; so this is not a very accurate use of the term. Strictly speaking, very few people truly hallucinate as a result of taking a hallucinogen.

All these terms are borrowed from medicine and are closely identified with pathology. In this sense, all are negative. It has been suggested that these drugs be called psychedelic ("mind manifesting"). This term shifts the emphasis to that aspect of the drug experience that involves an increased awareness of one's surroundings and also of one's own bodily processes—in brief, an expansion of consciousness. The term also shifts emphasis from the medical or therapeutic aspect to the educational or mystical-religious aspect of drug experience. Only certain people, however, ever have a psychedelic experience in its fullest meaning, and the question of its value to the individual is entirely subjective. The possibility of dangerous consequences, too, may be masked by such a benign term. None of these terms, then, is entirely satisfactory, and one or two are distinctly misleading. (These terms are used interchangeably henceforth with no particular intent other than to indicate membership in the LSD-type family of drugs.)

**Types of hallucinogens.** The psychoactive substances that have aroused widespread interest and bitter controversy are the LSD-type drugs that produce marked aberrations of behaviour. The most important of these are (1) d-lysergic acid diethylamide, commonly known as LSD-25, which originally was derived from ergot (*Claviceps purpurea*), a fungus on rye and wheat; (2) mescaline, the active principle of the peyote cactus (*Lophophora williamsii*), which grows in the southwestern United States and Mexico; and (3) psilocybin and psilocin, which come from Mexican mushrooms (notably *Psilocybe mexicana* and *Stropharia cubensis*). Bufotenine, originally isolated from the skin of toads, is the alleged hallucinogenic agent contained in banana peels. It has also been isolated in the plant *Piptadenia peregrina*, the mushroom *Amanita muscaria*, and is thought to be the active principle of the hallucinogenic snuff called cohoba and yopo and used by the Indians of Trinidad and by the Otomac Indians of the Orinoco Valley. Harmine is an alkaloid found in the seed coats of a plant (*Peganum harmala*) of the Mediterranean region and the Near East and also in a South American vine (*Banisteriopsis caapi*). There are some amides of lysergic acid contained in the seeds of the morning glory (*Rivea corymbosa*), which the Aztecs call *ololiuqui*. Synthetic compounds of interest are DMT (dimethyltryptamine) and STP (dimethoxyphenylethylamine; DOM). Cannabis (discussed separately below) is not usually included in this group of hallucinogenic drugs, but there is no particular justification for its exclusion. It is a resin obtained from the leaves and tops of the hemp plant (*Cannabis sativa*; see also HALLUCINOGEN).

**History.** Native societies of the Western Hemisphere have for 2,000 years utilized various naturally occurring materials such as the "sacred" mushroom of Mexico and the peyote cactus of the southwestern United States. Scientific interest in the hallucinogenic drugs developed slowly. A neurologist wrote about his experience with peyote before the turn of the 20th century, and his account attracted the serious attention of two distinguished psychologists, Havelock Ellis and William James. Mescaline was isolated as the active principle of peyote in

1896, and its structural resemblance to the adrenal hormone epinephrine was recognized by 1919. There followed some interest in model psychoses (that is, drug-induced simulations of abnormal behaviour patterns), but it was not until 1943, when a Swiss chemist accidentally ingested a synthetic preparation of lysergic acid diethylamide and experienced its psychedelic effects, that the search for a natural substance responsible for schizophrenia became widespread. An American mycologist called attention to the powers of the Mexican mushroom in 1953, and the active principle was quickly found to be psilocybin.

**Physiological and psychological effects.** The psychedelics are capable of producing a wide range of subjective and objective effects; however, there is apparently no reaction that is distinctive for a particular drug. Subjects are unable to distinguish among LSD, mescaline, and psilocybin when they have no prior knowledge of the identity of the drug ingested. These drugs induce a physiological response that is consistent with the type of effect expected of a central-nervous-system stimulant. Usually there is elevation of the systolic blood pressure, dilatation of the pupils, some facilitation of the spinal reflexes, and excitation of the sympathetic nervous system and the brain.

There is considerable difference in the potency of these drugs. A grown man requires about 500 milligrams of mescaline or 20 milligrams of psilocybin or only 0.1 milligram of LSD for full clinical effects when the substances are ingested orally. The active principle in the seeds of the morning glory is about one-tenth as potent as LSD. There are also differences in the time of onset and the duration of effects. Psilocybin acts within 20 to 30 minutes, and the effects last about five to six hours. LSD acts within 30 to 60 minutes, and the effects usually last for eight to ten hours, although occasionally some effects persist for several days. Mescaline requires two to three hours for onset, but the effects last for more than 12 hours. All psychedelics presumably are lethal if taken in large enough quantities, but the effective dose is so low as compared to the lethal dose that death has not been a factor in experimental studies. Physiological tolerance for these drugs develops quite rapidly in man—fastest for LSD, somewhat more slowly and less completely for psilocybin and mescaline. The effects for a particular dose level of LSD are lost within three days of repeated administration, but the original sensitivity is quickly regained if several days are allowed to intervene. Cross-tolerance has been demonstrated for LSD, mescaline, psilocybin, and certain of the lysergic acid derivatives. Tolerance to one of the drugs reduces the effectiveness of an equivalent dose of a second drug, thus suggesting a common mode of action for the group.

Most persons regard the experience with one of these drugs as something totally removed from anything they have ever encountered in normal, everyday experience. The subjective effects vary greatly among individuals and, for a particular person, even from one drug session to the next. The variations seem to reflect such factors as the mood and personality of the subject, the setting in which the drug is administered, the user's expectation of a certain kind of experience, the meaning for the individual of the act of taking the drug, and his interpretation of the motives of the person who is administering the drug to him. Nevertheless, certain invariant reactions seem to stand out. The one most easily described by users is the effect of being "flooded" with visual experience, as much when the eyes are closed as when they are open. Light is greatly intensified; colours are vivid and seem to glow; images are numerous and persistent, yielding a wide range of illusions and hallucinations; details are sharp; perception of space is enhanced; and music may evoke visual impressions, or light may give the impression of sounds. A second important aspect, which people have more difficulty in describing, involves a change in the feelings and the awareness of the self. The sense of personal identity is altered. There may be a fusion of subject and object; legs may seem to shrink or be-

LSD,  
mescaline,  
and  
psilocybin

Subjective  
experiences  
under the  
influence  
of hallucinogens

come extended, and the body to float; space may become boundless and the passage of time very slow; and the person may feel completely empty inside, or he may believe that he is the universe. This type of reaction has been called depersonalization, detachment, or dissociation. Increased suspiciousness of the intentions and motives of others may also become a factor. At times the mood shifts. Descriptions of rapture, ecstasy, and an enhanced sense of beauty are readily elicited; but there can also be a "hellish" terror, gloom, and the feeling of complete isolation. For some people the experience is so disturbing that psychiatric hospitalization is required. Studies of performance on standardized tests show some reduction in reasoning and memory, but the motivation of the subject probably accounts for much of the performance decrement, since many people are uncooperative in this type of structured setting while under the influence of a drug.

Interest in these drugs was routinely scientific for the first few years following the discovery of LSD, but in the 1950s some professional groups began to explore the use of the psychedelics as adjuncts to psychotherapy and also for certain purposes of creativity. It was at this juncture, when the drugs were employed to "change" people, that they became a centre of controversy. LSD is not an approved drug in most countries; consequently its therapeutic applications can only be regarded as experimental. In the 1960s, LSD was proposed as an aid in the treatment of neurosis with special interest in cases recalcitrant to the more conventional psychotherapeutic procedures. LSD also was being given serious trial in the treatment of alcoholism, particularly in Canada, where experimentation is not heavily restricted. LSD has also been employed to reduce the suffering of terminally ill cancer patients. The drug was also under study as an adjunct in the treatment of narcotic addiction, of autistic children, and of the so-called psychopathic personality; and the use of various hallucinogens continue to be advocated in the experimental study of abnormal behaviour because of the degree of control that they offer.

Undesirable or dangerous effects

LSD can be dangerous when used improperly. Swings of mood, time and space distortion, "hallucinations," and impulsive behaviour are complications especially hazardous to the individual when he is alone. Driving while under the influence of one of these drugs is particularly dangerous. Acts of aggression are rare but do occur. In the 1960s, the suicide rate was not high in the various investigational (legal use) groups, but the rate of serious untoward psychological effects requiring psychiatric attention climbed steadily. These drugs do induce psychotic reactions that may last several months or longer. Negative reactions, sometimes called bad trips, are most apt to occur in unstable persons or in other persons taking very large amounts of a drug or taking it under strange conditions or in unfamiliar settings. So far as is known, these drugs are nontoxic, and there are no permanent physical effects associated with their use. There is no physical dependence or withdrawal symptom associated with long-term use, but certain individuals may become psychologically dependent on the drug, become deeply preoccupied with its use, and radically change their life style with continued use.

A new dimension was added to the LSD controversy in 1967, when laboratory studies began to appear in the scientific literature that linked LSD to chromosomal and genetic damage, thus intimating that future generations of the LSD user might be subject to the fearful issue of malformation and genetic illness. Unfortunately, there remains only the poorest understanding of exactly what has been found, to date, in such studies. The findings are neither clear nor conclusive, and moreover they involve not only LSD but also several classes of drugs in rather common use, such as aspirin, caffeine, tranquilizers, and antibiotics. The LSD chromosome story, then, is the story not just of LSD-induced changes but also of possible chromosomal and genetic damage that might be induced by wide classes of drugs in general use. If the gene pool of the LSD user is in jeopardy, as these studies suggest, then, the gene pool of the whole population is also in

jeopardy, as these studies also suggest. The danger of drugs is the excessive reliance on drugs; the culprit is everywhere present.

The several types of research upon which these chromosomal and genetic findings are based are wrought with difficulties. Genetic studies that attempt to produce structural malformation use, of necessity, the experimental animal; and there is thus the basic problem of evaluating the extent to which these findings can be generalized to the human. The conditions of the experiments in general do not sufficiently parallel the conditions of natural LSD use to render the data very meaningful. The chromosomal studies present equal difficulties—trying to infer from the behaviour of a cell in the test tube how a mass of cells that are part of a living organism will act.

**Types of users.** Prior to the mid-1960s, LSD-type drugs were taken by several different types of persons including many who were respected, successful, and well-established socially. Intellectuals, educators, medical and mental health professionals, volunteer research subjects, psychiatric patients, theological students, and participants in special drug-centre communities were some of the first users of these hallucinogenic substances. Beginning in 1966, experimentation in most countries was severely restricted, and subsequent use has been almost entirely of a black market type. LSD use is markedly on the decline, being replaced by cannabis and the amphetamines. Currently, most users tend to be of the middle class—either young, college-educated persons or those who have drifted to the fringe of society. Drug initiation is typically by way of a personal friend or acquaintance. Employers or teachers also have a powerful influence over subordinates and students in terms of drug acceptance. The user of LSD seems often to have an almost fanatic need to proselytize others to drug use. Those who have taken a hallucinogenic substance generally have had experience with other drugs prior to the LSD experience, and there is also a tendency on the part of those who take these drugs to repeat the drug experience and to experiment with other drugs. The special language, method of proselytizing, and psychological dependence surrounding the use of psychedelics bear striking resemblance to the context of narcotics addiction. The chronic LSD user tends to be introverted and passive. Motives for LSD use are many: psychological insight; expansion of consciousness; the desire to become more loving, more creative, open, religious; a desire for new experience, profound personality change, and simple "kicks."

Prose-lytization among LSD users

#### BARBITURATES, STIMULANTS, AND TRANQUILLIZERS

There are many sanctioned uses for drugs that exert an effect on the central nervous system. Consequently, there are several classes of nonnarcotic drugs that have come into extensive use as sleeping aids, sedatives, hypnotics, energizers, mood elevators, stimulants, and tranquilizers.

Sedatives and hypnotics differ from general anesthetics only in degree. All are capable of producing central-nervous-system depression, loss of consciousness, and death (see also SEDATIVE-HYPNOTIC DRUGS).

The barbiturates, bromides, chloral hydrate, and paraldehyde are well-known drugs—with the barbiturates being of greatest interest because of the increasing number of middle and upper class individuals who have come to rely on them for immediate relaxation, mild euphoria, and an improved sense of well-being. But alcohol has been and continues to be the drug of choice for these same effects (see also SEDATIVE-HYPNOTIC DRUGS).

Of the drugs that excite the nervous system, nicotine, caffeine, the amphetamines, and the potentially addicting cocaine are well known. The use of stimulants to facilitate attention, sustain wakefulness, and mask fatigue has made the amphetamines an increasingly popular drug by students and those who engage in mental work. Originally the drug of truck drivers, amphetamine is now a common cause of arrest among teen-agers and young adults who commit drug offenses. Cocaine has always been a potentially dangerous drug, but it is not in wide use among the middle and upper classes. Stimulants do not

create energy, and the energy mobilized by these drugs is eventually depleted with serious consequences (see also STIMULANT).

The tranquilizers are a heterogeneous group, as are the behaviours that they are employed to alter. In general, tranquilizing drugs reduce hyperactivity, agitation, and anxiety, which tend to cause a loss of behavioral control. Tranquillizing drugs do not characteristically produce general anesthesia, no matter what the dose; this attribute tends to distinguish tranquilizing drugs from the barbiturates (see also TRANQUILLIZERS).

All the barbiturates, stimulants, and tranquilizers are widely prescribed by physicians, and all these drugs are available through nonmedical (illegal) sources. Most of these drugs are classified as "habit-forming." The minor tranquilizers are commonly associated with habituation and may induce physical dependence and severe withdrawal symptoms. The amphetamines and cocaine intoxicate at high dosages, and both are capable of inducing serious toxic and psychotic reactions under heavy use. The barbiturates are the leading cause of death by suicide. They are judged to be a danger to health by both the World Health Organization Expert Committee and the United Nations Commission on Narcotic Drugs, which have recommended strict control on their production, distribution, and use. The nonnarcotic drugs in widespread use among middle and upper class citizenry manifest considerable untoward consequences for the individual and for society when abused—thus placing their problem in a different perspective than that normally associated with the opiates, LSD, and marijuana.

**Barbiturates.** The barbiturates relieve tension and anxiety at low dose levels without causing drowsiness, although some tendency toward drowsiness may be an initial reaction for the first few days on the drug. These drugs exert a selective action in small amounts on higher cortical (brain) centres, particularly those centres that are involved in the inhibitory or restraining mechanisms of behaviour. As a consequence, there is an increase in uninhibitedness such as talkativeness and unrestricted social interaction following the taking of the drug. There is also an impairment of function at low dose levels. All the barbiturates are capable of inducing sleep when given in sufficient amounts. They do not affect the perception of pain as do the analgesics, but they do alter the individual's response to pain (*e.g.*, decreasing his anxiety) and are useful in this regard. Infrequently, the barbiturates produce undesirable reactions ranging from simple nervousness, anxiety, nausea, and diarrhea to mental confusion, euphoria, and delirium. Some tolerance is developed to these drugs, but no physical dependence occurs in the drug range (100 to 200 milligrams) normally employed clinically. Prolonged use may lead to drug habituation and psychic dependence. When the drug is used chronically in higher amounts (400 milligrams per day), physical dependence may develop. Sudden withdrawal of a barbiturate following chronic use is frequently associated with withdrawal symptoms that are more severe than those produced by the opiates. A barbiturate should never be withdrawn abruptly following long continued use. The barbiturate addict shows many of the symptoms associated with chronic alcoholism, including blackouts, irrationality, slurred speech, poor motor coordination, emotional deterioration, mood swings, and psychosis.

**Cocaine.** Cocaine is an alkaloid derived from the leaves of the coca plant (*Erythroxylon coca*), a bush that is natural to Bolivia, Chile, and Peru along the western slopes of the Andes Mountains. Cocaine has a pronounced excitant action on the central nervous system and, in small doses, produces a pleasurable state of well-being associated with relief from fatigue, increased mental alertness, physical strength, and a reduction of hunger. In greater amounts, cocaine is an intoxicant that produces excitement, mental confusion, and convulsions. The Incas were acquainted with the ability of cocaine to produce euphoria, hyperexcitability, and hallucinations; the practice of chewing the coca leaf as part of religious ceremonies was an established custom at the time of the

Spanish conquest in the 16th century. The natives who now work the mines high in the Andes chew coca leaves for increased strength and endurance. Coca plants are under cultivation in Sri Lanka (formerly Ceylon), India, and Java. The alkaloid, tropacocaine, is chemically related to cocaine and is obtained from the Java coca plant.

Cocaine is habit forming and may also be physically addicting in some individuals, but not to the extent of the opiates. Only certain persons display abstinence symptoms on withdrawal. Significant physiological tolerance does not develop. Chronic use is associated with severe personality disturbances, inability to sleep, loss of appetite, emaciation, an increased tendency to violence, and antisocial acts. When a toxic psychosis develops, it is characteristically accompanied by paranoid delusions. Hallucinations are prominent with continued use of cocaine, particularly the tactile hallucinations that give the impression that bugs are under the skin. The drug is a white crystalline powder in pure form and the practice of "snuffing" cocaine was common in Europe at the turn of the 20th century. It is less potent when taken by mouth. When injected by vein, a favourite method in the United States, the effects are rapid in onset, intense, but of short duration. This is followed by a correspondingly deep depression that prompts the user to repeat the dose to restore the sense of well-being. Cocaine is sometimes mixed with heroin to dampen any extreme excitability produced by the cocaine. The great number of undesired effects that come on continued use frequently prompts the cocaine user to turn to other drugs.

**Amphetamines.** These stimulants are of three types having closely related actions on the nervous system: amphetamine proper (Benzedrine), one of its isomers (Dexedrine), and methamphetamine (Methedrine). The amphetamines have been used to alleviate depression, fatigue, the hyperkinetic behaviour disturbances of children, postencephalitic Parkinsonism, enuresis, nausea of pregnancy, and obesity. More recently, the amphetamines have been used in combination with one of the barbiturates, such as amobarbital or phenobarbital, to produce mood elevating effects. It is the effects of the amphetamines on mood that have led to their widespread abuse. A toxic psychosis with hallucinations and paranoid delusions may be produced by a single dose as low as 50 milligrams if no drug tolerance is present. Although the normal lethal dose for adult humans is estimated to be around 900 milligrams, habitual use may increase adult tolerance up to 1,000 milligrams per day.

The ability of amphetamine to produce a psychosis having paranoid features was first reported in 1938, shortly after its introduction as a central stimulant. Sporadic reports of psychosis followed, and in 1958, a monograph on the subject of amphetamine psychosis included these statements:

Psychosis associated with amphetamine usage is much more frequent than would be expected from the reports in the literature. . . . The clinical picture is primarily a paranoid psychosis with ideas of reference, delusions of persecution, auditory and visual hallucinations in a setting of clear consciousness. . . . The mental picture may be indistinguishable from acute or chronic paranoid schizophrenia. . . . Patients with amphetamine psychosis recover within a week unless there is demonstrable cause for continuance of symptoms; *e.g.*, continued excretion of the drug or hysterical prolongation of symptoms.

There have been subsequent attempts to distinguish between amphetamine psychosis and paranoid schizophrenia. Whatever the outcome, amphetamine induces a psychosis that comes closer to mimicking schizophrenia than any of the other drugs of abuse, including LSD. Some behavioral symptoms such as loss of initiative, apathy, and emotional blunting may persist long after the patient stops taking the drug. Methamphetamine was used extensively by the Japanese during World War II, and by 1953 the habitual users of the drug in Japan numbered about 500,000 persons. This large-scale usage created such a serious social problem that the amphetamines were placed under governmental control in Japan in 1954. This Japanese experience has provided the op-

cation

portunity for systematic studies on chronic methamphetamine intoxication. One group of 492 addicts who had been institutionalized showed a 14 percent rate of chronic psychosis with evidence of permanent organic brain damage. In the language of the street, "Meth is death." The amphetamines produce habituation, drug dependency, physiological tolerance, and toxic effects, but no physical addiction.

**Tranquillizers.** Serendipity has played a major role in the discovery of tranquillizers (as it has in all facets of medicine). Tranquillizers were unknown to medical science until the middle of the 20th century when the therapeutic value of reserpine and chlorpromazine in psychiatry was discovered by chance. Reserpine was originally derived in the 1930s from *Rauwolfia serpentina*, a woody plant that grows in the tropical areas of the world, but it has since been synthesized. Because this drug has many undesirable side effects such as low blood pressure, ulcers, weakness, nightmares, nasal congestion, and depression, however, it has been largely replaced in psychiatric practice by chlorpromazine (Thorazine) and a number of other phenothiazine derivatives synthesized in the 1950s. These phenothiazines are inexpensive, easily available, produce little immediate pleasurable effects, can usually be taken in large amounts without harm, and are not physically addicting. They are used extensively in the treatment of various hyperactive and agitated states, and as antipsychotic agents. These drugs, however, may produce jaundice, dermatitis, or, infrequently, convulsive seizures, and they do not combine well with the drinking of alcohol. Chlorpromazine is effective in reversing "bad trips" such as an LSD-induced panic reaction, but it tends to strengthen rather than reverse the powerful hallucinogenic effects of STP (DOM). There is a second group of drugs, inappropriately termed minor tranquillizers, which have achieved popularity in the management of milder psychiatric conditions, particularly anxiety and tension. The major form is meprobamate (Miltown, Equanil). Although these minor tranquillizers are considered to be entirely safe in terms of side effects, they do produce serious complications, for they are commonly associated with habituation and psychic dependence. Heavy, prolonged use may result in physical dependence and severe withdrawal symptoms including insomnia, tremors, hallucinations, and convulsions.

#### CANNABIS

Marijuana,  
hashish,  
ghanja,  
and  
bhang

Cannabis is the general term applied internationally to the Indian hemp plant, *Cannabis sativa*, when the plant is used for its pleasure-giving effects. The plant may grow to a height of 16 feet, but the strains used for drug-producing effects are typically short stemmed and extremely branched. The resinous exudate is the most valued part of the plant because it contains the highest concentration of tetrahydrocannabinol (THC), an active hallucinogenic principle associated with the plant's potency. The term cannabis also encompasses the use of the flowering tops, fruit, seeds, leaves, stems, and bark of the hemp plant even though the potency of these plant parts is considerably less than that of the pure resin itself. Hemp grows freely throughout the temperate zones of the world, but the content of the resin in the plant differs appreciably according to the geographic origin of the plant and the climate of the region in which the plant is grown. A hot, dry, upland climate is considered most favourable in terms of the potency of the plant. Careful cultivation is also considered to be an important factor in resin production. The prevention of pollination and the trimming of top leaves to produce dwarfing enhances the content of resin at plant maturity.

**Types of cannabis preparations.** Marijuana, hashish, charas, ghanja, bhang, kef, and dagga are names that have been applied to various varieties and preparations of the hemp plant. Hashish, named after the Persian founder of the Assassins of the 11th century (Hasan-e Sabbāh), is the most potent of the cannabis preparations, being about eight times as strong as the marijuana used in the United States. Very few geographic areas are capable of produc-

ing a plant rich enough in resins to produce hashish. Unless sifted and powdered, hashish appears in a hardened, brownish form with the degree of darkness indicating strength. The North African either eats it in a confection or smokes it, the water pipe often being used to cool the smoke. The effects are more difficult to regulate when hashish is either ingested as a confection or drunk. In India, this resinous preparation of cannabis is called **charas**.

Ghanja is a less active form of cannabis. Whereas hashish and charas are made from the pure resin, ghanja is prepared from the flowering tops, stems, leaves, and twigs, which have less resin and thus less potency. Ghanja is nevertheless one of the more potent forms of cannabis. It is prepared from specially cultivated plants in India, and the flowering tops have a relatively generous resinous exudate. Ghanja is consumed much in the manner of charas.

Bhang is the least potent of the cannabis preparations used in India. It does not contain the flowering tops found in ghanja. As a result, bhang contains only a small amount of resin (5 percent). It is either drunk or smoked. When drunk, the leaves are reduced to a fine powder, brewed, and then filtered for use. Bhang is also drunk in Hindu religious ceremonials.

Marijuana is the variety of cannabis grown in the Western Hemisphere. Considered mild in comparison to other forms of cannabis, it is similar in potency to the bhang used in India. Typically, it is smoked, but occasionally it is brewed as a tea or baked into cakes. Marijuana varies considerably in potency, with most American marijuana being grown in Mexico.

**History.** Cannabis is an ancient plant in terms of use, having been known in central Asia and China as early as 3000 BC and in India and the Near East shortly thereafter. Its introduction to Europe and the Western Hemisphere was probably by way of Africa. Historically, cannabis has been regarded as having medicinal value and it was used as a folk medicine prior to the 1900s. Reportedly, it was considered valuable as an analgesic, topical anesthetic, antispasmodic, antidepressant, appetite stimulant, antiasthmatic, and antibiotic. In the 20th century the pattern of pleasure-giving use spread from the lower classes to the middle classes in the West, particularly among intellectuals. In the 1960s and 1970s it spread throughout various student populations from universities and colleges to secondary schools, finally reaching the elementary schools. This spread to "fad" proportions almost totally obscured the historic use of cannabis as a medicine. Although there are no established therapeutic uses for cannabis at present, cannabis may prove to be of some value in the treatment of depression, loss of appetite, high blood pressure, anxiety, migraine, and various gynecological and menstrual problems.

**Physiological and psychological effects.** The effects of cannabis are difficult to specify because of the wide variations in the potency of the various preparations of the hemp plant. Hashish or charas would be expected to produce a greater degree of intoxication than marijuana or bhang. It would also make a difference whether the drug is smoked, drunk, eaten, or received as an administration of synthetic tetrahydrocannabinol (THC). In general, hashish produces effects similar to those of mescaline or, in sufficient quantity, to those of LSD—extreme intoxication being more typical when the substance is swallowed. Marijuana, on the other hand, is more apt to produce effects at the opposite or mild end of the continuum from those of LSD. When smoked, physiological manifestations are apparent within minutes. These include dizziness, lightheadedness, disturbances in coordination and movement, a heavy sensation in the arms and legs, dryness of mouth and throat, redness and irritation of the eyes, blurred vision, quickened heartbeat, tightness around the chest, and peculiarities in the sense of hearing such as ringing, buzzing, a feeling of pressure in the ears, or altered sounds. Occasionally drug use is accompanied by nausea and an urge to urinate or defecate. There is also a feeling of hunger that may be associated with a craving

Antiquity  
of  
cannabis  
use

for sweets. Toxic manifestations are rare and include motor restlessness, tremor, ataxia, congestion of the conjunctivae of the eye, abnormal dilation of the pupil, visual hallucinations, and unpleasant delusions. Marijuana is not a drug of addiction. Use does not lead to physical dependence, and there are no withdrawal symptoms when the drug is discontinued. Psychological dependence does occur among certain types of users. Infrequently, a "cannabis psychosis" may occur, but generally this type of psychiatric reaction is associated only with heavy, long-term use of hashish, such as in India and Morocco. Other effects of chronic hashish use are a debilitation of the will and mental deterioration.

Psychological manifestations are even more variable in response to cannabis. Alterations in mood may include giggling, hilarity, and euphoria. Perceptual distortions may also occur, involving space, time, sense of distance, and sense of the organization of one's own body image. Thought processes may also become disorganized, with fragmentation, disturbances of memory, and frequent shifts of attention acting to disrupt the orderly flow of ideas. One may also experience some loss of reality contact in terms of not feeling involved in what one is doing; this may lead to considerable detachment and depersonalization. On the more positive side, there may be an enhancement in the sense of personal worth and increased sociability. Undesired subjective experiences include fear, anxiety, or panic. These effects vary considerably with practice and with the setting in which the drug is taken.

Many articles have been written on the subject of cannabis, but there is precious little worthwhile data to support any kind of a conclusion with regard to its use. One carefully controlled study on marijuana suggests that it is a very mild substance that requires considerable practice before its full (desired) effects are achieved. Alcohol clearly appears more potent and far more delirious. If, however, one spends any great amount of time around young people, it does not take long to notice the personal tragedies that are associated with marijuana use. One does not even need to look for them; they are there, and the personal accounts of these young people are very impelling (scientific literature notwithstanding). Perhaps their lives would have been tragedies in any event.

From the point of view of those who favour the legalization of marijuana, the drug is a mild hallucinogen that bears no similarity to the narcotics. They feel that the evidence clearly indicates that marijuana is not a stepping stone to heroin and that its use is not associated with major crimes. As a means of reducing tension and achieving a sense of well-being, they believe that it is probably more beneficial and considerably safer than alcohol. The current hysteria over the use of marijuana and the harsh penalties that are imposed are perceived by users as a greater threat to society than would be a more rational and realistic approach to drug use.

### III. Social and ethical issues of drug use

#### CONFLICTING VALUES IN DRUG USE

Modern industrialized societies are certainly not neutral with regard to the voluntary nonmedical use of psychotropic drugs. Whether one simply takes the position of psychologist Erich Fromm that people are brought up to desire and value the kinds of behaviour required by their economic and social system or whether one goes further and speaks of the Protestant ethic in the sense that Max Weber used it to delineate the industrialist's quest for salvation through worldly work alone, it is simply judged not "right," "good," or "proper" for man to achieve pleasure or salvation chemically. It is accepted that the only legitimate earthly rewards are those that have been "earned" through striving, hard work, personal sacrifice, and an overriding sense of duty to one's country, the existing social order, and family. This orientation is believed to be fairly coincident with the requirements of industrialization as it has been known up to the middle of the 20th century. But the social and economic requirements of modern society may have undergone a radical change in the last few decades, even though the inertia of

the existing social character, its desires and its values, will be felt for some time to come. In one major sense, current drug controversies are a reflection of this cultural lag with all of the consequent conflict of wishes and values that result from the lack of good correspondence between traditional teachings and the view of the world as it is now being perceived by large numbers within society. Modern society is in a state of rapid transition, and this transition is not without its untoward consequences in terms of stability.

Cultural transitions notwithstanding, the dominant social order has strong negative feelings about any non-sanctioned use of drugs that contradicts its existing value system. Can society succeed if individuals are allowed unrestrained self-indulgence? Is it right to dwell in one's inner experience and glorify it at the expense of the necessary ordinary daily pursuits? Is it bad to rely on something so much that one cannot exist without it? Is it legitimate to take drugs if one is not sick? Does one have the right to decide for oneself what one needs? Does society have the right to punish someone if he has done no harm to himself or to others? These are difficult questions that do not admit to ready answers. One can guess what the answers would be to the nonsanctioned use of drugs. The traditional ethic dictates harsh responses to conduct that is "self-indulgent" or "abusive of pleasure." But how does one account for the quantities of the drugs being manufactured and consumed today by the general public? It is one thing to talk of the few hundred thousand or so "hard" narcotic users who are principally addicted to the opiates. One might still feel comfortable in disparaging the widespread illicit use of hallucinogenic substances; these are still the "other guys." But the sedatives, tranquillizers, sleeping remedies, stimulants, alcohol, coffee, tea, and tobacco are complications that trap the advocate in some glaring inconsistencies. It may be asked by partisans whether the cosmetic use of stimulants or weight control is any more legitimate than the use of stimulants to "get with it?"; whether the conflict-ridden businessman or the conflict-ridden housewife is any more entitled to relax chemically (alcohol, tranquillizers, sleeping aids, sedatives) than the conflict-ridden adolescent?; whether physical pain is any less bearable than mental pain or anguish? Billions of pills and capsules of a nonnarcotic type are manufactured yearly.

Sedatives and tranquillizers account for somewhere around 12 to 20 percent of all doctor's prescriptions. In addition there are about 150 different sleeping aids that are available for sale without a prescription. The alcoholic beverage industry produces countless millions of gallons of wine and spirits and countless millions of barrels of beer each year. One might conclude that there is a whole drug culture; that the problem is not confined to the young, the poor, the disadvantaged, or even to the criminal; that existing attitudes are at least inconsistent, possibly hypocritical. One always justifies one's own drug use, but one tends to view the other fellow who uses the same drugs as an abuser who is weak and undesirable. It must be recognized that the social consensus in regard to drug use and abuse is limited, conflict ridden, and often glaringly inconsistent. The problem is not one of insufficient facts but one of multiple objectives that at the present moment appear unreconcilable.

#### YOUTH AND DRUGS

Young people seem to find great solace in the fact that the "establishment" is a drug user. One cannot deny that many countries today are drug-oriented societies, but the implications of drug use are not necessarily the same for the adult as they are for the adolescent. The adult has already acquired some sense of identity and purpose in life; he has come to grips with the problems of love and sex; he has some degree of economic and social skill; and he has been integrated or at least assimilated into some dominant social order. Whereas the adult may turn to drugs and alcohol for many of the same reasons as the adolescent, drug use does not prevent the adult from remaining productive, discharging his obligations, main-

Inconclusive data on effects of cannabis

Massive public use of psychotropic drugs

Escapism  
in drug  
use

taining his emotional and occupational ties, acknowledging the rights and authority of others, accepting restrictions, and planning for the future. The adolescent, in contrast, is apt to become ethnocentric and egocentric with drug usage. He withdraws within his narrow drug culture and within himself. Drug usage for many adolescents becomes a preposterous "cop-out" at a time when more important developmental experiences are required. To quote one observer:

It all seemed really quite benign in an earlier time of more moderate drug use, except for the three percent who became crazy and the ten percent we described as socially disabled. Since then, however, more and more disturbed kids have been attracted to the drug world, resulting in more unhappy and dangerous behavior. Increasingly younger kids have come into the scene. Individuals who, in psychoanalytic terms, are simply lesser people, with less structure, less ego, less integration, and hence, are less likely to be able to cope with the drugs. Adolescents are at a crisis period in their lives, and when you intrude regularly at this point with powerful chemicals, the potential to solve these problems of growing up by living them through, working them out, is stopped.

But it would appear that the "establishment" is a drug user, and this has important implications in terms of the expectations, roles, values, and rewards of the social order; but the "establishment" does not "cop-out" on drugs, and this is a fact of fundamental importance in terms of youth. Drugs may be physiologically "safe," but the drug experience can be very nonproductive and costly in terms of the individual's chances of becoming a fully participating adult.

**BIBLIOGRAPHY.** BERNARD BARBER, *Drugs and Society* (1967), provides an excellent introduction to the general topic of drugs, esp. ch. 1, 5, and 6; MADELINE H. ENGEL, *The Drug Scene* (1974), is a brief sociological treatment; ALFRED R. LINDESMITH, *The Addict and the Law* (1965), offers a broad analysis of the narcotic problem; ROBERT W. FERGUSON, *Drug Abuse Control* (1975), reports on agencies of control and rehabilitation in many countries; DAVID SOLOMON (ed.), *LSD: The Consciousness-Expanding Drug* (1964), provides the reader with some of the history, rationale, subjective accounts, and mystique that launched the drug movement. More specialized works of general interest include BRIAN WELLS, *Psychodelic Drugs: Psychological, Medical and Social Issues* (1973); DONALD R. WESSON and DAVID E. SMITH, *Barbiturates: Their Use, Misuse and Abuse* (1977); and SAMUEL S. EPSTEIN et al. (eds.), *Drugs of Abuse: Their Genetic and Other Chronic Nonpsychiatric Hazards* (1971). RICHARD R. LINGEMAN, *Drugs from A to Z: A Dictionary*, 2nd ed. (1974), offers an impressive array of general information on almost all aspects of drug use. Technical works covering the same broad scope are J.R. DIPALMA (ed.), *Drill's Pharmacology in Medicine*, 4th ed. (1971); and L.S. GOODMAN and A.Z. GILMAN (eds.), *The Pharmacological Basis of Therapeutics*, 6th ed. (1980). A useful summary of psychological and psychiatric views may be found in JAMES C. COLEMAN, *Abnormal Psychology and Modern Life*, 6th ed. (1980); THEODORE MILLON, *Modern Psychopathology* (1969); and SILVANO ARIETI (ed.), *American Handbook of Psychiatry*, 6 vol. (1974-75). For additional references see THEODORA ANDREWS, *A Bibliography of Drug Abuse, Including Alcohol and Tobacco* (1977), an annotated guide; and *Drug Abuse and Alcoholism Review* (bimonthly), abstracts of current periodical literature.

(W.G.St.)

## Druzes

The Druzes, a small sect of Middle Eastern Islamic people known for their belligerence, have attracted the attention of many scholars, travellers, and politicians. The Druzes are of particular significance because of the mystery in which they shroud their religious beliefs. They profess *tawhīd* (pure monotheism) and call themselves *muwahhidūn* (monotheists). The Druzes believe in the divinity of al-Ḥākim bi-Amr Allāh (Ruler by the Command of Allāh), the sixth caliph (996-1021) of the Fāṭimid dynasty of Egypt, whom they call al-Ḥākim bi-Amrīh (Ruler by His Own Command).

Nature and significance. Not all Druzes, however, know the secret doctrines of their sect, the Ḥākimīyah. They are divided into two groups: the *'uqqāl*—i.e., the sages initiated into the secret teachings of the *hikmah*, the Druze religious doctrine—and the *juhāl*—i.e., those igno-

rant of the *hikmah*. The *'uqqāl* are divided into several grades; those who achieve the highest degrees of perfection after long periods of meditation, study, ascetic practices, and seclusion are called the *ajāwīd* ("the generous"). Only the *ajāwīd* know the innermost secrets of the Ḥākimīyah.

To ask Druzes about their religious beliefs is considered improper, since the *juhāl* are ignorant of them, and the *'uqqāl* are not allowed to reveal the teachings to the *juhāl* until they have been initiated into the *'uqqāl*. All Druzes, however, united by a religious covenant, have a religious duty to help one another, especially against non-Druzes.

Although Druzes are generally considered to be very conservative, women hold a respected position in their community and are accepted into the *'uqqāl*. Strict monogamy is practiced, but it is possible to obtain a divorce. The divorced, however, cannot remarry their former spouses. Sexual modesty, nonsmoking, and abstinence from drinking wine are strictly observed, especially by the *'uqqāl*.

The Druzes live in villages that are scattered throughout Lebanon, Israel, Jordan, and southern Syria. These villages often have mixed populations of Muslims and Christians; in former times, Jews also inhabited many of these villages. There are many villages composed entirely of Druzes, however, especially in Syria. Although the exact number of Druzes is not known, estimates place their numbers between 300,000 and 320,000. Nearly half of them live in the Ḥawrān area in Syria. This area, known as Jabal ad Durūz (or Jabal Druze), has a Druze majority that comprises 88 percent of the population. About 110,000 live in Lebanon, 35,000 in Israel, and 10,000 in Jordan.

Sources. Although the Druzes cloak their religion in secrecy, the source materials for outsiders' knowledge of Druze history and religion are not as scarce as might be expected. There is, of course, information from non-Druze sources, though these sources are not always accurate. Muslim and Christian accounts of historical events, as well as comments and assessments on the Druze religion and customs, should be treated with reserve and caution because of their polemical character. Jewish sources contemporary with the first half of the reign of al-Ḥākim present him in a favourable light.

It would be unacceptable for a Druze sage, a member of the *'uqqāl*, to show a non-Druze one of the documents containing the secrets of their beliefs; by the end of the 18th century, however, there were approximately 120 manuscripts of the Druze religion in European libraries. The most important and authoritative source of the Druze religion is the *Kutb al-hikmah*, a book containing the fundamental doctrines of the sect. There are also other writings that have been attributed to al-Ḥākim or to his earliest disciples. The *at-Ta'lim* ("Instruction"), a type of catechism written by an anonymous author, presents most aspects of the *hikmah* in the form of questions and answers. The author of *at-Ta'lim* quotes from various sacred texts, such as *Risalat at-tahdhir wa at-tanbih* ("The Epistle of Warning and Reproof," by Hamzah), *Risalat an-nisid* ("Epistle to Women"), *Kutb al-mithaq* ("Book of the Covenant"), *Risalat ar-riḍā wa at-taslim* ("Epistle of Recognition," by Hamzah), and *as-Sijill al-mu'allaq* (proclamations after the disappearance of al-Ḥākim). The *at-Ta'lim* is regarded as representative of the teachings of the Druzes.

History. *Origins.* The Druzes trace their origins to the times of al-Ḥākim, the Fāṭimid caliph of Egypt, and the founder of their religion. The catechism notes that the years AD 1009-21 (or AH 400-411; i.e., 400 to 411 years after the Hijrah, the flight of Muhammad from Mecca to Medina) were decisive in their development.

In the year AH 400 (AD 1009-10) al-Ḥākim began a program of harassment against Muslims, especially against the Ismā'īlī sect of the Shī'ah, and also against Christians, whose Church of the Holy Sepulchre in Jerusalem was burned to the ground. After 1012 Jews also were persecuted. Only in the last years of the reign of al-Ḥākim did these persecutions cease. During the years 1017-20

("Instruc-  
tion")

he allowed the rebuilding of the places of worship of other religions. Those persons who had been forced to convert to the religion of al-Ḥākim were allowed to return to their former religions. In the year 1017 al-Ḥākim was publicly proclaimed by his followers as the incarnation of God.

Even before 1017 (year one of Hamzah, the first year of the Druze era), however, propagation of the tenets of the new religion had begun. Hamzah ibn 'Alī (from Zuzan, Khorāsān), regarded as the first disciple of al-Ḥākim, converted the Shi'ī missionary Muhammad ad-Darazi to the belief in the divinity of al-Ḥākim. From ad-Darazi's name the new religion took its name, Druze. Muhammad ad-Darazi preached the new religion in the Lebanese plain, an area rife with extreme Shi'ī sects; in 1019, however, he reportedly was killed, having been reproached by his opponents for allowing various vices to be practiced, such as sexual excesses and wine drinking. Allegedly, Hamzah was ad-Darazi's opponent. In 1021 al-Ḥākim disappeared. Though he apparently was murdered, his followers believed that he had gone into hiding and would appear a thousand years after he made his first appearance. After ad-Darazi's death, Hamzah developed the doctrines of the new sect, with the aid of Ismā'īl at-Tamimi, Salāmah as-Sāmīrī, Muhammad ibn al-Wahb al-Qurashī, and al-Muqtanā Bahā' ad-Din. Al-Muqtanā Bahā' ad-Din played an important role as the author of several sacred works. The last of his writings concludes the formative phase of the *tawḥīd* (1041).

The period following the founding of the Druze religion is obscure. Testimony about the beliefs and practices of that time is to be found in *The Itinerary* (in Hebrew) of Benjamin of Tudela, who travelled in Syria and Lebanon about 1167. During the period of the Crusades, Druzes reportedly inhabited areas near Bāniyās and Beaufort Castle, near Marj 'Uyūn, and in the 14th century they were known to have inhabited Zefat (Safed).

**The Ottoman period.** The Ottoman conquest of the area initiated a new phase in the Druze religion. Sultan Selim I, the conqueror of Syria and Egypt (1516-17), confirmed Fakhr ad-Din (died 1544) of the House of Ma'n as emir of the Druzes. Although his son Qurqomāz (1544-85) revolted against the Ottomans, Fakhr ad-Din II (1590-1635), son of the rebel, became the emir. He expanded his sphere of influence and made contacts with the Grand Duke of Tuscany. Because the Sublime Porte of the Turks received information about a possible establishment of a crusader state in Syria, Palestine, and Cyprus, he ordered the *wālī* of Damascus to attack Fakhr ad-Din. The Emir of the Druzes fled to Tuscany, returning to his home in 1618 after a five-year exile in Italy. With aid promised by the Grand Duke of Tuscany, Fakhr ad-Din continued his activities against the Porte. In 1635 he was defeated by the Turks at Ḥaṣḥayyā and with his two sons was executed in Constantinople.

The House of Ma'n died out in 1697. The daughter of the last Ma'ni emir named a member of the House of Shihāb. The Shihābs enhanced their position after the defeat of their opponents, the Yamani faction, in the Battle of 'Ayn Dārā in 1711. The Yamani faction migrated to Ḥawrān, an area of southern Syria bounded on the east by Jabal ad-Duriiz. An important emir of the Shihābs, Bashir II (1788-1840), became a Christian (in name only) and gained the support of the British. He was later deposed by the Sublime Porte, as was a relative after a year's reign. Because of antagonisms between the Maronites, who were supported by the French, and the Druzes, who had begun to assert themselves under Bashir with British support, two *qā'im-maḥāms* (subgovernors), one a Maronite and the other a Druze, were appointed. Leadership of the Druzes passed on to the House of Jānbulāt (Jumblatt), a Kurdish family that came from Aleppo and joined the Druzes rather late.

In 1860 a war broke out between the Druzes and the Christians. The Druzes were supported by the British and the Sublime Porte, the Christians by the French. An estimated 11,000 Christians were massacred or killed in battle, and 4,000 died because of destitution. A French landing force restored order. By the organic statute of

1861 (revised in 1864), an autonomous system of government was set up in Lebanon under a Christian governor general, and the people of the land enjoyed an era of prosperity and relative tranquillity that lasted until 1918.

**The modern period.** In the Jabal ad-Duriiz, the post-World War I division of much of the Middle East into mandated territories allowed the Atrash family possibilities for potential political power. Supported by the French, the spiritual leaders of the Druzes and part of the Atrash family proclaimed the independence of the Jabal ad-Duriiz within the framework of the French mandate over Syria. Sulṭān al-Atrash, however, negotiated with the British. Because the French were unable to control the situation, a revolt of the Druzes in 1925 spread over Syria and part of Lebanon. Damascus and Ḥaṣḥayyā were taken by the Druzes, but the revolt failed because of a lack of support from the Lebanese Druzes and the Mutawālī, a neighbouring Twelver Shi'ī sect. Sultan al-Atrash fled to Transjordan, returning only in 1938.

Though Druzes have inhabited Palestine, their stay there has had little historical significance. Some Druze settlements in Upper Galilee were reinforced in the 17th and 18th centuries but were abandoned in part after the defeat of Ibrāhīm Pasha in 1840. Under the Turks and during the British mandate, Druzes were recognized as Muslims and subject to Islāmic religious authorities in matters of personal status and property management. In Israel they are recognized as an independent community with its own autonomous leadership and religious courts.

**Beliefs, practices, and institutions.** *Doctrines.* The religious beliefs of the Druzes developed out of Ismā'īlī teachings. Various Jewish, Christian, Gnostic, Neoplatonic, and Iranian elements, however, are combined under a doctrine of strict monotheism.

In Ismā'īlī theology, the Neoplatonic doctrine of cosmic emanations finds its historical counterpart. With each periodical manifestation, al-'Aql (Universal Intelligence) is revealed more completely. Under such a system of successive stages of mystical insight, Ismā'īlī doctrines were successfully propagated.

The Druzes, as adherents of the Ḥākimīyah, are regarded as the most extreme of the Ismā'īlī sects. They believe that al-Ḥākim was the last incarnation of the Deity and that he was preceded by nine previous incarnations, each called a *maqām* ("locus" or "place").

From the light of the Creator (al-Bārī) is successively emanated *al-ḥudūd* ("boundaries, laws"), the five cosmic principles: Universal Intelligence (al-'Aql), Universal Soul (an-Nafs), the Word (al-Kalimah), the Preceder (as-Sābiq; or Right Wing [al-Janāḥ al-Ayman]), and the Succeder (at-Tālī; or Left Wing [al-Janāḥ al-Aysar]). These five emanations were historically manifested in the five highest ranking disciples of al-Ḥākim; i.e., Hamzah, Ismā'īl ibn Muhammad at-Tamīmī, Muhammad ibn Wahb al-Qurashī, Salāmah ibn 'Abd al-Wahhāb as-Sāmīrī, and al-Muqtanā Bahā' ad-Din, respectively. Just as there were previous incarnations of the Deity, so also there have been earlier incarnations of *al-ḥudūd*. Before Hamzah, Universal Intelligence had been incarnated in Shu'ayb (Jethro) in the days of Moses, and in the Messiah of True Justice in the days of Jesus, and in Salmān al-Fārisī in the days of Muhammad. To know the five *ḥudūd* is an obligation in the Druze religion.

Below the five ministers of the Deity, in successively lower ranks, are the emissaries: *da'ī* ("missionary"), *ma'dhan* ("licensed [to preach]"), and *mukāsīr* ("persuader"). All of these ranks have the duty of spreading knowledge of *tawḥīd* (monotheism) among the believers. They are to bring this knowledge to women and the *jūhhāl* who have reached physical and moral maturity. Because the number of believers has been determined from the time of the Creation, unbelievers are excluded from the true religion. In light of this teaching, Druzes believe in *tanāsukh* (metempsychosis, or transmigration of souls). They believe that whenever a Druze dies another Druze is born, and the soul of the dying enters the body of the born. Except for the period of al-Ḥākim's appearance, when it was possible for unbelievers to accept the *tawḥīd*, they are not allowed to learn the *ḥikmah* (religious doctrines),

tions

Transmi-  
gration  
of souls

which is regarded as an instrument of salvation. The Jānbulāt family, however, joined the Druzes long after the time of al-Ḥākim.

Relationships with other religious groups helped to shape the Druze doctrine of the Last Judgment. In *at-Ta'lim* there is a detailed description of the Last Times: al-Ḥākim will come again and judge the world twice. In the second and final judgment Christians, Jews, Muslims, and muwahhidiin (unitarians) will be judged. The righteous *muwahhidiin* will receive the power and the kingdom, gold, silver, and property, but the Mutawālī, Muslims, and Christians will receive a harsh judgment, and Jews a comparatively lighter punishment.

Practices. The five religious duties (arkdn) of Islam were abolished by Hamzah. Though the Fast of Ramadan and the 'Īd al-Fiṭr were not observed by Druzes, they apparently secretly observed the Muslim 'Īd al-Adḥā (Feast of the Offerings). Hamzah instead proclaimed seven fundamental duties for the Druzes: (1) recognition of al-Ḥākim and adherence to *tawḥīd*, (2) negation of all non-Druze tenets, (3) avoidance of unbelievers, (4) acceptance of al-Ḥākim's acts, (5) submission to al-Ḥākim, (6) truthfulness, and (7) mutual help and solidarity between fellow Druzes. The order and the number of the duties vary in different texts.

The duty of truthfulness in religious matters applies only to relations with fellow Druzes. Toward non-Druzes, strict secrecy (*kitmān*) is to be practiced. In times of persecution, however, a Druze is allowed to deny his faith outwardly if his life is in danger. This concession, or *taqiyyah*, is allowed according to *at-Ta'lim*: "Our Master commanded us to hide under the wings of the majority religion. When among Christians, we should act like Christians, when among Muslims we should act like Muslims, and so on. For our Master, al-Ḥākim bi-Amrih, said: 'If any community prevails over you, follow its lead [ostensibly], and keep me in your hearts.'"

Worship. The Druze house of worship, the *khilwah*, though not hidden, is often difficult to find. The *khilwah* is a rather austere building without architectural embellishments and without furniture, except for small lecterns on which one may lay books during a period of meditation. It is usually located outside the village, and some are in the mountains. Thursday night is the usual time for a Druze meeting, which even the *juhhāl* may attend. When prayer, study, and meditation begin, however, only the *'uqqāl*, male and female, may remain.

The highest ranking of the *'uqqāl*, the *ajawid*, retire for prayer and devotional exercises in the *khilawdt* (plural of *khilwah*). Some of the more important *khilawdt* are located at Qanawāt, the seat of the highest ranking *jawād* in the Jabal ad-Durfiz, in Bayyadā, the seat of the two spiritual leaders in Lebanon, and at the site of the grave of Nabi Shu'ayb (Jethro) near Tiberias in Israel. At this last site a mass pilgrimage and popular festival are held between April 23 and 25. Druzes from Lebanon and Jabal ad-Durfiz have attended the festival in the past. Other minor pilgrimages are made to various *khilawat* that are sites of holy graves.

**Conclusions.** Just as the whole Middle East population is in transition, so also is Druze society. During the last generation signs of social change have been increasing. After World War II, the great feudal families were forced to concede political positions to Druzes of other social classes. In Lebanon, Majid Arslan was minister of defense (1964) and Kamal Jumblatt (Jānbulāt) was home minister (1970); many younger Druze men also came into leading positions.

In Israel, the revolt of younger, more progressive Druzes against the conservative religious leaders was conspicuous. Many of the Druze progressives in Israel have served in the army and are university graduates, having attended coeducational schools and colleges. The continuing changes in Israel and Lebanon will probably also affect the Druze societies in Syria.

**BIBLIOGRAPHY.** SILVESTRE DE SACY, *Exposé de la religion des Druzes, tiré des livres religieux de cette secte*, 2 vol. (1838), still the classic work on the Druzes, containing an important list of approximately 120 manuscripts, with many excerpts; NAR-

CISSE BOURON, *Les Druzes* (1930; Eng. trans., *Druze History*, 1952), an account of the 1925–27 revolt; C.H. CHURCHILL, *The Druzes and the Maronites Under the Turkish Rule from 1840 to 1860* (1862), an account by a resident of Lebanon of the massacre of the Christians in 1860; P.K. HITT, *The Origins of the Druze People and Religion; with Extracts from Their Sacred Writings* (1928), a brief account written for the general reader; H.Z. (J.W.) HIRSCHBERG, "The Druzes," in A.J. ARBERRY (ed.), *Religion in the Middle East*, vol. 2 (1969), a short survey of the history and religious teachings of the Druzes, especially in Palestine, up to 1965; SAMI NASIB MAKARIM, *The Druze Faith* (1974), a well-written history containing a bibliography.

(H.Z.H./Ed.)

## Dryden, John

The greatest English poet of the later 17th century, John Dryden was the writer of almost 30 tragedies, comedies, and dramatic operas. He also made a valuable and permanent contribution to English literature in his amiable, civilized, and intelligent commentaries on poetry and drama, which are sufficiently extensive and original to entitle him to be considered, in the words of Dr. Samuel Johnson, as "the father of English criticism." He so dominated the literature of his time that it is frequently referred to by literary historians as "the age of Dryden."

In the National Portrait Gallery, London.

**Heritage, youth, and education.** The son of a country gentleman, Dryden was born on August 9 (August 19, new style), 1631, in the Northamptonshire village of Aldwinkle. Growing up in the country, he was 11 years old when the Civil War broke out, and most of his early manhood was spent in the protectorate of Oliver Cromwell. When the Civil War compelled Englishmen to stand up and be counted, both his father's and his mother's families sided with the Parliament against the King; but just where Dryden's own sympathies lay at that time there are no means of knowing.

About 1644 he was admitted to Westminster School, where John Locke was one of his contemporaries. Under the celebrated Richard Busby, who did not spare the rod but who seems to have retained the affection and respect of his pupils, the education Dryden received at this famous London school was predominantly classical. His easy and lifelong familiarity with classical literature and his ability to render it into idiomatic English undoubtedly stem from his tutelage under Busby.

In 1650 he entered Trinity College, Cambridge, where he took his B.A. degree in 1654. About the only record of his Cambridge years concerns his being disciplined in 1652 for disobedience to the vice master, and "his contumacy in taking of his punishment inflicted by him." College records, like newspaper reports, are apt to chronicle the less reputable happenings in a man's life: there is little reason to suppose that Dryden was an angry young man and still less that he neglected his studies. Cam-

Fellow of  
the Royal  
Society

bridge in the 1650s was full of new ideas; the traditional academic curriculum was being challenged, and, although classical studies were still the basis of the educational system for arts students, some colleges—notably Trinity—were now showing a considerable interest in science. It is significant that in 1663 Dryden, not yet 32 years old, was elected a fellow of the recently founded Royal Society. At Cambridge he could well have acquired his pronounced interest in science and that skeptical and undogmatic cast of mind with which Dryden afterward approached the problems of the day, always excepting political ones.

**Early poetic endeavours.** What he did between leaving the university in 1654 and the restoration of Charles II is not certainly known. If he was writing poetry, he had almost nothing to show for it, except some ambitious but cluttered verses contributed to a memorial volume on a young Lord Hastings who had died of smallpox (1649) and some complimentary lines the following year to one John Hoddesdon, who had published a volume of epigrams. When in 1659 he contributed a set of "heroic stanzas" to a memorial volume on Oliver Cromwell, he emerged as a poet who might be worth watching. Dryden's poem was mature, considered, sonorous, and sprinkled with those classical and scientific allusions that were to be characteristic of his later verse. This kind of public poetry was always one of the things that he did best.

In May 1660 came the restoration of the monarchy, which was no colonels' revolt, but something that the great majority of Englishmen, weary of the Cromwellian mixture of godliness and ruthlessness, now thoroughly approved. In common with most of his fellow countrymen, Dryden set about adapting himself to the new regime, and he made the necessary adjustments fast and apparently with complete conviction. The poets of the day, great and small, welcomed the young king with loyal effusions, and in June Dryden produced his tribute, *Astraea Redux*, a poem of over 300 lines in rhymed couplets. For the coronation, which took place in April 1661, he was ready with another set of verses, *To His Sacred Majesty*. Those two panegyric and magniloquent poems were designed to dignify and strengthen the new establishment and to invest the young monarch with an aura of majesty, permanence, and even divinity. Dryden has often been called a timeserver; but his welcome to the King and the new order that came with him seems to have been genuine. At all events, whatever had been holding back his literary development disappeared completely after 1660, and from then on his productivity was remarkable and his touch almost invariably confident and sure.

He had come to know Sir Robert Howard, a son of Thomas Howard, 1st earl of Berkshire, and on December 1, 1663, he was married to the Earl's youngest daughter, Elizabeth. In due course she became the mother of his three sons. In 1666 he was at work on *Annus Mirabilis*, by far his longest poem to date, written in measured quatrains to celebrate two stubborn battles fought out by the English and Dutch fleets in the summer and the Great Fire that destroyed a large part of the City of London in September. The two naval engagements were seen by Dryden as English victories and even the fire was a kind of victory—a triumph not only for the brave Londoners who could "take it" but also for their devoted king ("the father of the people"), who personally directed the fire-fighting operations and whose devout prayers to the Almighty had diverted the wind that was fanning the flames. Dryden was once again gilding the royal image and reinforcing the concept of a loyal nation united under the best of kings.

It was hardly surprising that, when Sir William Davenant died in 1668, Dryden was at once appointed poet laureate in his place and historiographer royal two years later. His salary was £200 (increased to £300 in 1677), but the payments were always in arrears, and the king died owing him more than £1,000.

**Restoration dramas.** One of the first casualties of the Civil War had been the theatres, which were closed in 1642. Soon after Charles II returned to London, he issued

patents to Davenant and Thomas Killigrew to form two companies of actors and erect two playhouses, and, before the end of 1660, both theatres had opened. For some time they had to rely on old plays; but Restoration theatregoers, as fashion conscious as any generation before or since, soon began to want new plays that would mirror their own way of life and that were not written in what was by now an antiquated language. In February 1663 Dryden joined the little band of new dramatists with his first play, *The Wild Gallant*, a farcical comedy with some strokes of humour and a good deal of licentious dialogue. It was a comparative failure, but in January 1664 he had some share in the success of *The Indian Queen*, a heroic tragedy in rhymed couplets in which he had collaborated with Sir Robert Howard. Dryden was soon to exploit very successfully this new and popular genre, with its conflicts between love and honour and its lovely heroines before whose charms the blustering heroes sank down in awed submission. In the spring of 1665 Dryden had his own first outstanding success with *The Indian Emperour*, a play that was a sequel to *The Indian Queen*.

Owing to the spread of the Great Plague of London, the theatres were closed by proclamation in June and did not reopen until November 1666. When they did, Dryden had another remarkable hit with a tragicomedy, *Secret Love, or the Maiden Queen*, which appealed particularly to the king. One of the innovations of the Restoration theatre was the substitution of actresses for the boys who had always played women's parts, and in Dryden's new play the part of Florimel, a gay and witty maid of honour, was played to perfection by the king's latest mistress, Nell Gwyn. Samuel Pepys was completely captivated and recorded in his diary: "I never can hope ever to see the like done again, by man or woman." In Florimel's rattling exchanges with Celadon, the Restoration aptitude for witty repartee reached a new level of accomplishment. Another comedy that Pepys laughed at till his head ached was *Sir Martin Mar-all* (1667), based on a translation by the aged William Cavendish, duke of Newcastle, of Molière's *L'Étourdi* (*The Blunderer*, 1762). Dryden revised the Duke's play, and because he ultimately allowed it to be published under his own name, he must have had a considerable share in it, but this rollicking comedy of humours was not in his usual mode. He had now tried his hand at various kinds of drama. That he had also thought a good deal about what he was doing became evident in 1668, when he published *Of Dramatick Poesie, an Essay*, a leisurely discussion between four contemporary writers, of whom Dryden (Neander) is one. This commentary is about dramatic principles and techniques and about the old drama and the new and the rival merits of French and English plays. The dialogue form of the *Essay* was well suited to his open-minded approach to the subject and to the easy colloquial style that came naturally to him.

In May 1668 he entered into an agreement to write exclusively for Killigrew's company and to give them three plays a year. In return, he became a shareholder, entitled to roughly one-tenth of the profits, which in a good year brought him in between £300 and £400. Dryden averaged only one play a year, but, even so, the company must have gained by the contract. In June 1669 he gave them *Tyrannick Love* with its blustering and blaspheming hero Maximin; in December of the next year came the first part of *The Conquest of Granada by the Spaniards*, followed by the second part about a month later. All three plays were highly successful; and in the character Almanzor, the intrepid hero of *The Conquest of Granada*, the theme of love and honour reached its climax. But the vein had now been almost worked out. In December 1671 London playgoers were being highly entertained by the witty burlesque of heroic drama *The Rehearsal*, by George Villiers, 2nd duke of Buckingham, in which Dryden (Mr. Bayes) was the main satirical victim. *The Rehearsal* did not kill the heroic play: as late as November 1675, Dryden staged his last example of the genre, *Aureng-Zebe*, in many ways the sanest and most intelligent of them all. In the prologue, however, he told

Commen-  
taries on  
drama

Appoint-  
ment as  
poet  
laureate

his audience that he had grown weary of "his long-lov'd mistress, rhyme," and had discovered that passion was "too fierce to be in fetters bound."

Neoclassical plays. In writing those heroic plays, he had been catering to an audience that was prepared to be stunned into admiration by drums and trumpets, rant and extravagance, stage battles, rich costumes, and exotic scenes. Some years later he admitted that there were passages in those plays that he knew to be "bad enough to please, even when I writ them," but for the future he would not seek any reputation from "the applause of fools." How intelligent he could be when he was not thinking exclusively of "pit, box, and gallery" he had shown by 1672, with his brilliant comedy, *Marriage A-la-Mode*, in which the Restoration battle of the sexes was given a sophisticated and civilized expression that only Sir George Etherege and William Congreve at their best would equal. Equally fine in a different mode was his tragedy *All for Love* (1677), based on Shakespeare's *Antony and Cleopatra* and written in a flowing but controlled blank verse. Dryden had now entered what may be called his Neoclassical period, and if his new tragedy was not without some echoes of the old extravagance, it was admirably constructed, with action developing naturally from situation and character. Of this dignified and at times moving play Dryden said some years later: "I never writ anything for myself but *Antony and Cleopatra*."

For some years Killigrew's mismanaged company had been in grave difficulties, and early in 1678 Dryden appears to have been at loggerheads with his fellow shareholders. When, in collaboration with Nathaniel Lee, he had completed the tragedy of *Oedipus*, he offered it to the rival company and must then or a little later have ceased to be a shareholder, with a consequent serious loss of income. In December 1679 he encountered a different sort of trouble: in an ill-lit London alley he was set upon by three ruffians by whom, in the words of an advertisement he inserted in the *London Gazette*, he was "barbarously assaulted and wounded." It is usually assumed that his assailants had been hired by some noble person whom he had offended, but the affair remains a mystery. It is even possible that he was mistaken for somebody else.

Verse satires. Since the publication of *Annus Mirabilis* 12 years earlier, Dryden had given almost all his time to playwriting. If he had died in 1680, it is as a dramatist that he would be chiefly remembered. Now, in the short space of two years, he was to make his name as the greatest verse satirist that England had so far produced. The immediate stimulus for this outburst of poetical activity was the political crisis that had begun to develop in 1678, when Titus Oates testified before a London magistrate that he possessed evidence of a Jesuit plot to kill the King and place his Catholic brother James on the throne. Led by the able and unscrupulous Anthony Ashley Cooper, 1st earl of Shaftesbury, the Whig Party (then in opposition) turned the so-called Popish Plot to political ends and twice introduced, unsuccessfully, a bill to exclude the Catholic Duke of York from the throne. When a new Parliament assembled in March 1681 at Oxford, the Whigs made a third attempt to bring in their exclusion bill, and, in the House of Lords, Shaftesbury proposed to the King that James Scott, the duke of Monmouth, his illegitimate son but a Protestant, should be declared his successor. The King's answer was to dissolve Parliament. He had played a waiting game with courage and skill, and from now on popular feeling began to turn against the Whigs. On July 2 Shaftesbury was sent to the Tower of London on a charge of high treason.

As poet laureate in those critical months Dryden could not stand aside, and in November he came to the support of the King with his *Absalom and Achitophel*, so drawing upon himself the wrath of the Whigs. Adopting as his framework the Old Testament story of King David (Charles II), his favourite son Absalom (Monmouth), and the false Achitophel (Shaftesbury), who persuaded Absalom to revolt against his father, Dryden gave a satirical version of the events of the past few years as seen from

the point of view of the King and his Tory ministers, and yet succeeded in maintaining the heroic tone suitable to the King and to the seriousness of the political situation. As anti-Whig propaganda, ridiculing their leaders in a succession of ludicrous satirical portraits, Dryden's poem is a masterpiece of confident denunciation; as pro-Tory propaganda it is equally remarkable for its serene and persuasive affirmation. But Shaftesbury was to survive a little longer. On November 24, one week after the publication of *Absalom and Achitophel*, a London grand jury refused to endorse the indictment of Shaftesbury (a necessary legal preliminary to his trial), and the triumphant Whigs had a medal struck to commemorate the occasion. Dryden went to work again, and he worked fast: in March 1682 he published *The Medall*, a hard-hitting satire of over 300 lines, prefaced by a vigorous and plain-spoken prose "Epistle to the Whigs." Apart from the ridicule of Shaftesbury, the most striking feature is the unsparing invective directed against those subversive "fanatics" who were trying to overthrow the established order. No poem of Dryden's shows more clearly his innate or acquired conservatism and his dread of mob rule. For a continuation of *Absalom and Achitophel* by Nahum Tate, Dryden also contributed a long passage of brilliant denigration of his fellow dramatists Elkanah Settle (Doeg) and Thomas Shadwell (Og).

Shadwell had a whole poem to himself when, in October 1682, anonymously and apparently without Dryden's authority, there appeared in print his famous extended lampoon, *Mac Flecknoe*, written about four years earlier. What triggered this devastating attack on Shadwell has never been satisfactorily explained, but with authors competing for the patronage of the great, the literary world was full of jealousy and bickering. It is true that Dryden was a convinced Tory and Shadwell an ardent Whig, but it was not until later that the two men were to clash on those grounds. In *Mac Flecknoe*, it is as a writer that Shadwell is ridiculed, so ludicrously and with such good-humoured contempt that his reputation has suffered ever since. The year 1682 had been Dryden's own "wonderful year" in poetry, and even now there was more to come. In November he published his *Religio Laici or a Layman's Faith*, which is at once the poet's own confession of his Anglican faith and a lucid statement of the Church of England's "middle way" between an infallible Church of Rome and the diverse individualism of the Protestant sects, with what Dryden saw as their excess of private judgment and their claim to "inspiration."

In February 1685 the death of Charles II (commemorated by his poet laureate in a long pindaric ode, *Threnodia Augustalis*) brought the prolonged crisis of the succession to a head. The accession of James II passed off peacefully, and when, in June, the young Duke of Monmouth appeared at the head of an ill-planned rebellion in the west country, he was easily defeated, captured, and promptly executed. Before long the new king was to give mortal offense to the Church of England by showing himself willing to grant toleration to dissenters and by favouring the small Catholic minority. The worst fears of the Whig politicians were coming true, and in the country at large there was a resurgence of the old anti-Catholic feeling. In this hush before the storm Dryden took a step that he may have been contemplating for some time: toward the end of 1685 the author of *Religio Laici*, who had so admirably defended the Church of England, was received into the Church of Rome. Coming when it did, Dryden's change of faith inevitably exposed him to the charge of *timeserving*, and the attacks upon him were redoubled; but however ill-timed it may have been, his conversion was almost certainly the outcome of deep and long-sought conviction. Certainly he never repented afterward, although it might have paid him to do so. When Dryden's thoughts had run clear on any subject it was natural and even necessary for him to put those thoughts in writing. What he now wrote was his longest poem, *The Hind and the Panther* (1687), an elaborate beast fable, in which he argued the case for his adopted church against the Church of England and, of course, the dissenting sects. Like *Religio Laici*, it shows

Conversion  
to Church  
of Rome

the delight that a great orator takes in putting a case, and it shows too, in its strange mixture of reverence and ribaldry, the conflicting forces in Dryden's diverse nature.

**Late works.** With the abdication of James II in 1688 Dryden's prospects became bleak. He had inherited a small property from his father, but in the new reign of William and Mary he had, as a Catholic, to pay double taxes. The worst blow of all was the loss of his laureateship, which went, ironically enough, to Shadwell. Now he had to depend almost entirely on his pen, and it was natural that he should turn again to the theatre, although he was apprehensive of the sort of reception he would get there. His fine tragedy *Don Sebastian* (1689) failed to please, but he was more successful the next year with his comedy *Amphitryon*, which was helped by the attractive music of Henry Purcell. He collaborated more fully with Purcell in a dramatic opera *King Arthur* (1691), which met with considerable success. A tragedy, *Cleomenes*, was for some time refused a license owing to some passages considered politically dangerous, and, when in 1694 his tragicomedy *Love Triumphant* failed completely, he gave up writing for the stage.

The theatre, however, was no longer his chief means of support. Since 1684 he had been supervising a series of poetical miscellanies for the successful publisher Jacob Tonson, and some of his own poems, mainly translations, appeared in them. In 1692 Dryden published *Eleonora*, a long memorial poem to the Countess of Abingdon that her sorrowing husband had commissioned and for which he paid the poet handsomely. For another Tonson volume, a translation of Juvenal and Persius (1693), he contributed all the Persius and five satires of Juvenal. But the great work of these later years was his translation of Virgil, for which Tonson contracted in 1694 and which appeared in the summer of 1697. Taking into account what he got from dedications and what Tonson paid him, it has been estimated that the Virgil, in many respects his magnum opus, brought him in about £1,400. Dryden was now the grand old man of English letters and was often to be seen at Will's Coffee-House discoursing amiably with the wits of a younger generation. His last work for Tonson was a volume of *Fables Ancient and Modern* (1700), consisting of verse translations mainly from the works of Ovid, Chaucer, and Boccaccio, as fresh as anything he ever wrote and introduced to the reader by the most urbane and friendly of all his critical prefaces.

For some time he had been in failing health, but he continued to write almost to the last. For a play that was to be performed for his benefit he wrote a "secular masque," which contains the well-known lines:

'Tis well an old age is out,  
And time to begin a new.

Dryden, however, never saw the promised land of the 18th century: he died on May 1, 1700, and was buried in Westminster Abbey, between Geoffrey Chaucer and Abraham Cowley in the Poets' Corner.

His reputation remained high for the next 100 years, and even in the Romantic period the reaction against him was never so great as that against Alexander Pope. In the 20th century there has been a notable revival of interest in his poems, plays, and criticism, and much scholarly work has been done upon them. In the 1970s his contemporary reputation probably stands as high as at any time since his death.

#### MAJOR WORKS

**POEMS:** *Astraea Redux* (1660), on the restoration of the monarchy; *Annus Mirabilis: the Year of Wonders 1666* (1667); *Absalom and Achitophel* (1681); *The Medal, A Satyre against Sedition* (1682); *Mac Flecknoe, or a Satyr upon the True-Blew-Protestant Poet* (pirated version, 1682; authorized edition, 1684; written c. 1679); *Religio Laici or a Laymans Faith* (1682); *Miscellany Poems*, 4 vol. (1684-94); *Threnodia Augustalis: a Funeral-Pindarique Poem Sacred to the Happy Memory of King Charles II* (1685); "To the pious Memory of . . . Mrs. Anne Killigrew, . . . An Ode" (1686); "A Song for St. Cecilia's Day" (1687); *The Hind and the Panther* (1687); "Alexander's Feast" (1697), second ode in honour of St. Cecilia's Day.

**PLAYS:** *Secret Love, or the Maiden Queen* (1666); *The Indian Emperour* (1667); *Tyrannick Love, or the Royal Martyr* (1670); *An Evening's Love, or the Mock-Astrologer* (1671); *The Conquest Of Granada by the Spaniards* (1672); *Marriage A-la-Mode* (1673); *Aureng-Zebe* (1676); *All for Love: or, The World well Lost* (1678); *Troilus and Cressida, or Truth Found too Late* (1679); *The Spanish Fryar* (1681); *Albion and Albanus* (1685), an opera; *Don Sebastian, King of Portugal* (1690); *Amphitryon; or, The Two Socias* (1690); *King Arthur: or, The British Worthy* (1691), an opera; *Cleomenes, The Spartan Heroe* (1692); *Love Triumphant; or, Nature will prevail* (1694).

**PROSE:** *Of Dramatick Poesie, an Essay* (1668); "Defence of the Epilogue, or an Essay on the Dramatique Poetry of the Last Age" (to his play *The Conquest of Granada*, 1672); "Dedication" to 'Examen Poeticum' (vol. 3 of *Miscellany Poems*); "A Discourse concerning the Original and Progress of Satire" (to his translations of Juvenal; 1693).

**TRANSLATIONS:** Of Persius and five satires of Juvenal (1693); of Virgil (complete 1697); selections of Horace, Ovid, Homer, Theocritus, and Lucretius.

**ADAPTATIONS:** "Creator Spirit, by Whose Aid" (1693, from "Veni, Creator Spiritus"); *Fables Ancient and Modern* (1700, paraphrases from Chaucer, Boccaccio, and Ovid).

**BIBLIOGRAPHY.** The standard bibliography is that of HUGH MACDONALD, *John Dryden: A Bibliography of Early Editions and of Drydeniana* (1939). It may be supplemented by additions and corrections supplied by JAMES M. OSBORN in *Modern Philology* (1941-42). GUY MONTGOMERY has compiled *A Concordance to the Poetical Works of John Dryden* (1957). Surviving Dryden manuscripts are practically confined to his letters, scattered in various collections. The *Letters* have been edited by CHARLES E. WARD (1942). Aside from the great national libraries, the most useful collection of Dryden's works and related material is that in the William Andrews Clark Memorial Library, University of California, Los Angeles.

**Editions:** Collected editions of the poems and plays were published by JACOB TONSON in the late 17th and early 18th centuries; and in 1800, EDMOND MALONE edited *The Critical and Miscellaneous Prose Works* . . . , 4 vol., with his long and valuable biographical account in vol. 1. The first edition of the complete *Works* is that of SIR WALTER SCOTT, 18 vol. (1808, 1821), which was rather lightly revised by GEORGE SAINTSBURY (1882-92). These will be superseded when *The Works of John Dryden* (University of California, 1956- ) has been completed. The best modern editions of the *Poetical Works* are those of GEORGE R. NOYES, rev. ed. (1950); and JAMES KINSLEY, 4 vol. (1958). The *Dramatic Works*, ed. by MONTAGUE SUMMERS, 6 vol. (1931-32), are usefully annotated but textually unreliable. Dryden's criticism was collected by W.P. KER, *Essays of John Dryden*, 2 vol. (1900); and by GEORGE WATSON, *Of Dramatic Poesy, and Other Critical Essays*, 2 vol. (1962). A useful guidebook, J.M. ADEN, *The Critical Opinions of John Dryden* (1963), gives short extracts arranged alphabetically under topics.

**Biography:** The standard modern biography is that of CHARLES E. WARD, *The Life of John Dryden* (1961). Information about Dryden's life is meagre, and derives mainly from Thomas Birch, Samuel Johnson, Malone (above), W.D. Christie, and more recently from JAMES M. OSBORN, *John Dryden: Some Biographical Facts and Problems*, rev. ed. (1965). The Life in Scott's edition (vol. 1) is still the most readable account, and that in the edition of Noyes (above) is closely packed with information.

**Critical studies:** Critical studies of Dryden's writings have become numerous in recent years. Of the earlier general studies, Samuel Johnson's critical appraisal in his *Lives of the Poets* (1779), is still basic; and GEORGE SAINTSBURY, *John Dryden* (1881), is at once enthusiastic and discriminating. *Essential Articles for the Study of John Dryden*, ed. by H.T. SWEDENBERG, JR. (1966), offers a selection of modern criticism. For the poetry, MARK VAN DOREN, *The Poetry of John Dryden*, rev. ed. (1960), is a humane and sensitive study. Recent general studies of distinction include A.W. HOFFMAN, *John Dryden's Imagery* (1962); ALAN ROGER, *Dryden's Poetic Kingdoms* (1965); and EARL MINER, *Dryden's Poetry* (1967). An important aspect of Dryden's writing is covered by WILLIAM FROST in *Dryden and the Art of Translation* (1953). General studies of the plays include A.C. KIRSCH, *Dryden's Heroic Drama* (1965); BRUCE KING, *Dryden's Major Plays* (1966); and F.H. MOORE, *The Nobler Pleasure: Dryden's Comedy in Theory and Practice* (1963). The standard study of Dryden's thought was for long that of LOUIS I. BREDVOLD, *The Intellectual Milieu of John Dryden* (1934), but this has been in part corrected and superseded by PHILIP HARTH, *Contexts of Dryden's Thought* (1968).

(J.R.Su.)

## Dualism, Religious

Dualism is the doctrine that the world (or reality) consists of two basic, opposed, and irreducible principles or substances (e.g., good and evil; mind and matter) that account for all that exists. It has played an important role in the history of thought and of religion.

### NATURE AND SIGNIFICANCE

In religion, dualism has meant the belief in two supreme opposed powers or gods, or sets of divine or demonic beings, that control the world. It may conveniently be contrasted with monism, which sees the world as consisting of one principle such as mind (spirit) or matter; with monotheism; or with various pluralisms and polytheisms, which see a multiplicity of principles or powers at work. As is indicated below, however, the situation is not always clear and simple, a matter of one or two or many, for there are monotheistic, monistic, or polytheistic religions with dualistic aspects.

Various distinctions may be discerned in the types of dualism in general. In the first place, dualism may be either absolute or relative. In a radical or absolute dualism, the two principles are held to exist from eternity; for example, in the Iranian dualisms, Zoroastrianism and Manichaeism, both the bright and beneficent and the sinister and destructive principles are from eternity.

In a mitigated or relative dualism, one of the two principles may be derived from, or presuppose, the other as a basis; for example, the Bogomils, a medieval heretical Christian group, held that the devil is a fallen angel who came from God and was the creator of the human body, into which he managed by trickery to have God infuse a soul. Here the devil is a subordinate being and not co-eternal with God, the absolute eternal being. This, then, is clearly a qualified, not a radical, dualism. Both radical and mitigated types of dualism are found among different groups of the late medieval Cathars, a Christian heretical movement closely related to the Bogomils.

Another and perhaps more important distinction is that between dialectical and eschatological dualism. Dialectical dualism involves an eternal dialectic, or tension, of two opposed principles, such as, in Western culture, the One and the many, or Idea and matter (or space, called by Plato "the receptacle"), and, in Indian culture, *maya* (the illusory world of sense experience and multiplicity) and *ātman-brahman* (the essential identity of mind and ultimate reality). Dialectical dualism ordinarily implies a cyclical, or eternally repetitive, view of history. Eschatological dualism—i.e., a dualism concerned with the ultimate destiny of man and the world, how things will be in the "last" times—on the other hand, conceives of a final resolution of the present dualistic state of things, in which evil will be eliminated at the end of a "linear" history constituted of a series of unrepeatable events, instead of a "cyclical," repetitive one. The ancient Iranian religions, Zoroastrianism and Manichaeism, and Gnosticism—a religiophilosophical movement influential in the Hellenistic world—provide examples of eschatological dualism. A type of thought, such as Platonism, that insists on a profound harmony in the cosmos, is thus more radically dualistic, because of its irreducibly dialectical character (see below) than Zoroastrianism and Manichaeism, with their emphasis on the cosmic struggle between two antithetical principles (good and evil). Midway between these extremes is Gnostic dualism, which has an ontology (or theory of being) of an Orphic-Platonic type (for Orphism, see below Among ancient civilizations and peoples) but which also affirms the final disappearance and annihilation of evil with the eventual destruction of the material world—and thus comprises both dialectical and eschatological dualism.

In philosophy, dualism is often identified with the doctrine of transcendence—that there is a separate realm or being "above" and "beyond" the world, as opposed to monism, which holds that the ultimate principle is inside the world (immanent). In the disciplines concerned with the study of religions, however, religious dualism refers not to the distinction or separation of God and the

world but to the doctrine of two basic principles; a doctrine that, moreover, may easily be compatible with a form of monism (e.g., Orphism or Vedānta) that makes the opposition between the One and the many absolute and sees in multiplicity merely a fragmentation (or illusory obliteration) of the One.

### HISTORICAL VARIETIES OF RELIGIOUS DUALISM

Among ancient civilizations and peoples. Dualism is a phenomenon of major importance in the religions of the ancient world. Those of the Middle and Near East will be considered here.

Egypt and Mesopotamia. While there was generally no explicit dualism in ancient Egyptian religion, there was an implicit dualism in the contrast between the god Seth and the god Osiris. Seth, a violent, aggressive, "foreign," sterile god, connected with disorder, the desert, and loneliness, was opposed to Osiris, the god of fertility and life, active in the waters of the Nile. Seth also possessed some typically dualistic marks of a mythological character; his action, as well as his personality itself, was ambivalent; and, as a typical trickster, he was also capable, at times, of constructive action in the cosmos. The myths of Osiris and Seth may be compared in various ways with those recently discovered among the Dogon peoples of the western Sudan, which contrast Nommo, a fertile and happily mated primordial being pictured in fish form, with Yurugu ("Pale Fox"), an unhappy, sterile character who lives in the wilderness without a mate. Yurugu is considered to be the element that makes the universe complete (the same role assigned to Seth in the Egyptian myth).

Dualism, broadly speaking, was also present in ancient Mesopotamian religion. In myths pertaining to the origin of the gods and of the cosmos, the opposition between the primordial deities (Apsu, the Abyss; and Tiamat, the Sea) and the new ones (particularly Marduk, the demiurge, or creator) displayed some dualistic aspects. Though the earlier deities had established the basic reality of the universe—its ontological core—because of their chaotic and selfish nature they resisted their own offspring, who were later to create the now existing, definite order of the cosmos. A dualism of the ontological—basic reality or being—versus the cosmological—the form or order of the material universe—is thus implicitly affirmed.

Greece and the Hellenistic world. Analogous dualistic concepts may be found in the early Greek Theogony of Hesiod (fl. c. 800 BC) in his myths of the gods Uranus, Cronus, and Zeus, and the conflict between primordial and later gods. It was in the later, classical Greek world, however, that dualism was most evident. Many of the pre-Socratic philosophers (6th and 5th centuries BC) were dualistic in various ways. In the teachings of Parmenides, for example, noted for reducing the world to a static One—a classical instance of monism—there is still a radical opposition between the realms of Being and Opinion—between ultimate reality and the world of human sense experience. On the other hand, in the doctrines of Heraclitus, noted for reducing the world to fiery Change, the conflict of opposites (hot–cold, day–night, beginning–end, the-way-up–the-way-down), called by Heraclitus *polemos* ("war"), was exalted to become a metaphysical principle. Though these opposites are piecemeal dyads ("pairs"), their effect, taken together, is, as a whole, dualistic. The dualism of Empedocles, simultaneously a religious teacher and a natural philosopher, is especially striking, for he viewed the primordial sphere of the universe as undergoing cycles alternately under the dominance of the antithetical principles of Love and Discord, which periodically break and then reconstruct it. In this context there exist *daimones* ("souls"), divine beings that have fallen from a superior world into this world and exist clothed in the "foreign robe of the flesh." These souls are therefore subject to transmigration through a series of vegetable, animal, and human bodies, owing to a primitive accident (for which credit was given "to the furious Discord").

The same antithetical principles are to be found in Or-

Osiris and  
Seth

Types of  
dualism

phism, a Greek mystical school, which constituted an independent development within Greek religion and philosophy; beginning in the 6th century BC, it was part of a "mysteriosophic" trend that sought to attain the wisdom of secret mystic and cultic doctrines. Orphism is characterized by its *sōma-sēma*, or body-tomb concept, which saw the body as a prison or tomb in which the soul—a divine element, akin to the gods—is incarcerated. In addition to this psychophysical dualism of soul and body, the Orphic idea that "everything comes from the One and returns to the One" demonstrates a typical dialectical dualism, in which an implicit monism is involved. Developing on an analogous level, Pythagorean numerical and mystical speculation, arising from the 6th-century-BC Greek philosopher and religious teacher Pythagoras, also stressed the dualistic opposition of Monad-Dyad (One–Two) and of other dialectical pairs of opposites.

Platonic  
dualism

Many of these dualistic ideas, especially the Orphic and Pythagorean ones, are also found in writings of the Greek philosopher Plato (428–348/47 BC), such as the *Timaeus*, *Phaedo*, *Gorgias*, and *Cratylus*. In these writings a divine part of the human soul that is directly infused by the divinity and a mortal part (passionate and vegetative) are defined and considered. The mortal part is assigned to man by inferior divinities, charged to do so by the supreme divinity; and the appetitive passions involved, if followed, are held to be responsible for the punishments that the soul will suffer during various periods of habitation in the other world and reincarnations in this one. Thus God remains free of blame for the destiny of man. The mortal or spoiled part of man is further attributed, in Plato's *Laws*, to the "titanic nature" within his makeup—an element of violence and impiety inherited from the primordial rebellious Titans, sons of the Earth.

Plato's notions of man were rooted in both ontology and cosmology; i.e., in views on being and on the orderly structure of the universe. In the *Timaeus* he considers the cosmos as a single harmony, which for the sake of completeness requires the existence of inferior levels that are bound not only to matter but also to Necessity (the realm of things that could not have been otherwise, and that are hence not amenable to divine activity). A different view is found in his *Laws*, which describes two "Souls" of the World, one of which causes good and one evil. The *Politicus* is concerned with two eternally recurring, alternating cycles in the cosmos, with successive epochs guided either by the gods or by men.

Plato's central inspiration, which unifies his metaphysics, his cosmology, his theory of man, and his doctrine of the soul, was basically dualistic (in the sense of dialectical dualism) with two irreducible principles: the Idea and the *chora* (or material "receptacle") in which the Idea impresses itself. All of this world is conditioned by materiality and necessity; and because of this, the descent of souls into bodies is said to be rendered necessary as well.

Neoplatonism, a 3rd-century-AD development from Plato's thought, conceived the cosmos as a harmony with a succession of levels emanating from an ultimate unit. There was in the system, nevertheless, a rupture of the harmony of the cosmos called *tolma* ("the audacity"), which served as an explanation for the descent of Soul into the material world—and thus constituted a dualistic element.

Gnosticism

In Gnosticism, a Hellenistic religious movement that entered original Christianity from earlier pagan sources, and which viewed matter as evil and spirit as good, dualism manifested itself in a more dramatic way. Gnostic dualism cannot be understood without reference to both Judaism and Christianity, and perhaps even to Zoroastrianism, since Gnostic eschatological characteristics were derived from them. Gnosticism was also connected with certain principles of Orphism and Platonism; reflecting the Orphic body-tomb doctrine, for example, Gnosticism adopted a firmly antisomatic stance (against the body), and similarly adopted the concept of the divine soul—the pneumatic, or spiritual, soul, as the Gnostic would say, of the same substance as the divinity—that is destined to

free itself from the tyranny of a material, cosmic demiurge (or subordinate deity). Certain Gnostics, moreover, developed a radical anticosmism, in which they registered their animosity against the material universe by cursing the stars—which brought them bitter reproach from Plotinus (c. AD 205–269/270), the founder of Neoplatonism. As viewed by the Gnostic Ophite sect, which venerated the *ophis* (or "snake") as a symbol of knowledge, the cosmos comprises three parts: the superior world, the inferior world (material and chaotic), and the intermediate world, or *logos* ("word" or "reason")—the *logos* being depicted as a snake that impresses spiritual forms into the chaotic matter. These forms—life, soul, vital masculine substance—are later freed again, a liberation that completely empties the material world. Such Gnostic views are of two types: Iranian and Syrian-Egyptian. Iranian Gnosticism is characterized by an absolute, radical dualism: light and darkness, *pneuma* ("spirit") and chaotic formless matter, oppose each other from eternity. Syrian-Egyptian Gnosticism is characterized by a dualism that is mitigated (as earlier defined) but also drastic: the inferior world, the chaotic darkness, begins to exist only at a special moment owing to an accident in the divine world; and this accident is usually also identified with an "audacity," a defect in one of the "aeons," or divine entities.

*Iran.* In the Indo-Iranian period (2nd millennium BC) there were already tendencies toward dualistic thought, especially in myths relating to monstrous and demonic beings who still the movement of the waters and thus make cosmic life impossible; in later-archaic Indian speculation there was also a tendency to oppose *devas* ("gods") to *asuras* ("demons"). Iranian dualism, however, expressed itself most characteristically in Zoroastrianism. In the Zoroastrian religious texts, the *Gāthās*, there is an opposition between two spirits, the Beneficent Spirit (Spenta Mainyu) and the Destructive Spirit (Angra Mainyu, or Ahriman). These two spirits are different, irreducible principles; at the beginning they have chosen life and nonlife, respectively. Though the Beneficent Spirit is almost an hypostasis (the substance) of the divinity (Ahura Mazda), nothing is said in the *Gāthās* about the origin of the Destructive Spirit. In any case, the very fact that the Destructive Spirit is said to be "twin brother" of the Beneficent One does not imply that he is a son of Ahura Mazda but only that the two spirits are "symmetrical"; i.e., equal and contrary as to their respective efficacy and orientation.

Medieval Zoroastrian treatises present radical and eschatological dualisms in their extreme forms. According to the *Bundahishn* ("Primordial Creation") text, Ormazd (Ahura Mazda) and Ahriman have always existed. Ormazd is represented as lofty, in the light, full of omniscience and goodness, while Ahriman is represented as debased, in darkness, full of aggressiveness and ignorance. Ormazd's omniscience allows him to conceive and to actualize the Creation and Time, because only these can offer him an arena in which to accost Ahriman and eliminate him.

The medieval Zoroastrian treatises also describe another "dual" formulation, the two realms of creation and of reality: the *mēnōk* ("potential, embryonic, initial, heavenly, and invisible") and the *gētīk* ("realized, final, worldly, concrete, and visible"). But this opposition does not imply a devaluation of the *gētīk*, of this world.

Zurvanism, a Zoroastrian heretical movement (c. 3rd/4th century BC–7th century AD), was also dualistic. The very names of Zurvān (Time-Destiny) and the partially synonymous *zamān* ("time") already appear in the later Avesta and in medieval treatises, in which Time is the milieu in which Ormazd and Ahriman fight. Also, a myth attributed to Zoroastrian priests by later, non-Iranian sources speaks of Zurvān as the father of Ormazd and Ahriman. At times "Zurvanite" mythology tends toward formulations of a Gnostic and Manichaean type (women paid allegiance, for example, to Ahriman, who has partial authority in the world). Zurvanism also developed theosophic characteristics (involving mystical insights), such as that which discerned the ambivalence of

Ahura  
Mazdā  
versus  
Ahriman

Zurvān—viz., that although an evil element (an evil thought or spiritual corruption) has always existed within him, he nonetheless, so it seems, eliminates the evil by expressing it and is thus worthy to be identified with the supreme divinity (Yazdān).

**Among religions of the East.** Dualisms have also appeared in various forms in the religions of India and China.

**India.** Indian dualism has involved the opposition of the One and the many: of reality and appearance. In an ancient Hindu hymn (R̥gveda, 10.90.), *Puruṣa*, "the Immortal that is in heaven," is opposed to this world; the three quarters of the *Puruṣa* that comprise the transcendent world are opposed to the other quarter of him (his limbs) that is this world; i.e., the divine foundation, the divine substance of this world, is made out of his limbs. Early speculation on the identity of the *ātman* ("self") and Brahman ("cosmos"), as opposed to the material and visible world that is subject to *māyā* (or "mundane illusion"), has been mentioned above.

The *Sāṃkhya* school of Indian philosophy presents another, probably later, formulation of dualism based on two eternal and opposed cosmic principles: *prakṛti* ("original matter") and *puruṣa* ("spirit"), the name of the ancient primordial Man, substance of the universe. Matter is differentiated into three different *guṇas* (or "qualities") that articulate the three levels of the being and essential nature of man in hierarchical connection with each other. Spirit, in itself free, eternal, and infinite, becomes involved in matter by the development of the latter. Salvation coincides with the knowledge of the state of things: "I (spirit) am one thing and It (matter) is another."

**China.** The first words of the Taoist text, the Tao-te Ching, express a doctrine that is typical of a pervasive Chinese dualism; i.e., that of the two opposed and complementary principles, the Yin and the Yang (respectively, feminine and masculine, lunar and solar, terrestrial and celestial, passive and active, dark and bright; in short, the entire series of opposites). The dialectics of Yin and Yang are the double manifestation of the one and only eternal, undividable, and transcendent principle: Tao ("the Way").

**African philosophies and religions.** A typically dual composition (involving the coexistence and cooperation of two elements), or even a dualistic opposition (as two opposed elements that function as principles in respect to the actual creation), is found in the *Dogon* (western Sudanese) notions about Nommo and Yurugu, already mentioned. A series of "words" refers to both principles; i.e., a series of realities and categories can be named that constitute the world in its functional variety, which transcend the simple good-evil opposition, and according to which both Nommo and Yurugu are dualistic "principles" essential to the actual dynamics of the world.

**Among religions of the West.** Dualisms have appeared in Western religions chiefly under the impact of Gnostic influences.

**Judaism.** No real dualism is found in Judaism, except in the Gnostic and theosophic forms of Jewish mysticism known as Kabbala. The presence of a vigorous and universal monotheism implies not only faith in a single creative god but also faith in a god who is the uncontested master of history; and neither Satan nor Belial detract from this absolute monotheism. Within these limitations, however, a tendency towards dualistic thought exists in such late noncanonical texts as the First Book of Enoch (c. 1st century BC), in which certain angels are said to have fallen as a consequence of their wedding with the daughters of men. These angels, it is held, taught mankind the malevolent arts of magic, seduction, and violence, together with such elements of culture as the use of metals and writing. Though there is no dualism in the stricter sense in the Manual of Discipline, one of the Qumran texts of the Dead Sea Scrolls, a certain polarity is nonetheless displayed in a passage that asserts of God that

he created man to have dominion over the world and made for him two spirits so that he may walk by them until the

time of his visitation: they are the spirits of truth and error. In the dwelling of light are the origins of the truth, and from a spring of darkness are the origins of error. In the hand of the Prince of Lights is dominion over all the children of righteousness, in the ways of light they walk. And in the hand of the angel of darkness is all dominion over the children of error; and in the ways of darkness they walk.

The context of this passage, however, is completely monotheistic. It expresses a doctrine also found in the Didachd, a Jewish-Christian work of the early 2nd century AD (better known as the Teachings of the Twelve Apostles), that of the two roads on which a man may walk, the good road and the bad, the road of life and that of death, with God leaving the choice of the road to man's free will; and also the later rabbinic doctrine of the struggle between the good and evil inclinations (*yetzer*) within man. There is also no hint of dualism in the two "sources" mentioned in the *Qumrān* texts, the bright source and the dark. These are hardly dualistic principles (in the ontological sense of the term) but are simply radical (i.e., original) polarities in spiritual orientation. (Not even the "Angel of Darkness," mentioned in the same context is a principle, though he is a person and a power.)

There is thus no possible hostile confrontation of two principles such as appears in Iranian Zurvanism. Elements of dualistic thought (in a Platonic sense) are also found in the works of the Jewish Hellenistic philosopher *Philo* of Alexandria (1st century AD), whose philosophy was dualistic in its doctrines about the universe and man, but without shaking his basic adherence to biblical monotheism.

**Christianity.** In Christianity dualistic concepts appeared principally in its Gnostic developments. But even in the 2nd-century Judaizing sect of the Encratites, which was not really Gnostic, there were dualistic aspects that had modified some tendencies in later Judaism. These teachings were also particularly prominent in the writings of the supporters of Docetism (the doctrine that Christ, being divine, did not suffer and die; 2nd century), who held that matter is essentially evil and that the soul is a pre-existent substance. According to the Encratites, the pre-existent soul, once it "gets effeminized by concupiscence," drops into the carnal world. Since generation perpetuates the soul's state of decay in this bodily world, they condemned all sexual relations. The dualism of *Marcion* (a 2nd-century semi-Gnostic Christian heretic) was really a ditheism (a system positing two gods), though the common Gnostic presuppositions—such as antisomatism and anticcosmism, the condemnation of the body and the material universe—were also present in his thought. For *Marcion*, the God of the Old Testament is an inferior and harsh creator demiurge, author of the world and man, who is nonetheless completely distinct from the supreme divinity, who manifested himself in Jesus and is a stranger to this world. For Saturninus (or Satornil) of Antioch, the founder of a 2nd-century Syrian Gnostic group that was commonly connected with the tradition of Simon Magus (reputed leader of an earlier Gnostic sect), the God of the Old Testament is only one of the angels, the martial angel of the Judaic nation, although (as with *Marcion*) he is distinct from the devil, who is in fact his opponent. According to Saturninus a primordial accident caused a wave of *pneuma* ("spirit") to land in the inferior darkness, where it is said to have remained prisoner and now continues its existence in those who, characterized by the presence in them of this superior element, will later be conducted back to their heavenly origin by Jesus, a messenger coming from above. Conceptions of a similar type are also found in the "Psalm (or Hymn) of the Naassenes" (Naassene is the Hebrew term for Ophite, mentioned above) and in the "Song of the Pearl" in the Gnostic Acts of Thomas; here also occurs the concept of a "saviour to be saved," who has been sent from above and was made a prisoner by darkness. This basic concept was developed fully only in Manichaeism. The Gnostic-dualist view survived in late antiquity and into the Middle Ages, both in the East, among the Mandeans. Yezidis ("devil-worshippers"), and

Non-dualistic polarities in late Judaism and Jewish Christianity

Encratism

Yin and Yang

some extreme sects within the **Shrāh** branch of **Islām** and in the West among the Bogomils and Cathars. It is still present today in modern theosophy.

**Among modern nonliterate religions.** Religious dualism also manifests itself among primitive peoples, especially in the concept of a "second" figure, an ambivalent demiurge-trickster who can be both a collaborator and rival of the supreme being and independent of the latter in origin. Such tricksters include the Coyote (in North American Indian mythology), the Raven (among Paleo-siberians), or the Crow (among the Southeast Australian tribes). To these animal figures are attributed the origin of such negative aspects of life as death and illness. But they are also credited as benefactors; *e.g.*, in creating utilities in the cosmos and in the invention of fire. The demiurge-trickster is typically ambivalent, tremendously frightful and efficacious, but also frequently limited in power. For example, such tricksters are often incapable of animating the beings that they have molded and must therefore request the help of the supreme being in bringing them to life. They are said to be selfish, lonely, and unhappy and this moves them, despite their arrogance, to attempt to relate themselves to or unite with the supreme being.

Other dualistic concepts among primitive peoples posit opposite the supreme being a violent and death-bearing "second" figure of a demiurgical type. The character of Erlik in the mythologies of the Central Asiatic Turks (*e.g.*, among the Altaics) is typical.

Erlik is a king of the dead and master of death who assumes the role of a fraudulent and unfortunate collaborator with the supreme being. In stories about the origin of the universe, he appears as an aquatic bird in charge (under the supreme being) of fishing a little earth from the bottom of the primordial sea—a theme also well-known in East European folklore. In other myths, a similar being spits on human beings at the time they are created by God or breathes his bad spirit into man or woman. Elsewhere there is depicted an opposition of two twin brothers, of whom one is the demiurge-creator of good things and the other of death; both, however, are the sons of a mother goddess of heavenly origin. This pattern is exemplified in the Iroquoian myth of **Yoskeha** and **Tawiskaron**—a myth curiously reminiscent of certain aspects of the Iranian **Zurvanite** mythology.

Other ethnological polarities, or pairs of opposites (eastern–western, celestial–terrestrial, solar–lunar divinities, right–left, full moon–dark moon, etc.) are dualistic in the sense of contrasting principles or creating agencies.

#### THEMES OF RELIGIOUS DUALISM

**The sacred and the profane.** Among the various themes of religious dualism the opposition between sacred and profane is also important. This distinction, appearing in some sense in nearly every religion, must be particularly acute, however, to qualify a religion as dualistic. Such an intensification of the sacred–profane opposition to the point at which it becomes a dualism is evident in the mid-20th century historian of religions **Mircea Eliade's** conception of religion (see also **SACRED OR HOLY**). This contrasts time (the *illud tempus*, "those times," of the intact, sacred, primordial creation that are periodically restored by ritual) and the historical time (marked by decay, profaneness, and loss of plenitude and significance).

**Good and evil.** More pertinent (even if not always dualistic) is the opposition between good and evil, in the various meanings of these words. Whenever the problem of the origin of evil is solved by conceiving the real existence of another principle separate from the prime principle of the world, or by affirming an inner ambivalence, limited sovereignty, or inadequacy of the prime principle, or of divine beings, a dualism then emerges; and through this good–evil opposition, the problems of **theodicy** (*i.e.*, of the doctrine of the justification of divine action in a world in which evil is present) are posed. If evil either is, or comes from, a self-existent principle antithetical to the principle of good, then this provides the divinity with a "justification." Such views are completely

different from the justification of God in nondualistic religions, especially the monotheistic ones. In monotheistic religions evil does not originate within the divinity nor in general within a divine world (*plērōma*) as it does in Gnosticism; it arises instead from the improper use of freedom by created beings. In monistic religions—all of which are based on the opposition between the One and the many, seen either as an illusion or as the decay or fragmentation of the One—along with a strong ascetic emphasis, there is a notion of evil as being for man a painful and fatal essence that issues from a metaphysical cause or an ontologically negative principle. For the same reason, it is necessary to distinguish between the **nondualistic** concept of "original sin" in Christian theology and the concept of "previous sin"—in monistic religions with a dualist aspect; whereas "original sin" arises and spreads within the human sphere, "previous sin" is consummated in some sort of a "prologue in heaven" and generates the very existence of the world and of humanity itself.

**Creation and destruction: life and death.** Another important dualistic theme is that which opposes life to death based on two opposing metaphysical principles. A typical example of this dualistic opposition is found in Zoroastrianism. Zoroastrian doctrine is strongly vitalistic: **Ahriman's** chief acolytes are **Aēshma** (the fury), the **Druj Nasu** (the deadly agent of putrefaction), **Jēh** (the infertile whore), and **Apaoša** (the demon of sterility)—death-bearing forces. There is also a strong vitalistic formulation of these principles in Gnostic doctrines, especially in the **Ophite** and **Barbelo-Gnostic** (worshipping **Barbelo** as the Great Mother of life) varieties, which identify the *pneuma* and the light with the vital substance. At other times the opposition of life and death is formulated in a dialectical manner as a recurring alternation of the two principles. The complex Egyptian opposition between **Osiris**, the "dead god," who is nonetheless the principle of fecundity and life, and his counterpart **Seth** has already been mentioned (see above Egypt and Mesopotamia). The same dialectic is typical of the "fecundity cults," in which a god-genius of vegetation, a "dying god," is featured, who undergoes a seasonal disappearance and return (not to be interpreted as a "resurrection"). To such vegetation gods, death- or decay-producing figures are sometimes opposed—as **Mot** (the Death) opposed to **Baal**, and an infernal and lethal wild boar opposed to **Adonis**, and (in German religion and mythology) **Loki** opposed to **Baldr**. These figures, the agents for disastrous occurrences, were already implicit in the figure of the dying god himself and in his relation to the seasonal cycle of vegetation. To be sure, the growing season is limited; and the new arrival of vegetation each spring (and the wedding of the fertility god) is terminated in the fall by the god's departure to the netherworld (with appropriate lamentation). But the rise of vegetation, though ephemeral, is nonetheless basically benevolent. This complexity is also manifest in those agricultural religions that present themselves as mystery cults (*e.g.*, the Eleusinian mysteries), bestowing upon the initiate a hope for life after death.

But the dualistic theme is far more evident in "mysteries"; *i.e.*, in the "sophic," or "wise," reinterpretation of mysteries (*e.g.*, Orphism). In this context, the divine soul replaces the dying god in the soul's descent from a superior world into the corporeal world—a concept that was later bequeathed to Gnosticism and is especially apparent in its transposed basic vitalism.

A dialectical formulation of the opposition of life and death is also found in the basic theology of Hinduism: with **Viṣṇu** (Vishnu) cast as the principle of creation (called **Nārāyaṇa**) and the sustenance of life and **Siva** (**Shiva**) as the principle of destruction and death. The ambivalence of life–death is also found in a series of Hindu divinities (*e.g.*, **Siva**, **Kālī**) and cults whose death-inflicting characteristics are justified in a paradoxical celebration of the recurring triumph of life.

**Polytheistic themes.** Among the instances of dualistic structure in polytheistic religions are those that oppose celestial and terrestrial, male and female, actual and mythical primordial-chaotic, "diurnal" and "nocturnal," especially when they do so within the context of mythol-

of evil

ogies and cosmogonies belonging to the ancient world's polytheistic "high cultures" (see above *Egypt and Mesopotamia: Greece and the Hellenistic World*). Such pairs of opposites often provide a framework for polytheistic pantheons that would otherwise appear anarchic or less than comprehensive (see also POLYTHEISM).

#### FUNCTIONS OF RELIGIOUS DUALISM

Cosmological and cosmogonic functions. The essential function of any religious dualism is obviously **ontological**—to account for a duality of opposed principles in being—even when the two principles are not regarded as coeternal; and this underlies the **cosmological-cosmogonic**, anthropological, and sociological functions and expressions of dualism. Both dialectical dualism (*e.g.*, in the fertility cults, Orphic mysteriosophy, and Platonism) and eschatological dualism (*e.g.*, in the Zoroastrian and Manichaean notion of the "mixture" between the two creations good and bad) have a basically cosmological function—the explanation of the structure of the universe. Whenever the concept of a distinct creator, transcendent with respect to his work, is missing (as, for example, in monistic formulations of the Indian type or in polytheistic milieus), dualism has a cosmogonic function—the explanation of the origin of the universe.

On a cosmogonic level, dualistic opposition may also be manifest in the celestial world; *e.g.*, in the late Zoroastrian opposition between the beneficent fixed stars and the planets (which are negative, because they are alleged to proceed in the reverse sense); or else between the world of the Heptad (again the seven planets, under the dominion of the tyrannic archons, or rulers, that cause human passions) and the superior heaven of the Ogdoad (the group of eight divine beings or aeons), *as* in Gnosticism and in **Mithraism**, in which the monstrous figure of **Leontocephalos** (a human figure with a lion's head, belted by a snake with astral signs) represents the power of astral Destiny-Time to be transcended by the soul—a power that is a basic presupposition of astrology and magic. On the other hand, the heaven-earth opposition cannot be regarded as dualistic if the two elements are represented merely as cosmic progenitors (see also CREATION, MYTHS AND DOCTRINES OF).

Anthropological functions. The anthropological functions of dualism (dealing with the nature and destiny of human beings) are present in all those doctrines that consider the individual as a duality, or, rather, as an irreconcilable duality of opposed elements. Of particular importance is the opposition between masculine and feminine, in which their opposition involves a remarkable difference in level of being. In mythologies (whether dualistic or not) with a "second" figure, a demiurge, there is frequently a connection between the demiurge and the origin of women (*e.g.*, the myths of Prometheus-Epimetheus in ancient Greece, and of **Paliyan** in southeast Australia) or between the demiurge and the origin of sexuality (*e.g.*, the myths of the trickster Coyote and of the Gnostic demiurge). In Platonic theory the first incarnation of the soul occurs in a masculine body, and only a subsequent incarnation, marking a later descent of the soul into the world of bodies, is feminine. In Gnosticism (**Ophite** sects) the vital substance that animates the universe is masculine (active), while the quality of the material world is feminine (passive); and in the last **logion** ("saying") of the Gnostic *Gospel of Thomas*, it is said that Mary will be saved by being made a male; *i.e.*, she will become a **pneuma** ("living spirit"). Gnostic and Manichaean antifeminism, as well as Encratite (and perhaps Orphic) antifeminism, are motivated by their hatred for procreation, which they believe implies the fall of the soul into the material world and its permanent abode there. At other times procreation is explained in terms of a division of a complete, originally androgynous (both male and female) being (as in Plato's *Symposium* and in the Gnostic *Gospel of Philip*). There are other nondualistic doctrines in which women are considered to be connected in some way with the origins of evil but are not the embodiment of the evil principle (*e.g.*, in Genesis and the apocryphal late-Judaic *Book of Adam*).

Sociological functions. The sociological functions of religious dualism are less relevant. Among some Australian Aborigines the "totems" of the two classes of a tribe that intermarry are the Falcon-Eagle (**Bundjil**), the supreme being, and the Crow (Waang), a detniurge-trickster. According to the Menominee Indians, the highest region of the universe is inhabited by benevolent gods (among whom the supreme being is Mate **Hawätük**) and the inferior region by bad ones; and these two groups are constantly fighting. The Menominee believe that they come from an alliance of families that at one time belonged to these two groups, whose respective descendants have particular places in the assembly and clearly differentiated functions.

Sociological and economic class oppositions, however, cannot provide a general explication for dualism. Not all dualities (*e.g.*, in the social structure) are necessarily relevant to religious dualism. On the ethnic level, sociological functions of dualism are found in the Zoroastrian opposition (even if not absolute) between Iran, with its so-called "good religion," and the Turanians, northern plunderers representing the aggressive world of evil. But this can by no means substantiate general hypotheses that explain dualistic oppositions between divinities or groups of divinities as a "projection" of a previously existing opposition between ethnic layers of conquerors and of conquered populations.

**BIBLIOGRAPHY.** UGO BIANCHI, *Il dualismo religioso: saggio storico ed etnologico* (1958), discusses the "dualistic area" extending from ancient Greece to Iran, eastern European folklore, northern and Central Asia, and North America; see also his "Le dualisme en histoire des religions," *Revue de l'histoire des religions*, 159:1-46 (1961), and *Le origini dello gnosticismo* (1967), a collection of papers (in French, German, English, and Italian) presented at the Colloquium of Messina, April 1966, many of which are devoted to dualism in various religions. MIRCEA ELIADE, "Prolegomenon to Religious Dualism: Dyads and Polarities," *The Quest: History and Meaning in Religion*, ch. 8 (1969), is concerned not only with dualism proper but also with the functions of "duality"; his *De Zalmoxis a Gengis-Khan*, ch. 2-3 (1970), is a study of dualism in folklore and ethnology. SIMONE PETREMENT, *Le Dualisme dans l'histoire de la philosophie et des religions* (1946), and *Le Dualisme chez Platon, les Gnostiques et les Manichéens* (1947), are two important general surveys but do not sufficiently distinguish the different meanings of dualism in the philosophical and the religious-historical terminologies. For an analytic exposition of the Gnostic ideology, with modern analogies, see HANS JONAS, *The Gnostic Religion*, 2nd ed. (1963); for a discussion of the varieties of Iranian dualism, R.C. ZAEHNER, *Zurvan: A Zoroastrian Dilemma* (1955). JACQUES DUCHESNE-GUILLEMIN, *The Western Response to Zoroaster* (1958), deals with the history of the problem of Iranian dualism. Other works include: GEO WIDENGREN, "Der iranische Hintergrund der Gnosis," in *Zeitschrift für Religions- und Geistesgeschichte*, 4:97-114 (1952), on dualism in the Indian *Upaniṣads*; F.K. NUMAZAWA, *Die Weltanfänge in der japanischen Mythologie* (1946), a comparative, ethnological appreciation of the Yin-Yang opposition; MARCEL GRIAULE and GERMAINE DIETERLEN, *Le Renard Pâle*, vol. 1, fasc. 1 (1965), an account of dualism in the ontology and the mythology of the **Dogon** of West Sudan; HELMER RINGGREN, "Dualism," *The Faith of Qumran*, ch. 2 (1963), a study of **Qumrānic** (dualism); and R.M. GRANT, *Gnosticism and Early Christianity*, rev. ed. (1966).

#### Dublin

The preeminent city of the republic of Ireland, Dublin (**Baile Átha Cliath**) is the last capital of the Western world whose winter streets are still smudged with the smoke of home fires, redolent of burning peat. It is also the legendary capital of English conversation. How long such agreeable vestiges of the past will endure is problematical: Dublin, so long a relic of a fading colonialism, is moving toward its long-denied future. There have been other occasions when **Dublin**, roused by some freshening of economic or political winds, has hurried to catch up with the rest of the world. What effect the current surge of modernization will have upon the charm of Dublin depends in large measure on the quality of the urban civilization it is hurrying to embrace.

Dublin's charm is architectural, geographical, and social. Its architectural heritage—the great garden squares and

Masculine  
and  
feminine

River Liffey Dublin At the right is the dome of the Four Courts

magnificent terraces of late 18th-century Georgian houses—has suffered badly, a result achieved by the passage of time, and also by the undoubted profitability of new buildings at old distinguished addresses. While the addresses may be distinguished, most of the new buildings are not.

The city's geographical site is superb. Situated at the head of a lovely bay, Dublin straddles the River Liffey where that stream flows eastward through a hill-ringed plain to the shores of the Irish Sea. (The dark bog water made the "black pool" that gave the city its name, Dubh Linn in Irish, Dyfflin in Norse.) Almost certainly it was this opening from the sea, leading through the mountains to the fruitful central plains of Ireland, that originally tempted the wandering Norse raiders to settle there. In spite of its long historical development, Dublin remains a physically small city, though its population did expand from 390,000 in 1922 to more than 985,000 by 1979 (resulting in nearly a third of the nation's total population living there). From Dublin Castle, it is little more than four miles (6.5 kilometres) to the furthest city boundary in any direction.

A new prosperity, free health care, social insurance, and new housing have substantially improved the lot of Dublin's poor. An erroneous impression of continued widespread misery is nevertheless abetted by the dress of manual labourers, who habitually wear worn, soiled street garb on the job instead of special work clothes. The traditional harpers, or ballad singers, have moved off the streets of Dublin and into the singing pubs, but its beggars—usually native gypsies, who were once called tinkers but are now referred to as "itinerants"—are still abroad in the streets.

Dublin is a low-built, steeped city, with few buildings dating from before the 17th century. The Roman Catholic churches are 19th- and 20th-century structures. One of the tallest new buildings—Liberty Hall, a trade union headquarters—reaches 17 stories in height, and most of the others are not higher than 10 stories because of a Dublin city ordinance. Although Dublin is the largest

manufacturing city in the Irish republic, the factories, aside from the breweries and distilleries, are engaged principally in light manufacture, and they do not unduly obtrude.

Thus Dublin remains a city of red brick, gray stone, and green parks, shade trees, front gardens, canal banks, copper cupolas, and front doorways. Each year the city's suburbs jut farther into the country, but the countryside nonetheless persists in trying to reclaim the city. Dublin is the capital of a predominately agricultural nation, and many of its urban vistas close on a rising blue note of wild mountain.

Country folk are often to be seen in town for the day, and from September to April Dubliners costumed as country gentlemen leave town to hunt with nearby packs of hounds. The biggest social and tourist event of the year is the August horse show at the Royal Dublin Society's grounds. Every winter the municipal government advertises for tenders from stockmen who want to graze cattle on the spring swards of the largest city park—Phoenix—which also houses the zoo and the establishments of the Papal nuncio, the American ambassador, and the president of the republic.

Altogether, the city belongs more to the hills and the fields around it than to the waters before it, even though Dublin is Ireland's largest port, handling half the country's imports and half of its domestic exports. Some ships berth right in the centre of town, and gulls fan out from the Liffey, mewing and wheeling their white wings. But the town's purest gift from the sea is the quality of its light. It enriches the old brick and softens the cold Dublin stone. In long summer twilights its luminosity gilds the cityscape, and it lends even the dreariest February afternoon a silvery sheen.

Another of the city's charms has been the tempo of its life—urban, yet leisurely, with the numerous pubs and churches offering a ready excuse from more mundane pursuits. However, the beat of Dublin life has been subtly accelerating, a change largely due to the growth of the city's businesses.

An agricultural heritage

Geographical advantages

Of all the charms of Dublin, the most pervasive and durable is the citizenry itself, a people who are notoriously hospitable and generous. Their speech is often helplessly poetic. Their celebrated conversations frequently are about religion, which is still a force in Irish life, and often touch on that other Irish trinity of interests: horses, politics, and personalities. But the Dubliners' humour is built on a long heritage of sorrow. After a thousand years of strife and treachery, their wit conceals an ingrained wariness.

A great deal of Dublin's flavour is that special taste of things at the source. The principal national seats of learning and the centres of financial and commercial power are located in the city, as is the central government of Ireland, which controls so many aspects of Irish life. Dublin has long had the habit of authority over the rest of Ireland. It is said that 100 men run the country, and all of them—the leaders of the professions, the arts, high finance, industry, government, and sports—are to be found in Dublin.

#### HISTORY

**Foundation and early development.** From prehistoric times men have dwelt in the area about Dublin Bay, and four of Ireland's five great roads converged near the spot called *Baile Átha Cliath* ("the town of the hurdle-ford"), the name stamped today on Dublin's postmark. Dublin appeared in Ptolemy's *Guide to Geography* (c. AD 140), and 151 years later "the people of Dublin," it was recorded, defeated a Leinster army. Yet, despite indications of habitation there 2,000 years ago, the first settlement for which one can discover any historical proof was not Irish, but Norse.

The Vikings came in the 9th century (c. 831) and built upon the ridge above the river's south bank, on the spot where Dublin Castle rose 400 years later. The Norse invaders beat off most Irish attacks against their bridgehead until 1014, when they were defeated at the Battle of Clontarf on the north shore of the bay. They nevertheless reoccupied the town, and Norse Dublin survived and grew, although eventually the Norse kings were reduced to mere earls under Irish overlords. In 1167 they supported Roderic (Rory O'Connor) of Connaught (Connacht), claimant to the high kingship, in driving Dermot MacMurrough, the hated king of Leinster, into exile. Dermot returned in 1170 with an army of Anglo-Normans from Wales, 60 miles away to the east across the Irish Sea, and retook Dublin. The following year the last of the Norse earls joined Roderic in a futile assault on Dublin. Alarmed lest his Norman vassals should claim Ireland for their own, King Henry II of England then hurried over with an army to affirm English sovereignty. This action was to be the key to the development of Dublin for the next 750 years, for it was to remain in English hands until 1922. For the bulk of this period, until the middle of the 17th century, Dublin remained a small walled medieval town, dominating only the "pale"—the thin strip of English settlement along Ireland's eastern seaboard. These were, nevertheless, troubled times, for, in those 500 years, three Irish uprisings in the city were suppressed, and a Scottish invasion and the ravages of the Black Death endured.

During the Reformation Dublin became Protestant, and, in the English Civil War, its Royalist defenders, after contemplating joining forces with an armed Irish Catholic confederacy, surrendered the city to Oliver Cromwell's English parliamentary army in 1649. By the end of the Cromwell era Dublin was a town of only 9,000 inhabitants. The turreted city wall with its eight gates was a shambles, the two cathedrals tottered, and the dilapidated castle was, as Cromwell himself put it, "the worst in Christendom."

**The 18th-century ascendancy.** Yet, in the 18th century, Dublin was to become the second city of the British Empire. This remarkable growth began at the end of the 17th century, when thousands of refugee Huguenot weavers from the European continent settled in Protestant Dublin after the revocation of the Edict of Nantes, in 1685, curtailed their privileges. Flemish weavers came in their

wake, and soon the cloth trades were flourishing, with high-gabled houses surrounding Weavers' Square, and it was not long before the excellence of the weavers' work provoked export restrictions by the English. In the course of the 18th century, Dublin burst its walls, more bridges were built over the Liffey, and splendid new sections arose to the north and east. The streets—many of them 40 yards (36 metres) broad—were paved and were lighted by oil lamps, while beautifully proportioned brick town houses and an occasional palace built for a wealthy lord bordered the newly laid out squares and thoroughfares. The philanthropic institutions, for which Dublin later came to be admired, were also founded in this period, and a number of hospitals—including the first maternity hospital in the British Isles—were built. The new Parliament House was built on the mound of the Thingmote, the site of the Viking assembly, and behind the new quays on the north bank of the Liffey two great public buildings rose, the Custom House and the Four Courts, the work of the Dublin-born architect James Gandon. The steeples of new churches added to the changing skyline, and a modern port was constructed. Trinity College, founded in 1591, added some of its most beautiful buildings. The urban landscape that emerged is, in essence, that of the Dublin of today.

In the New Musick Hall, Handel conducted the first public performance of his *Messiah* in 1742, while such noted literary figures as Oliver Goldsmith, Richard Steele, Richard Brinsley Sheridan, and William Congreve also were active in Dublin during this period. For members of the Protestant Ascendancy, as the English establishment was called, Dublin was a gay, fashionable city of elegance and wit.

The city was something less than that for the Roman Catholics, however. Toward the beginning of the 18th century the Penal Laws had disenfranchised the Catholics, leaving them without possessions, without professions, without representation, and, in many instances, without education.

**The 19th and 20th centuries.** The 1800 Act of Union between England and Ireland abolished the Irish Parliament and drastically reduced Dublin's status. With no governmental duties to compel their presence in Dublin, the leading figures of the Ascendancy returned to England, followed by the lesser English exploiters. The city fell into a decline from which it recovered only 150 years later. Dispossessed farmers crowded into the tenantless Georgian houses of the city, reducing these once elegant structures to slums. Anyone who owed more than 10 shillings could be imprisoned, and until the legislation was revised in 1864, five of Dublin's nine jails overflowed with debtors.

With the abatement of the Penal Laws, however, a Roman Catholic middle class emerged, sending its sons to university, to law, and to medical school. The political dexterity of the Irish Catholic lawyer Daniel O'Connell won full citizenship for Irish Catholics when he achieved passage of the Emancipation Act by the English Parliament in 1829, and in 1841, after reforms in Dublin's municipal government, O'Connell became the first Roman Catholic lord mayor of the city.

The railways came to Ireland in 1834 when a seven-mile link connected Dublin with the port of Kingston (Dun Laoghaire). A few light industries subsequently opened, and on the city's eastern fringes new houses went up, Victorian in date but Georgian in flavour. For the first time in 200 years Roman Catholic churches and schools were built, and in 1851 the Catholic University of Ireland was founded on Saint Stephen's Green, with John Henry Newman as rector. Urban growth nevertheless remained slow, and Dublin continued to flourish modestly on the surface, but to fester beneath. The nationalist rebellions that broke out there in 1803, 1848, and 1867 were quickly suppressed. The legalist Home Rule movements, despite frequent reverses, did win a measure of home rule for Ireland in 1914; yet, with the outbreak of World War I in the same year, the English government acquired other preoccupations, and home rule appeared to become a dead letter.

influences

Cultural  
revival

The condition of the poor people of Dublin remained wretched: a 1910 survey showed that 20,000 families were each living in only one room; wages were very low, and a two-week survey of 22 public houses, or taverns, showed that over 46,000 women, and 28,000 children, were among the customers.

By the middle of World War I the cultural renaissance that is known as the Irish Revival was well under way, with Dublin playing a leading role. This movement had begun with the establishment, in 1884, of the Gaelic Athletic Association for the revival of Irish games, and was broadened in 1893 by the foundation of the Gaelic League for the revival of Irish language and folklore. Early in the 20th century it received strong impetus with the opening of Dublin's famous Abbey Theatre for the revival of Irish drama, an enterprise associated with, among others, the great Irish poet William Butler Yeats and the playwright John Millington Synge. The net effect of these developments was to help crystallize a strong sense of national identity and a renewed pride in Irish heritage. The nascent Irish labour movement, fighting the Ascendancy, grew increasingly patriotic, even forming a small citizen army. The 1848 Fenian rebel movement awoke from half a century's hibernation, and the secret, revolutionary Irish Republican Brotherhood (IRB) was born. These trends were to prove of momentous significance to Dublin, for it was in Dublin, on Easter Monday, 1916, that leaders marched at the head of 1,000 men of the recently formed Irish Volunteers and the Citizen Army, proclaimed a republic, and occupied public buildings, which they held for a week against attacks by British troops and artillery. The bottom half of Sackville Street, Dublin's principal thoroughfare, was destroyed in the melee. Commerce and industry were halted, and fully a quarter of the city's population of 390,000 went on public relief. Finally defeated, the rebels were marched through the streets of Dublin to the jeers of the populace. But British martial law, execution of the leaders, and imprisonment of many of the survivors roused the Irish as the rebellion itself had not. Guerrilla warfare started throughout the nation in August 1919, continuing through two years of terror and counterterror, with the forces of both sides directed from Dublin. After a final truce was concluded in 1921, the British offered Ireland—except the northern province of Ulster—dominion status as a free state. Although the subsequent treaty was accepted by the revolutionary parliament, an antitreaty contingent of the republican army soon took possession of one of Dublin's great public buildings, the Four Courts. Eventually they were driven out by artillery, whose booming initiated 11 months of murderous civil war between the two Irish factions. Dublin again suffered heavily in the conflict that ensued, and the upper half of Sackville Street (later named O'Connell Street) was destroyed. The end of the civil war in 1922 did not mean the end of gunfire in the Dublin streets. Political assassinations and armed raids continued until 1927, and bitterness between protreaty and antitreaty partisans marked much of Dublin life.

Post-  
World War  
II develop-  
ments

It was not until a decade after World War II that the government in Dublin launched new schemes which were designed to steer Ireland into the mainstream of the 20th century. Among these were detailed five-year plans for economic development; active pursuit of investment for new industry, especially from foreign sources; membership in more international political, economic, and cultural organizations; vigorous reorganization of national companies; and heavy investment in the tourist trade. All had great significance for the development of Dublin, and, consequently, these acts of social and economic renewal marked the full flowering of the city as an essentially Irish capital.

#### THE CONTEMPORARY CITY

**Topography and institutions.** The Norse, the Norman, and the Georgian, the three elements that comprise the architectural legacy of Dublin, all meet in Dublin Castle. In the first two decades of the 13th century the Normans obliterated the Viking stronghold and reared a *château-fort*. When the Georgians built the present red brick

castle they left two towers of the old structure standing. The castle, the seat of British authority in Ireland until 1922, is now used for inauguration of the republic's presidents, who subsequently reside in the former Vice-regal Lodge in Phoenix Park.

Close to the castle, Sigtryggur Silkeskjegg (Silkenbeard), Viking king of Dublin, built Christ Church Cathedral (c. 1030), which was replaced about 140 years later by a more magnificent Norman structure. By the 19th century the edifice was in ramshackle condition and required extensive repairs. At enormous cost, it was restored from 1870 to 1878. Christ Church is the cathedral for the diocese of Dublin and Glendalough, whereas its neighbour, St. Patrick's, is the national cathedral. Both are Protestant churches.

St. Patrick's, founded just outside the city walls, was originally a Danish church. The Normans rebuilt it in 1191, and, although it was enlarged and partially rebuilt over the centuries, it was in a state of collapse when Sir Patrick Guinness, the Irish brewery magnate, paid for its rebuilding, from 1846 to 1849.

The area between St. Patrick's and the Guinness Brewery on the Liffey is known as the Liberties, having been outside the city walls and under the sole jurisdiction of the archbishop. It was made up of the liberties of St. Patrick's and St. Sepulchre's, the latter the archiepiscopal palace, whose gateway is now the entrance to the Kevin Street police barracks. Since World War II large tracts of this district have been cleared for low-cost housing, and many of the district's inhabitants have been relocated in the new town of Ballymun.

The Guinness Brewery, a distinctive Dublin institution, is Ireland's largest single private employer, with a total of 7,000 employees, and the country's largest industrial exporter.

Barrels of export beer and stout, piled picturesquely on the quays, are important cargo for many of the 6,500 ships that clear Dublin's port each year. The basis of the modern port, the largest in the republic, was laid with remarkable prescience by the Ballast Office, founded in 1705. The office embanked the Liffey as it wound through the city harbour, constructing walls that reached more than five miles out into the bay. They also scoured a deep water entrance through the roaring sand bars (the North and South Bull), and thus facilitated the reclamation of harbour-side wastelands.

Similar foresight enriched the work of city builders in the same period. Dublin's early private speculators had a sense of order and beauty as acute as their sense of profit. The city's streets were broad, its garden squares capacious. For their time, the 18th century, the houses were ultramodern—Georgian and neoclassical, in the manner of the great English architects Inigo Jones and Christopher Wren. The elegant yet simple facades were severe rectangles of red brick, lightened by the superb proportions of well-placed windows, usually trimmed in white. Standing in long terraces with no space between the buildings, the sweep of homes made a harmonious whole that still stands as a felicitous achievement of urban architecture. In the sections still maintained today, the street doors are painted in many different colours and embellished with burnished brass fittings; they are remnants of a heritage giving way, perhaps irreversibly, to concrete and steel.

Terraces  
and  
squares

In the southern half of the town, between Trinity College and St. Stephen's Green, Joshua Dawson, one of Dublin's leading citizens, built an impressive residence in 1705, selling it a decade later to the city of Dublin for the lord mayor's residence; it still serves this purpose. It was there that the first Irish republican parliament, the Dail Éireann, met in 1919 to ratify the 1916 rebel declaration of the establishment of the republic.

Dawson's neighbours, the equally prominent Molesworths, followed his example and began building houses and entire streets. In 1745 the Earl of Kildare built, at the end of Molesworth Street, a palace that was renamed Leinster House when he became duke of Leinster. Although it is now the seat of the Irish parliament, it is still referred to by its original name. This huge town-built

The house  
of  
Parliament

country house is believed by some experts to be the prototype for the White House in Washington, D.C., which was designed by the Irish architect James Hoban in 1780. The Irish Senate, the upper house, meets in the 18th-century salon, and the Dáil in the remodelled octagonal lecture theatre that was built by the Royal Dublin Society after its purchase of Leinster House in 1815. Twin Victorian buildings, which were built on the same grounds in 1885, house the National Library and the National Museum of Ireland.

While the first duke of Leinster was still in residence, Merrion Street was laid out along the eastern edge of the property. Immediately to the east, Merrion Square, another of the great Georgian brick squares, was begun in 1762, while Fitzwilliam Square, to the south, was built at the end of the 18th century.

Today the square is largely given over to institutions of higher study and diplomatic representation, though the fine houses remain generally intact. The oldest and largest of the city's squares is St. Stephen's Green, which was recorded in 1224 as common grazing land, and was enclosed and bordered with houses in 1663, although the imposing mansions now surrounding it were built principally in the 18th century. By 1887 the parkland was run down and the Guinness family, whose former residence now houses the Department of Foreign Affairs, paid for its rehabilitation.

From the western side of St. Stephen's Green to the river, and from there up the northern bank to Parnell Square, runs the city's north-south axis, Grafton Street, which has long been the street of Dublin's smart shops. It emerges onto College Green between Trinity College and the 1729 Parliament House, which has since become the headquarters of the Bank of Ireland. Further north O'Connell—formerly named Carlisle—Bridge crosses the Liffey. Built as a narrow hump-backed bridge in 1794, it was renamed, flattened, and widened in 1880, and is popularly believed to be as broad as it is long. The river is also spanned by eight other road bridges, two railway bridges, and a pedestrians' crossing which is called Metal Bridge.

Along the quays are Dublin's finest monumental buildings, with the neoclassical masterpieces the Custom House (1781-91) to the east and the Four Courts (1786-1802) to the west. The former was set afire in 1921 by Republicans who wished to destroy British administrative records, and burned for five days. The latter was reduced by shell fire and mines at the outbreak of civil war in June 1922. Both have since been rebuilt, by government departments, with approximate authenticity but some loss of grace. O'Connell Street—at first called Drogheda and then Sackville Street—is Dublin's "downtown," an assemblage of shops, cinemas, and snack bars. The only building of any distinction to survive the warfare that swept the street in 1916 and in 1923 is the General Post Office, headquarters of the 1916 rising. Badly damaged in the rebellion, it was reconstructed behind its surviving 1814 classical facade in 1929.

O'Connell Street was built in two installments. The upper half of the street was created in 1744 by the Dublin banker Luke Gardiner, later Lord Mountjoy, and to this portion, 40 years later, the Wide Street Commissioners joined a lower half that ran all the way down to the Liffey. At the top of the street Dr. Bartholemew Mosse constructed his Lying-In Hospital, adding over a period of 20 years a pleasure garden, assembly rooms, and the Rotunda, a concert and meeting hall, the profits from which were used to help support his hospital. Part of the assembly rooms served as the historic Gate Theater, and another part as a dance hall. The hospital is still devoted to obstetrics.

Behind the hospital Gardiner placed Rutland (now Parnell) Square in 1750. Many of the original Georgian houses are still intact. One, built for the Earl of Charlemont in 1762, now houses the Municipal Gallery of Modern Art. The same developer built nearby Mountjoy Square and the surrounding elegant streets, most of which have fallen into decay. On Marlborough Street, east of O'Connell, the Roman Catholic Pro-Cathedral was built

The Four Courts on the River Liffey, Dublin, completed in 1802.

J. Allan Cash

in 1816. The Ascendancy would not allow it to be built on the main thoroughfare. The Wide Street Commissioners, in addition to their other creations, circumscribed the whole of the new city with the North and South Circular roads. Describing the part of the North Circular Road he inhabited in the 1920s, the playwright Sean O'Casey called the houses "a long, lurching row of discontented incurables." Close to the South Circular Road, on Synge Street, is the birthplace of the dramatist George Bernard Shaw. North of these peripheral streets, the Grand Canal was constructed in 1756, and south of them, the Royal Canal, in 1789. Their banks were planted with elms, not for the arboreal pleasure that still endures, but to assure the supply of wooden water mains. Both came into the Liffey at the harbour entrance, and both connect with the Shannon River, though only the seldom-used Grand is navigable today. The Grand Canal superseded a 13th-century weir near the Dublin Mountains as the city's source of drinking water and is still used by industry. In 1868 a 22-mile-long aqueduct from the Wicklow Hills was opened, and this now brings in soft, filtered, fluoridated drinking water.

In Phoenix Park Dublin has one of the world's great city parks, covering nearly three square miles (7.5 square kilometres) on the north bank of the Liffey. Initially a royal deer park, it was laid out in the middle of the 18th century, and remains little changed today. Its zoo, celebrated for big-cat breeding (known locally as Ireland's lion industry), was founded in 1830.

Phoenix Park contains one of Dublin's three racecourses. There is also a greyhound track at the opposite end of town, at Harold's Cross and Ringsend. Fourteen golf courses are dotted around the city. The sacred turf of the traditional Gaelic games, hurling and Irish football, is Croke Park, on the north bank of the Royal Canal. The whole of the bay front is an aquatic playground, while there are a dozen or more other spots officially designated as bathing places. Possibly the best known is five miles from the centre of town, at Sandymount. Above the rocks at Sandymount is the Martello Tower, celebrated in the opening pages of James Joyce's *Ulysses*. It is now a Joyce museum.

South along the coast from Sandymount are Dalkey, Bray, and Greystones—the latter, 16 miles from the city centre, marking the outer limits of the Dublin suburbs. The first seven miles to Dun Laoghaire, where the ferries from Britain land, are heavily built upon, but beyond are stretches of wild hillside and seafront. These shores harbour considerable numbers of retired folk, many of them English, many of them Protestant. They combine with a crescent of suburbs and former suburbs around the southern rim of Dublin—among them Terenure, Rathgar, Rathfarnham, and Ballybride—to complete Dublin's "Protestant belt." The Dublin area contains half of the Presbyterian clergy in the republic, and most of the com-

Outlying  
improvements

Suburbs

municants of the (Protestant) Church of Ireland. Protestants prosper in Dublin, as in the country generally, and include a notably high proportion of business executives and professional men.

The suburb of Ballsbridge, in addition to becoming the legation quarter of Dublin, also houses the new steel-and-glass quarters of some government agencies. After the establishment of the Free State in 1922, the Royal Dublin Society, vacating Leinster House, moved there with large grounds for its horse, dog, and livestock shows. The Royal Dublin Society was founded in 1731 by progressive landlords to improve Irish agriculture and general culture. The National Library, Museum, and College of Art are outgrowths of the Society's activities.

Across the street is the home of the Irish Sweepstakes, established in 1930. Its profits, which contribute a considerable part of the amount spent on medical facilities in the nation, have aided in the construction of more than 400 hospitals and dispensaries.

**Administration.** Dublin is a county borough, and its administrative history goes back to the first charter granted by Henry II of England in 1172. The subsequent turbulent fortunes of the city are mirrored by the numerous later charters—over 100 in all—preserved in the city archives. For parliamentary purposes, Dublin sends 26 members (from six constituencies) to the Dáil Éireann, and is itself governed by an elected corporation and a salaried manager. The functions of the lord mayor, who serves a one-year term, are now largely ceremonial, a marked departure from the situation in earlier centuries. The corporation has the power to impose rates, raise loans, and make bylaws. The city manager, on the other hand, has control of the municipal officers. Political relations between the city and the national authorities became strained during the 1960s and early 1970s, and the urban government was suspended on one occasion.

**BIBLIOGRAPHY.** The best introduction to Dublin is V.S. PRITCHETT, *Dublin: A Portrait* (1967), a study that seizes the essential character and brings out the flavour of the city; briefer and more general approaches, depending largely on illustrations, are J.H. HARVEY, *Dublin* (1949, reprinted 1977); and DESMOND GUINNESS, *Portrait of Dublin* (1967); while *Dublin Phoenix* by OLIVIA ROBERTSON (1957), is an account illustrated by the author. For the history of the city, see D.A. CHART, *The Story of Dublin*, rev. ed. (1932). For special periods, the following should be consulted: G.A. LITTLE, *Dublin Before the Vikings* (1957); CHARLESHALIDAY, *The Scandinavian Kingdom of Dublin*, 2nd ed. (1884, reprinted 1969), a basic work illustrated by plates, facsimiles, maps (some coloured), and plans; J.P. MAHAFFY, *An Epoch in Irish History* (1903, reprinted 1970), concerned with the foundation and early fortunes of Trinity College, Dublin, during the years 1591–1660; MAURICE CRAIG, *Dublin 1660–1860: A Social and Architectural History*, new ed. (1960); C.E. MAXWELL, *Dublin Under the Georges: 1714–1830*, rev. ed. (1956); J.J. ## Du Bois, W.E.B.

W.E.B. Du Bois, America's first black sociologist, was also its most important Negro protest leader in the first half of the 20th century. In the early years of the century he was the most influential critic of Booker T. Washington's philosophy of accommodation to white supremacy. As a founder of the Niagara Movement (1905), an organization of black intellectuals agitating for civil rights, and

Du Bois.

of the interracial National Association for the Advancement of Colored People (NAACP; 1909), Du Bois played a crucial role in developing the strategy and program that dominated black protest until the rise of the direct-action movement in the 1950s and 1960s. He was also a seminal influence in the Pan-African movement, which attempted to unite blacks all over the world in their struggle for freedom.

William Edward Burghardt Du Bois was born in Great Barrington, Massachusetts, on February 23, 1868. He graduated from Fisk University, a black institution, in 1888 and received a Ph.D. from Harvard University in 1895. His doctoral dissertation, *The Suppression of the African Slave-Trade to the United States of America, 1638–1870*, was published in 1896. Although Du Bois earned an advanced degree in history, he was broadly trained in the social sciences; and at a time when sociologists were theorizing about race relations, he was conducting empirical inquiries of the conditions of blacks. For more than a decade he devoted himself to sociological investigations of blacks in the United States, producing no fewer than 16 research monographs published between 1897 and 1914 at Atlanta University, where he was a professor, as well as *The Philadelphia Negro: A Social Study* (1899), the first case study of a black community in the United States. Although originally he had believed that social science could provide the knowledge to solve the race problem, he gradually came to the conclusion that in a climate of virulent racism, expressed in such evils as lynching, peonage, disfranchisement, Jim Crow segregation laws, and race riots, social change could be accomplished only through agitation and protest. In this view, he clashed with the most influential black leader of the period, Booker T. Washington, who, preaching a philosophy of accommodation, urged Negroes to accept discrimination for the time being and elevate themselves through hard work and economic gain, thus winning the respect of whites. In 1903, in his famous book *The Souls of Black Folk*, Du Bois charged that Washington's strategy, rather than freeing blacks from oppression, would serve only to perpetuate it. This attack crystallized the opposition to Booker T. Washington among many Negro intellectuals, polarizing the leaders of the black community into two wings—the "conservative" supporters of Washington and his "radical" critics.

Two years later, in 1905, Du Bois took the lead in founding the Niagara Movement, which was dedicated chiefly to attacking the platform of Booker T. Washington. The small organization, which met annually until 1909, was seriously weakened by internal squabbles and Washington's opposition. But it was significant as an ideological forerunner and direct inspiration for the interracial NAACP founded in 1909. Du Bois played a prominent part in the creation of the NAACP and became the association's director of research and editor of its *Crisis* magazine. In this role he wielded an unequalled influence

Dispute  
with  
Booker T.  
Washington

among middle class blacks and progressive whites as the propagandist for the Negro protest from 1910 until 1934.

Both in the Niagara Movement and in the NAACP Du Bois acted mainly as an integrationist, but his thinking always exhibited, to varying degrees, separatist-nationalist tendencies. In *The Souls of Black Folk* he had expressed the characteristic dualism of black Americans:

One ever feels his twoness—an American, a Negro; two souls, two thoughts, two unreconciled strivings; two warring ideals in one dark body, whose dogged strength alone keeps it from being torn asunder. . . . He simply wishes to make it possible for a man to be both a Negro and an American, without being cursed and spit upon by his fellows, without having the doors of Opportunity closed roughly in his face.

Du Bois's black nationalism took several forms—the most influential being his pioneering advocacy of Pan-Africanism, the belief that all people of African descent had common interests and should work together in the struggle for their freedom. Du Bois was a leader of the first Pan-African Conference in London in 1900 and the architect of four Pan-African congresses held between 1919 and 1927. Secondly, he articulated a cultural nationalism. As editor of the *Crisis* he encouraged the development of black literature and art and urged his readers to see "Beauty in Black." Thirdly, Du Bois's black nationalism is seen in his belief that Negroes should develop a separate "group economy" of producers-and-consumers cooperatives as a weapon for fighting economic discrimination and black poverty. This doctrine became especially important during the economic catastrophe of the 1930s and precipitated an ideological struggle within the NAACP.

He resigned from the NAACP in 1934, charging that the organization was dedicated to the interests of the black bourgeoisie and ignored the problems of the masses. Du Bois's interest in cooperatives was not only part of his nationalism but it also developed out of his Marxist leanings. At the turn of the century, he had been an advocate of black capitalism and Negro support of Negro business, but by about 1905 he had been drawn toward Socialist doctrines. Although he joined the Socialist Party only briefly in 1912, he remained sympathetic with Marxist ideas throughout the rest of his life.

Upon leaving the NAACP he returned to Atlanta University, where he devoted the next ten years to teaching and scholarship. In 1940 he founded the magazine, *Phylon*, Atlanta University's "Review of Race and Culture." In 1945 he published the "Preparatory Volume" of a projected encyclopaedia of the Negro, for which he had been appointed editor in chief. He also produced two major books during this period. *Black Reconstruction: An Essay toward a History of the Part Which Black Folk Played in the Attempt to Reconstruct Democracy in America, 1860–1880* (1935) was an important Marxist interpretation of the Reconstruction era (the period following the Civil War during which the seceded Southern states were reorganized according to the wishes of Congress), and more significantly, it provided the first synthesis of existing knowledge on the role of black men in that critical period of American history. In 1940 appeared *Dusk of Dawn*, subtitled *An Essay Toward an Autobiography of a Race Concept*. In this brilliant book, Du Bois explained his role in both the African and Afro-American struggles for freedom, viewing his career as an ideological case study illuminating the varied and complex facets of the black-white conflict.

After giving up the editorship of the *Crisis* in 1934, Du Bois's influence as a race leader ended. Following a fruitful decade of teaching and publication at Atlanta University, he returned once more to a research position at the NAACP (1944–48). This brief connection ended in a second bitter quarrel, and thereafter Du Bois moved steadily leftward politically in his sympathies and writings. Identified with pro-Russian causes, he was indicted in 1951 as an unregistered agent for a foreign power. Although a federal judge directed his acquittal, Du Bois had become more disillusioned than ever about the United States. In 1961 he joined the Communist Party and, mov-

ing to Ghana, renounced his American citizenship over a year later. On August 27, 1963, at the age of 95, he died in Accra, Ghana.

**BIBLIOGRAPHY.** There are two major biographies of Du Bois: FRANCIS L. BRODERICK, *W.E.B. Du Bois: Negro Leader in a Time of Crisis* (1959); and ELLIOTT M. RUDWICK, *W.E.B. Du Bois: Propagandist of the Negro Protest*, 2nd ed. (1968). See also *Dusk of Dawn* (1940), and *Autobiography of W.E.B. Du Bois* (1968), two autobiographical works; MEYER WEINBERG (ed.), *W.E.B. Du Bois: A Reader* (1970); and PHILIP S. FONER (ed.), *W.E.B. Du Bois Speaks* (1970), two anthologies of selected writings. Other relevant books are: AUGUST MEIER, *Negro Thought in America, 1880–1915* (1963); and CHARLES F. KELLOGG, *NAACP: A History of the National Association for the Advancement of Colored People, vol. 1, 1909–1920* (1967).

## Duccio di Buoninsegna

In the work of Duccio di Buoninsegna, one of the greatest Italian painters of the Middle Ages and the founder of the Sienese school, the formality of the ancient Byzantine tradition, strengthened by a clearer understanding of its evolution from classical roots, is fused with the new spirituality of the Gothic style, introducing a model blend of East and West. Although his formal style was quickly superseded by the radical innovations of Giotto, who was slightly younger than he, Duccio exerted immense influence on the painters of his own time and of the succeeding generations. The intimate, lyrical quality of his creations infused with soft religious fervour, his rich yet very delicate colours, and the exquisite musical quality of his lines are some of the elements that served to distinguish Sienese painting from Florentine and to establish Siena as one of the particularly important 14th-century schools of art not only in Italy but throughout all of Europe.

**Beginnings.** Documented information about Duccio's life and career is somewhat scarce. In large part his life must be reconstructed from the evidence of those works that can be attributed to him with certainty, from the evi-

dence contained in his stylistic development, and from the learning his paintings reveal. Duccio was born in Siena a little after the middle of the 13th century. His father was from the town of Buoninsegna, near Siena, but at the time of Duccio's birth he lived in the town of Camporegio. He is first mentioned in 1278, when the treasurer of the commune of Siena commissioned him to decorate 12 strongboxes for documents. The following year he was given the task of decorating one of the wooden covers of the account books of the treasury. That Duccio was doing work more appropriate for an artisan than an artist must not lead one to assume that even at this time he was only a beginner. It is known that services of this type were requested, both in Siena and in Florence, of already established painters. Further, the fact that he was designated as "painter" and was working for himself demonstrate that he was a mature and independent artist by 1278. In 1280 Duccio was fined the large sum of 100 lire by the commune of Siena for some unrecorded misconduct. This was the first of a considerable number of fines that the artist incurred at various times and for various reasons, and they suggest that he was of a restless and rebellious temperament. He was fined more than once for nonpayment of debts; in 1295 he was penalized for refusing to pledge allegiance to the head of the *popolo* party; in 1302 for not appearing for military duty; and in the same year for what appears to have been practicing sorcery.

**The "Madonna Rucellai."** On April 15, 1285, the Compagnia dei Laudesi, or singers of praise, of the Virgin Mary at the church of Sta. Maria Novella in Florence, commissioned "Duccio di Buoninsegna, painter of Siena" to paint a great altarpiece that was to represent the Madonna and Child together with other figures. For the work he was to be paid 150 florins, but if the painting, which had to be "a most beautiful picture" and had to have a gold border, was not satisfactory, the artist would receive no reimbursement. Despite the fact that this employment contract, preserved in the State Archives of Florence, came to light in 1790 and was published in 1854, it was only in 1930 that it was indisputably determined that the document referred to the Madonna of Sta. Maria Novella, now called the "Madonna Rucellai." From the time of Giorgio Vasari, a minor Florentine Renaissance painter who was the earliest, and probably the most influential, biographer of early Italian artists, this altarpiece, which was the largest yet painted, was considered to be a masterpiece of the Florentine painter Cimabue. Vasari's attribution, whereas it was probably due in part to a desire not to deprive the Florentine school and its founder of credit for so brilliant a work, was accepted almost unanimously until the present century because of strong similarities to the work of Cimabue in the "Madonna Rucellai." Some recent critics, no longer able to deny that the work is by Duccio, have concluded that he was a pupil, and in all essentials of his art even an imitator, of Cimabue.

Influence  
of  
Cimabue  
on Duccio

The problem of the relative influence of Cimabue upon Duccio is critically very complex. The "Madonna Rucellai" shows affinities with the work of Cimabue in the type of the Virgin, in the serious and robust Child, and in the faces of the six adoring angels; nevertheless, it reveals strikingly new stylistic innovations in the softness of the angels set in midair, in the elegant and subtle lines, in the first feeling of French Gothic animated sweetness and spirituality, and in the light and shade modulation of the free-flowing, clear brush strokes.

There is no doubt that his knowledge of Cimabue's work was one of the components of Duccio's style at this time, but it was not the predominant, nor even the earliest influence; very probably Cimabue's influence was a late insertion into a personal style that had already evolved within the framework of the well-developed Siennese tradition. In the years between 1260 and 1280, largely due to the inspiration of its magnificent cathedral, Siena had emerged as one of the most vital centres of art in Italy. A remarkable succession of altarpieces by Siennese painters testifies to the simultaneous work of a number of artists, some of whom possessed quite distinct personalities.

The variety of orientations of these painters shows that they did not work in conditions of provincial isolation but were sensitive to the diverse influences of the age, including Cimabue.

Duccio certainly studied these painters and was influenced by them. Notably evident in his style are the influence of the older painter, Guido da Siena, with the serene dignity of his figures, permeated by lyrical tenderness and grace, in the now-fading stylized postures of the Byzantine tradition, and of the master of the "St. John the Baptist Altarpiece" in the Pinacoteca Nazionale of Siena, with his complex Byzantine iconography and his vivid, dense colouring. Duccio was able to draw from sources outside Siena as well: from the combination of linear stylization and Hellenistic types that characterized the illustrations of books imported from Constantinople and also from contemporary French Gothic miniatures, with their lively tone and lyrical, animated stylizations of clothing and gesture. Duccio may also have travelled to Florence in his early years, coming into contact with Cimabue, but such an explanation is not entirely necessary to account for the formation of his style. In fact, in Duccio's only certain work prior to the "Madonna Rucellai," echoes of Cimabue are even less apparent than in the Rucellai altarpiece. The conclusion that Duccio was nothing more than a follower of Cimabue at the time he painted the "Madonna Rucellai" is implausible and overlooks the originality, as well as the excellence, of the work. If, in fact, he was in 1285 entrusted with a work of such significance at Florence, his reputation must have already been established and have spread beyond the confines of his native Siena.

**Later commissions.** Traces of Duccio's association with Cimabue remain in the large round stained-glass window of the choir of the Siena Cathedral, for which Duccio made the designs. This work was commissioned between 1287 and 1288 and is the earliest known example of stained glass produced by an Italian.

Numerous documents attest to Duccio's action in Siena during the 20 years following the creation of the "Madonna Rucellai." He was by now the leading painter of the city and as such executed in 1302 an altarpiece, now lost, for the altar of the chapel of the Palazzo Pubblico, the city hall. During this period, some unsigned and undocumented altarpieces appeared, and some of these are certainly Duccio's work; the most significant of these is a small altarpiece representing the Virgin enthroned with angels and called "The Madonna of the Franciscans" because of the three monks kneeling at the foot of the throne. In this work a developed Gothic style appears in the curving outlines, which give an exquisite decorative effect.

**The "Maestl."** But the work in which the genius of Duccio unfolds in all its brilliant fullness and the one to which the painter owes his greatest fame is the "Maestà," the altarpiece for the main altar of the Cathedral of Siena. He was commissioned to do this work on October 9, 1308, for a payment of 3,000 gold florins, the highest figure paid to an artist up to that time. On June 9, 1311, the whole populace of Siena, headed by the clergy and civil administration of the city, gathered at the artist's workshop to receive the finished masterpiece. They carried it in solemn procession to the accompaniment of drums and trumpets to the cathedral. For three days alms were distributed to the poor and great feasts were held. Never before had the birth of a work of art been greeted with such public jubilation and never before had there been such immediate awareness that a work was truly a masterpiece and not just a reflection of the religious fervour of the people. Duccio himself was aware of the work's significance; he signed the throne of the Virgin with an invocation that was devout yet proud for the time: "Holy Mother of God, grant peace to Siena, and life to Duccio because he has painted you thus."

The "Maestà" is in the form of a large horizontal rectangle, surmounted by pinnacles, and with a narrow horizontal panel, or predella, as its base. It is painted on both sides. The entire central rectangle of the front side is a single scene showing the Madonna and Child en-

Other  
stylistic  
influences

Form  
of the  
"Maestà"

throned in the middle of a heavenly court of saints and angels with the four patron saints of Siena kneeling at their feet. The back is subdivided into 26 compartments that illustrate the Passion of Christ. The front and back of the predella contain scenes of the infancy and the ministry of Jesus, and the pinnacles, crowning the entire work, represent events after the Resurrection. In all, there are 59 narrative scenes.

The rigorous symmetry with which the groups of adoring figures at the sides of the Virgin are arranged in the imposing scene of the central panel is inspired by compositions of the Byzantine tradition and gives evidence of Duccio's keen architectural sensibility by its power to draw attention to the "Maestà" as the true focal point of the cathedral's spatial and structural organization. Like elements of a living architecture, the 30 figures, through the slightest of gestures and turnings of the head, are intimately related, their positions repeated to give a feeling of intense lyrical contemplation. The consonance of feeling that arises from this contemplation gives the facial features of each a distinct, spiritual beauty, reminiscent, especially the faces of the angels, of the more idealistic creations of Hellenistic art. The Madonna, slightly larger than the other figures, seated on a magnificent and massive throne of polychrome marbles, inclines her head gently as if trying to hear the prayer of the faithful. Duccio thus succeeds in reconciling perfectly the Byzantine ideal of power and dignity with the underlying tenderness and mysticism of the Sienese spirit. The scenes in the predella, pinnacles, and back are filled with the Byzantine iconographic schemes from which Duccio finds it difficult to detach himself, and they are developed with a deeper concern for their narrative significance. The scenes are not, however, merely descriptions or chronicles. They include many touches from daily life, which provide a lyrical synthesis that harmonizes the character and gestures of the figures with their landscape and architectural surroundings.

**Last years.** Only scanty bits of information are available about the few years that Duccio lived after the completion of the "Maestà." He had a prosperous workshop from which other works emerged, but they seem to have been executed in great part by students. His financial condition must have been quite sound because by 1304 he bought a vineyard in the neighbourhood of Siena. Nevertheless, in 1313 he was once again deep in debt. He died either at the end of 1318 or in the first half of 1319, survived by his wife Taviana and seven children. At least two of his children, Galgano and Giorgio, were painters, but nothing is known about their work or their merits. The identity of one of his direct followers is known, his nephew Segna di Buonaventura.

#### MAJOR WORKS

"Madonna Rucellai" (1285; Uffizi, Florence); "Triptych: The Virgin and Child with Saints" (c. 1300; National Gallery, London); "Madonna with Child and Angels" (c. 1300; Galleria Nazionale dell'Umbria, Perugia); "Maestà," altarpiece (1302; Palazzo Pubblico, Siena; now lost); "Maesti," altarpiece (1308–11; Museo dell'Opera del Duomo, Siena; panels from this altarpiece can be seen in the National Gallery, London; the Frick Collection, New York; and the National Gallery of Art, Washington, D.C.); "Madonna and Child of St. Cecilia a Crevole" (undated; Museo dell'Opera del Duomo, Siena); "Madonna Enthroned with Angels" (undated; Kunstmuseum, Bern); "The Madonna of the Franciscans" (undated; Pinacoteca Nazionale, Siena); "Madonna and Child" (undated; Stoclet Collection, Brussels); "St. Paul" (undated; Christian Museum [Keresztény Múzeum], Esztergom, Hungary); "The Annunciation" (undated; National Gallery, London); "Nativity with the Prophets Isaiah and Ezekiel" (undated; National Gallery of Art, Washington, D.C.); "The Presentation in the Temple" (undated; Museo dell'Opera del Duomo, Siena); "The Marriage at Cana" (undated; Museo dell'Opera del Duomo, Siena).

**BIBLIOGRAPHY.** C.H. WEIGELT, *Duccio di Buoninsegna* (1911), the first and the longest monograph on the artist (in German), prepared with great scientific exactitude, although some of the conclusions have been modified or superseded by succeeding studies; R.S. VAN MARLE, *The Development of the Italian Schools of Painting*, vol. 2 (1924), the chapter on Duccio constitutes the fullest treatment of the artist pub-

lished in English, although it does not present any original ideas (also important for its treatment of the school of Duccio); E. CECCHI, *Trecentisti senesi* (1928), contains some very fine pages on Duccio written by an author who was an excellent art critic; P. BACCI, *Documenti e commenti per la storia dell'arte*, pp. 1–47 (1944), a chapter dedicated to the research in the archives on Duccio and his family; E. CARLI, *Vetrata duccesca* (1946), a study of the great stained-glass window in the choir of the Siena Cathedral, establishing the time it was executed and revealing the authorship of Duccio; *Duccio di Buoninsegna* (1961), a wise interpretation, in Italian, of the work of Duccio, including the entire corpus of his established works reproduced in colour; C. BRANDI, *Duccio* (1951), a thoroughly researched, critical study (in Italian) of the works of Duccio in the light of modern aesthetic theories, with an appendix containing accurate biographical data, chronological lists of documents, and philological notes; G. VIGNI, "Duccio di Buoninsegna," in the *Encyclopedia of World Art*, vol. 4, col. 503–509 (1961), an accurate and acute biographical and critical synthesis founded on the most recent research

(E.Ca.)

## Duchamp, Marcel

As artist and anti-artist, Marcel Duchamp is considered one of the leading spirits of 20th-century painting. With the exception of the "Nude Descending a Staircase, No. 2," however, a painting that created a sensation in New York in 1913, his works were ignored by the public for the greater part of his life. Until 1960 only such avant-garde groups as the Surrealists claimed that he was important, while to "official" art circles and sophisticated critics he appeared to be merely an eccentric and something of a failure. He was well over 70 when he emerged in the United States as the secret master whose entirely new attitude toward art and society, far from being negative or nihilistic, had led the way to "Pop art," "Op art," and many of the other movements embraced by younger artists everywhere. Not only did he change the visual arts but he also changed the mind of the artist.

**Early years.** Marcel Duchamp was born at Blainville in Normandy, France, on July 28, 1887. Although his father was a notary, the family had an artistic tradition stemming from his grandfather, a shipping agent who practiced engraving seriously. Four of the six Duchamp children became artists. Gaston, born in 1875, was later known as Jacques Villon, and Raymond, born in 1876, called himself Duchamp-Villon. Marcel, the youngest of the boys, and his sister Suzanne (born in 1889) both kept the name Duchamp as artists.

**Journey through styles.** When Marcel arrived in Paris in October 1904, his two elder brothers were already in a position to help him. He had done some painting at home, and his "Portrait of Marcel Lefrançois" shows him already in possession of a style and of a technique. During the next few years, while drawing cartoons for comic magazines, Duchamp passed rapidly through the main contemporary trends in painting—Postimpressionism, the influence of Paul Cézanne, Fauvism, and finally Cubism. He was merely experimenting, seeing no virtue in making a habit of any one style. He was outside artistic tradition not only in shunning repetition but also in not attempting a prolific output or frequent exhibition of his work. In the Fauvist style Marcel painted some of his best early work three or four years after the Fauvist movement itself had died away. The "Portrait of the Artist's Father" is a notable example. Only in 1911 did he begin to paint in a manner that showed a trace of Cubism. He had then become a friend of the poet Guillaume Apollinaire, a strong supporter of Cubism and of everything avant-garde in the arts. Another of his close friends was Francis Picabia, himself a painter in the most orthodox style of Impressionism until 1909, when he felt the need of complete change. Duchamp shared with him the feeling that Cubism was too systematic, too static and "boring." They both passed directly from "semirealism" to a "nonobjective" expression of movement. There they met "Futurism" and "Abstractionism," which before they had known only by name.

**The "Nude."** To an exhibition in 1911, Duchamp sent a "Portrait" that comprised a series of five almost mono-

chromatic, superimposed silhouettes. In this juxtaposition of successive phases of the movement of a single body appears the idea for the "Nude Descending a Staircase, No. 2." The main difference between the two works is that in the earlier one the kangaroo-like silhouettes can be distinguished. In the "Nude," on the other hand, there is no nude at all but only a descending machine, a non-objective and virtually cinematic effect that was entirely new in painting.

When the "Nude" was brought to the 28th Salon des Indépendants in February 1912, the committee, composed of friends of the Duchamp family, refused to hang the painting. These men were not reactionaries and were well accustomed to Cubism, yet they were unable to accept the novel vision. A year later at the Armory Show in New York, the painting again was singled out from among hundreds that were equally shocking to the public. Whatever it was that made the work so scandalous in Paris, and in New York so tremendous a success, prompted Duchamp to stop painting at the age of 25. A widely held belief is that Duchamp introduced in his work a dimension of irony, almost a mockery of painting itself, that was more than anyone could bear and that undermined his own belief in painting. The title alone was a joke that was resented. Even the Cubists did their best to flatter the eye, but Duchamp's only motive seemed to be provocation.

**Farewell to art.** In 1912, after the "Nude," Duchamp did a few more paintings. Some of these, notably "Le Passage de la Vierge à la Mariée" and "Mariée" (Philadelphia Museum of Art), both done in Munich, are among the finest works of the period. Again they were neither Cubist, nor Futurist, nor Abstract, but they expressed Duchamp's typical vision of the body perceived in its inmost impulses.

**New values.** There was no question that as a painter Duchamp was on a footing with the most gifted. What he lacked was faith in art itself, and he sought to replace aesthetic values in his new world with an aggressive intellectualism opposed to the so-called common-sense world. As early as 1913 he began studies for an utterly awkward piece. "The Large Glass, or The Bride Stripped Bare by Her Bachelors, Even." For it, he repudiated entirely what he called retinal art and adopted the geometrical

methods of industrial design. It became like the blueprint of a machine, albeit a symbolic one, that embodied his ideas of man, woman, and love.

Like the "Nude," "The Large Glass" was to be unique among works of modern painting. Between 1913 and 1923, Duchamp worked almost exclusively on the preliminary studies and the actual painting of the picture itself. His farewell to painting was by no means a farewell to work.

During this period a stroke of genius led him to a discovery of great importance in contemporary art, the so-called ready-made. In 1913 he produced the "Bicycle Wheel," which was simply an ordinary bicycle wheel. In 1914, "Pharmacy" consisted of a commercial print of a winter landscape, to which he added two small figures reminiscent of pharmacists' bottles. It was nearly 40 years before the ready-mades were seen as more than a derisive gesture against the excessive importance attached to works of art, before their positive values were understood. With the ready-mades, contemporary art became in itself a mixture of creation and criticism.

**Conquest of America.** When World War I broke out, Duchamp, who was exempt from military service, was living and working in almost complete isolation. He left France for the United States, where he had made friends through the Armory Show. When he landed in New York in June 1915, he was welcomed by reporters as a famous man. His warm reception in intellectual circles as well raised his spirits. The wealthy poet and collector Walter Arensberg arranged a studio for him in his own home, where the painter immediately set to work on "The Large Glass." He became the centre of the Arensberg group, enjoying a reputation that led to many offers from art galleries eager to handle the works of the painter of the "Nude." He refused them all, however, not wanting to start a full-time career as a painter. To support himself, he gave French lessons. He was then, and remained, an artist whose works would have been sought after but who was content to distribute them free among his friends or to sell them for intentionally small amounts. He helped Arensberg buy back as many of his works as could be found, including the "Nude." They became a feature of the Arensberg Collection, which was left to the Philadelphia Museum of Art.

Critical  
reaction  
to the  
"Nude"

The  
ready-  
made  
revolution

**Alliance with Dadaism.** Besides "The Large Glass," on which he worked for eight more years until abandoning it in 1923, Duchamp did only a few more ready-mades. One, a urinal entitled "Fountain," he sent to the first exhibition of the Society of Independent Artists, in 1917. Although he was a founder-member of this society, he had signed the work "R. Mutt," and therefore it was refused. His ready-mades had anticipated by a few years the Dada movement, which Picabia introduced to New York in the magazine 291 (1917). As an echo of the movement, Duchamp helped Arensberg and H.P. Roché to publish *The Blind Man*, which had only two issues, and *Rongwrong*, which had only one. Later, with the painter Man Ray, he published a single issue of *New York Dada* in 1921.

In 1918 he sold "The Large Glass," which was still very much unfinished, to Walter Arensberg. With the money from this and another painting, his last, he spent nine months in Buenos Aires, where he heard of the armistice and of the deaths of his brother Raymond Duchamp-Villon and of Guillaume Apollinaire. In Paris in 1919, he stayed with Picabia and established contact with the first Dada group. This was the occasion of his most famous ready-made, a photograph of the "Mona Lisa" with a moustache and a goatee added. The act expressed the Dadaists' scorn for the art of the past, which in their eyes was part of the infamy of a civilization that had produced the horrors of the war just ended.

In February 1923, Duchamp stopped working on "The Large Glass," considering it definitely and permanently unfinished. As the years passed, art activity of any kind interested him less and less, but the cinema came to fulfill his pleasure in movement. His works to this point had been only potential machines, and it was time for him to create machines that were real, that worked and moved. The first ones were devoted to optics and led to a short film, *Anemic Cinema* (1926). With these and other products, including "optical phonograph records," he acted as a kind of amateur engineer. The modesty of his results, however, was a way by which he could ridicule the ambitions of industry. The rest of the time he was absorbed in chess playing, even taking part in international tournaments and publishing a treatise on the subject in 1932.

**To Surrealism.** Although Duchamp carefully avoided art circles, he remained in contact with the Surrealist group in Paris, composed of many of his former Dadaist friends. When in 1934 he published the *Green Box*, containing a series of documents related to "The Large Glass," the Surrealist poet André Breton perceived the importance of the painting and wrote the first comprehensive study of Duchamp, which appeared in the Paris magazine *Minotaure* in 1935. From that time on there was a closer association between the Surrealists and Duchamp, who helped Breton to organize all the Surrealist exhibitions from 1938 to 1959. Just before World War II he assembled his *Boite-en-valise*, a suitcase containing 68 small-scale reproductions of his works. When the Nazis occupied France, he smuggled his material across the border in the course of several trips. Eventually he carried it to New York, where he joined a number of the Surrealists in exile, including Breton, Max Ernst, and Yves Tanguy. He was instrumental in organizing the Surrealist exhibition in New York in October and November 1942.

Unlike his co-exiles, he felt at home in America, where he had many friends. During the war, the exhibition of "The Large Glass" at the Museum of Modern Art, New York, helped to revive his reputation, and a special issue of the art magazine *View* was devoted to him in 1945. Two years later he was back in Paris assisting Breton with the Surrealist exhibition, but he returned to New York promptly and spent most of the remainder of his life there, becoming a U.S. citizen in 1955. After his marriage to Teeny Sattler in 1954, he lived more than ever in semiretirement, content with chess and with producing, as the spirit moved him, some strange and unexpected object.

This contemplative life was interrupted around 1960, when the rising generation of American artists realized

that Duchamp had found answers for many of their problems. Suddenly tributes came to him from all over the world. Retrospective shows of his works were organized in America and Europe. Even more astonishing were the replicas of his ready-mades produced in limited editions with his permission, but the greatest surprise was still to come. After his death in Neuilly, near Paris, on October 2, 1968, his friends heard that he had worked secretly for his last 20 years on a major piece called "Étant donnés: 1. la chute d'eau, 2. le gaz d'éclairage" (Given: 1. the waterfall, 2. the illuminating gas"). At the Philadelphia Museum of Art, it offers through two small holes in a heavy wooden door a glimpse of Duchamp's enigma.

#### MAJOR WORKS

"Church at Blainville" (1902; Philadelphia Museum of Art); "Portrait of Marcel Lefrançois" (1904; Philadelphia Museum of Art); "Nude on Nude" (1909?; Arnold D. Fawcett Collection, Paris); "Portrait of the Artist's Father" (1910; Philadelphia Museum of Art); "Red Nude" (1910; Mary Sisler Collection, New York); "The Chess Players" (1910; Philadelphia Museum of Art); "Landscape" (1911; Museum of Modern Art, New York); "Sad Young Man in a Train" (1911; Peggy Guggenheim Collection, Venice); "Nude Descending a Staircase, No. 1" (1911; Philadelphia Museum of Art); "Portrait" (1911; Philadelphia Museum of Art); "Apropos of Little Sister" (1911; Solomon R. Guggenheim Museum, New York); "Nude Descending a Staircase, No. 2" (1912; Philadelphia Museum of Art); "Le Passage de la Vierge à la Mariée" (1912; Museum of Modern Art, New York); "The King and Queen Surrounded by Swift Nudes" (1912; Philadelphia Museum of Art); "Bride" (1912; Philadelphia Museum of Art); "Bicycle Wheel" (1913; replica, Museum of Modern Art, New York); "3 Standard Stoppages" (1913-14; Museum of Modern Art, New York); "Glider Containing a Water Mill in Neighbouring Metals" (1913-15; Philadelphia Museum of Art); "Bottle Dryer" (1914; replica, Moderna Museet, Stockholm); "Network of Stoppages" (1914; Museum of Modern Art, New York); "Nine Malic Moulds" (1914-15; Mrs. Marcel Duchamp Collection, New York); "In Advance of the Broken Arm" (1915; replica, Yale University Art Gallery); "With Hidden Noise" (1916; Philadelphia Museum of Art); "Nude Descending a Staircase, No. 3" (1916; Philadelphia Museum of Art); "Fountain" (1917; replica, Sidney Janis Collection, New York); "Tu m'..." (1918; Yale University Art Gallery); "Nude Descending a Staircase, No. 4" (1918; Museum of the City of New York); "To be Looked at (from the Other Side of the Glass) with One Eye, Close to, for Almost an Hour" (1918; Museum of Modern Art, New York); "L.H.O.O.Q." (1919; Mary Sisler Collection, New York); "Why Not Sneeze Rose Sélavy?" (1921; Philadelphia Museum of Art); "The Large Glass" (1915-23; Philadelphia Museum of Art); "The Brawl at Austerlitz" (1921; W.N. Copley Collection, New York); "Rotary Demi-Sphere" (1925; Museum of Modern Art, New York); "Discs Inscribed with Puns" (1926; W.N. Copley Collection, New York); *The Green Box* (1934); *Rotoreliefs* (1935); "Door for Gradiwa" (1937; replica, Dieter Keller Collection, Stuttgart, West Germany); *Boite-en-valise* (1938-42; Mary Sisler Collection, New York); "In the Manner of Delvaux" (1942; V. and A. Schwarz collection, Milan); "Pocket Chess Set" (1943; New York); "George Washington" (1943; André Breton Estate, Paris); "Given the Illuminating Gas and the Waterfall" (1948-49; Maria Martins Collection, Rio de Janeiro); "Female Fig Leaf" (1950; Mary Sisler Collection, New York); "Object-Dard" ("Dart-Object"; 1951; Mrs. Marcel Duchamp Collection, New York); "Wedge of Chastity" (1954; Mrs. Marcel Duchamp Collection, New York); "Self-Portrait in Profile" (1958; New York); "Cols alités" (1959; R. Lebel Collection, Paris); "With My Tongue in My Cheek" (1959; R. Lebel Collection, Paris); "Torture-morte" (1959; R. Lebel Collection, Paris); "Sculpture-morte" (1959; R. Lebel Collection, Paris); *Nine Etchings for the Large Glass and Related Works* by A. Schwarz (1967; A. Schwarz Collection, Milan); *Nine Etchings for the Large Glass and Related Works* by A. Schwarz (1968; A. Schwarz Collection, Milan); "Étant donnés: 1. la chute d'eau, 2. le gaz d'éclairage" (1946-66, assembled 1969; Philadelphia Museum of Art).

#### BIBLIOGRAPHY

**Monographs and catalogues raisonnés:** ROBERT LEBEL, *Marcel Duchamp* (1959, reprinted with an addenda to the catalogue raisonné and an updated bibliography, 1967), is the first major biography and critical study. The catalog includes a list of replicas, editions, working studies and documents, single copies or reconstructions, and variations on Duchamp's projects. ARTURO SCHWARZ (ed.), *The Complete*

The mus-  
tachoed  
"Mona  
Lisa"

*Works of Marcel Duchamp* (1969), is the most extensive catalogue raisonné and includes Duchamp's very last works.

*Studies:* GUILLAUME APOLLINAIRE, *Les Peintres cubistes* (1913; Eng. trans., *The Cubist Painters*, 2nd ed., 1949); CALVIN TOMKINS, *The World of Marcel Duchamp* (1966); PIERRE CABANNE, *Entretiens avec Marcel Duchamp* (1967); ARTURO SCHWARZ, *The Large Glass, and Related Works*, 2 vol. (1967–68); OCTAVIO PAZ, *Marcel Duchamp* (1968), in Spanish.

*Major exhibition catalogs:* *Marcel Duchamp, Pasadena Art Museum: A Retrospective Exhibition, October 8 Through November 3, 1963* (1963), the first major exhibition of Duchamp's works; *Not Seen and/or Less Seen of/by Marcel Duchamp/Rose Selavy, 1904–64, Mary Sisler Collection. Exhibition January 14–February 13, 1965* (1965); *The Almost Complete Works of Marcel Duchamp: Catalogue of an Exhibition at the Tate Gallery 18 June–31 July 1966* (1966); ROUEN, MUSEE DES BEAUX-ARTS, *Les Duchamps* (1967), and PARIS, MUSEE NATIONAL D'ART MODERNE, *Marcel Duchamp* (1967), the first comprehensive exhibition of Duchamp's works in France.

(R.Le.)

## Dulles, John Foster

John Foster Dulles, generally regarded as the most powerful and controversial secretary of state in the history of the United States, became one of the most redoubtable protagonists of the Cold War, the power struggle that arose between the United States and the Soviet Union after World War II. A deeply committed anti-Communist, Dulles, serving as the 53rd secretary of state under Pres. Dwight D. Eisenhower from January 1953 to April 1959, extended the anti-Communist alliance system begun in Europe with the North Atlantic Treaty Organization (NATO) by forming a series of regional pacts with pro-United States Asian governments.

photograph, Harris and Ewing

Dulles.

Dulles was born in Washington, D.C., on Feb. 25, 1888, one of five children of Allen Macy and Edith (Foster) Dulles. His maternal grandfather was John Watson Foster, who served as secretary of state under Pres. Benjamin Harrison. Robert Lansing, Dulles' uncle by marriage, was secretary of state in the cabinet of Pres. Woodrow Wilson.

Dulles was educated in the public schools of Watertown, N.Y., where his father served as a Presbyterian minister. A brilliant student, he attended Princeton and George Washington universities and the Sorbonne, and in 1911 entered the New York law firm of Sullivan and Cromwell, specializing in international law. By 1927, he was head of the firm.

But Dulles, who never lost sight of his goal of becoming secretary of state, actually started his diplomatic career in 1907 when, aged 19, he accompanied his grandfather John Foster, then a private citizen representing China, to the second international peace conference at The Hague. At 30, Dulles was named by Pres. Woodrow Wilson as legal counsel to the American delegation to the Ver-

sailles Peace Conference, at the end of World War I, and afterward he served as a member of the war reparations commission.

In World War II, Dulles helped prepare the United Nations charter at Dumbarton Oaks and in 1945 served as a senior adviser at the San Francisco United Nations conference. When it became apparent that a peace treaty with Japan acceptable to the United States could not be concluded with the participation of the Soviet Union, Pres. Harry Truman and his secretary of state, Dean Acheson, decided not to call a peace conference to negotiate the treaty. Instead, they assigned to Dulles the difficult task of personally negotiating and concluding the treaty. Dulles travelled to the capitals of many of the nations involved, and in 1951 the previously agreed to treaty was signed in San Francisco by Japan and 48 other nations.

Emboldened by his formidable achievements, Dulles viewed his appointment as secretary of state by President Eisenhower, in January 1953, as a mandate to originate foreign policy, which is normally regarded as the domain of the President. "The State Department," Dulles once told an aide, "can only keep control of foreign policy as long as we have ideas." A man bent on realizing his ideas, he was an assiduous planner; and once he enjoyed President Eisenhower's complete confidence, policy planning flourished during his administration.

Dulles, fully aware that NATO would be effective only for the defense of Western Europe, leaving the Near East, the Far East, and the Pacific islands unprotected, was eager to fill these gaps. He initiated the Manila conference in 1954, which resulted in the Southeast Asia Treaty Organization (SEATO) pact that united eight nations either located in Southeast Asia or with interests there in a neutral defense pact. This treaty was followed in 1955 by the Baghdad Pact, later renamed the Central Treaty Organization, uniting the so-called northern tier countries of the Middle East—Turkey, Iraq, Iran, and Pakistan—in a defense organization.

In Europe, Dulles was instrumental in putting into final form the Austrian State Treaty (1955), restoring Austria's pre-1938 frontiers and forbidding a future union between Germany and Austria, and the Trieste agreement (1954), providing for partition of the free territory between Italy and Yugoslavia.

Three factors determined Dulles' foreign policy: his profound detestation of Communism, which was in part based on his deep religious faith; his powerful personality, which often insisted on leading rather than following public opinion; and his strong belief, as an international lawyer, in the value of treaties. Of these three, passionate hostility to Communism was the leitmotif of his policy. Wherever he went, he carried with him Joseph Stalin's *Problems of Leninism* and impressed upon his aides the need to study it as a blueprint for conquest similar to Adolf Hitler's *Mein Kampf*. He seemed to derive personal satisfaction from pushing the U.S.S.R. to the brink. In fact, in 1956 he wrote in a magazine article that, "if you are scared to go to the brink, you are lost." Once, during the Austrian State Treaty negotiations, he refused to compromise on some minor points, even though the Austrians themselves pleaded with him to do so for fear the U.S.S.R. would walk out. Dulles stood his ground, and the U.S.S.R. yielded.

But Dulles could be equally intransigent with the allies of the United States. His insistence upon the establishment of the European Defense Community (EDC) threatened to polarize the free world, when in 1953 he announced that failure to ratify EDC by France would result in an "agonizing reappraisal" of the United States' relations with France. That expression, and Dulles' announcement in a Paris speech that the United States would react with "massive nuclear retaliation" to any Soviet aggression, found a permanent place in the vocabulary of American foreign policy. It can also be argued that Dulles' brusque rejection in July 1956 of Pres. Gamal Abdel Nasser's request for aid in building Egypt's Aswān Dam was the beginning of the end of the influence that the United States had exerted in the Mid-

Secretary  
of state

Policy of  
brink-  
manship

dle East. In a complete reversal of his former pro-Egyptian policy, Dulles claimed that the president of Egypt was "nothing but a tin-horn Hitler." Although Dulles later conceded that his refusal could have been more subtle, he never wavered in his belief that Nasser, who had already purchased arms from the Soviet bloc, was bound to turn decisively against the United States because he felt that he had the Soviet Union on his side.

Dulles' detractors in the United States and abroad viewed him as harsh, inflexible, and a tactician, rather than an architect of international diplomacy. But President Eisenhower ignored all criticisms. He said of his secretary of state, "He is one of the truly great men of our time." Whatever their opinion of the man and his policies, many leading statesmen of the non-Communist nations credited his firmness with having checkmated Communist Cold War strategy. Seriously ill with cancer, Dulles resigned his Cabinet position on April 15, 1959. Shortly before he died, at Washington, D.C., the following May 24, he was awarded the Medal of Freedom.

**BIBLIOGRAPHY.** JOHN R. BEAL, *John Foster Dulles*, rev. ed. (1959), a formal biography written by an admirer, a former State Department correspondent for *Time* magazine; EDWARD WEINTAL and CHARLES BARTLETT, *Facing the Brink* (1967), a critical and intimate account of crisis diplomacy and management by Presidents Eisenhower, Kennedy, and Johnson and their Secretaries of State; RICHARD GOOLD-ADAMS, *John Foster Dulles: A Reappraisal* (1962), a critical biography concluding that upon reevaluation Dulles' concepts and policies will rank higher than his methods used in implementing them; ELEANOR LANSING DULLES, *John Foster Dulles: The Last Year* (1963), a friendly biography by his sister, replete with anecdotal material. (E.W.)

## Duncan, Isadora

Among the first of her profession to raise the interpretive dance from artificiality to the status of a creative art, Isadora Duncan was acclaimed by the foremost musicians, artists, and writers of her day. Although an inspiration to the intelligentsia, with whom she remained a cult figure, she was often an object of attack by the less broad-minded. Her ideas were too much in advance of their time, and she flouted social conventions too flamboyantly to be regarded by the wider public as anything but an advocate of "free love."

She was born in San Francisco on May 26, 1877, one of four children brought up in genteel poverty by their mother, a music teacher. (Previously her date of birth was thought to have been May 27, 1878. Her baptismal certificate, discovered in San Francisco in 1976, shed new light on her origins and revealed that her name originally was Angela, which, by 1894, she had changed to Isadora.) As a child she rejected the rigidity of the classic ballet and based her dancing on more natural rhythms and movements, an approach she later used consciously in her interpretations of the works of the great composers—particularly Brahms, Wagner, and Beethoven. Her earliest public appearances, in Chicago and New York City, met with little success, and at the age of 21 she left the United States to seek recognition abroad. With her meagre savings she sailed on a cattle boat for England. There her crusading spirit was soon rewarded. At the British Museum her study of the art of ancient Greece confirmed the classical use of those dance rhythms that hitherto instinct alone had caused her to practice and upon a revival of which her method was largely founded. Through the patronage of the celebrated actress Mrs. Patrick Campbell, she was invited to appear at the private receptions of London's leading hostesses, where her dancing, distinguished by a complete freedom of movement, enraptured those who were familiar only with the conventional forms of the ballet, then in a period of decay. It was not long before the phenomenon of a young woman dancing barefoot, as scantily clad as a woodland nymph, crowded theatres and concert halls throughout Europe. Her controversial first visit to Russia, in 1905, brought the dance to the attention of the art critic Sergey Diaghilev, who as impresario was soon to lead a resurgence of ballet throughout western Europe. At one time or another she

Isadora Duncan, c. 1919.

By courtesy of the Dance Collection (Irma Duncan Collection) The New York Public Library at Lincoln Center, Astor Lenox and Tilden Foundations

founded dance schools in Germany, Russia, and the United States, but none of these survived.

Her private life, quite as much as her art, kept her name in the headlines, a situation she deplored yet unwittingly encouraged by her constant defiance of existing taboos. The father of her first child, Deirdre, was the stage designer Gordon Craig, who shared her abhorrence of marriage; the father of her second child, Patrick, was Paris Singer, the heir to a sewing machine fortune and a prominent art patron. With him she enjoyed a love-hate relationship for some years until they finally parted; but not before a tragedy occurred, from which she never really recovered. In 1913 the car in which her two children and their nurse were riding in Paris rolled into the Seine and all three were drowned. In an effort to sublimate her grief she was about to open another school when the advent of World War I put an end to her plans. Her subsequent tours in South America, Germany, and France were less successful than before, but in 1920 she believed the chance had come to realize a lifelong ambition: she was invited to establish a school of her own in Moscow. To someone with her revolutionary temperament, Russia seemed the land of promise. In fact she met Sergey Aleksandrovich Yesenin, a poet 17 years younger than she, whose work had won him a considerable reputation. She married him in 1922, sacrificing her scruples against marriage in order to take him with her on a tour of the United States. She could not have chosen a worse time for their arrival. Fear of the "Red Menace" was at its height, and she and her husband were unjustly labelled as Bolshevik agents. When, at the Symphony Hall, Boston, she introduced him at one of her concerts, members of the audience shouted abuse at her. She harangued them from the stage and the evening ended in uproar. Leaving her native country once more, she told reporters: "Good-bye America, I shall never see you again!" She never did. There followed an unhappy period with Yesenin in Europe, where his increasing mental instability turned him against her. He returned alone to the Soviet Union and, in 1925, committed suicide.

During the last years of her life she was a somewhat pathetic figure, living precariously in Nice on the French

Last  
American  
tour

Success in  
England

Riviera, where she met with a fatal accident on September 14, 1927. While riding in a car, her scarf became entangled in the rear wheel and she was thrown onto the pavement and strangled.

André Maurois' comment on the French novelist, George Sand, applies equally to Isadora Duncan: "Though not technically a chaste woman, she always looked upon an alliance as a marriage. She gave herself freely, entrusted herself wholly. She behaved like an honourable man." Certainly her place as a great innovator in dance is secure: her repudiation of artificial technical restrictions and reliance on the grace of natural movement helped to liberate the dance from its dependence on rigid formulas and on displays of brilliant but empty technical virtuosity, paving the way for the later acceptance of modern dance as it was developed by Mary Wigman, Martha Graham, and others.

**BIBLIOGRAPHY.** The most comprehensive account of the dancer's life and career is *Isadora: A Revolutionary in Art and Love* by A.R. MACDOUGALL (1960); an excellent profile of Isadora is "The Gloves of Isadora" by R.E. JONES, *Theatre Arts Magazine*, 31:17–22 (1947). The most complete bibliography to date is provided by E.C. WAGENKNECHT in *Seven Daughters of the Theatre* (1964), and the essay contained in it is of particular interest, as are the essays in *Twelve Against the Gods* by W. BOLITHO (1929); and *Here Lives the Heart* by M. DE ACOSTA (1960). Their authors' personal relationships with Isadora Duncan are interestingly related in: *Index to the Story of My Days: Some Memoirs, 1872–1907* by GORDON CRAIG (1957); and *Duncan Dancer: An Autobiography* by IRMA DUNCAN (1966). An exclusive account of Isadora Duncan's South American tour is *An Amazing Journey* by M. DUMESNIL (1932); an account of her years in Russia during the early 1920s is I.I. SCHNEIDER, *Isadora Duncan: The Russian Years*, trans. by D. MAGARSHACK (1969). Studies of the dancer's technique useful for students of the dance are *The Merry-Go-Round* by C. VAN VECHTEN (1918); and *The Technique of Isadora Duncan* by IRMA DUNCAN (1937). Important also for her statement of attitudes and beliefs is ISADORA DUNCAN, *My Life* (1927; reissued as *Isadora*, 1968).

(S.St.)

## Duns Scotus, John

John Duns Scotus, called Doctor Subtilis, was a Scholastic philosopher and theologian who pioneered the classical defense of the doctrine that Mary, the mother of Jesus, was conceived without original sin (the Immaculate Conception) and argued that the Incarnation was not dependent on the fact that man had sinned, that will is superior to intellect and love to knowledge, and that the essence of heaven consists in beatific love rather than the vision of God. Though his claim that universal concepts are based on a "common nature" in individuals made him a prime target for the Nominalism of William of Ockham in the 14th-century controversy between Realists and Nominalists concerning the question whether general types are figments of the mind or are real, it later deeply influenced Charles Sanders Peirce, an American philosopher, who considered Duns Scotus the greatest speculative mind of the Middle Ages as well as one of the "profoundest metaphysicians that ever lived." His strong defense of the papacy against the "divine right" of kings made him unpopular with the English Reformers of the 16th century for whom "dunce" (a Dunsman) became a word of obloquy, yet his theory of intuitive cognition suggested to John Calvin, the Genevan Reformer, how God may be "experienced."

**Early life and career.** As Ernest Renan, a 19th-century French historian and philosopher, noted, there is perhaps no other great medieval thinker whose life is as little known as that of Duns Scotus. Yet patient research during the past half-century has unearthed a number of facts. Early 14th-century manuscripts, for instance, state explicitly that John Duns was a Scot, from Duns, who belonged to the English province of Friars Minor (the order founded by Francis of Assisi), that "he flourished at Cambridge, Oxford, and Paris and died in Cologne." In selecting 1966 for an International Congress to commemorate the seventh centenary of his birth and in erecting a cairn near the Pavilion Lodge of the Duns Castle in

Berwickshire, scholars honoured not only a centuries-old tradition as to where he was born but also when.

Though accounts of his early schooling and entry into the Franciscan Order are unreliable, Duns Scotus' own remark that "a 13 year old today is better versed in sacred matters than a 20 year old adult in the primitive Church" does suggest an early interest in religion and entrance into the order. As a novice, he would have learned not only of St. Francis' personal love for Christ in the Eucharist, his reverence for the priesthood, and his loyalty to "the Lord Pope"—themes given special emphasis in Duns Scotus' own theology—but also of St. Bonaventure's interpretation of the Franciscan ideal, namely a striving for God through learning that will culminate in a mystical union of love. In his early *Lectura Oxoniensis*, Duns Scotus insisted that theology is not a speculative but a practical science of God and that man's ultimate goal is union with the divine Trinity through love. Though this union is known only by divine revelation, philosophy can prove the existence of an infinite being and herein lies its merit and service to theology. Duns Scotus' own intellectual journey to God is to be found in his prayerful *Tractatus de primo principio* (Eng. trans., *A Treatise on God As First Principle*, 1966), perhaps his last work.

Jurisdictionally, the Scots belonged to the Franciscan province of England, whose principal house of studies was at Oxford where Duns Scotus apparently spent 13 years (1288–1301) preparing for inception as master of theology. There is no record of where he took the eight years of preliminary philosophical training (four for a bachelor's and four for the master's degrees) required to enter such a program.

After studying theology for almost four years, John Duns was ordained priest by Oliver Sutton, bishop of Lincoln (the diocese to which Oxford belonged). Records show the event took place at St. Andrew's Church in Northampton on March 17, 1291. In view of the minimum age requirements for the priesthood, this suggests that Duns Scotus must have been born no later than March 1266, certainly not in 1274 or 1275 as earlier historians maintained.

Duns Scotus would have spent the last four years of the 13-year program as bachelor of theology, devoting the first year to preparing lectures on Peter Lombard's *Sentences*—the textbook of theology in the medieval universities—and the second to delivering them. A bachelor's role at this stage was not to give a literal explanation of this work but rather to pose and solve questions of his own on topics that paralleled subject "distinctions" in Lombard. Consequently the questions John discussed in his *Lectura Oxoniensis* ranged over the whole field of theology. When he had finished, he began to revise and enlarge them with a view to publication. Such a revised version was called an *ordinatio* in contrast to his original notes (*lectura*) or a student report (*reportatio*) of the actual lecture. If such a report was corrected by the lecturer himself, it became a *reportatio examinata*. From a date mentioned in the prologue, it is clear that in 1300 Duns Scotus was already at work on his monumental Oxford commentary on the *Sentences*, known as the *Ordinatio* or *Opus Oxoniense*.

Statutes of the university required that the third year be devoted to lectures on the Bible and in the final year, the bachelor *formatus*, as he was called, had to take part in public disputations under different masters including his own. In John's case this last year can be dated rather precisely, for his name occurs among the 22 Oxford Franciscans, including the two masters of theology, Adam of Howden and Philip of Bridlington, who were presented to Bishop Dalderby on July 26, 1300, for faculties, or the proper permissions to hear confessions of the great crowds that thronged to the Franciscans' church in the city. Because the friars had but one chair of theology and the list of trained bachelors waiting to incept was long, regent masters were replaced annually. Adam was the 28th and Philip the 29th Oxford master, so that Philip's year of regency was just beginning. It must have coincided with Duns Scotus' final and 13th year because an extant disputation of Bridlington as master indicates

Study in  
theology

John Duns was the bachelor respondent. This means that by June of 1301, he had completed all the requirements for the mastership in theology, yet in view of the long line ahead of him there was little hope of incepting as master at Oxford for perhaps a decade to come.

**Years at the University of Paris.** When the turn came for the English province to provide a talented candidate for the Franciscan chair of theology at the more prestigious University of Paris, Duns Scotus was appointed. One *reportatio* of his Paris lectures indicates that he began commenting on the *Sentences* there in the autumn of 1302 and continued to June 1303. Before the term ended, however, the university was affected by the long smoldering feud between King Philip IV the Fair and Pope Boniface VIII. The issue was taxation of church property to support the King's wars with England. When Boniface excommunicated him, the monarch retaliated by calling for a general church council to depose the Pope. He won over the French clergy and the university. On June 24, 1303, a great antipapal demonstration took place. Friars paraded in the Paris streets. Berthold of Saint-Denis, bishop of Orleans and former chancellor of the university, together with two Dominicans and two Franciscans, addressed the meeting. On the following day royal commissioners examined each member of the Franciscan house to determine whether he was with or against the King. Some 70 friars, mostly French, sided with Philip, while the rest (some 80 odd) remained loyal to the Pope, among them John Duns Scotus and Master Gonsalws Hispanus. The penalty was exile from France within three days. Boniface countered with a bull of August 15 suspending the university's right to give degrees in theology or canon and civil law. As a result of his harassment and imprisonment by the King's minister, however, Boniface died in October and was succeeded by Pope Benedict XI. In the interests of peace, Benedict lifted the ban against the university in April 1304, and shortly afterwards the King facilitated the return of students.

Where Duns Scotus spent the exile is unclear. Possibly John's Cambridge lectures stem from this period, although they may have been given during the academic year of 1301–02 before coming to Paris. At any rate, Duns Scotus was back before the summer of 1304, for he was the bachelor respondent in the *disputatio in aula* (public disputation) when his predecessor, Giles of Ligny, was promoted to master. On November 18 of that same year, Gonsalws, who had been elected minister general of the Franciscan order at the Pentecost chapter, or meeting, assigned as Giles' successor "Friar John Scotus, of whose laudable life, excellent knowledge, and most subtle ability as well as his other remarkable qualities I am fully informed, partly from long experience, partly from report which has spread everywhere."

The period following Duns Scotus' inception as master in 1305 was one of great literary activity. Aided by a staff of associates and secretaries, he set to work to complete his *Ordinatio* begun at Oxford, using not only the Oxford and Cambridge lectures but also those of Paris. A search of manuscripts reveals a magisterial dispute Duns Scotus conducted with the Dominican master, Guillaume Pierre Godin, against the thesis that matter is the principle of individuation (the metaphysical principle that makes an individual thing different from other things of the same species), but so far no questions publically disputed *ordinarie*—i.e., in regular turn with the other regent masters—have turned up. There is strong evidence, however, that some questions of this sort existed but were eventually incorporated into the *Ordinatio*. Duns Scotus did conduct one solemn quodlibetal disputation, so-called because the master accepted questions on any topic (*de quodlibet*) and from any bachelor or master present (*a quodlibet*). The 21 questions Duns Scotus treated were later revised, enlarged, and organized under two main topics, God and creatures. Though less extensive in scope than the *Ordinatio*, these *Quaestiones quodlibetales* are scarcely less important because they represent his most mature thinking. Indeed, Duns Scotus' fame depends principally on these two major works.

The short but important *Tractatus de primo principio*, a

compendium of what reason can prove about God, draws heavily upon the *Ordinatio*. The remaining authentic works seem to represent questions discussed privately for the benefit of the Franciscan student philosophers or theologians. They include, in addition to the *Collationes* (from both Oxford and Paris), the *Quaestiones in Metaphysicam Aristotelis* and a series of logical questions occasioned by the Neoplatonist Porphyry's *Isagoge* and Aristotle's *De praedicamentis*, *De interpretatione*, and *De sophisticis elenchis*. These works certainly postdate the Oxford *Lectura* and may even belong to the Parisian period. Antonius Andreus, an early follower who studied under Duns Scotus at Paris, expressly says his own commentaries on Porphyry and *De praedicamentis* are culled from statements of Duns Scotus *sedentis super cathedram magistralem* ("sitting on the master's chair").

**Final period at Cologne.** In 1307 Duns Scotus was appointed professor at Cologne. Some have suggested that Gonsalvus sent Scotus to Cologne for his own safety. His controversial claim that Mary need never have contracted original sin seemed to conflict with the doctrine of Christ's universal redemption. Duns Scotus' effort was to show that the perfect mediation would be preventative, not merely curative. Though his brilliant defense of the Immaculate Conception marked the turning point in the history of the doctrine, it was immediately challenged by secular and Dominican colleagues. When the question arose in a solemn quodlibetal disputation, the secular master Jean de Pouilly, for example, declared the Scotist thesis not only improbable, but even heretical. Should anyone be so presumptuous as to assert it, he argued impassionedly, one should proceed against him "not with arguments but otherwise." At a time when Philip IV the Fair had initiated heresy trials against the wealthy Knights Templars, Jean's words have an ominous ring. There seems to have been something hasty about Duns Scotus' departure in any case. Writing a century later, the Scotist William of Vaurouillon referred to the traditional account that John received the Minister General's letter while walking with his students and set out at once for Cologne taking little or nothing with him. Duns Scotus lectured at Cologne until his death, on November 8, 1308. His body at present lies in the nave of the Franciscan church near the Cologne Cathedral and in many places he is venerated as blessed.

Whatever the reason for his abrupt departure from Paris, Duns Scotus certainly left his *Ordinatio* and *Quodlibet* unfinished. Eager pupils completed the works, substituting materials from *reportationes examinatae* for the questions Duns Scotus left undictated. The critical Vatican edition begun in 1950 is aimed, among other things, at reconstructing the *Ordinatio* as Duns Scotus left it, with all his corrigenda, or corrections.

Despite their imperfect form, Duns Scotus' works were widely circulated. Even today they are found in hundreds of manuscripts, and from 1472 onward went through more than 30 different editions. During the 16th to 18th centuries among Catholic theologians his following rivalled that of Thomas Aquinas and in the 17th century outnumbered that of all the other schools combined.

**BIBLIOGRAPHY.** ODULF SCHAFER, *Bibliographia de vita, operibus et doctrina Iohannis Duns Scoti, saec. XIX-XX* (1955), continued in "Resenha Abreviada da Bibliografia Escotistica Mais Recente (1954-1966)," *Revista Portuguesa de Filosofia*, 23:338-363 (1967), are exhaustive bibliographies prepared for the Scotistic Commission. *De doctrina Iohannis Duns Scoti*, 4 vol. (1968), contains 125 papers given at the 2nd International Scotistic Congress 1966 on the philosophy, theology, and influence of Scotus; *Deus et Homo ad mentem I. Duns Scoti* (1972), is a similar collection from the 3rd International Scotistic Congress 1970. A.B. WOLTER (trans.), *Duns Scotus, Philosophical Writings* (1962), includes selections from the *Ordinatio*; and *A Treatise on God As First Principle* (1966), the *De Primo Principio* and selections from the *Lectura*. On the theology of Scotus, see the article by c. BALIC in the *New Catholic Encyclopedia*, vol. 4 (1967). On his philosophy, the following are particularly recommended: A.B. WOLTER in the *Encyclopedia of Philosophy*, vol. 2 (1967), a concise general introduction; EFREM BETTONI, *Duns Scotus: The Basic Principles of His Philosophy* (1961), a more detailed

## Diirer, Albrecht

Albrecht Durer was the foremost German painter, engraver, and woodcut and decorative designer of the Renaissance, as well as the author of a number of theoretical works. His art has been accepted as a model by painters and engravers of succeeding ages, but his significance does not rest on that fact alone. The versatility of his creativity and his ability to reflect on his own individuality and on his activity and to set down methodically on paper the result of his reflections have also contributed to his importance. He was, like Leonardo, an intellectual artist who was capable of taking part in the great contemporary intellectual upheavals brought about by the Reformation and the humanist movement and who was personally associated with various humanists and members of the circles around Martin Luther.

By courtesy of the Alte Pinakothek, Munich

Diirer, self-portrait, oil on wood panel, 1500. In the Alte Pinakothek, Munich. 65 cm X 48 cm.

The influence that Diirer exerted and still exerts arises mainly from the fact that, as a true Renaissance man who felt himself to be a distinct, important "personality," he left behind a large amount of self-revealing material, including painted and sketched self-portraits, letters, a family chronicle (1524), a fragmentarily preserved *Gedenkbuch* (journal) for the years 1502-03 and 1514, a diary from his trip to the Netherlands (1520-21), the account of an apocalyptic vision (1525), and his poetry.

**Education and early career.** Diirer was born in Nürnberg, Germany, on May 21, 1471. He was the second son of the goldsmith Albrecht Durer the Elder (1427-1502), who had left Hungary to settle in Nürnberg in 1455, and of Barbara Holper, who was born in Nürnberg. Diirer began his training as a draughtsman in the goldsmith's workshop of his father. His precocious skill is evidenced by a remarkable self-portrait done in 1484, when he was 13 years old (Albertina, Vienna), and by a "Madonna with Musical Angels," a pen drawing done in 1485 (Kupferstichkabinett, Staatliche Museen Preussischer Kulturbesitz, Berlin), which is already a finished work of art in the late Gothic style. In 1486, Durer's father arranged for his apprenticeship to the painter and woodcut illustrator Michael Wohlgemuth (1434-1519), a skillful, somewhat prosaic Nürnberg artist, whom he portrayed in 1516 as a pious 82-year-old man (panel in Germanisches Nationalmuseum, Nürnberg). After three years in Wohlgemuth's workshop, he left for a period of travel. In 1490 Diirer completed his earliest known painting, a portrait

of his father (Uffizi, Florence) that heralds the familiar characteristic style of the mature master.

Diirer's years as a journeyman from 1490 to 1494 probably took the young artist first to the Netherlands and then in 1492 to Colmar in Alsace. There he found that Martin Schongauer, the leading German graphic artist of the time, was no longer alive; several of Diirer's drawings from the time immediately preceding his travels, however, bear signs that he had already seriously studied the work of Schongauer. In the same year, 1492, Diirer went to Basel, Switzerland; there he completed his first authenticated woodcut, a picture of "St. Jerome Curing the Lion" (Kupferstichkabinett, Kunstmuseum, Basel), which seems somewhat ungainly and archaic in comparison with the 1490 portrait of the elder Durer. During 1493 or 1494 Durer was in Strasbourg for a short time, returning again to Basel to design several book illustrations. A few surviving works have been ascribed by later research to this series, the *Comedies of Terence*, drawings on wood blocks: "Der Ritter vom Turn" ("The Knight of Turn"), dated 1493, and "Das Narrenschiff" ("Ship of Fools"), dated 1494, both woodcuts. In these works can be seen certain stylistic affinities with Durer's authenticated and, in general, more mature drawings from the years 1493-95. An early masterpiece from this same period is a self-portrait with a thistle painted on parchment in 1493 (Louvre, Paris). Several small religious paintings (one example is in Staatliche Kunsthalle, Karlsruhe) also belong to this period of Durer's travels.

**First journey to Italy.** At the end of May 1494, Diirer returned to Nürnberg, where on July 7, 1494, he married Agnes Frey, the daughter of a merchant. His wife was his only survivor, for they had no children. In the autumn of 1494 Diirer seems to have undertaken his first journey to Italy, where he remained until the spring of 1495. A number of bold watercolours dealing with subjects from the Alps of the southern Tirol are generally linked with this journey; they are among Diirer's most beautiful creations. Depicting segments of reality cleverly chosen for their compositional values, they are painted with broad strokes, in places roughly sketched in, with an amazing harmonization of detail. Diirer used predominantly unmixed, cool, sombre colours, which, despite his failure to contrast light and dark adequately, still suggest depth and atmosphere.

After Durer's return to Nürnberg, he began to associate frequently with a boyhood friend, the humanist Willibald Pirckheimer (1470-1530), with whom he eventually formed a lifelong friendship. Pirckheimer, who had studied at the great universities of Padua and Pavia, was a leading German humanist scholar. His knowledge of the history and languages of classical times, as well as his extensive library, probably contributed decisively to Durer's intellectual growth.

The trip to Italy had a strong effect on Durer; direct and indirect echoes of Italian art are apparent in most of his drawings, paintings, and graphics of the decade between 1495 and 1505, the date of his second trip. Between 1494 and 1496 especially, Diirer produced a large number of drawings based mainly on engravings from northern Italy, copies of which he may have seen before his journey there. Some of these drawings are taken from engravings by the Venetian Andrea Mantegna (Winckler 59, 60; 1494; Albertina, Vienna), an artist greatly preoccupied with classical themes and with precise linear articulation of the human figure. Twenty of the drawings follow the so-called tarocchi ("tarot cards") engravings from about 1460 based on drawings by an unknown Ferrarese artist (W 122-141; British Museum, London; Louvre, Paris; Museum Boymans-van Beuningen, Rotterdam). Diirer's teacher, Wohlgemuth, had also copied these works. The "Dying Orpheus" of one of the tarocchi engravers inspired Diirer to a free re-creation (drawing of 1494 in Kunsthalle, Hamburg, etching Bartsch 73). While in Venice and perhaps also before he went to Italy, Diirer saw engravings by masters from central Italy. Of these artists, the Florentine Antonio Pollaiuolo influenced the young Diirer most. Pollaiuolo, with his sinuous, energetic line studies of the movement of the human body, inspired

water-  
colours

Preco-  
ciousness  
of Dürer's  
first works

a generation of Florentine artists to make significant advances in this area, and Diirer also learned much from him. He copied several of Pollaiuolo's works, including his "Rape of the Sabine Women" in a drawing of 1495 (W 82; Musée Leon Bonnat, Bayonne, France).

Early  
paintings  
in the  
Italian  
spirit

Dürer's secular, allegorical, and frequently self-enamoured paintings of this period are often either adaptations of Italian models or entirely independent creations that breathe the free spirit of the new age. Dürer adapted the figure of Hercules from Pollaiuolo's "The Rape of Deianira" (Yale University Art Gallery, New Haven, Connecticut) for a painting of "Hercules and the Birds of Stymphalis" (Germanisches Nationalmuseum, Nürnberg). A purely mythological painting in the Renaissance tradition, its subject makes it exceptional among Dürer's pictures. The centre panel from the "Dresden Altarpiece," which Dürer painted perhaps around 1498, is stylistically similar to the "Hercules" and betrays influences of Mantegna. In most of Dürer's free adaptations the additional influence of the more lyrical, older painter Giovanni Bellini (c. 1430–1516), with whom Dürer had become acquainted in Venice, can be seen.

The most striking painting illustrating Dürer's growth toward the Renaissance spirit is a self-portrait, painted in 1498 (Prado, Madrid). Here Dürer sought to convey, in the representation of his own person, the aristocratic ideal of the Renaissance. He liked the way he looked as a handsome, fashionably attired young man, confronting life rather conceitedly. In place of the conventional, neutral, monochromatic background, he depicts an interior, with a window opening on the right. Through the window can be seen a tiny landscape of mountains and a distant sea, a detail that is distinctly reminiscent of contemporary Venetian and Florentine paintings. The focus on the man in the interior distinguishes his world from the vast perspective of the distant scene, another world to which the artist feels himself linked.

Italian  
influences  
in Dürer's  
graphics

Italian influences were slower to take hold in Dürer's graphics than in his drawings and paintings. Strong late Gothic elements dominate the visionary woodcuts of his *Apocalypse* series (the Revelation of St. John), published in 1498; all the woodcuts display emphatic expression, rich emotion, and crowded, frequently overcrowded, composition. The same tradition influences the earliest woodcuts of Dürer's *Great Passion* series, also from about 1498. Nevertheless, the fact that Dürer was adopting a more modern conception, a conception inspired by Classicism and humanism, during the long period in which these series were taking form, is indicative of his basically Italian orientation. The woodcuts "Samson and the Lion" (B 2; c. 1497) and "Hercules Conquering Cacus" (B 127), and many prints from the woodcut series *The Life of the Virgin* (especially B 77, 79–83, 88, 91, 93–95; c. 1500–10) have a distinct Italian flavour. Many of Dürer's copper engravings are in the same Italian mode. Certain elements of late Gothic tradition do occasionally appear in these engravings, but this may well be because their reproduction was addressed to a broad audience that was, as yet, mistrustful of new ideas in art. Some examples that may be cited are "Fortune" (B 78; c. 1496), "The Four Witches" (B 75; 1497), "The Temptation of the Idler" ("The Dream of the Doctor"; B 76; c. 1497–98), "The Sea Monster" (B 71; c. 1498), "Hercules" (B 73; c. 1498), "Adam and Eve" (B 1; 1504), "Apollo and Diana" (B 68; c. 1505), "Musical Satyr and Nymph with Baby" (B 69; 1505), and "The Small Horse" (B 96; 1505), and "The Large Horse" (B 97; 1505). Dürer's influence in the field of graphics later influenced the art of the Italian Renaissance that had originally inspired his creative efforts.

Consolidation of his artistic aims. Dürer's style continued to vacillate between Gothic and Italian Renaissance art until about 1500. Then his restless striving finally found definite direction. He seems clearly to be on firm ground in the penetrating half-length portraits of Oswolt Krel (Alte Pinakothek, Munich), in the portraits of three members of the aristocratic Tucher family of Nürnberg (Kunstsammlungen, Weimar, West Germany, and Staatliche Kunstsammlungen, Kassel, West Ger-

many)—all dated 1499—and in the "Portrait of a Young Man" of 1500 (Alte Pinakothek, Munich). In the same year Dürer painted another self-portrait (Alte Pinakothek, Munich), a flattering Christ-like portrayal.

During this period of consolidation in Dürer's style, the Italian elements of his art were strengthened by his contact with Jacopo de' Barbari, a minor Venetian painter and graphic artist who was seeking a geometric solution to the rendering of human proportions and whose acquaintance Dürer had made in Venice in 1494–95. Later, Dürer encountered him often while de' Barbari was in the service of the Holy Roman emperor Maximilian I in Nürnberg in 1500 and during the Venetian's stay in Wittenberg between 1503 and 1505; it is perhaps due to his influence that Dürer began, around 1500, to grapple with the problem of human proportions in true Renaissance fashion. Initially, the most concentrated result of his efforts was the great engraving "Adam and Eve" (B 1; 1504) in which he sought to bring the mystery of human beauty to an intellectually calculated ideal form. In this he followed not only Jacopo de' Barbari but also the greatest of the Italian artist-theoreticians, particularly the 15th-century Umbrian painter Piero della Francesca and the Florentine Leonardo da Vinci. In all aspects Dürer's art was becoming strongly classical. One of his most significant classical endeavours is his painting "Altar of the Three Kings" (1504), which was executed with the help of pupils. The Italian character of this altar composition is immediately evident because it is made up of five separate pictures. Dürer's intellect and imagination went beyond direct dependence on Italian art, however, for he had by this time freely grasped and internalized the whole of it. From this maturity of style comes the bold, natural, relaxed conception of the centre panel, "The Adoration of the Magi" (Uffizi, Florence), and the ingenious and unconventional realism of the side panels, one of which depicts the "Drummer and Piper" and the other "Job and His Wife" (Wallraf-Richartz-Museum, Cologne).

Second journey to Italy. In the autumn of 1505, Dürer made a second journey to Italy, where he remained until the winter of 1507. Once again he spent most of his time in Venice. Of the Venetian artists, Dürer now most admired Giovanni Bellini, the leading master of Venetian early Renaissance painting, who, in his later works, completed the transition to the High Renaissance. Dürer attested to this admiration in a letter to Pirkheimer of November 7, 1506; and his pictures of men and women from this Venetian period reflect the sweet, soft portrait types especially favoured by Bellini. One of Dürer's most impressive small paintings of this period, a compressed half-length composition of the "Young Jesus with the Doctors" of 1506, harks back to Bellini's free adaptation of Mantegna's "Presentation in the Temple" (Staatliche Museen Preussischer Kulturbesitz, Berlin). Dürer's work is a virtuoso performance that shows mastery and close attention to detail. That Dürer himself so considered it is shown by the inscription on the scrap of paper out of the book held by the old man in the foreground, which reads, *Opus quinque dierum* ("the work of five days"). Dürer thus must have executed this painstaking display of artistry, which required detailed drawings, in no more than five days. Of greater artistic merit than this quickly executed work, however, are the half-length portraits of young men and women painted between 1505 and 1507, which seem to be entirely in the style of Bellini. In these paintings there is a flexibility of the subject, combined with a warmth and liveliness of expression and a genuinely artistic technique, that Dürer otherwise only rarely attained. The paintings include a half-length "Portrait of a Venetian Woman" of 1505 (Kunsthistorisches Museum, Vienna), a "Portrait of a Young Woman," tentatively dated around 1506 (Staatliche Museen Preussischer Kulturbesitz, Berlin), a half-length portrait of a cheerful young girl with a fashionable little hat, dated 1507, in the same museum, and that of a spirited young man, also done in 1507, on the reverse side of which is a dreadful allegorical representation of "Avarice" (Kunsthistorisches Museum, Vienna). In 1506, in Venice, Dürer also completed his great altarpiece "The Feast of the Rose Gar-

Period of  
stylistic  
consolidation

Admiration  
for  
Bellini

lands" for the funeral chapel of the Germans in the church of S. Bartholomew, Venice. This is a bold extension of the "Madonna with Donors" type of picture, an altarpiece composition typically showing portraits of the financial benefactors of the church in panels appended to a central scene of the Virgin and Child; "The Feast of the Rose Garlands" is one panel showing, as well as the Virgin and Child, the recognizable portraits of over a dozen contemporaries, including such notables as Pope Julius II, the emperor Maximilian I, Cardinal Domenico Grimani, and a portrait of Dürer himself.

Sojourn in  
Bologna

Later in 1506 Dürer went to Bologna "for the sake of art, in a hidden perspective, which someone wants to teach me," ostensibly one Agostino dalle Prospettive. In the course of this brief trip, estimated to be eight or ten days, it is likely that Dürer also took the opportunity to familiarize himself with the art circle of the nearby city of Emilia-Romagna, which was largely independent of Venetian influence. There the works of older, more austere masters like Francesco del Cossa (1436–78) and Ercole de' Roberti (c. 1456–96) probably influenced him more strongly than those of the sentimental younger painters Francesco Francia (1450–1517/18) and Lorenzo Costa (died 1535). He later returned to Venice for a final three months, where, as he complained, he was "the object of much envy." He also met with great favour, however, particularly from the aged Bellini, of whom he wrote, "[Bellini] has praised me before many noblemen. He wants something of mine very much and has himself come to me and asked that I make him something, and wants to pay well." The extent to which Dürer viewed Italy as his artistic and personal home is revealed by the frequently quoted words in his last letter from Venice (dated October 1506) to Pirkheimer, anticipating his imminent return to Germany: "O, how cold I will be away from the sun; here I am a gentleman, at home a parasite."

**Development after the second Italian trip.** By February 1507 at the latest, Dürer was back in Nurnberg, where two years later he acquired a fairly impressive house across from the gateway of the zoological gardens. (The "Dürer-Haus" is still standing today, an old-fashioned, four-story house with a high sloping roof.) It is clear that the artistic impressions gained from his Italian trips continued to influence Dürer to employ classical principles in creating largely original compositions. Among the paintings belonging to the period after his second return from Italy, the "Martyrdom of the Ten Thousand," painted in 1508 for Frederick the Wise, elector of Saxony, and the "Adoration of the Trinity," painted for M. Landauer for the Zwölfbrüderhäuser in Nurnberg, a painting showing tiers of saints and angels in Italian High Renaissance fashion (1511), are both crowd scenes whose failure is in varying ways due to the intractability of the design. The problem of crowd composition is solved more successfully in the "Assumption of the Virgin" (known only through a copy) from "The Heller Altarpiece," which was commissioned by Jakob Heller for the Dominikanerkirche, in Frankfurt am Main (1508–09). The drawings for this picture recall Mantegna and betray Dürer's striving for classical perfection of form through sweeping lines of firmly modelled and simple drapery. Even greater simplicity and grandeur characterize the diptych of "Adam and Eve" (1507; Prado, Madrid, with a variant in Uffizi, Florence), in which the two figures stand calmly in relaxed classical poses against dark, almost bare, backgrounds.

The  
"Passion"  
series

Between 1507 and 1513 Dürer completed a "Passion" series in copperplate engravings and, between 1509 and 1511, the *Small Passion* in woodcuts, both of which are characterized by their tendency toward spaciousness and serenity. Dürer's four "Passion" series, one in copper engraving, two in woodcut, and the so-called "Green Passion" (Albertina, Vienna), which consists of drawings on greenish-tinted paper, are small graphic "stations of the cross" for private home use. In 1511, the book editions of *The Great Passion*, the *Small Passion*, and *The Life of the Virgin* appeared, as did the second edition of the *Apocalypse*, to which had been added a title illustration. During 1513 and 1514 Dürer created the greatest of his

copperplate engravings: the "Knight, Death and Devil," "St. Jerome in His Study," and "Melencolia I,"—all of approximately the same size, varying from 24.2 by 19.1 centimetres (9.5 by 7.5 inches) to 24.8 by 19.1 centimetres (9.8 by 7.5 inches). The extensive, complex, and often contradictory literature concerning these three engravings deals largely with their enigmatic, allusive, iconographic details. Although repeatedly contested, it probably must be accepted that the engravings were intended to be interpreted together. There is general agreement, however, that Dürer, in these three so-called master engravings, wished to raise his artistic intensity to the highest level, which he succeeded in doing. Finished form and richness of conception and mood merge into a whole of classical perfection. To the same period belongs Dürer's most expressive portrait drawing—that of his mother (Staatliche Museen Preussischer Kulturbesitz, Kupferstichkabinett, Berlin).

**Service to Maximilian I.** While in Nurnberg, from February 4 to April 21, 1512, the emperor Maximilian I enlisted Dürer—by now recognized as the greatest painter of the city—into his service, and Dürer continued to work mainly for the Emperor until 1519. He collaborated with several of the greatest German artists of the day on a set of marginal drawings for the Emperor's prayer book (Staatliche Museen Preussischer Kulturbesitz, Kupferstichkabinett; Staatliche Graphische Sammlung, Munich; Bibliothèque Municipale, Besançon). He also did a number of etchings in iron (between 1515 and 1518) that proclaim his complete mastery of the medium and his freedom of imagination. In contrast to these pleasing improvisations are the monumental woodcuts, overloaded with panegyrics, made for Maximilian; "The Emperor Maximilian I's Triumphal Arch" (1515; overall size 3.409 by 2.922 metres [11.184 by 9.587 feet]), a complicated Roman triumphal arch with three passageways and a dome atop the centre passage, done in the Northern Renaissance style; and "The Emperor Maximilian I's Triumphal Chariot" (1522; total length 2.318 metres [7.605 feet]). In these somewhat stupendous, ornate woodcuts, Dürer had to strain to adapt his creative imagination to his client's mentality, which was foreign to him.

Woodcuts  
for Maxi-  
milian

Besides a number of formal show pieces—a painting entitled "Lucretia" (1518; Alte Pinakothek, Munich), and two portraits of the Emperor (1519; Germanisches Nationalmuseum, Nurnberg, and Kunsthistorisches Museum, Vienna)—during this decade Dürer also did a number of more informal paintings of considerably greater charm. He also travelled. In the fall of 1517 he stayed in Bamberg. In the summer of 1518 he went to Augsburg in the company of two friends who were to represent Nurnberg in the Imperial Diet, or German legislative assembly; the Diet was to deliberate on the actions of Martin Luther, who had in the previous year posted his 95 Theses denouncing the sale of papal indulgences on the door of the Wittenberg Castle Church. Dürer later became a devoted follower of Luther. In May or June of the following year he spent some time in Switzerland with his friend Pirkheimer. Dürer had achieved an international reputation by 1515, when he exchanged works with the illustrious High Renaissance painter Raphael.

**Final journey to the Netherlands.** In July 1520 Dürer embarked with his wife on a journey through the Netherlands. He travelled through the countryside and visited Antwerp, Brussels, Aachen, and Mechelen. In Aachen, at the October 23 coronation of the emperor Charles V, successor to Maximilian I (who had died January 12, 1519), Dürer met the mystical and dramatic Matthias Grinewald, who stood second only to Dürer in contemporary German art, and presented him with several etchings. Dürer returned to Antwerp by way of Nijmegen and Cologne, remaining there until the summer of 1521. He had maintained close relations with the leaders of the Netherlands school of painting—Lucas van Leyden, Quentin Massys, Jan Provost, and Bernard van Orley. In December 1520 Dürer visited Zeeland and in April 1521 travelled to Bruges and Ghent, where he saw the works of the 15th-century Flemish masters Jan and

Meeting  
with  
Matthias  
Grinewald

Hubert van Eyck, Rogier van der Weyden, and Hugo van der Goes, as well as the Michelangelo Madonna. Durer's sketchbook of the Netherlands journey contains immensely detailed and realistic drawings. While in the Netherlands, he also began numerous other sketches, most of which are executed with an extreme precision that betrays Diirer's increasing tendency toward over-exactitude. Some paintings that were created either during the journey or about the same time seem spiritually akin to the Netherlands school; for example, the portrait of Anna Selbdritt (Metropolitan Museum of Art, New York), a half-length picture of St. Jerome (1521, Museu Nacional de Arte Antiga, Lisbon), and the small portrait of Bernhard von Resten, previously Bernard van Orley (Gemaldegalerie, Dresden).

**Final works.** On July 12, 1521, the travellers were back in Niirnberg and, from this time on, Diirer's health began to decline. He devoted his remaining years mostly to theoretical and scientific writings and illustrations, although several well-known character portraits and some important portrait engravings and woodcuts also date from this period. One of Durer's greatest paintings, the so-called "Four Apostles" (St. John, St. Peter, St. Paul, and St. Mark), was done in 1526. With this work Diirer reached his final and certainly his highest level of achievement as a painter. His constant delight in his own virtuosity no longer stifled the ideal of a spaciousness that is simple, yet deeply expressive.

Diirer's  
writings

Durer's writings encompass widely varied subject matter. They consist of autobiographical writings, letters, poems, and three treatises: *Underweyssung der Messung, mit dem Zirckel un Richtscheit, in Linien, eben und Gantzen Corporen, Durch Albrecht Diirer* (1525; a "Treatise on Mensuration with the Compasses and Ruler in Lines, Planes, and Whole Bodies"), which was intended as a guide for artists; *Herinn sind Begriffen vier Bucher von Menschlicher Proportion Durch Albrecht Diirer* (1525; published posthumously in Nurnberg in 1528; "Treatise on Human Proportions"); and a treatise on fortification (1527), which appeared under the title *Etliche Underricht, zu Befestigung der Stett, Schloss, und Flecken* ("Instruction on the Fortification of Cities, Castles, and Towns"). The woodcut illustrations for the treatise on mensuration are typical of Durer's final style, while in those for the treatise on proportion the classical aesthetic ideal takes on mannerist features. The illustrations for the treatise on fortification are distinguished by a naïve realism that detracts from their artistic merit. The language in the treatises and in his personal writings is simple, powerful, and picturesque, less abstract than might be anticipated in view of Diirer's frequently theoretical approach to art.

**Influence and significance.** On April 6, 1528, Diirer died and was buried in the churchyard of Johanniskirchhof in Niirnberg. That he was one of his country's most influential artists is manifest in the impressive number of pupils and imitators that he had. Even Dutch and Italian artists did not disdain to imitate Durer's graphics occasionally; probably the most gifted of his Dutch and Italian imitators was Jacopo Pontormo (1494–1557), one of the creators of Florentine Mannerism. In the period around 1600, when artists frequently sought models in the art works of Diirer's time, there was a virtual "Durer Renaissance."

The extent to which Diirer was internationally celebrated is apparent in the literary testimony of the Florentine artist Giorgio Vasari (1511–74), in whose *Lives of the Most Eminent Italian Architects, Painters and Sculptors*, the importance of Albrecht Durer, the "truly great painter and creator of the most beautiful copper engravings," is repeatedly stressed. Durer himself recorded with satisfaction the numerous honours accorded to him, in his letters from Venice and especially in his diary of the journey to the Netherlands (1520–21):

And on Sunday, . . . the painters invited me, along with my wife and servant, to their chambers, where they had all sorts of things, a silver service, other costly appurtenances, and overly expensive food . . . And when I was ushered to the table, the people stood off on both sides, as one behaves toward a great gentleman. There were also among them very

fine people of rank, who all presented themselves to me with deep bows, in the most gracious way.

Like most famous Italian artists, Diirer probably felt himself to be an "artist-prince," and his self-portraits seem incontestably to show a man sure of his own genius.

## MAJOR WORKS

### Paintings

**RELIGIOUS PAINTINGS:** "Mater Dolorosa" (polyptych; 1496–97; Alte Pinakothek, Munich); "Dresden Altarpiece," (commissioned, 1496; Gemaldegalerie, Dresden, East Germany); "Lamentation of Christ" (c. 1500; Alte Pinakothek, Munich); "Salvator Mundi" (1502; Metropolitan Museum of Art, New York); "The Paumgartner Altarpiece" (1502–04; Alte Pinakothek, Munich); "The Adoration of the Magi" (1504; Uffizi, Florence); "The Ober St. Veit Altarpiece" (1505–06; Ober St. Veit, Archbishop's Palace, Austria); "The Feast of the Rose Garlands" (1506; National Museum, Prague); "Young Jesus with the Doctors" (1506; Thyssen Bornemisza Collection, Castagnola, Switzerland); "Adam and Eve" (1507; Prado, Madrid); "Martyrdom of the Ten Thousand" (1508; Kunsthistorisches Museum, Vienna); "Adoration of the Trinity" (1511; Kunsthistorisches Museum, Vienna); "St. Jerome" (1521; Museu Nacional de Arte Antiga, Lisbon); "Four Apostles" (1526; Alte Pinakothek, Munich).

**PORTRAITS:** "Self-Portrait" (1493; Louvre, Paris); "Frederick the Wise" (1496; Staatliche Museen Preussischer Kulturbesitz, Berlin); "Self-Portrait" (1498; Prado, Madrid); "Self-Portrait" (1500; Alte Pinakothek, Munich); "Portrait of a Young Man" (1500; Alte Pinakothek, Munich); "Portrait of a Young Man" (1506; Hampton Court, Middlesex); "Portrait of Charlemagne" (1512–13; Germanisches Nationalmuseum, Niirnberg); "Lorenz Sterck" (1521; Isabella Stewart Gardner Museum, Boston).

### Graphic works

**ENGRAVINGS:** "Adam and Eve" (1504); "Agony in the Garden" (1508); "Man of Sorrows" (1509); *Small Passion* (series, 1509–11); "Ecce Homo" (1512); "Knight, Death and Devil" (1513); "St. Jerome in His Study" (1513); "Melancholia I" (1514); "Erasmus of Rotterdam" (1526).

**WOODCUT CYCLE:** *Apocalypse* (1498; title page, 1511).

**BIBLIOGRAPHY.** The Bartsch numbers given throughout the article refer to ADAM VON BARTSCH, *Le Peintre graveur*, 21 vol. (1803–21) and the Winckler numbers to FRIEDRICH WINCKLER, *Die Zeichnungen Albrecht Dürers*, 4 vol. (1936–39). See also the bibliography of M.J. FRIEDLANDER's article on Diirer in the Thieme-Becker, *Allgemeines Lexikon der bildenden Künstler*, vol. 10, pp. 63–70 (1914). The most important publications since then are: ERWIN PANOFKY, *Diirers Kunsttheorie* (1915); GUSTAV PAULI, "Die Durer-Literatur der letzten drei Jahre," *Repertorium für Kunstwissenschaft*, 41:1–34 (1919); M.J. FRIEDLANDER, *Albrecht Diirer* (1921), in German; ERWIN PANOFKY, *Diirers Stellung zur Antike* (1922); CAMPBELL DODGSON, *Albrecht Diirer* (1926); PIERRE DU COLOMBIER, *Albrecht Diirer* (1927), in French; HANS TIETZE and ERICA TIETZE-CONRAT, *Kritisches Verzeichnis der Werke Albrecht Dürers*, 2 vol. (1928–38); JOSEPH MEDER, *Diirer-Katalog* (1932); EMIL WALDMANN, *Albrecht Diirer* (1933), in German; *Drawings and Water-Colours*, selected and with an introduction by E. SCHILLING (1949); FRIEDRICH WINKLER, *Diirer und die Illustrationen zum Narrenschiff* (1951); H.T. MUSPER, *Albrecht Diirer* (1952), in German; *Watercolours by Albrecht Diirer*, selected and with an introduction by A.M. CETTO (1954); ERWIN PANOFKY, *The Life and Art of Albrecht Diirer*, 4th ed. (1955); FRIEDRICH WINKLER, *Albrecht Diirer, Leben und Werk* (1957); and the catalog of the exhibition "Albrecht Diirer 1474–1971" in the Germanisches Nationalmuseum, Nurnberg-Munich (1971).

(Eb.R.)

## Duricrusts

The term duricrust (Latin *durus*, "hard") was first applied in Australia to layered materials at or near the Earth's surface, such as laterites, bauxites, and quartzites. These crusts are not of themselves landforms but represent the chemical alteration of the upper parts of plains and other features of low relief. In a sense, they are soils (q.v.) of an extreme type. In general, duricrust connotes a surface or near-surface, hardened accumulation of silica (SiO<sub>2</sub>), alumina (Al<sub>2</sub>O<sub>3</sub>), and iron oxide (Fe<sub>2</sub>O<sub>3</sub>), in varying proportions. Admixtures of other substances commonly are present and duricrusts may be enriched with oxides of manganese or titanium within restricted areas. Thus, siliceous, ferruginous, and aluminous crusts constitute duricrusts proper but the term also is applied, by extension,

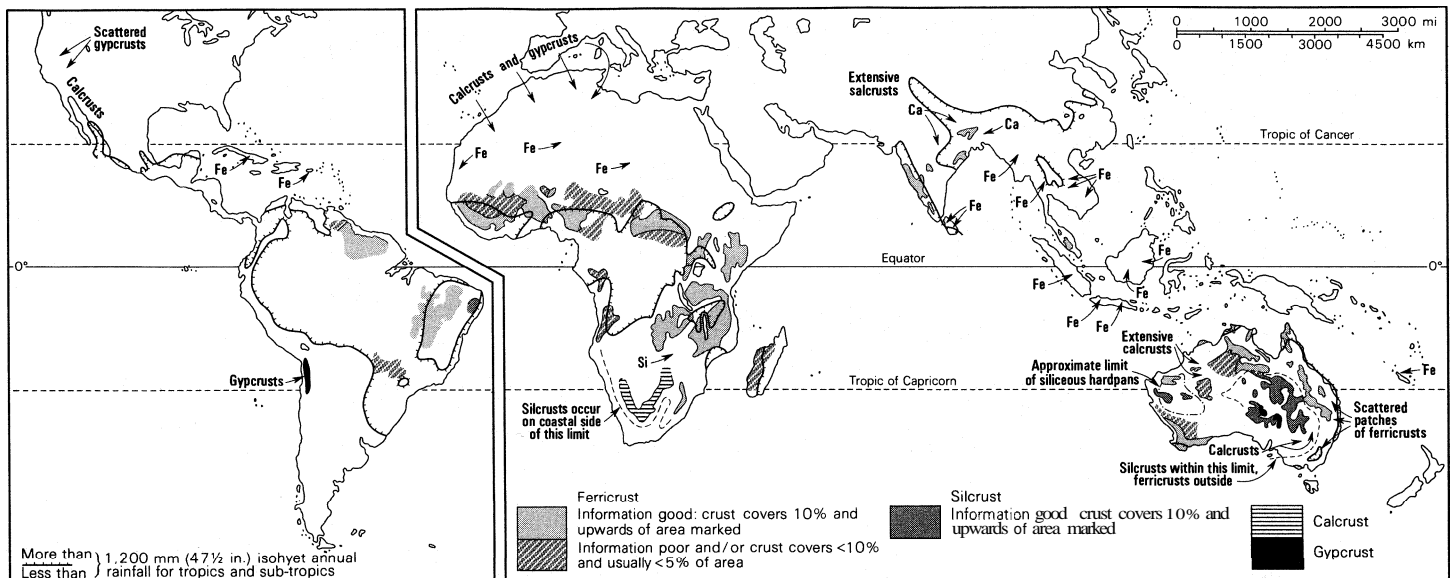

Figure 1: World distribution of duricrusts.

### Classification and general distribution

to encrusted layers of calcium carbonate, gypsum, and salt.

Two partial classifications use compound names ending in -crete, to indicate the kind of cementation, or in -crust, to indicate the basic chemical content (Table 1, first two columns). Both classifications are defective, although the working distinction between silcrusts and ferricrusts is useful. A more serviceable classification (Table 1, third column) adapts and extends the nomenclature developed by soil scientists in Africa. The type boundaries that fall within duricrusts proper must be considered transitional.

Where best preserved, duricrusts proper are the most continuous and extensive types of those listed in Table 1. Representing the end-products of weathering (*q.v.*), denudation, and soil formation, they occur mainly on erosional platforms such as pediments (*q.v.*) or as **cappings** and residuals on stream divides. The crusts usually form parts of deep-weathering profiles that may be as thick as 120 metres (400 feet). Alternatively, they occur at the bases of cliffs and scarps, in river terraces, or on valley bottoms, usually near to and lower than residual **cappings**. Except at the wasting or developing edges of crusts, the thickness ranges from about 0.5 m (1.5 ft) to at least 12 m (40 ft). This contrasts with the platelike weathering rinds as thick as 15 centimetres (6 inches) that are often associated with cavernous (alveolar) weathering, particularly in arid areas.

Duricrusts are concentrated in intertropical to subtropical areas, with notable extratropical extensions, especially in South Africa and Australia (Figure 1). They

normally are absent from equatorial rain forests. Many are fossil crusts, in the sense that they relate to past climatic, biologic, and geomorphic environments and are not forming under present conditions in these areas.

Other types of crust are associated with subhumid to arid climates, although not necessarily with the arid climatic zones of today. Crusts of calcium carbonate (calcrests) and calcium sulfate (gypcrusts), up to 4 m (about 13 ft) thick, occur in basins of inland drainage, where they form initially as evaporites (*q.v.*). Alternatively, calcrests form as surface to subsurface soil horizons, or zones, at and near the extreme end of the calcium-rich soil range. Gypsum-rich horizons, common in many desert and semidesert soils, seem not resistant enough to erosion to become crusts. Calcsilicic crusts, which result from the silification of calcrests or other surficial limestones, have been little studied in this context. Salcrusts (salt crusts) form in depressions along desert coasts or wherever saline groundwater emerges, but unless they crystallize into rock salt these crusts also lack resistance to erosion and can be ephemeral.

This article treats the physical and chemical characteristics of the several kinds of duricrusts, their present distribution, and the factors that are involved in their formation. For additional information on the latter topic, see SOILS; WEATHERING; GEOCHEMICAL EQUILIBRIA AT LOW TEMPERATURES AND PRESSURES; and CLIMATIC CHANGE. See also DESERTS; PEDIMENTS; and PLAYAS, PANS, AND SALINE FLATS for relevant information on duricrust environments.

Salcrete	salcrust	halitic	NaCl (usually impure; rock salt)

\*Characteristic minerals in the fersiallitic range: SiO<sub>2</sub>, quartz + chalcidonic silica; Al<sub>2</sub>O<sub>3</sub>, amorphous, to Al<sub>2</sub>O<sub>3</sub>·2H<sub>2</sub>O, gibbsite, and AlOOH, boehmite; Fe<sub>2</sub>O<sub>3</sub>, hematite, to FeOOH, goethite, and Fe<sub>2</sub>O<sub>3</sub>·2H<sub>2</sub>O, limonite (where unhydrated); TiO<sub>2</sub>, rutile/anatase; MnO<sub>2</sub>, pyrolusite/psilomelane.

Figure 2: Relationships of duricrusts and weathering profiles in West Africa.

PHYSICAL CHARACTERISTICS AND CHEMICAL COMPOSITION

**Ferricrusts and silicrusts.** The size, shape, and arrangement of materials in ferricrusts (iron-rich crusts) and silicrusts (silica-rich crusts) ranges from nodular, through slaggy, to blocky or massive. Bedrock structures can be entirely destroyed or, as in some silicrusts, perfectly preserved. Silt-sized material is rare to absent. Duricrusts observed in the field exhibit a range of colours, but silica-rich crusts often are yellowish or yellowish-red, the several iron-rich crusts (Table 1) are more definitely reddish or reddish-brown, and allitic crusts (alumina-rich) are usually iron-stained and exhibit reddish hues on their exterior surfaces.

The name laterite (properly, lateritic crust) is widely applied to ferricrusts and even to silicrusts. This usage is unfortunate in the opinion of some, but it dates back to 1807, when F. Buchanan described a zone below the upper part of a deep-weathering profile (thick zone of weathered material above bedrock) as laterite. Ferricrusts result from the hardening *in situ*, however caused, of subsurface oxides of iron and aluminum; this material is termed plinthite in the soils classification used by the U.S. Department of Agriculture. The hydrated forms of these oxides, the minerals goethite and gibbsite, are often present, but others, such as limonite and boehmite, are less common or less abundant (see Table 1). Silica content, which consists of residual quartz and combined silica, usually is less than 20 percent and can fall below 1 percent (Table 2). Fe<sub>2</sub>O<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub> content, after igni-

allitic (aluminum-rich), ferritic (iron-rich), and ferman-gitic (iron-manganese) crusts in West Africa. The deep-weathering profile beneath the highly leached, residual allitic cap consists of kaolinitic clay, at least partly blotched and reddened, often with a sandy horizon just above bedrock. Crusts at lower levels (so-called detrital and groundwater laterites) form from detritus and solutes supplied mainly by the eroding cap. In eastern Africa and in Australia the profiles are strongly differentiated into a light-coloured kaolinitic zone at the bottom, a mottled zone in the middle, and a so-called indurated (hardened) zone at the top. This subdivision is imprecise, however, because the mottled zone can be partly or wholly indurated.

Figure 3 summarizes the transition from ferricrusts to silicrusts in the eastern half of Australia. Silicrusts contain as much as 99 percent silica in the form of sand and pebbles, and chalcedony and other kinds of silica. The crusts weather into bouldery blocks and angular fragments and supply a common type of gibber material from their receding edges. Thin hematite skins on quartz grains in silicrust can produce misleading red colours. Deep-weathering profiles topped by silicrust may be highly siliceous throughout; Al<sub>2</sub>O<sub>3</sub> content rises only as the light-coloured zone becomes increasingly kaolinized (Table 2).

In Australia, India, Africa, and South America, the main expanses of duricrust mantle pediments and plains in varying states of dissection, although some crusts occur in valleys in terrain of high relief. Allitic crusts yield commercial bauxite. Detrital and valley-floor duricrusts occur in all these countries, chiefly adjacent to the margins of residual caps. These crusts include economic reserves of manganese ore in western Africa and silicified terrace gravels in southern Australia. Possible combinations of terrain, weathering, erosion and dissection of duricrusts and continued or renewed duricrust formation are highly complex. Additionally, some duricrusts now lie buried beneath continental (nonmarine) sediments.

Rough limits to present-day ferricrust formation are the 500- to 700-millimetre (20- to 27.5-inch) isohyet (contour of equal rainfall values), below which iron is not readily mobilized, and the 1,200-mm (47.5-in.) isohyet (shown in Figure 1), above which dehydration is unusual. High mean annual temperatures, on the order of 20° to 25°C (68° to 77° F), also are necessary. Duricrusts that occur beyond the indicated limits are generally fossil (related to former climatic regimes), and many within these limits also are fossil. Ages determined by stratigraphic or radiometric methods are as great as 50,000,000 years in western Africa and more than 23,000,000 years in Australia, but duricrust formation is occurring today in some places. Phenomena related to fossil crusts include the Tertiary deep weathering of the southern Piedmont area of the United States, of massifs in western and north-western Europe, and the Tertiary formation of residual bauxite at latitude 65° N in Siberia.

Weathering profiles in West Africa and Australia

tion loss, can exceed 80 percent; combined water is usually between 5 percent and 25 percent. Local enrichment with MnO<sub>2</sub> or TiO<sub>2</sub> can amount to 20 percent. Interstices in ferricrusts, if not barren, contain mainly kaolinitic to halloysitic clays (see CLAY MINERALS).

Figure 2 illustrates characteristic interrelationships of

Limits of modern formation

Figure 3: Structures of duricrusts in vertical sections in eastern Australia.

**Calcrests and gypcrusts.** Calcrests formed in basins of inland drainage are largely calcitic, and calcite content often exceeds 85 percent. They frequently display a travertine-like structure but range in origin from shoreline deposits as with the Lake Bonneville tufas, to depression-floor sheets, as in western and central Australia. Calcrests formed as soil horizons are especially well known from the southern High Plains and southwestern U.S. Varying in structure from massive and well cemented to loose and friable, and ranging in thickness to about 2 m (7 ft), they are most resistant when they contain appreciable silica.

Gypcrusts (gypsum-rich crusts) typically contain more than 95 percent gypsum and vary from massive crystalline gypcrete to loose, powdery deposits. Initially an evaporite, loose gypsum may be transported by the wind and redeposited to encrust sand dunes and rockcut pediments, as in northern Africa.

Calcrests and gypcrusts are widely scattered through the world's deserts, where some record a former pluvial period (moist period of the Pleistocene Epoch); Figure 1 can only indicate selected occurrences. Salcrusts (salt crusts) in flat-bottomed depressions typify the sabkha (saline flats) of northern Africa and Arabia and corresponding features in other countries. Parts of the Punjab are affected by saline crusting on low-angled alluvial fans.

#### FACTORS INVOLVED IN THE FORMATION OF DURICRUSTS

**Leaching and end products of weathering.** The formation of ferricrust requires the selective removal of the mobile (easily leached) soil constituents sodium, potassium, calcium, and usually magnesium, and also the removal of silica other than residual quartz. Conversely,  $\text{Fe}_2\text{O}_3$ ,  $\text{Al}_2\text{O}_3$  or its hydrates, and sometimes  $\text{TiO}_2$  become

concentrated. In addition, the oxide-rich soil horizon must eventually dry out and the overlying material be stripped off to reveal the indurated crust.

Mobilization and leaching of Na, K, Ca, and Mg offers no problem, and nonquartzose silica is recognized as more mobile than  $\text{TiO}_2$ ,  $\text{Fe}_2\text{O}_3$ , or  $\text{Al}_2\text{O}_3$ . Although the rate of silica removal can be matched in other humid areas, silica in solution provides about half the dissolved load of tropical rivers generally. For some catchments, a denudation rate of 4 to 5 cm (1.6–2 in.) per 1,000 years is indicated. Silica solubility rises with increasing alkalinity or pH; the mineral can readily be transported as a hydrous oxide gel or in allophane gel (an amorphous or unstructured state) and forms a significant bulk fraction of many tropical plants. In acid environments (pH less than 7) silica undergoes imprecisely known processes to combine with aluminum oxides and hydroxides, and with hydroxyls to form kaolinitic clays, but severe and repeated wetting can recombine these into  $\text{Al}_2\text{O}_3$  and  $\text{Si}(\text{OH})_4$ .  $\text{Fe}_2\text{O}_3$  is insoluble except under highly acid conditions (below about pH = 4), and  $\text{Al}_2\text{O}_3$  is soluble in the same range as well as at pH = 10. Varying combinations of relative mobility are therefore possible.

The formation of crusts involves great loss of weathered material. A generalized example from the tropical weathering of a nepheline-syenite (intrusive igneous rock) shows a reduction of silica ( $\text{SiO}_2$ ) from 55 percent in the fresh rock to 5 percent in the duricrust, but an increase of alumina ( $\text{Al}_2\text{O}_3$ ) from 1 percent to 45 percent, of iron oxide ( $\text{Fe}_2\text{O}_3$ ) from 5 percent to 23 percent, and of combined water from 1 percent to 25 percent (Table 2).

The circulation of nutrients between plants and soil in tropical forests involves excess uptake by the plants, and this in turn promotes deep weathering. Within the deep-weathering profile, silt-size material is broken down or

Selective removal of soil constituents

Figure 4: (Left) Boulderly silicrust on summit of residual; vertical divisions on picket are one foot (25 centimetres). (Centre) Coastal section of indurated plinthite, part of a ferricrust profile. (Right) Quartz and hematite skins; width of field is two millimetres.

leached out. Clay minerals tend to be dispersed and moved downward, especially where high rainfall and vigorous plant growth lower the electrolyte concentration. The remaining oxides tend to aggregate into forms in which spheroidal microstructures are common.

Mechanisms that are capable of promoting dehydration and hardening of ferricrusts, whether before, during, or after stripping of the overlying soil, include the destruction of forest and lowering of the water table, both of which can occur in several ways. Aside from clearance by man, for example, forest destruction may be caused by climatic change and downcutting by fluvial processes.

Silcrust formation requires the selective concentration of silica, a fact that has led some writers to consider silcrusts as the lower parts of ferricrust profiles. The distributional contrast between silcrusts and ferricrusts is clear, however, and the transition between the types is well documented (Figures 1 and 3). Silcrusts often, but not invariably, result from the silicification of sandstones and quartzitic conglomerates. They occur in areas that are currently drier than those with ferricrusts, but the fossil nature of many, plus the deep-weathering profiles to which they usually belong, presumably indicate humid climates at the time of formation and inhibit direct reference to existing controls. Like ferricrusts, silcrusts are usually taken to have originated below the ground surface, possibly under a layer of erodible, fine material.

#### **Mobilization, migration, and concentration of ions.**

Soil-formation processes of selective concentration of oxides of iron and aluminum, and in some circumstances of silica, include ion exchange as a most important factor. Although not yet completely understood, this involves the exchange of ions held by negative charges with other ions in the electrolyte (soil solution). Ion exchange is influenced by the fit of ions into a mineral structure. Relevant processes include hydration (adsorption of water), hydroxylation (adsorption of  $H^+$  and  $OH^-$  ions), oxidation (combination of oxygen, with loss of electrons to weathering agents), and reduction (depletion of combined oxygen). Ion exchange is controlled by the cation exchange capacity (CEC) expressed as the amount of exchangeable cations in milliequivalents per 100 grams clay at pH 7. Low CEC values are typical of kaolinitic clays and of actual or potential duricrusts.

Soil water will separate into oppositely charged ions,  $H^+$  and  $OH^-$ , and the  $CO_2$  of the atmosphere and soil will yield  $HCO_3^-$  and free  $H^+$  ions in solution. These products promote displacement of some metal cations, especially those in mineral silicates, largely by  $H^+$  ions that combine with  $OH^-$  in removable solutes. The  $H^+$  ions are small and highly charged in relation to their size and can readily enter many crystal lattices;  $OH^-$  ions neutralize the small charges of  $Na^+$ ,  $K^+$ , and the larger charges of  $Ca^{++}$  and  $Mg^{++}$ . Positive charges in soil particles are partly related to hydrous oxides of iron, aluminum, and manganese. Negative charges, increasing with falling pH, are neutralized by positive ions, among which  $Al(OH)_2^+$  is one of the more significant. Negatively charged colloidal  $SiO_2$  and colloidal  $Al_2O_3$  and positively charged  $Fe_2O_3$  probably interact at high concentrations of  $H^+$  ions to form clay minerals. Among these, the most stable are the one-to-one layer silicates of the kaolin family, in which each silicon-oxygen sheet is condensed with one aluminum hydroxide sheet.

At least part of the ion-exchange process involves organisms and organic substances. Chelating agents, complex amino acids, and allied compounds inactivate ions of aluminum and iron and hold them firmly in lattice structures. The ions then behave as if they were not present, except when acidity markedly decreases and they are redeposited. Manganese and silicon can be similarly treated. The combined processes of solution and eluviation (soluviation) and of chelation and eluviation (cheluviation) appear to act powerfully in the formation of oxide-rich plinthite prior to duricrust formation. In the mobilization and fixing of iron, as in the general production of organic acids, bacteria also play a part. Some act to form soluble iron, others oxidize soluble ferrous iron

( $Fe(OH)_2$ ) to insoluble ferric iron ( $Fe_2O_3$ ); and soil micro-organisms, including bacteria, are specifically involved in the production of a number of prominent chelating agents.

**Rock type, terrain, and water table fluctuations.** Duricrusts occur on a wide range of igneous, metamorphic, and sedimentary rocks, including granites, basalts and gabbros, arenites, and argillites. There is only the roughest of tendencies for duricrust chemistry to be controlled by bedrock chemistry, even in similar climates, although nepheline-syenites characteristically weather into allitic (aluminum-rich) crusts, basic igneous rocks into ferritic (iron-rich) to tiallitic (titanium-aluminum) crusts, and arenites and argillites, in some areas, into silitic (silica-rich) crusts. Ferritic crusts are more highly indurated, more variable in structure, and less strongly hydrated than aluminous crusts. Although structures in silitic crusts vary from pea-sized nodules to blocky and massive, with natural, subsurface erosion pipes at lower levels, these crusts are not hydrous.

Profile drainage is influential; ready leaching and alkaline to neutral conditions favour removal of silica and concentration of aluminum and also of titanium if available. Nearness to the water table promotes concentration of iron, whereas poor site drainage and acidity possibly favour accumulation of silica. As previously stated, however, known distributions suggest geographic contrasts between ferricrust and silcrust formation, rather than lithological control, which appears to be effective only in transitional belts.

Terrain requirements for duricrust formation include gentle slopes or situations where groundwater can supply oxides of iron and manganese or both of these. Well-preserved fossil crusts on pediments or plains with maximum slopes of  $8^\circ$  to  $10^\circ$  (and average slopes of  $2^\circ$  or less) suggest feeble lateral movement of groundwater and relative enrichment of crusts by leaching. This contrasts with the active translocation responsible for the absolute enrichment of crusts at the base of scarps and on valley floors. Also indicative of groundwater action are the light-coloured and mottled zones of many deep-weathering profiles; the former are regarded as the result of kaolinization in a reducing (de-ionizing) environment, and the latter from seasonal fluctuation of the groundwater level. Incapacity of these zones to supply the iron content of numerous crusts confirms relative enrichment.

**Effects of climate and time.** Calccrusts, gypcrusts, and salcrusts are referable to dry climates, but duricrusts proper, at least in present and late Holocene occurrences, are referable to humid tropical climates, probably with seasonal dryness, coincident wet and warm seasons, and soil temperatures in the average range  $25^\circ$  to  $30^\circ$  C (about  $75^\circ$  to  $85^\circ$  F). Under these conditions, 50 percent or more of the original rock volume can be lost during weathering, but the preservation of structures in some profiles indicates downward thickening rather than overall diminution.

A span of 30 to 50 years will convert a drying ferallitic clay to a ferallitic duricrust; but extrapolation from

indicators  
of climatic  
change

known values suggests that up to 15,000,000 years may be required to form really deep-weathering profiles. Such time spans seem to be well within the range of duration of humid tropical forests in the Tertiary, however.

Climatic change presumably is responsible for the presence of duricrusts in equatorial areas that now receive more than 1,200 mm (about 47 in.) mean annual precipitation. The former northward extension of aridity in Africa, with Kalahari sand extending 1,600–3,000 km (1,000–1,900 mi) beyond its present limit, is well documented. Similarly, former climates of the current humid tropical type are probably responsible for fossil crusts outside the tropics and for relict Tertiary deep weathering. Such climates seem explicable in terms of reduced pole-to-equator temperature gradients. Increased temperatures are indicated by oxygen-isotope analysis, and increased humidities by floral records, including those of Tertiary soft coals. These climates are not explicable by continental drift (*q.v.*), the influence of which, in northward-moving Australia, they more than offset.

Although dehydration and hardening of duricrusts are often called irreversible, this is not true over the long term. Apart from disaggregation of eroding caps, residual ferricrusts can be attacked by renewed soil-formation processes, which remobilize iron and produce red-yellow soils called "lateritic podzolics" in older classifications.

**Remaining problems.** Further elucidation of ionic and micro-organic action in the formation of tropical weathering profiles are essentially soil-science problems. Geomorphic and stratigraphic problems relating to duricrusts include the refinement of the world distribution map (Figure 1) and the establishment of a well-based history of deep weathering and crust formation. Lower limits of the requisite temperature and precipitation need to be fixed, with particular reference to the reconstruction of Tertiary climates, for which it seems necessary to postulate a general pattern of atmospheric circulation unlike that of today. Exact analogues of duricrusts proper have still to be demonstrated in the geological column, although numerous writers relate the formation of red beds to processes like those currently responsible for red (hematitic) tropical weathering. Silicified arenites (silica-rich sandstones) of terrestrial origin are also known. The contrast between silicrust formation and ferricrust formation has yet to be explained in terms other than those of parent rock type. There also is room for study of the relationship of the silicrust formation associated with deep weathering and thorough silicification, which affects bedrock on steep slopes and high residuals above the general silicrusted pediplain at some Australian sites.

(G.H.D.)

## Durkheim, Émile

Émile Durkheim was the first social scientist to subject specific phenomena of everyday life to close sociological study and to formulate a vigorous methodology. His influence on his discipline has probably not been matched in the 20th century. A modest and a generous man, he paid tribute to the 18th-century French political philosopher Montesquieu as the precursor of his sociological approach to law and government studies, and to Henri de Saint-Simon and to Auguste Comte as his more direct predecessors in the investigation of society.

By courtesy of Presses Universitaires de France

Durkheim.

Durkheim was born in April of 1858, in the small town of Épinal, in the Vosges region of eastern France. His family was Jewish and of very modest means. It was taken for granted that he would study to become a rabbi, like his father. The death of his father before Durkheim was 20 burdened him with heavy responsibilities. That, and the atmosphere of France's eastern provinces bordering on Germany, during an intense period of national rivalry, may have contributed to making Durkheim a severely disciplined young man. As early as his late teens Durkheim became convinced that effort and even sorrow are more conducive to the spiritual progress of the individual than pleasure or joy. His outstanding success at school designated him clearly as a candidate to the renowned École Normale Supérieure in Paris—the most prestigious teachers' college in France. While preparing for the École Normale at the lycée Louis le Grand, Durkheim took his board at the Institution Jauffret in the Latin Quarter, where he became acquainted with another gifted young man from the provinces, Jean Jaurès, later to lead the French Socialist Party and at that time inclined like Durkheim toward philosophy and the moral and social reform of his countrymen. Durkheim passed the stiff competitive examination for the École Normale one year after Jaurès, in 1879. It is clear that his religious faith had vanished by then. His thought had become altogether secular but with a strong bent toward moral reform. Like a number of French philosophical minds during the Third Republic, he looked to science and in particular to social science and to profound educational reform as the means to eschew the perils of anarchistic individualism or "anomie," as he was to call this condition in which norms for conduct were either absent, weak, or conflicting.

He enjoyed the intellectual atmosphere of the École Normale—the discussion of metaphysical and political issues pursued with eagerness and animated by the utopian dreams of young men destined to be among the

Childhood  
and  
education

leaders of their country. He soon enjoyed the respect of his peers and of his teachers, but he was impatient with the excessive stress then laid in French higher education on elegant rhetoric and surface polish. His teachers of philosophy struck him as too fond of generalities and of monotonous worship of the past. Fretting at the conventionality of formal examinations, he passed the last competitive examination in 1882, but without the brilliance that his friends had predicted for him. He then accepted a series of provincial assignments as a teacher of philosophy at the state secondary schools of Sens, Saint-Quentin, and Troyes between 1882 and 1887. In 1885–86 he took a year's leave of absence to pursue research in Germany, where he was impressed by Wilhelm Wundt, pioneer experimental psychologist. In 1887 he was appointed as lecturer at the University of Bordeaux, where he subsequently became professor and taught social philosophy until 1902.

Durkheim was familiar with several foreign languages and reviewed volumes in German, English, and Italian at length in the learned journal *L'Année Sociologique*, which he founded in 1896. But it has been noted, at times with disapproval and amazement, by non-French social scientists, that he travelled little and that, like many French scholars as well as the noted British anthropologist Sir James Frazer, he never undertook any fieldwork. The vast information he studied on the tribes of Australia or of New Guinea or on the Eskimos was all collected by other anthropologists, travellers, or missionaries. This was not, in Durkheim's case, due to provincialism or lack of attention to the concrete. He did not resemble the French philosopher Auguste Comte in making venture-some and dogmatic generalizations and disregarding empirical observation. He did, however, maintain that concrete observation in remote parts of the world does not always lead to illuminating views on the past or even on the present. To him facts had no meaning for the intellect unless they were grouped into types and laws. He claimed repeatedly that it is from a construction erected on the inner nature of the real that knowledge of concrete reality is obtained, a knowledge not perceived by observation of the facts from the outside. He thus constructed concepts such as that of the sacred or of totemism, exactly in the same way that Karl Marx developed the concept of class.

In truth, Durkheim's vital interest did not lie in the study for its own sake of so-called primitive tribes, but rather in the light such a study might throw on the present. The outward events of his life as an intellectual and as a scholar may appear undramatic. Still, much of what he thought and wrote stemmed from the events that he witnessed in his formative years, in the 1870s and 1880s, and in the earnest concern he took in them. The Second Empire, which collapsed in the French defeat of 1870 at the hands of Germany, had seemed an era of levity and dissipation to the earnest young man that Durkheim was. France, with the support of many of her liberal and intellectual elements, had plunged headlong into a war for which she was unprepared; her leaders proved incapable. The left-wing Commune that took over Paris after the French defeat in 1871 led to senseless destruction, which appeared to Durkheim's generation, in retrospect, as evidence of the alienation of the working classes from capitalist society. The bloody repression that followed the Commune was taken as evidence of the ruthlessness of capitalism and of the selfishness of the frightened bourgeoisie. Later, the crisis of 1886 over Georges Boulanger, minister of war who demanded a centralist government to execute a policy of revenge against Germany, was one of several events that testified to the resurgence of nationalism, soon to be accompanied by anti-Semitism. Such major French thinkers of the older generation as Ernest Renan and Hippolyte Taine interrupted their historical and philosophical works, after 1871, to analyze those evils and to offer remedies. Durkheim was one of several young philosophers and scholars, fresh from their *École Normale* training, who became convinced that progress was not the necessary consequence of the development of science and technology; that it could not be represented

by an ascending curve, justifying complacent optimism. He perceived around him an absence of moral norms or "anomie," an excess of individualism bordering on anarchy; material prosperity set free greed and passions that threatened the equilibrium of society.

These sources of Durkheim's sociological reflections, never remote from moral philosophy, were first expressed in his very important doctoral thesis, *De la division du travail social* (1893; *The Division of Labour in Society*) and in *Le Suicide* (1897; *Suicide*). In his view ethical and social structures were being endangered by the advent of technology and mechanization. The division of labour rendered workmen both more alien to one another and more dependent upon one another, since none of them any longer built the whole product by himself. Suicide appeared to be less frequent where the individual was closely integrated with his culture; thus the apparently purely individual decision to renounce life could be explained through social forces. These early volumes, and the one in which he formulated with scientific rigour the rules of his sociological method, *Les Règles de la méthode sociologique* (1895; *The Rules of Sociological Method*), brought Durkheim fame and influence. But the new science of society frightened timid souls and conservative philosophers, and he had to endure many attacks. The Dreyfus affair—resulting from the false charge against a Jewish officer, Alfred Dreyfus, of spying for the Germans—erupted in the last years of the century, and the slurs or outright insults aimed at Jews that accompanied it opened Durkheim's eyes to the latent hatred and passionate feuds hitherto half concealed under the varnish of civilization. He took an active part in the campaign to exonerate Dreyfus. He was not elected to the Institut de France, although his stature as a thinker suggests that he should have been named to that prestigious, learned society. He was, however, appointed to the University of Paris in 1902 and made a full professor there in 1906.

More and more, the sociologist's thought became concerned with education and religion as the two most potent means of reforming man or of molding the new institutions required by the deep structural changes in society. His colleagues admired Durkheim's zeal in behalf of educational reform. His efforts included participating in numerous committees to prepare new curriculums and methods; working to enliven the teaching of philosophy, which too long had dwelt on generalities; and attempting to teach teachers how to teach. A series of courses that he had given at Bordeaux on the subject of *L'Évolution pédagogique en France* ("Pedagogical Evolution in France") was published posthumously in 1938; it remains one of the best informed and most impartial books on French education. The other important work of Durkheim's latter years dealt with the totemic system in Australia and bore the title of *Les Formes élémentaires de la vie religieuse* (1915; *The Elementary Forms of the Religious Life*). The author, despite his own agnosticism, evinced a sympathetic understanding of religion in all its stages. French conservatives, who in the years preceding World War I turned against the Sorbonne, which they charged was unduly swayed by the prestige of German scholarship, railed at Durkheim who, they thought, was influenced by the German urge to systematize, making a fetish of society and a religion of sociology. In fact, Durkheim did not make an idol of sociology as did the positivists schooled by Comte, nor was he a "functionalist" who explained every social phenomena by its usefulness in maintaining the existence and equilibrium of a social organism. He did, however, endeavour to formulate a positive social science that might direct men's behaviour toward greater solidarity.

The outbreak of World War I came as a cruel blow to him. For many years he had expended too much energy on teaching, on writing, on outlining plans for reform, on ceaselessly feeding the enthusiasm of his disciples, and eventually his heart had been affected. His gaunt and nervous appearance filled his colleagues with foreboding. The whole of French sociology, then in full bloom thanks to him, seemed to be his responsibility. The breaking

Effect of  
Dreyfus  
affair

Attitude  
toward  
fieldwork

point came when his only son was killed in 1916, while fighting on the Balkan front. The father stoically attempted to hide his sorrow; but the loss, coming on top of insults by nationalists who denounced a professor of "apparently German extraction" who taught a "foreign" discipline at the Sorbonne, was too much for him. He died on November 15, 1917.

He left behind him a brilliant school of researchers. He had never been a tyrannical master; he had encouraged his disciples to go farther than himself and to contradict him if need be. His nephew, Marcel Mauss, who held the chair of sociology at the Collège de France, was less systematic than Durkheim and paid greater attention to symbolism as an unconscious activity of the mind. Claude Lévi-Strauss, who has since occupied the same chair of sociology and resembles Durkheim in the way he combines reasoning with intensity of feeling, also offered objections and corrections to Durkheim's views. With Durkheim sociology had become in France a seminal discipline that broadened and transformed the study of law, of economics, of Chinese institutions, of linguistics, of ethnology, of art history, and of history.

**BIBLIOGRAPHY.** HARRY ALPERT, *Émile Durkheim and his Sociology* (1939, reprinted 1961), offers, in its first section, a good account of Durkheim's life. The article by TALCOTT PARSONS in *The International Encyclopedia of the Social Sciences*, 4:311-20 (1968), is clear and succinct. A collective volume, *Émile Durkheim, 1858-1917: A Collection of Essays with Translations and a Bibliography*, ed. by K.H. WOLFF (1960; issued in paperback as *Essays on Sociology and Philosophy, with Appraisals of Durkheim's Life and Thought*, 1964), contains a full chapter on Durkheim's life. The two best volumes in French are those of A.P. LA FONTAINE, *La Philosophie d'Émile Durkheim* (1926); and of JEAN DUVIGNAUD, *Durkheim: sa vie, son œuvre* (1965).

(H.M.P.)

## Duse, Eleonora

The most fluent and expressive actress of her day, Eleonora Duse created afresh every role she played and was different in each of them. Her gift was in marked contrast to the talented contemporary star of the French theatre, Sarah Bernhardt, a great technician who always strove to project her own personality from the stage, whatever character she might be playing. Duse found her great interpretative roles in the heroines of the Norwegian playwright Henrik Ibsen, but she could also lend her soul to the puppet-like creations of such dramatists as Victorien Sardou and the younger Dumas, bringing to life on stage the characters they themselves had failed to animate.

Eleonora Duse was born in a railway coach on October 3, 1858, near Vigevano, Italy. Most of her family were actors who played in the same touring troupe, and Eleonora made her first stage appearance at the age of four in a dramatization of Victor Hugo's *Les Misérables*. By the age of 14, when she played Juliet at Verona, her talents were already being recognized by critics; but after her family died she moved from one company to another, without a great deal of success, until her appearance at Naples in 1878. This marked the turning point of her career. Her performances there as Electra and Ophelia were admired, but it was her characterization of the title role in Émile Zola's *Thérèse Raquin* that won greatest acclaim, with audiences and critics united in the opinion that a woman's anguish had never before been played with such truth.

In 1882 Duse took an opportunity to watch Bernhardt perform. The French actress's success in modern roles gave Duse the idea also of appearing in plays by contemporary French dramatists (for she had discovered that Italian audiences were bored by the stale pieces that formed the traditional repertory), and so for three years she acted in a number of plays by the younger Dumas. The first of these was Lionette in *La Princesse de Bagdad*, a play from which Parisians had recoiled when a French actress played the lead. Duse, however, scored a triumph and followed it up with Cesarine in *La Femme de Claude*; in 1884 she created the title role of Dumas's latest play, *Denise*, and also the part of Santuzza in Giovanni Verga's

Eleonora Duse.

By courtesy of the Library of Congress, Washington, D.C.

*Cavalleria rusticana*. With Cesare Rossi, a prominent actor-manager, she toured South America in 1885, but after her return to Italy she formed her own company, the Drammatica Compagnia della Città di Roma, and with it toured Austria, Germany, England, France, Russia, Egypt, Belgium, and Portugal, making visits also to the United States in 1893, 1896, and 1902. Idolized wherever she went, she felt most appreciated as an artist in the city of Vienna.

In 1894 she met and fell in love with a rising young poet, Gabriele D'Annunzio, and he wrote for her a number of plays. Her belief in his talent was boundless, and his cult of beauty added another dimension to her acting. A radiant glow is said to have emanated from her whenever she played one of his characters. D'Annunzio told the story of their love in his novel *Il fuoco* (1900; Eng. trans., *The Flame of Life*).

Aside from D'Annunzio's plays, Duse found an inexhaustible source of self-expression in the dramas of Ibsen. She never tired of playing Nora in *A Doll's House*, Rebecca West in *Rosmersholm*, Ella Rentheim in *John Gabriel Borkman*, and, above all, Ellida in *The Lady from the Sea*. To the title role in *Hedda Gabler* she brought a demonic quality, a touch of the fantastic—deeply troubling to Ibsen when he saw her perform it—as though she had gone beyond the frontiers of realism.

The British playwright George Bernard Shaw was one of the many critics fascinated by Duse's ability to produce an illusion "of being infinite in variety of beautiful pose and motion." He confessed that "in an apparent million of changes and inflexions" he had never seen her at an "awkward angle" in defiance of the "natural gravitation toward the finest grace" (*Dramatic Opinions and Essays*, 1907). She had a thousand faces; her physical command, range, and choice of gesture were superb; she had a different way of walking for each part; she even mastered the colour of her face, which was unspoiled by makeup, and Shaw's professional curiosity was aroused when he pondered the question of whether Duse's blush could always be summoned at her will. Yet the total effect was of more than "naturalistic" acting: Duse acted not only the reality, she also commented on the characters she played

Love affair  
with  
Gabriele  
D'Annunzio

Style of  
acting

—she "knew" far more about Nora, for instance, than Ibsen's heroine could possibly have known about herself. One of her critics wrote that Duse played what was between the lines; she played the transitions. A tremor of her lips could reveal exactly what went on in her mind; and, where the character's inner life was lacking, because the dramatist had failed his task, she supplied motivation herself. To watch her was to read a psychological novel.

In 1909 Eleonora Duse quit the stage, mainly for reasons of health. Financial losses incurred during World War I, however, obliged her to emerge from retirement in 1921. Her acting powers were undiminished, but her health was still not good and interfered with her late career. In 1923 she appeared in London for six matinee performances, then played three nights in Vienna, before she embarked upon her last tour of the United States. This began with an appearance on the vast stage of the Metropolitan Opera House in New York City and ended in Pittsburgh where the actress died on April 21, 1924. Her body was taken back to Italy and, in compliance with her request, she was buried there in the small cemetery of Asolo.

**BIBLIOGRAPHY.** JEANNE BORDEUX, *Eleonora Duse: The Story of Her Life* (1925), the first biography in English—a simple, occasionally naïve account of the actress's tribulations and triumphs; EDOUARD SCHNEIDER, *Eleonora Duse, souvenirs, notes et documents* (1925), contains new material related to the last years of Duse's life, based upon conversations with the actress; ARTHUR SYMONS, *Eleonora Duse* (1926), rhapsodic impressions of the actress at various stations of her career; E.A. RHEINHARDT, *Das Leben der Eleonora Duse* (1928; Eng. trans., *The Life of Eleonora Duse*, 1930), a biography that reads like a novel and is basically uncritical—no attempt is made to analyze her acting style; O.R. SIGNORELLI, *La Duse* (1938), chronologically arranged anecdotes; BERTITA HARDING, *Age Cannot Withstand: The Story of Duse and D'Annunzio* (1947), a narrative concentrating on the celebrated love affair; EVA LE GALLIENNE, *The Mystic in the Theatre: Eleonora Duse* (1966), a fellow artist's attempt to evoke the ephemeral fascination of another; the only study that pays attention to Duse's technique and the spiritual aspects of her art.

(A.M.N.)

## Dvina River, Northern

One of the largest rivers and certainly the most important waterway of the northern part of the European portion of the Soviet Union, the Northern Dvina (Severnaya Dvina) flows slowly and majestically through a cold and inhospitable terrain. It is formed by the junction of the Sukhona and Yug rivers (349 miles [562 kilometres] and 357 miles [574 kilometres] long, respectively) at the city of Velikiy Ustyug, which lies in the Vologodskaya oblast (region) of the Russian Soviet Federated Socialist Republic just north of 61° north latitude. The river flows in a generally northwestern direction through the Vologodskaya and Arkhangelskaya oblasti and enters the Dvina inlet of the White Sea below the city of Arkhangelsk, just south of 65° north latitude, 140 miles from the Arctic Circle. The river's length is 462 miles (744 kilometres), and it drains a basin that, at 138,000 square miles (357,000 square kilometres), is larger than the whole of Poland. The fall of the river along its course is only about 160 feet; the flow is calm and, especially near the river mouth, very slow. (For related information see RUSSIAN SOVIET FEDERATED SOCIALIST REPUBLIC.)

The course of the river. Until its confluence with the tributary Vychegda River, the Northern Dvina is also occasionally called the Little Northern Dvina (Malaya Severnaya Dvina) with the remainder of its course known as the Greater Northern Dvina (Bolshaya Severnaya Dvina). A four-part division of the whole consists of an initial section downstream to the city of Kotlas; a portion downstream to the confluence of the Vaga; from the Vaga to the Pinega; and, finally, downstream to the mouth.

In the first section, the river flows northeast in the middle of a wide valley, with high banks alternating on the left and right. The width of the river is 1,000–1,600 feet and the depth from seven to 16 feet. In the second sector the amount of water in the river more than dou-

bles with the influx of the Vychegda, the wide valley has been strewn with alluvial deposits, and the many-braided river bed—in which there are many shoals and sandbars—is contained between high banks. The well-established main channels include the Novinsky, Peschansky, Tikhyy, and Syamovsky, and the strong spring floods constantly promote the formation of new channels. Near the river, extensive meadowlands, often marshy and containing dried-up river channels, are vulnerable to the swollen river waters. The river in this portion is 1,300–2,600 feet wide and from ten to 26 feet deep.

In the Vaga–Pinega section the river valley narrows considerably, and the river itself runs between steep limestone banks. Its width is now 2,000–3,300 feet and the depth 20–40 feet; it contains islands and shoals and occasionally spills over into narrow flood meadows. In its final section, the average width of the river valley is from three to four miles, but this conceals variations from 0.6 miles below the confluence with the Pinega to 11 miles at the village of Kholmogory, the home of the world-famous 18th-century scientist and poet M.V. Lomonosov. The river is single branched only at the beginning of this sector and at Arkhangelsk, but its basic bed averages 3,000–3,900 feet in width, and water depth is 23–39 feet; the floodplain is mainly on the left bank. At its mouth, the Northern Dvina Delta has an area of 425 square miles and is laced with a multitude of channels and branches, among which the Nikolsky, Korabeliny (both from Arkhangelsk to the sea), Kuznechikha, Maymaksy, and Murmanskyy are the most important.

**The basin.** The landscape drained by the Northern Dvina Basin is formed of low, undulating plains, falling away to the White Sea. It is bounded on the east by the low Timanski Ridge (Timanskiy Kryazh; where the Vychegda and its tributaries have their source) and the Severnye Uvaly Hills, which form the watershed with the Volga Basin to the south. The northern and central portions of the basin have a thick coating of coniferous forests, while mixed forests, with conifers predominant, are found to the south. In all, more than half the basin is forest clad. The soils of the region are mainly leached in type, reflecting their forest origins. Beyond the left bank of the river there are many low-lying bogs and lakes (including the large Lake Kubena [Ozero Kubenskoye]), which are often the source of tributary rivers. The Yemtsa (left-bank) and Pinega (right-bank) tributary basins are carved into karst scenery, with the limestone rocks of the areas permeated by water-dissolved holes and crevasses, springs, and disappearing streams; the erratic Sheleksa River is, in fact, a tributary of several other rivers.

The climate of the southern portion of the basin is moderately continental, becoming more extreme in the north. The average January temperatures range from 10° F (–12° C) to –4° F (–18° C), and the July readings are 50° F (10° C) to 64° F (18° C). Annual precipitation decreases from about 20 inches (500 millimetres) in the south to nearly half that figure in the north.

The banks of the Northern Dvina are largely covered by forests and shrubs, although in the scattered peopled sections they adjoin partly plowed areas crisscrossed by drainage canals. The floodplain is generally meadow-like in character and mostly marsh ridden. The mouth of the river is rich in fish, with about 30 species regularly caught.

**Water flow.** The Northern Dvina is primarily fed by melting snow, with widespread fluctuations in the water level occasioned by the building up of ice dams and ensuing spring floods. Highest levels occur in May, the lowest in late summer and autumn. The river-mouth sections are also influenced by the White Sea tides. The flow of water in the river shows a remarkable variation; although the average amount passing a point in the middle sections, for example, is about 70,600 cubic feet per second, the range is from a minimum of 2,300 cubic feet per second to a maximum of 700,000 cubic feet per second in flood time. Average figures for the upper and lower reaches (which also conceal variations) are 26,500 and

Source of  
the river

Water-flow  
variations

120,000 cubic feet per second, respectively. Most of the annual river flow (some 55–70 percent) is concentrated in the April–June period, as compared with only 6–8 percent the first three months of the year. In its upper course, the Northern Dvina begins to freeze around the end of November, becoming ice-free again by the end of April; the lower course is frozen for a slightly longer period. The spring witnesses frequent ice jams and floods along the whole river, particularly at Kotlas, around the Pinega confluence, and at Arkhangelsk.

The human imprint. The Northern Dvina Basin has undergone extensive improvement work in recent decades, most of it directed at facilitating the drainage of marsh, forest, and floodplain. Navigable sections of the river network of the basin have been improved by the straightening of portions of many smaller rivers, by the construction of timber dams, and by the formation of small reservoirs. The Northern Dvina itself is the main waterway of the northern European section of the Soviet Union and is linked—via the Sukhona River, Lake Kubena, the Porozovitsa River, and Northern Dvina Canal—with the important Volga–Baltic waterway and also, through the Pinega River, with the Kuloy and Mezen rivers. Navigation is possible for an average of 174 days each year in the upper course and 168 days in the lower. The main dock facilities are at Velikiy Ustyug, Kotlas, Krasnoborsk, Verkhnyaya Toyma, Yemetsk, and the famous northern port of Arkhangelsk. Prospects for the construction of a number of medium-sized hydroelectric stations in the upper and middle portions of the Northern Dvina attest to its emerging regional importance. (A.M.Ga.)

## Dvina River, Western

The Western Dvina, or Zapadnaya Dvina in Russian (Zapadnaja Dvina in the transliteration system of the Soviet Akademiya Nauk) and Daugava in Lettish, is a major river in the European part of the Union of Soviet Socialist Republics, with a total length of 632 miles (1,020 kilometres). Its source is the small Lake Dvinets on the western slope of the Valdai Hills not far from the source of the Volga, in Kalinin *oblast* of the Russian Soviet Federated Socialist Republic. It flows southward for about 150 miles, then southwest and west for 185 miles through the Belorussian Soviet Socialist Republic; at Beshenkovichy it turns to the northwest and flows through the Latvian S.S.R., where it is known as the Daugava, discharging into the Gulf of Riga on the Baltic Sea just north of the city of Riga.

Most of the river basin is between 300 and 700 feet above sea level—a rolling plain with many swamps and forests. The river drains an area of 34,000 square miles (88,000 square kilometres), but its tributaries are all small; they include the Mezha, Kasplya, Ulla, and Disna entering from the left; and the Toropa, Drissa, Aivieksste, with its tributary the Pededze, and Ogre entering from the right. The basin has more than 5,000 lakes, most of them quite small; among the larger are lakes Rezna and Lubana, in Latvia; Zhizhitsa, in the upper reaches of the river; Osveya and Drisvyaty, in the middle part of the basin on the border of Belorussia and Latvia; and Lukoml, in the southernmost part.

The basin has a humid climate with warm summers and mild winters. Average July temperatures are 61°–64° F (16°–18° C). January temperatures at Riga average about 23° F (–5° C) and at Velizh in the upper basin about 18° F (–8° C). Precipitation ranges from 28 to 30 inches in the middle part of the basin to 32 to 38 inches near the sea.

The character and size of the Western Dvina change gradually from its upper reaches to its mouth. In the upper reaches it flows on loamy, and then on morainic (glacially deposited) soils. Above the city of Vitebsk, it enters an area of sand and dolomite interspersed with seams of clay and marl. Throughout its middle course and much of its lower, the river flows along a valley with high, steep slopes cut with eroded ravines. It winds slowly, with few forks, until it approaches the mouth,

where it divides into numerous branches that enter the gulf. Just above the city of Riga is the largest island of the Western Dvina, Dalen Island. Near the Latvian city of Daugavpils, the river is 650–1,000 feet wide, and it broadens to more than 2,000 feet in the lower reaches. Throughout its course there are rapids, rocks, and shallows, notably in the middle part around Disna and Kraslava and above Daugavpils. The current is fast and the slope steep.

The Western Dvina draws much of its water from melting snow, and, consequently, like other rivers of the eastern European plains, it has high spring floodwaters. It also floods after heavy rains. In spring the water level rises by 20 to 35 feet or more at various places. Its annual discharge is about 5.2 cubic miles. The average discharge is 301 cubic yards per second at Vitebsk, increasing to 406 at Polotsk, 615 near Daugavpils, and 890 at the mouth. The icebound period begins in the upper reaches in late November or early December and somewhat later in the middle part of the course. Thawing begins near the mouth of the river about the end of March, and in the upper reaches the water is open by about the middle of April.

The Western Dvina has been an important water route since early times. Connected in its upper reaches by easy portages to the basins of the Dnepr, Volga, and Volkhov, it formed part of the great trade route from the Baltic region to Byzantium and to the Arabic east. At the beginning of the 19th century, it was joined by canals through its tributary the Ulla to the Berezhina and thus to the Dnepr, but this system was never much used except for rafting timber. Through another tributary, the Drissa, it is connected with Lake Sebezha, and a small canal unites the Western Dvina with the Gavya River.

The river was first studied intensively in 1701, when, by command of Peter I, a survey was made from its source to the city of Polotsk. In 1790–91 a detailed atlas of the Western Dvina from Vitebsk to Riga was published.

The abundance of rapids and, in recent decades, the presence of dams have restricted navigation on the river to separate stretches: in the upper part, from Velizh to the mouth of the Ulla; in the middle and lower parts, from Kraslava to Livana and the dams of the Plyavinsky Hydroelectric Station; and in the lower part, from Marushka to Riga. The main items carried are lumber, construction materials, and grain. Seagoing vessels navigate the mouth of the river as far as Riga, nine miles from the sea.

Two hydroelectric stations have been built on the Western Dvina at Kegum (70,000 kilowatts) and Plyavinsky (825,000 kilowatts). Plans in the early 1970s called for a series of other stations with a total capacity of more than 1,000,000 kilowatts, the construction of additional irrigation systems, and various other measures to develop the river basin. (A.P.D.)

## Dvořák, Antonín

The first Bohemian composer to achieve worldwide recognition, Antonín Dvořák became one of the leading figures in the movements that injected traditional native folk materials, both musical and thematic, into the general framework of musical Romanticism that was characteristic of the 19th century. His fellow Bohemian Bediich Smetana, 17 years his senior, already had laid the foundations of the Bohemian nationalist movement in music, while in Russia such composers as Aleksandr Borodin, Modest Mussorgsky, and Nikolay Rimsky-Korsakov were following a similar trend from the stores of that nation's past. His *Symphony No. 9 (From the New World; 1893)* remains his best known work partly, no doubt, because it was thought to be based on Negro spirituals and other influences gained during Dvořák's years in the United States. Although this may be true to some extent, the music is also characteristically Bohemian in its themes, possibly revealing the composer's nostalgia for his homeland.

Dvořák was born in Nelahozeves, a Bohemian (now Czechoslovakian) village on the Vltava River north of

Musical  
kinship

The river  
basin

Prague, on September 8, 1841. He came to know music early, in and about his father's inn, and as a youngster became an accomplished violinist contributing to the amateur music making that accompanied the dances of the local couples. In 1857, a perceptive music teacher, understanding that young Antonín had gone beyond his own modest abilities to teach him, persuaded the elder Dvořák to enroll his son in an organ school in Prague. Later, without his father's financial assistance, Dvořák completed a two-year course and played the viola in various inns and with theatre bands, augmenting his small salary with a few private pupils.

Dvořák, portrait by Max Švabinský, c. 1900. In the Muzeum Antonína Dvořáka, Prague.

The 1860s were trying years for Dvořák, who was hard pressed for both time and the means, even paper and a piano, to compose. In later years he said he had little recollection of what he wrote in those days, but around 1864 two symphonies, an opera, chamber music, and numerous songs lay unheard in his desk. The varied works of this period show, however, that his earlier leanings toward Beethoven and Schubert were becoming increasingly tinged with the influence of Wagner and Liszt. In November 1873, at a time when a few successful concerts of his works had begun to make his name well-known in Prague, he married Anna Čermáková and began an unusually happy family life.

In 1875 Dvořák was awarded a state grant by the Austrian government, and this award brought him into contact with Brahms, with whom he formed a close and fruitful friendship. Brahms not only gave him valuable technical advice but also found him an influential publisher in Fritz Simrock, and it was with his firm's publication of the *Moravian Duets* (composed 1876) for soprano and contralto and the *Slavonic Dances* (1878) for piano duet that Dvořák first attracted worldwide attention to himself and to his country's music. The admiration of the leading critics, instrumentalists, and conductors of the day continued to spread his fame abroad, which led naturally to even greater triumphs in his own country. In 1884 he made the first of ten visits to England, where the success of his works, especially his choral works, was a source of constant pride to him, although only the *Stabat Mater* (1877) and *Te Deum* (1892) continue to hold a position among the finer works of their kind. In 1890 he enjoyed a personal triumph in Moscow, where two concerts were arranged for him by his friend Tchaikovsky. The following year he was made an honorary doctor of music of the University of Cambridge.

Dvořák accepted the post of director of the newly established National Conservatory of Music in New York in 1892, and, during his years in the United States, he

travelled as far west as Iowa. Though he found much to interest and stimulate him in the New World environment, he soon came to miss his own country, and he returned to Bohemia in 1895. The final years of his life saw the composition of several string quartets and symphonic poems and his last three operas. He died in Prague on May 1, 1904.

The appeal of Dvořák's music lies chiefly in its teeming melodic invention and heart-warming simplicity. He essayed all of the musical genres and left (several) works that are regarded as classics in all of them; only his operas have failed to enjoy lasting success.

## MAJOR WORKS

### Orchestral works

**SYMPHONIES:** (revised numbers)—No. 5 in F Major, op. 76 (1875, rev. 1887; originally No. 3, op. 24); No. 6 in D Major, op. 60 (1880; originally No. 1); No. 7 in D Minor, op. 70 (1885; originally No. 2); No. 8 in G Major, op. 88 (1889; originally No. 4); No. 9 in E Minor (*From the New World*), op. 95 (1893; originally No. 5).

**CONCERTOS:** *Piano Concerto in G Minor*, op. 33 (1876); *Violin Concerto in A Minor*, op. 53 (1880); *Cello Concerto in B Minor*, op. 104 (1895).

**SYMPHONIC POEMS:** *Vodník*, op. 107 (*The Water-Goblin*, 1896); *Polednice*, op. 108 (*The Noonday Witch*, 1896); *Zlatý kolovrat*, op. 109 (*The Golden Spinning-Wheel*, 1896); *Holoubek*, op. 110 (*The Wood Dove*, 1896); *Píseň bohatýrská*, op. 111 (*Hero's Song*, 1897).

**OVERTURES:** *Domov můj*, op. 62 (*My Home*, 1881); *V přírodě*, op. 91 (*In Nature's Realm*, 1891); *Carnival*, op. 92 (1891); *Othello*, op. 93 (1892); opp. 91, 92, 93, originally a cycle of overtures entitled *Příroda, Život a Láska* (*Nature, Life and Love*).

**RHAPSODIES AND DANCES:** *Rhapsody in A Minor* (1874); *Three Slavonic Rhapsodies*, op. 45 (1878); *Slavonic Dances*, opp. 46, 72 (1878, 1886; orchestral version of piano duets).

**MISCELLANEOUS:** *Serenade in D Minor*, for two oboes, two clarinets, two bassoons, double bassoon, three horns, cello, and double bass, op. 44 (1878).

### Chamber music

Thirteen string quartets; three piano trios; two piano quartets; quintets for piano and string quartet, for string quartet and viola, string quartet and double bass; sextet for string quartet and viola and cello; *Terzetto* for two violins and viola, op. 74 (1887); *Dumky Trio* for piano, violin, and cello, op. 90 (1891); pieces for violin and piano.

**PIANO MUSIC:** Waltzes, mazurkas, impromptus; *Slavonic Dances* for piano duet; *Eight Humoresques*, op. 101 (1894); *Ze šumavy*, op. 68 (*From the Bohemian Woods*, 1884), for piano duet.

### Vocal music

**OPERAS:** *Král a uhlíř*, op. 14 (*King and Collier*, first performed 1874); *Tvrde palice*, op. 17 (*The Pig-headed Peasants*, 1881); *Selma sedlák*, op. 37 (*The Peasant a Rogue*, 1878); *Dimitrij*, op. 64 (1882); *Jakobín*, op. 84 (*The Jacobin*, 1889); *Cert a Káča*, op. 112 (*The Devil and Kate*, 1899); *Rusalka*, op. 114 (1901); *Armida*, op. 115 (1904).

**CHORAL WORKS:** *Hymnus*, patriotic hymn for chorus and orchestra, op. 30 (*The Heirs of the White Mountain*, 1872; rev. 1880); *Stabat Mater*, for solo voices, chorus, and orchestra, op. 58 (1876–77); *The 149th Psalm* for male chorus and orchestra, op. 52 (1879), and mixed choir, op. 79 (1887); *V přírodě*, op. 63 (*Amid Nature*, 1882), five choral pieces for mixed voices; *Svatební kofile*, op. 69 (*The Spectre's Bride*, 1884), dramatic cantata for solo voices, chorus, and orchestra; *Hymna československý rolnictva*, op. 28 (*Hymn of the Czech Peasants*, 1885), for chorus and orchestra; *Svatá Ludmila*, op. 71 (*St. Ludmilla*, 1886), oratorio for solo voices, chorus, and orchestra; *Mass in D Major*, for solo voices, chorus, and orchestra, op. 86 (1887; orchestral version, 1892); *Requiem Mass* for solo voices, chorus, and orchestra, op. 89 (1890); *Te Deum*, for soprano and bass solo, chorus, and orchestra, op. 103 (1892); *The American Flag*, cantata for alto, tenor, and bass solo, chorus, and orchestra, op. 102 (1893).

**SONGS:** *Moravské dvojzpěvy*, op. 32 (*Moravian Duets*, 1876), for soprano and contralto.

**BIBLIOGRAPHY.** The definitive work is OTAKAR SOUREK, *Život a dílo Antonína Dvořáka*, 2nd–3rd ed. rev., 4 vol. (1954–57), which has been published only in Czech. Books in English include Sourek's *Antonín Dvořák: His Life and Works* (1954); ALEC ROBERTSON'S informative and scholarly *Dvořák* (1945); JOHN CLAPHAM, *Antonín Dvořák: Musician and Craftsman* (1966), an admirable and erudite study of the

composer's working methods; and GERVAISE HUGHES, *Dvořák: His Life and Music* (1967), in which Dvořák's compositions are discussed within a biographical framework and in relation to his sociological background. A comprehensive international bibliography complete up to 1959 is incorporated with JARMIL BURCHAUER, *Antonín Dvořák: Thematic Catalogue* (1960).

(D.M.L.-J.)

## Dyes and Dyeing

Most modern dyes are coloured substances synthesized from certain chemical compounds called **benzenoid** hydrocarbons, obtained from either coal tar or petroleum. Their most important use is in dyeing textiles. Wool or cotton fabrics may have dyes applied at any stage of manufacture from fibre to finished garment, depending on the nature of the textile, its subsequent processing, and the requirements in use. Dyeing, as the term is generally understood, occurs only when the dye is in solution, usually in an aqueous medium. Some dyes whose solubility is small are called **disperse dyes**, because they are dispersed rather than dissolved in the water. Some colorants, called **pigments**, are completely insoluble; they are melted together with synthetic resins to impart colour before the synthetic fibres are extruded. Synthetic textiles such as nylon are coloured in this way. (The term **colorant** is used to describe both dyes and pigments.) At the present time, dyeing from nonaqueous solvents, called simply **solvent dyeing**, shows considerable promise as a low-cost process that conserves water and reduces pollution.

Very few dyes of natural (animal or vegetable) origin are presently used by the commercial dyer; but before the mid-19th century they were the only colorants available. Their use over the centuries, especially from the Middle Ages on, laid the foundations of the art, and later the science, of the modern dyeing industry, which is of considerable complexity. Over 7,000 synthetic organic colorants are presently in commercial use, differing in fastness and other properties, and requiring different methods of application. Most of the dyestuffs are used by the textile industry, but the leather, paper, food, and cosmetic industries are also important users. Synthetic organic pigments are used in the manufacture of printing inks, paints, and automobile finishes, and for incorporation in plastics and rubber. Since each industry requires different properties in the dyes and pigments it employs, the large dye-making concerns usually provide technical service and advice to their customer industries on the selection and use of products. Despite the fact that colorants form only a small proportion of the cost of a finished article (less than 1.5 percent of the cost of a woman's dress and less than one percent of that of a woollen overcoat), the dye-making industry remains of considerable economic importance.

### HISTORY

**Dyes of natural origin.** The discovery of red ochre in very ancient burial sites indicates that the use of colour for aesthetic and other purposes is at least 15,000 years old. The art of dyeing cloth is believed to have been known in China as long ago as 3000 BC. On the evidence of cultural and religious records, both madder, a dye prepared from the root of the madder herb, and indigo, a blue dye obtained from indigo plants, were used in India from around 2500 BC. At relatively the same time, dyeing of cloth in yellows, reds, and greens was also practiced in Egypt, where the earliest known textiles, linen mummy wrappings dating from 2000 BC, have been found dyed blue with either indigo or woad, a dye prepared from the leaves of the woad plant, which contains indigo as an essential constituent. The safflower, an Old World herb also called **dyer's thistle**, was used by the Egyptians around 2000 BC to obtain yellow and red shades; by 1450 BC ways of dyeing fine fabrics, principally linen, in a full range of hues had been gradually evolved.

Wool, the chief material of the Babylonian and Assyrian textile industries that arose from the 15th century BC,

was generally dyed in the raw state before spinning. Linen, in contrast, was dyed as thread before being woven into cloth. Homer mentions dyed textiles, and **purple-dyed leather**.

The art of purple dyeing, though not invented by the Phoenicians, was brought to a high standard by them. The dye they employed, **Tyrian purple**, was of excellent fastness even by modern standards and was extracted at great cost from the *purpura* shellfish found in Mediterranean countries. Pliny the Elder writes of the dyeing recipes used in his day and refers to the Egyptians' use of mordants (*i.e.*, chemicals that fix dyes in the material by forming insoluble compounds). He also mentions the skillful dyers of Gaul, who used vegetable dyes that vied with the finest purple.

Few records of the arts and crafts have survived from the early Middle Ages. Dyers' guilds were in existence in many places in the high Middle Ages. Dyes and dyed fabrics were carried to Europe from places as distant as Peking along the famous Silk Route. Surviving specimens of richly coloured silks testify to the range of natural colorants available to Chinese and Japanese dyers of the period. The "Arte di Calimala," the cloth industry of Florence, was famed for its excellent dyeing and finishing. In Venice the charter of the Dyers' Guild, the "*Marie-gola dell'arte dei Tintori*" contains recipes used by the guild. Guilds of dyers sprang up in France, Flanders, Germany, Britain, and European countries.

The natural dyes used up to the middle of the 19th century, the greater part of them of vegetable origin, involved many problems, both in respect to sources and to processes. Tyrian purple mysteriously disappeared about the middle of the 15th century. The use of natural indigo involved protracted fermentation processes to liberate the dye in a soluble, colourless form. After cloth had been steeped in a vat, oxidation in air gave blue dyeings on cotton and wool. Many natural dyes have no affinity per se for textile fibres until such fibres have been treated with aluminum, iron, or tin compounds to receive the dye (mordanting). Chief among the mordant dyes was **alizarin** derived from madder root, widely cultivated at one time in Europe, Turkey, and India. It yielded a fast red on aluminum mordant, a purplish black on iron mordant; intermediate shades were obtained by using a mixture of mordants. The discovery of the New World and the establishment of trade routes to the Americas led to the introduction into Europe of new mordant dyes such as **brazilwood**, giving reds on aluminum, browns on iron, and a rose-pink on tin mordants, and **logwood**, or **haematoxylin**, giving fine blacks on a chromium oxide mordant. Scarlets were obtained either from **kermes**, which consists of the dried bodies of certain female insects, or **cochineal**, produced in Mexico from the dried female insect *Coccus cacti*, which lives on the Indian fig tree or nopal. Until 1954 the traditional scarlet of British Guards' uniforms was obtained by dyeing tin-mordanted wool with cochineal.

**Synthetic dyes.** The year 1856, in which William Henry Perkin (1838–1907), English chemist, discovered the synthetic dye **mauveine**, marks the beginning of synthetic dyestuffs, which ultimately supplanted natural dyes. The synthetic-dye manufacturing industry was founded by Perkin in 1857, when he set up facilities near London for the commercial production of mauveine and, later, of other synthetic dyes. Other dye-making factories followed both in the U.K. and continental Europe, and new dyes began to appear on the market. Research was directed toward determining the structures of important natural dyes and then to synthesizing them. The first success was the synthesis of artificial **alizarin** from coal-tar anthracene in 1868. Indigo was first synthesized in 1880 though an economic manufacturing process was not devised until almost 20 years later. The cultivation of madder and indigo rapidly declined as the synthetic products came to be accepted by dyers. Organic chemistry flourished in the research centres of Europe, and new dyes, many of them owing nothing to nature, were perfected by dye makers. These included **azo** dyestuffs,

The discovery of mauveine

certain organic compounds having the general formula  $RN = NR'$  (1862), which today comprise the largest group of synthetic dyes; congo red, the first direct cotton dye requiring no mordanting or fixing process (1884); azoic dyes, a group of organic dyes derived from azo benzene, mostly reds and yellows (1911); acetate dyes, mainly azo or anthraquinone dyes, highly dispersed to render them capable of penetrating acetate fibres (1922–23); and fibre-reactive dyes, those which combine chemically to form a link with the material (1956). Dyestuffs research continues, as indicated by the large annual volume of patent literature.

#### RAW MATERIALS FOR MANUFACTURE OF DYES

The primary raw materials from which the dye maker synthesizes dyestuffs and pigments are the coal-tar chemicals called aromatic hydrocarbons, chiefly benzene, toluene, orthoxylene, metaxylene, paraxylene, naphthalene, and anthracene. Dye manufacture thus involves the process of first deriving these intermediate chemicals from raw materials and then building up dyes from the intermediates.

Coal tar, the traditional source of dye intermediates, is obtained from bituminous coal by distillation. Coal tar is a complex mixture of substances, which, on distillation, is commonly separated into light oil (boiling point up to 170° C), middle oil (boiling point 170°–230° C), heavy oil (boiling point 230°–270° C), anthracene oil (boiling point above 270° C), and pitch (nonvolatile still residue). The light oil is redistilled and separated into fractions of narrower boiling-point range: 80°–110° C, 110°–140° C, and 140°–170° C. These fractions are purified by successive contact with caustic soda (sodium hydroxide) solution, and concentrated sulfuric acid. The treated fractions are again distilled to yield respectively 90 percent benzol, 50 percent benzol, and solvent naphtha. By fractional distillation the 90 percent benzol may be separated into its constituents, benzene, toluene, and the xylenes. The commercial benzene thus obtained is not pure enough for successful synthesis into dye intermediates and must be purified even further. This is accomplished by a freezing process, followed by treatment with sulfuric acid. Toluene and the xylenes are brought to a similar degree of chemical purity by a combination of chemical and physical means.

Naphthalene is obtained from middle oil (170°–230° C), from which it separates, on cooling, as crystals, which are pressed, treated with caustic-soda solution, then with sulfuric acid, and finally distilled or sublimed (vaporized and recondensed to solid form).

Anthracene is separated from anthracene oil in the form of crude crystals. These are then dissolved in naphtha, distilled in superheated steam, and recrystallized in pure form.

Although coal tar remains an important source of aromatic hydrocarbons, the petrochemicals industry is an increasingly important supplier; in the United States it is the principal source. Distillation of crude oil yields substances that can be reformed either by thermal or catalytic processes and suitable purification into the aromatic hydrocarbons. Largest users are the synthetic fibre, synthetic rubber, detergent, and plastics industries, but sizable quantities are consumed by the dye-making industry (see also PETROLEUM REFINING).

#### MANUFACTURING PROCESSES FOR INTERMEDIATES

All synthetic organic dyes and pigments contain a ring structure of atoms. The same formation is present in dye intermediates. It is usual also for the dye intermediate to have one or more of the groups of atoms that react chemically to form salts.

A simple example of an intermediate is p-naphthol, which is obtained from naphthalene by heating it with 96 percent sulfuric acid at 160° C (320° F), adding sodium sulfate, and volatilizing the remaining naphthalene with steam. Sodium naphthalene-2-sulfonate, left behind after this steam treatment, is then fused with caustic soda to yield  $\beta$ -naphthol. The  $\beta$ -naphthol is separated from

the mixture by diluting it with water and treating it with sulfuric acid. These reactions, known respectively as sulfonation and alkali fusion, are given the name unit processes.

A number of such unit processes are available to the chemical manufacturers, and by means of various permutations, it is possible to synthesize the several hundred intermediates needed for the manufacture of the modern range of colorants.

**Nitration.** In nitration, a nitro group is substituted for a hydrogen atom in an aromatic hydrocarbon molecule by the action of nitric acid. Benzene yields nitrobenzene by reaction with a mixture of nitric and sulfuric acids at a temperature not exceeding 50° C (122° F). Toluene, with mixed acid at 30°–35° C (86°–95° F), yields ortho-nitrotoluene, metanitrotoluene, and paranitrotoluene. Technical quality nitrotoluenes are obtained from the crude nitration product by physical separation methods including fractional distillation; 1-nitronaphthalene is obtained when naphthalene is nitrated.

Nitration is a strongly exothermic, or heat-releasing, reaction; in large-scale nitrations the temperature must be maintained between established limits and efficient means of cooling provided. Cast-iron, mild steel, or stainless-steel vessels are used, arranged to permit agitating the mixture. The addition of nitric acid is carefully controlled by instruments that detect incipient rises in temperature. Other safeguards stop the addition in case the stirring mechanism is halted by a power or mechanical failure.

**Reduction.** Amines, chemical compounds formed by substituting organic radicals for the hydrogen atoms of ammonia, may be obtained from nitro compounds by reduction; that is, replacement of oxygen by hydrogen. This is accomplished by mixing the nitro compound with iron borings and a minimum quantity of aqueous hydrochloric acid in a cast-iron reducer with a powerful agitator. The end products are aniline, or other amines, and ferric oxide. The aniline, which separates as an upper layer above the aqueous suspension of iron and oxide, is removed mechanically and purified by steam distillation followed by fractionation. Analogous processes are employed in making other amines from their corresponding nitro compounds.

**Halogenation.** Halogenation is the introduction, by direct or indirect means, of a halogen (fluorine, chlorine, or bromine) into molecules of dye intermediates. In many cases direct substitution can be effected using elemental chlorine or bromine with or without a catalyst. In other cases a diazotized amine is treated with cuprous chloride or bromide. Indirect means must be employed for introducing fluorine. Hydrogen fluoride (HF), for example, is used to displace chlorine in chloro compounds.

**Amination.** The amination, or conversion of chloro compounds to amines, can be accomplished by ammonolysis, a process that involves heating the chloro compound with aqueous ammonia in a steel autoclave (equipment for working at pressures above atmospheric). Chloronitrobenzene, for example, is transformed into nitroaniline by this process. Several industrial amination processes exist. In the Dow Process monochlorobenzene is converted into aniline by heating it with aqueous ammonia at 240° C (464° F) in the presence of a copper oxide catalyst. In the Halcon Process phenol undergoes ammonolysis to yield aniline.

**Hydroxylation.** Hydroxylation is the introduction of a hydroxyl, or OH, group into the dye-intermediate molecule. Among the methods used for this are fusion by sodium hydroxide, Bucherer reaction (conversion of aromatic amines into phenolic compounds by aqueous sulfite or bisulfite), hydrolysis of chloro compounds under various reaction conditions according to the reactivity of the chloro compound, decomposition of diazonium salts by hot aqueous sulfuric acid, hydrolysis of sulfo groups, and oxidation (described below); for example, the compound cumene yields phenol and acetone.

**Oxidation.** Oxidation, the combination of a substance with oxygen, or, generally, any reaction in which an atom

Unit  
processes

New  
sources of  
hydro-  
carbons

Phenol  
and  
acetone

loses electrons, is a ubiquitous chemical reaction in dye chemistry; only a few examples can be given here. The conversion of methyl groups into carboxylic acids, and more especially into styryl compounds, is effected by various oxidants such as sodium hypochlorite, potassium permanganate, and sodium dichromate. The catalyzed oxidation of naphthalene with air leads to phthalic anhydride. Other important reactions include oxidation of leuco compounds to dyes and the formation of complex polycyclic substances from simpler molecules.

**Benzidine rearrangement.** The benzidine rearrangement consists of the conversion of nitrobenzene and its derivatives into derivatives of biphenyl in a two-stage process. The first stage consists of alkaline reduction with zinc dust to the hydrazobenzene; and the second of treatment with hydrochloric acid.

The above and other unit processes are used in various combinations in order to produce the important intermediate chemicals that are, in turn, used to manufacture the dyes themselves.

**H Acid.** H Acid, which is 1-amino-8-hydroxynaphthalene-3,6-disulfonic acid, an important dye intermediate, is produced from naphthalene by a combination of the unit processes of sulfonation, nitration, reduction, and hydrolysis. H Acid is used in the manufacture of a large number of azo dyes.

**Diaminostilbene disulfonic acid.** 4,4'-diaminostilbene-2,2'-disulfonic acid is produced from p-nitrotoluene by a combination of the unit processes of sulfonation, oxidation, and reduction. This product is used in large quantities for manufacture of fluorescent brightening agents.

#### MANUFACTURING PROCESSES FOR DYES AND PIGMENTS

In the early synthetic dye plants, the equipment was primitive, consisting of simple iron vessels and wooden vats. In the latter half of the 19th century new processes arising from the discovery of an increasing number of new dyes led to improvements in the design of reaction vessels, autoclaves, pumps for the transfer of liquids, compressors, and vacuum pumps. The development of vitreous coating techniques, the use of lead and copper, and improvements in the centrifuge, drying stove, grinding, and mixing equipment also proceeded at that time and has continued to the present. The advent of stainless steel and the introduction of plastic and polymer materials and of the newer techniques, especially the rubber coating of mild steel, has resulted in the gradual disappearance of the wooden vat and has reduced the use of lead and copper as constructional materials. In modern plants multipurpose vessels constructed for easy linking to one another and to filters, separators, etc. are employed wherever possible. Rapid changes may be made from one combination to another for efficient production. Stainless steel and rubber-covered steel may be quickly and easily cleaned in contrast to the former laborious process of cleaning wooden vats. In the larger modern plants, flow rates, heating, cooling, and other services are usually automatically controlled. Inlet and outlet valves are actuated, usually pneumatically, by sensing probes that detect changes in temperature, pressure, and hydrogen ion concentration that have occurred in the reaction vessel or other part of the plant. Intermediates, dyes, and pigments are usually manufactured in batches, discontinuously, because the total annual requirements of each may not amount to more than 10–100 tons (9–90 metric tons). If an annual output greatly in excess of these quantities is required, semicontinuous or continuous processes may be adopted, relatively small amounts of reactants coming together at any one time. This increases the safety factor in strongly exothermic reactions, such as nitrations and sulfonations.

Many of the unit processes used to produce intermediates are also used to make dyes and pigments. In the processes described below, only the penultimate and final stages leading to the particular colorant are given. For precision, the Part I Reference, and the Part II number, where known, are given from the *Colour Index* (C.I.), the standard reference work published jointly by the Society

of Dyers and Colourists in Great Britain, and the American Association of Textile Chemists and Colorists in the United States, with the cooperation of manufacturers in Belgium, Brazil, Chile, France, Germany, Greece, India, Italy, Japan, The Netherlands, Poland, Spain, and Switzerland. Part I of the *Colour Index* classifies dyes and pigments according to usage while Part II classifies them according to chemical constitution.

**Nitroso dyes.** By treating  $\beta$ -naphthol with nitrous acid,  $\alpha$ -nitroso- $\beta$ -naphthol is obtained, which reacts with an iron salt such as ferrous sulfate to give Pigment Green B, C.I. Pigment Green 8, 10006.

**Nitro dyes.** Celliton Fast Yellow RR, C.I. Disperse Yellow 1, 10345, results from the condensation of 2,4-dinitrochlorobenzene with 4-aminophenol. The process may be carried out in alcoholic solution. The final product, like all disperse dyes, must be ground to a particle size of 1–10 microns (1,000 microns = 1 millimetre) in an aqueous medium containing a dispersing agent.

**Azo dyes.** Almost all azo dyes are made by diazotization of a primary aromatic amine in an acid solution by using nitrous acid in the presence of ice. The diazo compound so formed is coupled with a suitable component, such as an aromatic amine, naphthol, or other phenolic substance, to form an azo compound.

These reactions are usually carried out in aqueous solution in rubber-lined steel equipment of capacities varying from 2,000 to 5,000 gallons (7,600–19,000 litres). Isolation of the final dye is usually achieved by addition of common salt in sufficient quantity to precipitate the dye, while leaving small amounts of undesirable, often dulling, by-products in solution. The dye precipitate is then separated from the solution in a filter press. As "press cake," it undergoes the finishing processes usual for most dyes, such as wet milling, drying, grinding, and reduction to a standard strength by mixing with diluents. Monoazo colorants contain a single azo group. Examples are the wool dye Acid Orange II, C.I. Acid Orange 7, 15510; and Permanent Red FRR, C.I. Pigment Red 2, 12310. Examples of diazo colorants, the molecules of which contain two azo groups, include Congo Red, C.I. Direct Red 28, 22120; and the solvent-soluble Fat Red B, C.I. Solvent Red 24, 26105. Triazo dyes contain three, and tetrakisazo dyes contain four, azo groups.

**Acid alizarine dyes.** Valuable greens and blues are derived by the process of sulfonation of diaminoanthraquinones to give dyes with the requisite degree of water solubility. Processes of sulfonation, nitration, reduction, alkylation, and other steps are also used to obtain certain disperse dyes from anthraquinone.

The more complex vat dyes, often with elaborate molecular structures, are built up from simpler compounds by many of the common unit processes such as sulfonation, as well as more specialized chemical reactions.

**Indigoid and thioindigoid dyes.** The sodamide process (1901) for Indigo, C.I. Vat Blue I, 73000, begins with aniline, which, by reaction with formaldehyde and sodium cyanide, yields phenylglycine; the latter on fusion with a mixture of sodamide and caustic potash is changed into indoxyl, oxidation of which leads to indigo. The thioindigoid, Durindone Orange R, C.I. Vat Orange 5, 73335, is also synthesized by a complicated route.

**Triphenylmethane dyes.** Crystal Violet, C.I. Basic Violet 3, 42555, has a typical structure containing a central carbon atom, which is introduced by various methods including the employment of phosgene,  $\text{COCl}_2$ , formaldehyde,  $\text{HCHO}$ , and intermediate chemicals containing the groups  $\text{C}=\text{O}$  and  $\text{CH}-\text{OH}$ .

**Cyanine dyes.** Dyes in this class commonly contain two ring systems of atoms linked by conjugate chains ( $\text{N}-\text{C}=\text{C}-\text{N}$ , for example). There are many different methods of preparation, among which are the condensation of complex aldehydes with amines.

**Fibre-reactive dyes.** Fibre-reactive dyes react chemically to combine with and become part of the fibre substance. The simpler types are monochlorotriazinyl and dichlorotriazinyl compounds. An amino compound

Discontinuous batch operation

Sodamide Indigo process

with an azo, phthalocyanine, or anthraquinone group in its molecule is condensed in an aqueous medium with cyanuric chloride.

**Phthalocyanine pigments.** Copper phthalocyanine, a blue pigment, is manufactured in hundreds of tons annually by heating phthalonitrile, or some other related substance derived from phthalic anhydride, with a copper (cuprous) salt. For a high-grade pigment quality, the raw pigment must be subjected to special conditioning processes to achieve the required physical form. Valuable green pigments are obtained from copper phthalocyanine by halogenation processes.

#### TECHNIQUES AND EQUIPMENT

The dyeing of a fibre or textile is carried out in a solution, generally aqueous, known as the dye liquor or dyebath. For true dyeing (as opposed to mere staining) to have taken place, the coloration must be relatively permanent, that is, not readily removed by rinsing in water or by normal washing procedures; moreover, the dyeing must not fade rapidly on exposure to light. The process of attachment of the dye molecule to the fibre is one of absorption, that is, the dye molecules concentrate on the fibre surface.

**Binding forces.** There are four kinds of forces by which dye molecules are bound to fibre: (1) ionic forces, (2) hydrogen bonding, (3) van der Waals' forces, and (4) covalent chemical linkages. In the dyeing of wool, which is a complex protein containing about twenty different  $\alpha$ -amino acids, the sulfuric acid added to the dyebath forms ionic linkages with the amino groups of the protein. In the process of dyeing, the sulfate anion (negative ion) is replaced by a dye anion. In the dyeing of wool, silk, and synthetic fibres, hydrogen bonds are probably set up between the azo, amino, alkylamino, and other groups, and the amido,  $-\text{CO}-\text{NH}-$ , groups. Van der Waals' forces (the attractive forces between the atoms or molecules of all substances) are thought to act in the dyeing of cotton between the molecular units of the fibre and the linear, extended molecules of direct dyes. Covalent chemical links are brought about in the dyebath by chemical reaction between a fibre-reactive dye molecule, one containing a chemically reactive centre, and a hydroxy group of a cotton fibre, in the presence of alkali.

In any dyeing process, whatever the chemical class of dye being used, heat must be supplied to the dyebath; energy is used in transferring dye molecules from the solution to the fibre as well as in swelling the fibre to render it more receptive. The technical term for the transfer process is exhaustion. Evenness of dyeing, known as levelness, is an important quality in the dyeing of all forms of natural and synthetic fibres; it may be attained by control of dyeing conditions, that is, by agitation to ensure proper contact between dye liquor and substance being dyed, and by use of restraining agents to control rate of dyeing, or strike.

**Solvent dyeing.** Serious consideration has recently been given to methods of dyeing in which water as the medium is replaced by solvents such as the chlorinated hydrocarbons used in dry cleaning. There are a number of technical advantages in solvent dyeing, apart from the elimination of effluent (pollution) problems associated with conventional methods of dyeing and finishing. Advantages include more rapid wetting of textiles, less swelling, increased speed of dyeing per given amount of material, and savings in energy, because less heat is required to heat or evaporate perchlorethylene, for example, than is needed for water.

#### FIBRE PREPARATION

**Cotton.** The impurities associated with natural fibres, and the materials added during processing of natural, modified, and synthetic fibres into yams and cloth must be removed if dyeing is to be successful. Cotton in the raw state contains organic impurities such as proteins, waxes, tannins, and colouring matters, along with inorganic compounds. During the course of being woven into cloth, cotton is treated with size, fungicides, and other

materials, all of which must be removed before dyeing. The cloth is first passed through a singeing machine to burn off surface fibres, then through a bath of enzyme preparations to remove the starch used as a size. Next it is heated with aqueous alkali under pressure in a boiler, or kier, to saponify, or hydrolyze fats, break down proteins and tannic acid, and solubilize the tough sheath surrounding the fibres. Finally the cloth is rinsed, treated with dilute acid, and washed acid free with weak ammonia. Sometimes a second alkali treatment, mercerization, is given, using 18–30 percent sodium hydroxide solution; this causes the fibres to swell and to acquire greater dye affinity. Bleaching with hypochlorite then removes the natural yellowness that would otherwise cause dull shades on dyeing.

**Wool.** The chief impurities in raw wool are (1) vegetable matter, removed in part mechanically and in part by carbonizing, that is, the preferential destruction of cellulose-like matter by sulfuric acid; (2) suint, dried perspiration of sheep, removed by rinsing in water in which it is readily soluble; and (3) wool grease, the source of such valuable by-products as lanolin and cholesterol, removed for recovery by scouring, or washing, and emulsification, or conversion into a mixture with a liquid. In subsequent spinning and weaving, saponifiable oil such as oleine is added to replace the natural grease and must be removed later by scouring with sodium carbonate solution. Small quantities of mineral oils may be removed by emulsification; larger quantities may require the addition of a solvent to the cleaning solution. Knitting yams are scoured by emulsification; carpet yams, usually heavily loaded with oleine, are scoured by saponification with sodium carbonate and a synthetic detergent. Woollen goods are bleached with hydrogen peroxide. As noted, dyeing is not necessarily the final stage of processing; wool may be dyed at any point from raw wool (dyed in the wool) to finished article.

**Other natural fibres.** Silk is degummed with hot soap solution to remove the sericin that binds the filaments in the natural state.

The modified natural fibres, viscose and cellulose acetate, are sized with either starch or gelatin; these are removed by enzyme or mild aqueous treatments respectively.

**Synthetic fibres.** In general, synthetic fibres possess excellent mechanical strength. Even so, they are usually sized with starch, water-soluble plastics, gelatin, and other agents to strengthen them against the stresses of knitting and weaving. The kind of scouring applied to remove the sizing depends on the properties of the particular fibre. In the case of blended fibres, the scouring conditions are limited by the most sensitive fibre present; thus a wool-nylon blend is treated as wool.

**Solvent scouring processes.** Shorter, more economical scouring processes using chlorinated hydrocarbon solvents such as stabilized trichloroethylene are currently being developed. In these processes the solvent may be recovered and reused.

#### DYE APPLICATION

For each application the dyer selects the combination of dyes best suited to the particular fibre or blend he plans to dye, and best able to withstand the conditions the textile will encounter in further processing and in use in the finished article. In general, the higher the standard of fastness, the more expensive the dye, and the final choice may be a compromise between the desired fastness standards and the cost of the dyes. Fastness tests and standards have been the subject of work by the American Association of Textile Chemists and Colorists (AATCC), Europäische-Continental Echtheitsconvention (ECE), and the Society of Dyers and Colourists (SDC), Bradford, Yorkshire. Efforts have been made to set up a unified system by the International Organization for Standardization (ISO). Light fastness is assessed on a scale of 8; 1 represents the poorest fastness and 8 the best. Fastness to other agents, among them water, bleach, acid, alkali, detergent solution, and perspiration, is measured on a scale of 5.

Mercerization

Fastness standards

Dyes are generally used in combination to achieve a desired hue or fashion shade. If the substance to be dyed consists of only one type of fibre, such as wool, the dye mixture will be made up solely of wool dyes. But if the fabric contains more than one kind of fibre and they differ in dyeing properties, then mixtures of different application classes of dyes are used.

Table 1 shows the application classes most suited to various fibres; minor usages are indicated in parentheses.

Table 1: Fibres and Dyes	
fibres	application classes
<b>Natural fibres</b>	
<b>Animal</b>	
Wool	acid, basic, mordant, reactive, (solubilized vat)
Wool blends (wool-cotton, wool-viscose, etc.)	acid, direct, mordant, reactive
Silk	acid, basic, direct, mordant, (reactive), (solubilized vat)
<b>Vegetable</b>	
Cotton	azoic, basic, direct, mordant, oxidation, reactive, sulfur, vat
Bast (linen, flax, hemp, jute, ramie)	acid, direct, (disperse), reactive, vat, solubilized vat
<b>Modified cellulose Ebres</b>	
Viscose	direct, mordant, pigment, reactive, sulfur, vat, solubilized vat
Secondary acetate	disperse
Triacetate	disperse
<b>Synthetic fibres</b>	
Polyamide (nylon, Perlon, Rilsan)	acid, disperse, mordant, pigment, reactive
Polyester (Dacron, Terylene)	disperse, pigment
Polyacrylonitrile (Acrilan, Courtele, Orlon)	basic, disperse, pigment
Polyvinyl chloride (Environ, Thermovyl)	basic, disperse
Polyolefines (Meraklon, Prolene)	disperse
Elastomers (Glospan, Lycra)	acid, disperse, reactive. (wool), vat

**Dyebath preparation.** Details vary according to the class of dye and the nature and form of the substance dyed. Variables include the percentage of dye in the dyeing solution, the other chemicals added, the temperature of the dyebath, and the time of heating.

Acid-levelling dyes are heated in solution with sulfuric or formic acid after Glauber's salt (sodium sulfate) is added to restrain the reaction when dyeing wool. Nylon is dyed in a similar manner at as high a temperature as possible with acetic or formic acid.

Direct dyes are applied to cotton from a solution having common salt (sodium chloride) or Glauber's salt added to promote the process of transfer of the dye from the solution to the material. In the case of certain dyes, the colourfastness may be improved by aftertreatments with bichromate, cooyer. or formaldehyde. and by development (diazotization and coupling with an added component).

Vat dyes and sulfur dyes are introduced into the fabric in the form of a soluble compound, which then reacts by oxidation with air, or an added chemical (bichromate or perborate) to form or regenerate the pigment in the fibre. Any loosely held pigment must then be carefully removed by soaping.

Disperse dyes usually require the addition of some dispersing agent to the solution to prevent aggregation. When polyester fibres, which are hydrophobic, are being dyed, chemicals such as chlorobenzenes, called carriers, are needed, or the process may be carried out quickly at high temperature in pressure vessels, without a carrier. Dry methods are also used, such as padding fabric with the disperse dye and then exposing it for a very short time to very high temperatures (200° C, or 392° F).

**Textile printing.** Textile printing can be regarded as localized dyeing. Colorants are used in the form of a printing paste containing a thickener such as gum tragacanth to prevent diffusion of the dye, and hence to preserve a sharp edge to the imprint. Various techniques are employed. In the ancient style the pattern was printed with a mordant fixed by steaming, and then the fabric was dyed; only the mordanted parts retained the colour.

In direct style the fabric is printed with colorants or their precursors and then subjected to ageing and various fixing processes. Almost all classes of dyes are used in this style.

**Finishing.** Various finishing treatments may be applied to dyed fabrics and garments to impart shrink resistance, crease resistance, permanent pleating, or waterproofing. The processes may influence hue and fastness and may require special properties in the colorants.

#### MATERIALS

**Forms in which textiles are dyed.** Loose stock consists of randomly distributed wool or cotton fibres; tow is the corresponding term for synthetic fibres. Sliver is a more orderly arrangement of fibres in a loosely connected, continuous form suitable for spinning. It is wound into either hanks or tops, loose balls about one foot in diameter. After spinning, the yarn is either made up into hanks or into packages weighing about two pounds each, by winding the yarn round perforated metal tubes. The packages are curiously named, some according to their shapes; for example, cones, cheeses, cakes, beams, and rockets. Piece goods, woven cloth or textiles knitted in rope form, and garments, a term that includes stockings, tights, hose, and half hose, are also dyed as such.

**Forms in which textiles are printed.** The chief form of textiles for printing is piece goods, woven material. For special melange-printing effects, sliver or slubbing, slightly twisted roving, is printed and then spun, for example into carpet thread.

#### MACHINERY AND EQUIPMENT FOR DYEING AND PRINTING

Modern dyeing machines are made from stainless steels. Steels containing up to 4 percent molybdenum are favoured to withstand the acid conditions that are common. A dyeing machine consists essentially of a vessel to contain the dye liquor, provided with equipment for heating, cooling, and circulating the liquor into and around the goods to be dyed or moving the goods through the dye liquor. The kind of machine employed depends on the nature of the goods to be dyed. Labour and energy costs are high in relation to total dyeing costs; the dyer's aim is to shorten dyeing times to save steam and electrical power and to avoid spoilage of goods.

**Machines for dyeing loose stock.** A widely used machine is the conical-pan loose-stock machine; fibres are held in an inner truncated-conical vessel while the hot dye liquor is mechanically pumped through. The fibre mass tends to become compressed in the upper narrow half of the cone, assisting efficient circulation. Levelling problems are less important because uniformity may be achieved by blending the dyed fibres prior to spinning.

**Hank-dyeing machinery.** The Hussong machine is the traditional apparatus; it has a long, square-ended tank as dyebath into which a framework of poles carrying the hanks can be lowered. The dye liquor is circulated by an impellor and moves through a perforated false bottom that also houses the open steam pipe for heating. In modern machines, circulation is improved especially at the point of contact between hank and pole. This leads to better levelling and elimination of irregularities caused by uneven cooling.

**Package-dyeing machines.** Dye liquor may be pumped in either of two directions: (1) through the perforated central spindle and outward through the package, or (2) by the reverse path into the outer layers of the package and out of the spindle. In either case levelness is important. In the case of soluble dyes the dye liquor must be free of suspended matter. In the case of disperse dyes, in which particles of dye are dispersed in, rather than dissolved in, the solution, no gross aggregates can be allowed; otherwise the packages would retain undesirable solids on the outer and inner surfaces. Some package-dyeing machines are capable of working under pressure at temperatures up to 130° C.

**Piece-dyeing machines.** The winch is the oldest piece-dyeing machine and takes its name from the slatted roller that moves an endless rope of cloth or endless belt of

Hanks and packages

The Hussong machine

cloth at full width through the dye liquor. **Pressurized-** winch machines have been developed in the U.S. In an entirely new concept, the Gaston County jet machine circulates fabric in rope form through a pipe by means of a high-pressure jet of dye liquor. The jet machine is increasingly important in high-temperature dyeing of synthetic fibres, especially polyester fabrics.

Another machine, the jig, has a V-shaped trough holding the dye liquor and guide rollers to carry the cloth at full width between two external, powered rollers; the cloth is wound onto each roller alternately, that is, the cloth is first moved forward, then backward through the dye liquor until dyeing is complete. Modern machines, automatically controlled and programmed, can be built to work under pressure.

**Padding mangles.** Solutions or suspensions of colorants or their precursors may be padded onto piece goods by passing the cloth through a trough containing the liquor and then between rollers under pressure. Development and fixation processes such as steaming or dry-heat treatment can be carried out in other apparatus. The method is used in semicontinuous and continuous operations.

**Garment-dyeing machines.** Partly manufactured or finished garments, hosiery, and felt hats are dyed in drum or paddle type machines. In the rotating-drum machine an inner, perforated drum, rotating horizontally, contains the garments; the dye liquor and means of heating are housed in an outer, stationary drum. In the side-paddle machine, also known as a Gorrie, a vertical paddle wheel moves dye liquor and garments round an oval dyebath. To avoid entanglement, articles are placed in freely permeable bags. For hosiery dyeing and finishing, automated machines have been developed; stockings are held on metal formers onto which circulating dye liquor is sprayed.

**Textile-printing equipment.** The traditional methods of hand-block printing, batik, screen printing, and others are still employed, but the bulk of production is on roller-printing machines. Engraved rollers, one for each colour, apply dye paste to the fabric from the channels incised in the surface; surplus paste is removed from unmarked parts by a doctor blade, similar to that used in ink printing. Rollers are usually of copper or are copper-faced and may be chromium plated for durability. After receiving the imprint, the fabric enters a drying chamber, then a steamer where it is raised to the temperature at which fixation takes place. The fabric is then rinsed, soaped, rinsed again, and dried. Highly mechanized silk-screen printing is becoming widespread and is overtaking roller printing largely on cost grounds.

#### NONTEXTILE APPLICATIONS

Synthetic colorants are widely used to impart colour to materials other than textiles.

**Paper.** The coloration of paper is usually carried out by addition of colorants to the beater containing the cellulose pulp. The choice of colorants is determined by their cost, fastness, and the end-use requirements of the manufactured paper. Acid, basic, and direct dyes as well as pigments are used. Pigments are also applied as a surface coating to finished cardboard. Crepe paper is made by padding dye solution on to absorbent, white paper and then drying by a special process.

**Leather.** Acid, basic, direct, and mordant dyes are applied to leather by methods related to those of the textile dyer or by a technique that consists in spraying the leather with a pigment suspension or a dye solution.

**Fur.** Among the fur colorants are oxidation bases, reactive dyes, and acid dyes including azo-metal complexes. Woolled sheepskins are dyed with disperse dyes.

**Oils.** Oils are coloured by dyes that dissolve in solvents rather than those that dissolve in water. The oleate derivatives of certain triarylmethane dyes are also used, as is the fluorescent dye Fluorol 5G, C.I. Solvent Green 4,45550.

**Soaps.** Colorants selected for tinting soap must have high strength and no tendency to stain skin or towels.

Selected pigments and a few acid and basic dyes are used.

**Food.** The use of synthetic colouring agents in food is governed by law in many countries; certain products are prohibited. In general, nontoxic, water-soluble dyes proven to be noncarcinogenic, having extremely low arsenic and heavy-metal content, and designated as foodstuffs quality by dye makers are used.

**Cosmetics.** A few inorganic pigments are used to make eye cosmetics; for many years eosin, a red fluorescent dye, has been one of the colorants used in lipstick formulations. Hair dyes are chiefly in the class of substituted amines known as oxidation colours. Some countries regulate the types of colorants that may be used in cosmetics.

**Printing inks.** Modern organic pigments of good fastness are used (see PRINTING).

**Plastics.** High-grade modern pigments, able to withstand the high temperatures and severe conditions inherent in processing, are widely used in plastics of all kinds, including those for outdoor use.

**Metal surfaces.** Anodized aluminum is dyed, in sheets or as articles, with acid dyes, especially the 1:1 azo-metal complexes. Modern organic pigments of good fastness are used for automobile finishes.

**Camouflage.** Dyes and pigments fast to light and weather are required for camouflage. Their infrared spectral characteristics are important because by the use of infrared photography, an unsuitable green can be made to appear in sharp contrast to the vegetation with which it is a satisfactory match in ordinary daylight. Specialized, high-grade vat dyes have been developed for this purpose.

**Coloured smokes.** A number of relatively simple dyes made from anthraquinone sublime on heating to give strongly coloured smokes and are used for military, signalling, and other purposes. The dye Quinoline Yellow Spirit Soluble, C.I. Solvent Yellow 33,47000, is also used.

**Fluorescent dyes.** The powerful water-soluble dye fluorescein has long been used as a marker for tracing the course of underground streams and in sea-rescue operations. A range of basic dyes, in association with certain resins, for example toluene-sulfonamide-formaldehyde condensation products, give strikingly luminous effects and are applied in poster and display work. Fluorescent brightening agents, sometimes known as colourless dyes, selectively absorb ultraviolet radiation and emit light in the blue region of the spectrum; they are used in large quantities as ingredients in soap and washing powders, and also in papermaking.

**Indicators.** Some dyes such as phenolphthalein, methyl orange, and Congo red undergo a change in hue with change in acidity (pH); these are used in analytical and industrial laboratories as indicators in titrations. Vat Yellow 1 papers are used to test for hydrosulfite in vat dyeing, litmus papers for determining acidity and alkalinity.

**Biological stains.** A few natural dyes and some synthetic dyes are used for the differential staining of sectioned tissues for microscopic examination. Carmine, haematoxylin, eosin, and Safranin O are commonly used in this way.

**Photography.** There are four main uses of dyes in photography.

1. Sensitizing agents, chiefly cyanines and merocyanines, confer sensitivity on a photographic emulsion in certain spectral regions in which it would otherwise be absent.

2. Antihalation dyes, mostly modified triarylmethane dyes and cyanines of special structure, are painted on the back of the emulsion to prevent reflection of transmitted incident light and consequent spreading of the image.

3. Desensitizing agents such as Pinakryptol Green and special cyanine dyes.

4. Dyes for colour photography, for example, the azo-methines, provide the subtractive primary colours yellow, magenta, and cyan, which, since each can absorb part of the daylight reflected by the others, may be combined to yield a maximum number of object colours.

**Medicinal uses.** Classical examples of dyes used in medicine include the mild laxative phenolphthalein; the

Gorrie

Marker  
use

internal, bladder, and urinary-tract antiseptic methylene blue; and the surface antiseptics gentian violet and acriflavine.

#### STATISTICS ON MANUFACTURE AND USE

The production of synthetic dyes for the major producing countries for 1960 and 1970 is given in Table 2.

**Table 2: Manufacture of Synthetic Dyestuffs\***

country	production (metric tons)	
	1960	1970
United States	70,000	106,379
Germany, Federal Republic of†	56,234	104,563
Union of Soviet Socialist Republics	84,099	94,765
United Kingdom	40,200	52,600
Japan‡	26,625	52,403
Switzerland	...	§
France	14,396	24,610
Poland	9,783	20,980
Spain	...	16,754
Italy	18,258	14,100
German Democratic Republic	8,423	13,437
Czechoslovakia	5,163	9,616
Romania	3,695	9,312
Total¶	345,486	579,111

\*Synthetic organic dyestuffs (including pigment dyestuffs), synthetic organic products of a kind used as luminophores, products of the kind known as optical bleaching agents, substantive to the fibre, natural indigo, colour lakes, in terms of 60 percent concentration basis. †Excluding luminophores, optical bleaching agents, natural indigo and colour lakes. ‡Excluding pigment resin colours and lakes. §In 1970 probably exceeded 40,000 metric tons. ||Including lithopone. ¶Includes production and estimated production for other minor producers. #### BIBLIOGRAPHY

*History*: Authoritative articles on dyes and dyeing from ancient times to the present may be found in the journal *CIBA Reviews* (1937– ). The commemorative volume, *Perkin Centenary*, London: 100 Years of Synthetic Dyestuffs (1958), contains a chapter on the life and work of Sir William Perkin by J. READ. The article by C. PAINE surveys the development of the synthetic-dye-making industry.

*Industrial dye chemistry*: EN. ABRAHART, *Dyes and Their Intermediates*, rev. ed. (1977); and HE. FIERZ-DAVID and L. BLANGEY, *Fundamental Processes of Dye Chemistry* (1949, Eng. trans. from the 5th Austrian ed. of 1943), are textbooks written from the industrial viewpoint. Articles on special topics (e.g., wool dyes, acetate silk dyes, etc.) may be found in the *Kirk-Othmer Encyclopedia of Chemical Technology*, 3rd ed. (1978– ), in progress.

*Technology of dyeing*: The standard reference work is the *Colour Index*, 3rd ed., 4 vol. (1971), and *Additions and Amendments* (annual), published jointly by the Society of Dyers and Colourists and the American Association of Textile Chemists and Colorists. Research papers and discursive articles are published in the *Journal of the Society of Dyers and Colourists* (monthly). Textbooks include: T. VICKERSTAFF, *The Physical Chemistry of Dyeing*, 2nd ed. rev. (1954), an advanced treatise on dye-substrate relationships; S.R. COCKETT, *Dyeing and Printing* (1964); E.R. TROTMAN, *Dyeing and Chemical Technology of Textile Fibres*, 5th ed. (1975); and JOYCE STOREY, *The Thames and Hudson Manual of Dyes and Fabrics* (1978), good general introductions. The following monographs are useful sources of specialized information: S.R. COCKETT and K.A. HILTON, *The Dyeing of Cellulosic Fibres and Related Processes* (1961); C.L. BIRD, *The Theory and Practice of Wool Dyeing*, 3rd ed. (1963); and EDWARD GURR, *Synthetic Dyes in Biology, Medicine and Chemistry* (1971).

## Dyestuffs and Pigments

Dyestuffs and pigments are intensely coloured substances that are used for imparting colour to other materials. Technically, the difference between them is that dyestuffs are soluble in the medium in which they are applied, whereas pigments are insoluble.

Colour in materials originates either from organic or inorganic substances present in the material, or from a purely physical effect, such as that observed in oil films on water. Organic colouring matters are compounds of the element carbon, including animal or vegetable colouring matters, as well as synthetic material, like the coal-tar

dyes. Colour in inorganic substances is commonly observed in rocks, minerals, ceramics, fired enamels, coloured glass, precious stones, and certain pigments. Colours produced by physical effects result from dispersion, refraction, or scattering of light. Examples of such physically produced colours are the rainbow; the blue of the sky; the iridescence of opal; and the blue, green, and violet colorations of birds, butterflies, fish, and insects. In some living organisms physical and organic coloration occur together.

There is scarcely any manufactured product that does not at some stage incorporate or require the use of products of the dyestuff and pigment industry. About 7,000 different dyestuffs are currently made, under some 35,000 different trade names, and about 200 new ones are introduced every year. The total annual world production was around 700,000 tons in the late 1970s, with a value of about \$3,000,000,000.

Reasons for the existence of the great number of commercial dyestuffs include the variety of fibres and other materials requiring coloration and the fact that colour in textiles must withstand a variety of stresses, depending upon the methods of manufacture and use.

All dyestuffs and many pigments are complex organic compounds, mainly prepared synthetically from chemical products of the coal-tar and petrochemical industries. The syntheses consist typically of sequences of carefully regulated procedures carried out under strict scientific control, and they are the result of extensive research. Dyeing itself is mostly done by means of water solutions, and dyestuffs are applied to textiles, paper, leather, and many other substances. Pigments are used as finely ground solid particles rather than as solutions. They are employed, for example, in paints, printing inks, and plastics. Some pigments are entirely inorganic in origin; e.g., iron oxide. These are cheap, but rather dull in hue. The brighter pigments are organic compounds, and in fact may simply be dyestuffs insoluble in the medium. Many products are thus used in both capacities; i.e., in soluble form as dyes for dyeing textiles, paper, and other materials and in insoluble form as pigments for colouring such substances as paints and inks.

All organic coloured substances, whether they are natural animal and vegetable materials or synthetic dyestuffs, rely for their colour on certain aspects of their chemical structures. Organic dyestuffs and pigments, with which this article is primarily concerned, are classified as colorants.

#### HISTORY

**Development of natural dyestuffs.** Some 3,000 years ago Moses was instructed to accept gifts of "blue, and purple, and scarlet and fine linen and goats' hair." These names of colours most probably referred to materials dyed with dyes that were known as indigo, Tyrian purple, and kermes. Indigo was extracted from plants of the *Indigofera* genus, Tyrian purple from mollusks of the genera *Murex* and *Purpura*, and kermes from a dried insect, *Kermes ilicis*. The Bible, therefore, illustrates the antiquity of the craft of dyeing and the variety of natural products used in ancient times as sources of dyestuffs. Dyed fabrics discovered in Egyptian tombs show that dyeing was practiced at least as early as the 25th century BC. It is believed that the craft originated in India (the name indigo being derived from *indikos*, the Greek word for Indian) and spread westward to Persia, Phoenicia, and Egypt.

The method of producing a variety of hues by mixing together red, blue, and yellow dyestuffs was known in ancient times. Fabrics found in caves in the Dead Sea area and dating from as early as AD 135 were found to have been dyed with various mixtures of safflower yellow on alum mordant (fixative), kermes on alum, and indigo blue.

Until the 19th century all dyestuffs were natural products, obtained primarily from vegetable sources. A wide variety of plants were used. The craft of dyeing demanded a high degree of skill, and details of its recipes were largely kept secret. Some of the most important natural dye-

Organic and inorganic colouring matters

stuffs that were in use until the advent of synthetic products are shown in Table 1.

With few exceptions these natural dyestuffs have no affinity for cellulose, and thus they could be applied to

**Table 1: Sources of Some Important Natural Dyestuffs**

\*Used with mordants. †Before the discovery of America, blacks were prepared from tannins (e.g., from oak galls or sumac) and salts of iron.

cotton only with the aid of an auxiliary inorganic chemical or mordant (Lat. *mordere*, "to bite"), which precipitated the colouring matter in a less soluble form in the fibre. Mordants were also used on wool and silk, both to improve fastness and to obtain a wide variety of hues, different mordants yielding different hues with the same dye. The mordants in common use in ancient times were mainly alum (potassium aluminum sulfate) and salts of iron, copper, or tin. Salts of chromium came into use about 1850. Eventually, on account of the superiority in fastness of the dyeings they produce, chromium mordants almost entirely displaced all other metal salts. Chromium mordants are still widely used for dyeing wool and to a lesser extent for silk and nylon, but are no longer of importance for cellulose fibres.

Following the introduction of synthetic dyes in the 19th century, natural dyestuffs have steadily declined in importance. Now only one, logwood, employed to dye nylon black, is used in any significant quantity.

**Development of the chemistry of dyestuffs and dyeing.** "The Liquors that Dyers employ to tinge," wrote Robert Boyle, an English physicist, in 1664 in the first book dealing with the science of coloration, "are qualified to do so by multitudes of little Corpuscles of Colour . . . insinuating themselves into, and filling all the Pores of the Body to be Dyed, . . ." Even today this remains a good description of the chemistry of dyeing.

As early as the mid-17th century, therefore, leading scientists were concerned with the processes of dyeing, and one of the first actions of the Royal Society after its foundation was to assist dyers by publication of a paper, "An Apparatus to the History of the Common Practices of Dyeing," read to them by Sir William Petty in 1662, describing the methods of dyeing then in use.

Petty, in his paper, classified dyestuffs into the fundamental colours, red, yellow, and "blew," and discussed the use of alum as a mordant, suggesting that it first is taken up by the fibre, where it then becomes combined

with the dye. Thus, the dye is fixed in the fibre. This is also the modern view.

From that period onward the craft of dyeing was aided by the discoveries of chemists and, especially in the period 1670–1830, by a series of French chemists, whose interest appears to have stemmed from the action of Louis XIV's comptroller general of France, who, in order to establish high standards in the wool textile industry, laid down regulations controlling dyeing methods. Distinction was made at that time between *bon teint* and *petit teint*, or fast and nonfast colours; i.e., dyeings that were fast or fugitive, respectively, to light and washing. When in 1729 the regulations were redrafted, the first system of controlled testing of fastness of dyed textiles was introduced.

During the early part of the 19th century, dyeing continued to attract some scientific notice. Even greater interest was created by the advent of synthetic dyestuffs. William Henry Perkin's discovery (1856) of mauve, the first commercial synthetic dyestuff (see below), and the subsequent development of a great variety of dyestuffs of known chemical constitution initiated the modern development of the subject into a distinct branch of chemistry. This development has been particularly noteworthy since World War I. In addition to the availability of a continually growing number of dyestuffs, the reasons for this development include improved instrumentation, increased knowledge of the structure of fibres, and the application of classical chemical principles to the dyeing process.

The introduction of synthetic dyestuffs challenged organic chemists with the problem of determining the molecular structure of these complex materials and opened the way to the development of theories of the causes of colour in organic compounds in general. The idea of valence (fixed numbers of bonds for atoms of different kinds), and in particular the quadrivalence of carbon, had already been formulated when the new dyestuffs began to appear. Shortly afterward the ring structure of the benzene molecule and the three-dimensional nature of organic molecules in general were suggested. These advances greatly assisted in the understanding of the molecular structures of organic dyestuffs.

One of the most important contributions to the understanding of the relationship between colour and structure was the so-called "chromophore" theory proposed in 1876 by a German chemist, Otto N. Witt. In every dye, Witt identified a chromophoric ("colour-bearing") group together with one or more "auxochromes"; i.e., associated groups whose function was to intensify the colour. In 1888 an English chemist, Henry Edward Armstrong, showed that the chromophores could generally be depicted as quinones (oxidized structures derived from the benzene ring). These theories are substantially those held today, although they have been broadened by recognition that the function of the chromophore is to produce a strong absorption of radiation, either in the ultraviolet or in the visible region of the spectrum, and that of the auxochrome is to shift the absorption to give more intense coloration (see below *Dependence of properties upon molecular structure*).

The development of the quantum theory in the 20th century also brought greater insight into the mode of interaction between light and organic molecules. In current terminology, the absorption of visible radiation by a dye raises the electronic energy of the molecule to a so-called "excited state." The energy must then be dissipated either as heat, as phosphorescence or fluorescence, or in a chemical reaction with the surroundings, in which case the dye decomposes and loses its original colour.

**Development of synthetic dyestuffs.** In 1856 William Henry Perkin, a chemistry student in London, discovered a purple colouring matter that had dyeing properties in a product he obtained by chemical treatment of aniline, a material from coal tar. This chance discovery, made in a simple laboratory Perkin had fitted out at his home, laid the foundation of the manufacture of synthetic dyestuffs and pigments, and indeed of the entire world-wide synthetic organic chemical industry.

Early chemical interest in dyeing

Chromophores and auxochromes

Ancient use of mordants

The  
discovery  
of mauve

With foresight and courage, **Perkin**, in 1857, established a factory to manufacture the patented dye, at first called Aniline Purple, or Tyrian Purple, and later Mauve, a French word for the mallow, a plant with a purplish flower. **Perkin**, moreover, developed new methods of applying the dyestuff and visited dyers to show them how they should be used.

Mauve was an immediate success and the general method of its preparation, the oxidation of aniline, was varied and elaborated by other investigators to produce many new dyestuffs, first the crimson coloured Fuchsine or magenta, and later, blues, violets, and green. These were the first basic or cationic (positively charged) dyestuffs, a class that later became overshadowed in importance by others, though in recent years interest in it has revived. Because of their origin, these earliest synthetic dyestuffs were called aniline dyes, a term still used. Unfortunately, their somewhat fugitive nature caused all synthetic dyestuffs to be considered inferior to the natural products, though this is certainly not the case.

From Journal of the Oil and Colour Chemists Association (January 1963)

Colours obtained from various anthraquinone pigments. By modifying the benzene rings of the anthraquinone group, a range from yellow to purple can be produced. A great many other derivatives of anthraquinone are used for industrial purposes.

In 1868 a team of German chemists proved that alizarin, the colouring principle of madder root, is a derivative of the chemical compound anthraquinone. (The Figure shows the colours yellow to purple obtained with pigments manufactured by modifying the molecular structures of anthraquinone compounds.) Their synthesis of alizarin from anthraquinone was the first preparation of a natural vegetable dyestuff by purely chemical means. With the introduction of synthetic alizarin, the use of the natural madder root died out. But, at the same time, new and related products were introduced. The technique of sulfonation (that is, the introduction of sulfonic acid groups), developed earlier, was applied from 1893 onward to the development of a new class of valuable bright, fast dyestuffs for wool, the sulfonated anthraquinone derivatives. This class is one of the most important for wool, and the unsulfonated counterparts are used to dye modern man-made fibres.

Meanwhile, an entirely new type of colouring matter, the azo dyes, which now comprise the largest group of dyestuffs, was being developed. Johann Peter Griess, a young German, then working in the laboratory of an English brewery, discovered the diazonium compounds in

1858. These are very reactive substances, formed from the reaction of aromatic amines (nitrogen-containing organic compounds) with nitrous acid. Diazonium salts readily combine with aromatic amines or phenols to give deeply coloured substances containing the azo group (two nitrogen atoms joined by a double bond). The discovery was not, however, fully exploited until the 1870s, when the full tide of development of the azo dyestuffs set in, stimulated by the discovery that the addition of sulfonic acid groups gives highly water-soluble materials with excellent affinity for wool. By treating naphthalene derivatives with sulfuric acid, various sulfonated aminonaphthalene and hydroxynaphthalenes were made, from which azo dyestuffs could be prepared in a range of shades — from orange to black. And by use of derivatives of pyrazolone instead of naphthalene, yellow azo dyestuffs also were prepared. In 1884 Congo red was produced; this is a bisazo dyestuff; *i.e.*, one containing two azo groups in its molecules. Congo red was the forerunner of a long series of successful dyestuffs, still of importance, named "direct cotton" or "direct" dyestuffs, which can dye cotton without a mordant.

Indigo for a time was the sole example of a "vat" dyestuff; *i.e.*, one applied from a "vat" containing alkali and a reducing agent in which the insoluble dyestuff was temporarily solubilized during dyeing. In 1901, however, Indanthrene blue, the first of the modern type of vat dyestuff, based on anthraquinone, was introduced; and this class, including dyestuffs of the very greatest fastness, has become of great importance.

Four other important new classes of dyestuffs were introduced in the 20th century:

1. The azoic dyestuffs. As early as 1880, a substance called p-naphthol had been applied in alkaline solution to cotton and then coupled with a diazonium compound to produce an insoluble dyestuff in the cotton fibre. Little progress was made with this type of dyeing, however, until Naphthol AS (a more complex chemical compound derived from p-naphthol) was discovered in 1912 and used to replace p-naphthol. Later a whole series of such compounds — and new bases to be diazotized and coupled with them — appeared, giving bright, fast dyes, ranging in colour from yellow to black, but especially useful for oranges and reds.

2. The disperse or nonionic dyestuffs. These substances were discovered in 1923 and at first were used with the then new cellulose acetate fibre, but later also used for nylon and polyester fibres.

3. The phthalocyanine dyestuffs and pigments. Discovered originally in 1907 and 1927 by European chemists, who failed to realize their importance, phthalocyanine derivatives (a class of metal-containing organic compounds) were rediscovered by accident in Scotland in 1928. The first member of this class, a brilliant blue, was found to have a remarkable molecular structure, resembling those of chlorophyll and hemoglobin, natural colouring matters. It proved to be a pigment of outstanding properties. Chlorinated and brominated derivatives gave bright green dyes that together with the parent compound are used in very large quantities mainly as pigments; modified products are used for dyeing. Although no other useful shades have been obtained from phthalocyanine derivatives, quinacridone (a red compound discovered in 1955) is capable of preparation in red or violet forms as a pigment of fastness comparable to phthalocyanine.

4. The reactive dyestuffs for cellulose. First introduced in 1956, these dyes represent an entirely new principle, in that the dyestuff becomes a part of the actual fibre molecule and, therefore, is highly resistant to washing. Unlike other fast dyestuffs for cellulose, many reactive dyestuffs have very bright shades. Later, reactive dyestuffs adapted for wool and nylon were introduced.

#### DEPENDENCE OF PROPERTIES UPON MOLECULAR STRUCTURE

Much of the following discussion depends upon knowledge of the properties and behaviour of atoms and molecules. (Detailed information may be found in the articles

CHEMICAL BONDING; CHEMICAL REACTIONS; CHEMICAL COMPOUNDS, ORGANIC; and MOLECULAR STRUCTURE.)

To be useful, dyestuffs and pigments must have: (1) intense colour and (2) fastness; *i.e.*, resistance to the various chemical and mechanical stresses they meet in the manufacture or use of the finished coloured product. In addition, dyestuffs, but not pigments, must have: (3) solubility in the medium of application, which in almost all cases is water, and (4) ability to be adsorbed and retained by the fibre (substantivity) or to be chemically combined with it (reactivity). Pigments also have to meet unique requirements somewhat different from those of dyestuffs, including such physical and mechanical properties as flow properties in the media of application and insolubility in oily media. These properties are favoured by making the molecule large, and insolubility is also promoted by particular dispositions of the substituent groups—that is, the peripheral units attached to the main body of the molecule.

In all cases these properties depend in large part upon the molecular structures of the colorants themselves. The relationship between the properties of the dyestuffs and pigments and their molecular structure is dealt with in the following sections.

**Colour.** Organic colouring matters are complex unsaturated compounds—that is, compounds with multiple bonds between the atoms—and each such compound has a molecular structure containing one of the fundamental chromophores. Three of the most important chromophores in dyestuffs are called azobenzene, triphenylmethane, and anthraquinone. Their molecular structures are as follows:

Structures of chromophores

in which the letters N, C, H, and O stand for atoms of nitrogen, carbon, hydrogen, and oxygen, respectively; the short single and double lines represent single and double bonds between them, and the hexagons with circles in them represent benzene rings—circular units each composed of six carbon atoms. The chromophoric compounds themselves usually have very weak colours because the conjugated chain (the system of alternate single and double bonds, including the benzene ring) in the molecules is relatively short. If this chain is greatly extended, as in the natural carotene pigments, for example (see below), deep colour develops. Such extended chains, however, are not conveniently introduced into synthetic dyestuffs, which instead rely upon the above-mentioned substituent groups called auxochromes for colour intensification. Auxochromes generally are polar substituents—that is, atoms or groups favouring separation of electrical charges—including such substituents as chloro, nitro, hydroxy, methoxy, amino, methylamino, dimethylamino, and trifluoromethyl groups.

In the conjugated systems of alternate double and single bonds of the chromophores, one or more of the mobile electrons, called pi electrons, are able to move through the molecule. It is then possible to write various electronic structures of the molecule; *i.e.*, the so-called resonance forms. None of these structures describes the molecule as it really exists, but the molecule may be con-

sidered as a hybrid to which the imaginary structures contribute. Thus forms i-v below represent some of the forms contributing to the hybrid structure of azobenzene. Of these, iii is the most stable, because no energy is required to separate charges (as in the other forms).

In this representation, double-headed arrows are used between resonance forms of a single hybrid structure.

The function of the auxochromic groups is to increase the stability of the alternative resonance forms. They do so because they can retain electrical charges more readily than carbon atoms can. For example, when two auxochromic groups are attached to an azobenzene molecule, the resulting structure may consist of new hybrid forms, as in the example below:

Influence of auxochromes

In this instance the alternative electronic configuration vii is more stable than i, ii, iv, or v above, because the charges are now held on oxygen and nitrogen atoms, which can retain them more readily than carbon. The result is that this compound has a more intense colour than azobenzene does.

With the increase in stability of the contributing electronic structures of a molecule, its electrons may be considered to move more readily along the chromophore. Thus its natural frequency of vibration is decreased. A simple analogy can be drawn with a violin string: the longer the string, the lower is the frequency and the longer is the wavelength of the note it emits when plucked. In general, the wavelength increases with the length of the oscillator. This applies to the absorption as well as the emission of energy, whether it be sound energy or light energy, because any oscillator absorbs energy most readily at the wavelength of its natural frequency of vibration.

The chromophores described above absorb most energy at short wavelengths—that is, in the ultraviolet region of the spectrum; and consequently they appear colourless or have only a faint yellow colour. When an auxochrome is present the wavelength of absorption increases and moves into the visible region, thus causing colour to appear. For example, anthraquinone is almost colourless, but 1-methylaminoanthraquinone has an intense red colour. The resulting hue is said to be "deeper."

Table 2 shows the changes that occur in the colour of a given chromophoric system with the progress of its main absorption band across the spectrum from short to long wavelengths. Such a succession of changes can often be produced by substitution of the chromophore with a

**Table 2: Effect of Wavelength of Absorption on Colour Observed**

region of maximum absorption*	colour seen†

Light  
absorption  
and colour

succession of selected auxochromes, one or more at a time, if these auxochromes have increasing effectiveness in enhancing the mobility of the electrons of the chromophoric system. In the case of azo dyestuffs, for example, the hue can be deepened by substitution in either of the aromatic nuclei attached to the azo group, and if both are substituted, the effect is further enhanced.

The intensity of the colour of dyestuffs is among the highest found in any type of substance. The degree of this intensity, known as the molar extinction coefficient, is measured at the wavelength of maximum absorption of light. The molar extinction coefficient for dyestuffs is about  $10^4$ . In practice, this means that a 1 gram percent solution of a dyestuff only 1/100th of a millimetre deep reduces the intensity of the most strongly absorbed light to about one-half of the original value. There is another way to visualize the colour intensity of dyestuffs; it requires from about 10 to 100 single layers of dyestuff molecules, placed one on top of another, to produce a visible colour; and, allowing for the minimum area the substance must have in order to be seen by the naked eye under the best conditions, a total of about 10,000 molecules, or about  $10^{-18}$  gram, must be concentrated together before the colour becomes visible.

**Fastness.** Ability to withstand washing without changing colour, "wash fastness," and ability to withstand exposure to light, "light fastness," are two of the properties of most importance to the user of coloured fabrics. Dyestuffs that are chemically bonded to the fibre—*i.e.*, reactive dyestuffs—or those that are present as water-insoluble particles of low solubility in soap solutions, such as vat dyestuffs, have the highest wash fastness. Water-soluble dyestuffs often have lower wash fastness, but the resistance to removal by soap varies greatly from one dyestuff to another, fastness generally being aided by high molecular weight of the dyestuff molecule and a minimum number of solubilizing groups.

All organic colouring matters fade when exposed to light; hardly any inorganic colours, and no physically produced colours, do. Light fading is the most complex of the reactions that dyestuffs undergo during use, and a great deal of research has been devoted to discovering its causes, which are not yet fully understood.

The light fastness of any dyed material depends not only on the nature of the dyestuff itself, but also on many other factors, including the method of application, the depth of shade, the type of fibre and its moisture content, the relative humidity and oxygen content of the air, and the nature of the illumination.

**Solubility.** Because normal dyeing takes place from aqueous solutions, the dyestuff must contain substituent groups conferring solubility in water. Table 3 includes the most important solubilizing groups used in dyestuff molecules.

Solubility in water may be needed only temporarily during the actual dyeing operation, the dye later being treated so that it becomes water-insoluble on the fibre. Such temporary solubility may be obtained with an insoluble, nonionic dyestuff molecule containing quinone groups, for example, by chemical reduction (addition of electrons) in the presence of alkali to produce a salt of the corresponding hydroquinone; the original quinone

**Table 3: Solubilizing Groups Used With Various Classes of Dyestuffs**

name	structure*	type of dyestuff
Permanent Sodium sulfonate	$-\text{SO}_3\text{Na}$	direct cotton, acid wool, chrome mordant; 1:1 dye-metal complex for wool
Amine hydrochloride	$-\text{NH}_2\text{Cl}^+ - \text{NR}_2\text{Cl}^-$	basic, for cellulose, wool, silk, and acrylic fibres
Hydroxy, amino, and sulfamido groups	$-\text{OH}, -\text{NH}_2, -\text{SO}_2\text{NH}_2$	disperse, for cellulose acetate, nylon, polyester fibres; 2:1 dye-metal complexes for wool and nylon

\*R = an alkyl or aryl group.

is then regenerated on the fibre after dyeing by oxidation. This reduction-oxidation procedure is the basis of the vat dyeing process. Usually sodium dithionite (also called sodium hydrosulfite, formula  $\text{Na}_2\text{S}_2\text{O}_4$ ) is the reducing agent used, and sodium hydroxide is the alkali, with the result that the sodium salt of the reduced form of the dye, known as the leuco compound, is formed. The entire process of alkaline reduction is known as vatting. The leuco compound is generally unstable in air, being rapidly oxidized back to the original dye. This sequence of chemical reactions involved may be shown by the following equations:

In the method of dyeing cellulose fibres known as azoic coupling, a single soluble component, usually a naphthol, is applied to the fibre from solution in sodium hydroxide; this component is then converted into a water-insoluble azo dyestuff on the fibre by coupling with a soluble diazotized base. The procedure is illustrated in the following reaction sequence:

Fastness  
to light  
and to  
washing

Porosity  
and  
surface  
area

The so-called disperse dyestuffs used to colour cellulose acetates, nylon, and polyester fibres are employed as dispersions—that is, as fine suspensions of the solid in liquid—rather than as true solutions. These substances, however, are slightly soluble in water due to the presence of several nonionic water-attracting substituent groups on their molecules, and dyeing probably takes place from the very dilute solutions they produce.

There is considerable interest in processes for dyeing certain man-made fibres with disperse dyestuffs from solutions in organic solvents instead of water. Another process also being considered is the use of vaporized dyestuffs, at high temperature (above 200° C, 392° F).

**Attachment.** Many solid materials adsorb dyestuffs from their solutions, but fibres do so particularly well because of their porosity and their ability to exert chemical forces upon the dyestuff molecules. There is an immense number of submicroscopic pores in a fibre, mainly directed parallel to the length of the fibre; there are, in fact, about ten million in the cross section of a normal textile fibre. The total surface of the walls of these pores is extremely high, and in natural fibres, such as cotton or wool, the pore surface amounts to no less than about five acres per pound. This value is about one thousand times as great as the external surface of the fibres.

Since 1,000 to 10,000 single layers of dyestuff molecules placed one above another are needed to produce a deep coloration, a single layer of dyestuff molecules adsorbed on the walls of all the pores of a fibre would be more than enough to produce a satisfactory depth of shade. Actually, a large proportion of the pores are too small to allow a dyestuff molecule to enter, but, even so, enough dye is adsorbed to produce satisfactory depth of shade. For this action to occur, however, forces on the molecular scale must operate between the fibre molecules exposed in the pore surfaces, and the dyestuff molecules in the contiguous solution. The strongest of these forces are the forces of true chemical bonding by which the so-called reactive dyestuffs are fixed. Other types of dyestuff are attracted by a variety of weaker forces that operate between molecules. As already mentioned, some types of dyestuff are solubilized only during the dyeing operation; in such cases, after the subsequent insolubilization, the dyestuff particles remain held in the fibre by purely mechanical action.

With regard to the dyestuff molecule, attachments to the fibre resulting simply from intermolecular attraction are considered substantive, whereas those involving chemical bonding are considered reactive.

**Substantivity.** The presence of one or more of certain specific groups in a dyestuff molecule determines its substantivity, or affinity, for any given type of fibre, and hence its dyeing method. These groups include the following:

1. Anionic or cationic groups. These (respectively) negatively- or positively-charged groups confer solubility on dyestuffs and also affinity for the appropriate fibres with ionic properties.
2. Polar groups. Although these substituents are electrically neutral they do contribute to charge separation within a molecule. This effect increases the affinity of nonionic (disperse) dyestuffs for man-made fibres and considerably influences the colour.
3. Groups that induce flatness (planarity) in the molecule as a whole. Substituents promoting planarity are essential in producing useful affinity in dyestuffs for cellulose acetates, or polyesters.
4. Lengthy conjugated chains. If a dyestuff molecule is planar, its affinity for cellulose fibres increases regularly with the length of its chain of alternate single and double bonds. To have useful affinity it should have at least eight conjugative double bonds.
5. Phenolic groups. When situated in dyestuff molecules adjacent to certain other groups, phenolic groups confer the ability of combination with a metal mordant.
6. Quinone groups. In the absence of permanent ionic groups, quinones enable a dyestuff to be used for dyeing cellulose fibres by temporary solubilization.

7. Primary amino groups. Primary amino groups on the bases used for azoic dyestuffs can be diazotized and coupled with naphthols (or other materials) already adsorbed on the fibre.

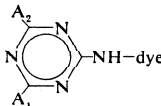

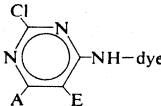

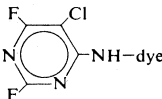

8. Paraffinic chains. Saturated hydrocarbon (paraffinic) chains are used in a few members of several classes of dyestuff. For example, when attached to an acidic molecule for dyeing wool, a paraffin chain of moderate length (containing four to 12 carbons) improves fastness to washing and other wet treatments. Also, when inserted between the polar group and aromatic nucleus of a disperse dyestuff molecule, a short (two- or three-carbon) chain improves the fastness to dry heat. And when inserted between a quaternary ammonium group and an aromatic nucleus, such a chain appears to improve the light fastness of cationic dyes applied to polyacrylonitrile fibres.

In an overall sense, a dye molecule that is either small in total volume, or slim in its cross section, makes rapid dyeing possible because of its ready accessibility to the pores of the fibres.

**Reactivity.** The reactive dyestuffs rely for their retention on the fibre on a principle different from that which controls the dyeing of most other types of dyestuff; that is, they form a covalent (nonionic) chemical bond with the fibre molecules. Such bonds are formed by a reaction between a specific chemical substituent group in the dyestuff molecule with part of the molecule of the fibre.

The reactive groups associated with several classes of dyestuffs are shown in Table 4. Other groups also are employed, and new types of groups are introduced from time to time.

Formation  
of  
chemical  
bonds

Table 4: Types of Reactive Groups in Dyestuffs		
class	chemical structure	
Reactive dyestuffs for cellulose		
Triazine		A <sub>1</sub> = aryl or Cl; A <sub>2</sub> = Cl
Pyrimidine		A = Cl; E = H or Cl
Vinyl derivative	HO <sub>3</sub> SOCH <sub>2</sub> CH <sub>2</sub> -X-dye	X = -SO <sub>2</sub> -, = -CONH-, = -SO <sub>2</sub> NH-
Reactive dyestuffs for wool		
Acrylamide	CH <sub>2</sub> =CHCONH-(dye-metal complex) CH <sub>2</sub> =C(Br)CONH-dye	
Vinylsulfonyl	NaO <sub>3</sub> SOCH <sub>2</sub> CH <sub>2</sub> SO <sub>2</sub> -dye	
Trihalopyrimidine		

In summary, the molecule of any colouring matter can be viewed as a structure built up step by step, each step designed to give the molecule certain properties and enable it to fulfill certain functions. In Table 5 details of chemical structure that confer the above listed properties on the molecule are presented, and the molecular constitutions of some typical important colouring matters, chosen from nature and from industry, illustrate these principles.

TECHNOLOGY

In this section will be found limited aspects of the classification, manufacture, use, and testing of dyes (for a de-

tailed account of the technology of dyeing, see the article DYES AND DYEING).

**Classification.** Dyestuffs and pigments are classified by chemical constitution, by method of application, by hue, or even by the name of the manufacturer. Generally, the commercial name of a particular colorant consists of: (1) a brand name denoting application class (each one specific to each manufacturer); (2) the name of the hue; (3) suffix letters (often German in origin)—*e.g.*, B, G, or R (blau, gelb, rot); (4) a strength indication—*e.g.*, 150 percent, 250, denoting brands with less diluent (usually salt) than the normal.

In addition, there is a **Colour Index** which lists (and describes) all commercial dyestuffs, by application class, and by chemical constitution. For example, the dye Orange II has a **Colour Index** Part I reference as "C.I. Acid Orange 7" and a Part II reference as "C.I. 15510." In the first it is described as a dye for wool, silk, or nylon, used for garment dyeing and for colouring coir and sisal fibres. Also included are details of the grading for fastness to thirteen different agents such as washing, milling, chlorination, light, and so on. Further, the dye is shown as being marketed by about 60 different manufacturers under about 45 commercial names. The Part II reference gives the chemical constitution, method of manufacture, and colour reactions of the dye with common reagents, together with a number of literature references and the information that the dyestuff was discovered by one Z. Roussin in 1876. The manufacturing process for this dyestuff is outlined below.

**Manufacture.** The dyestuff industry uses hundreds of different chemical compounds to produce the thousands of different colorants it markets. These are manufactured by complex and often lengthy series of chemical reactions and utilizing a variety of techniques. The starting materials are relatively few in number, mainly the aromatic hydrocarbons, of which benzene, toluene, naphthalene, and anthracene are the most important.

From these compounds many hundreds of other substances, known as intermediates, are manufactured. The intermediates usually are not dyestuffs but from them, ultimately, the dyes are derived. In general, intermediates are formed by one or more of a variety of chemical operations, such as nitration, sulfonation, chlorination, acylation, and so on. Among the most important of the products thus formed are aniline, alkylaniline, acylaniline, chloroaniline, nitroaniline, alkoxyaniline; a large variety of sulfonated aminonaphthalenes and hydroxynaphthalenes; and aminoanthraquinone and hydroxyanthraquinone.

To illustrate, the various reaction sequences used to prepare dyestuffs are outlined below. The first is a relatively simple procedure for making an azo dyestuff, Orange II; the other is a complex series of processes, given here only in a shortened form, for making an anthraquinone vat dye, Caledon Jade Green.

**Orange II.** Numerically, the azo class of dyes is by far the largest group, containing examples of all hues and including products suitable for colouring all types of material. The preparation of azo dyes is based on the diazo-coupling reaction already described, in which an aromatic amine is treated in an aqueous solution with nitrous acid, thus forming a diazonium salt. The diazonium salt is unstable, and without separation from solution it is allowed to couple with a phenolic substance slowly added in an alkaline solution. The result of the coupling reaction is a highly coloured azo compound. The formation of the acid wool dye, Orange II, from the intermediates sulfanilic acid and  $\beta$ -naphthol is a good example. The reactions involved are shown below:

**Caledon Jade Green.** Caledon Jade Green was discovered in 1920 in the laboratories of a Scottish dye maker; it has been one of the outstanding dyestuff inventions of all time, remarkable both for its attractive bright shade and for its excellent all-round fastness properties. The chemical reactions involved in its synthesis are shown below in somewhat abbreviated form.

**Uses.** Although the principal use of dyestuffs is in the dyeing of fibres and fabrics, dyestuffs and pigments are used in large quantities for many other purposes, including the printing of textiles and the colouring of many materials other than textiles, such as leather, paper, and plastics. Pigments are widely employed in paints, varnishes, printing inks, artists' colours, and writing and copying inks. Several colorants are used in foodstuffs, oils, and cosmetics. Dyestuffs also are important as histological stains and for measuring the surface area and porosity of industrial powders.

Special types of dyestuff (chiefly cyanine dyes) are used in making photographic emulsions and others in colour photography. Furs and human hair are dyed by processes involving the application of dyestuffs or related chemical

Colour Index references

Manufacture of intermediates

compounds. For foodstuff colouring, specially purified dyestuffs, free from poisonous metals, are used. Only a few dyestuffs are permitted in foods in most countries; these have been rigorously screened, particularly for freedom from carcinogenic properties.

Plastics may be mass-coloured; *i.e.*, the plastic may be ground with a pigment before the final shaping operation, a process that gives an opaque product, or they may be surface-dyed after shaping, by immersion in a dye solution. The latter method does not produce opacity and is suitable for colouring rolls of transparent plastic film or small, transparent articles, such as toothbrush handles.

**Standardization, testing, analysis, and identification.** After manufacture, water-soluble dyestuffs can be separated from the solution in which they have been prepared by salting out—that is, made insoluble by the addition of salts—after which the dyestuffs are filtered off and dried. Insoluble dyestuffs, which must be in a form in which they can easily be suspended in water, are finely ground in water with a dispersing agent before drying.

Commercial dyestuff products must meet standards of shade, strength, wettability, and so on, so that successive deliveries of any particular material are the same. Even with the best control of manufacturing processes, however, the shade varies slightly from one manufactured batch to another, and the products in their final processing may have to be adjusted to the shade and strength of a standard by addition of a little colouring matter of a different hue (but with similar properties) or of a diluent such as salt.

For normal dyeing operations on a technical or a laboratory scale, commercial dyestuffs are used without pretreatment, but for laboratory research purposes it is often necessary to use specially purified dyestuffs, and to check their purity by chemical analysis. Most water-soluble dyestuffs are not as readily purified as are most organic compounds because dyestuffs often are strongly ionic and therefore insoluble in organic solvents. They cannot, therefore, be recrystallized from such solvents. Recrystallization from water often is not satisfactory either because the dyestuff is not sufficiently soluble, or because it does not separate readily on cooling (or if it does, it may do so in a form difficult to remove by filtration). Moreover, most commercial dyes contain large quantities of diluent material, usually common salt, which is difficult to remove completely. For chemical research, therefore, the so-called batch dyestuffs, *i.e.*, dyes obtained directly from the manufacturing plant and unmixed with diluent, are preferable. To purify a water-soluble dyestuff for which a process has not been previously worked out, recrystallization usually is attempted, first from water alone and then, if this is not suitable, from a simple water-miscible solvent, such as acetone, ethanol, propanol, or butanol, or from mixtures of these with water. If all such methods fail, repeated salting out of the dyestuff from water, by additions of sodium acetate, is used, followed by filtration and washing of the precipitate with ethanol, which removes any residual sodium acetate. This procedure gives a product of high purity but in a rather low yield, because much of the dyestuff is lost in the filtrates and in the washings.

Dyestuffs and pigments can be analyzed by the normal methods of analysis used in organic chemistry; *i.e.*, by determination of the total content of the various elements present—carbon, hydrogen, oxygen, sulfur, and so on. With improvement in speed and accuracy, these methods, which now require very small amounts of the test sample, have tended to displace older procedures. They do not, however, detect traces of the coloured impurities, which are often present even after careful purification and which may or may not interfere with the use of the product. Detection of these is best made by the separation method known as chromatography, which is based upon adsorption of the material to be separated on a solid support.

Often it is necessary to identify dyes on samples of textile or other coloured material. This usually involves a systematic analysis in which the material is treated in succession with a variety of chemical reagents and solvents, the changes in colour produced or the amount of colour dissolved by the solvent being observed. Such schemes of analysis often are designed merely to identify the dyeing class to which the colouring matter belongs,

Methods  
of stan-  
dardization

Methods  
of analysis

and this may be all the information needed. Other schemes, however, enable a precise identification of many individual dyes.

## Eads, James Buchanan

James Buchanan Eads, one of the outstanding civil engineers of the 19th century, is known chiefly for his con-

Eads

struction of the steel triple-arch Eads Bridge at St. Louis, Missouri, and for successfully deepening and fixing the ship channel at the mouth of the Mississippi.

Eads was born in Lawrenceburg, Indiana, on May 23, 1820. He was named for his mother's cousin, James Buchanan, a Pennsylvania congressman who later became president of the United States. The boy spent a migrant youth with a minimum of formal education, for his father's never very successful business ventures took the family to Cincinnati, then Louisville, and finally St. Louis. James Eads educated himself by reading books from the

library of his first employer, a St. Louis dry-goods merchant. At 18 he became purser on a Mississippi riverboat. Soon, he began to consider a means of salvaging the heavy losses caused by riverboat disasters. When he was 22, he invented a salvage boat, which he called a submarine. It actually was a surface vessel from which he could descend in a diving bell, which he had also designed, and walk the river bottom. He used his inventions to recover lead and iron pigs and other valuable freight. Once he retrieved a cargo that included a large crock of butter in a good state of preservation. So successful was his equipment that after 12 years of operations on the Mississippi and its tributaries he had made his fortune.

Eads retired from the river to marry and settle down. He set himself up briefly as a glass manufacturer, but the promising enterprise, the first glass factory in the West, was ruined by the Mexican War. By 1848 he was back in the salvage business. He built three new submarines, the third of which was capable of pumping out and raising a sunken hull from the river bottom. Within a few years he had 10 boats in his fleet.

As the Civil War threatened, Eads foresaw the struggle that would take place for control of the Mississippi river system, and he advanced a radical idea. He proposed that ironclad steam-powered warships of shallow draft be built to operate on the rivers. The U.S. government was slow to take up his offer to build such a flotilla. When it did, he built the ships in record time, working 4,000 men on day and night shifts seven days a week. The novel craft he set afloat spearheaded Grant's offensive against Forts Henry and Donelson, the first important Union victories of the war. They continued to play a conspicuous role under Andrew Foote and David Farragut at Memphis, Island No. 10, Vicksburg, and Mobile Bay. The vessels were the first ironclads to fight in North America and the first in the world to engage enemy warships. (The "Monitor" and "Merrimac," two ironclads that battled in the U.S. Civil War, were the first such vessels to close against each other in combat.) Immediately after the war, Eads was chosen to direct a construction project of extraordinary difficulty, the bridging of the Mississippi at St. Louis.

His knowledge of the river and of the fabrication of iron and steel enabled Eads to secure, against opposition, some of it unscrupulous, a contract for a steel triple-arch bridge over the river at St. Louis, which he began on August 20, 1867. Its three spans, 502, 520, and 502 feet (152, 158, and 152 metres), respectively, consisted of triangularly braced 18-inch (46-centimetre) hollow steel tubes linked in units and set in piers based on bedrock. Since the rock lay some 100 feet below the river surface, reaching it posed major problems. The work of digging through the mud bottom had to be carried on under compressed air, and some workers developed caisson disease (the bends). Following the deaths of two workers on March 19, 1870, Eads established a floating hospital, provided nourishing food for his workers, insisted on slow decompression on emerging from the caissons, and installed a lift.

The steel used in constructing the bridge was subject to similar rigorous standards. It was inspected at the works and on the site. Indeed, its supplier, the famed industrialist Andrew Carnegie, was forced to reroll some batches three times, and some were still rejected as not conforming to the specified strength of 60,000 pounds per square inch (4,200 kilograms per square centimetre). Many other problems arose. To construct his first steel arches without disturbing navigation on the river, Eads used timber cantilevers to support them, with the halves of each arch held back by cables passing over the top of towers that he had built on the piers. In order to join the two halves of the middle arch, Eads's deputy, Col. Henry Flad, had planned to hump the middle arch slightly to bring the two halves together; then, with the cantilevering removed, the arch would assume its normal shape. Eads, on the other hand, had prepared a wrought-iron plug fitted with threads. The last two arch ribs could be shortened by five inches each and cut with screw threads to receive the plug, which would close the distance between the ribs. Because of an unusual mid-September warm spell, which warped the bridge arches toward the north, Flad could

Contract  
for the  
Eads  
Bridge

not close the arches by the method he had chosen and, after trying to cool the steel tubes with ice packs, fell back on Eads's screw-plug connection. The first arch was closed on September 17, 1873.

The Eads, or St. Louis, Bridge, the largest bridge of any type built up to that time, was recognized throughout the world as a landmark engineering achievement, with its pioneering use of structural steel, its foundations planted at record depths, and its cantilevering technique used for raising the arches. The bridge was officially opened on July 4, 1874.

Soon after, Eads's rare understanding of the Mississippi was enlisted at New Orleans to provide a year-round navigation channel for the city. Despite widespread skepticism, he successfully altered the sedimental behaviour of the river by building a series of jetties, and within five years, by 1879, he had created a practical channel for shipping. In this important work he employed a technique of carrying out the project at his own expense, simply on the basis of guarantees if successful. On the same conditions he sought to promote a ship-carrying railway across the Isthmus of Tehuantepec, in Mexico, as a more economic and viable alternative to a canal across the Isthmus of Panama. Two bills to promote the railway failed in Congress, doubtless a great aggravation to one of such drive and dedication, and Eads's doctors ordered him to rest. He went to Nassau in the Bahamas, where he died on March 8, 1887.

James B. Eads was the first U.S. engineer to be honoured with the Albert Medal of the Royal Society of Arts in London. He had been a consultant for Liverpool docks, as well as for installations in Toronto and in Vera Cruz and Tampico, Mexico. Twice married, he had two daughters and three stepdaughters.

**BIBLIOGRAPHY.** ESTILL MCHENRY (ed.), *Addresses and Papers of James B. Eads* (1884); LOUIS HOW, *James B. Eads* (1900), biography by Eads's grandson; H.J. HOPKINS, *A Span of Bridges* (1970), offers a good account of the building of the bridge; FLORENCE DORSEY, *Road to the Sea and the Mississippi River: The Story of James B. Eads* (1947), the standard work, a well-documented biography, based on research in technical and family papers.

(W.H.G.A.)

## Eakins, Thomas

One of the greatest artists of the United States, Thomas Eakins worked in the mainstream tradition of Realism in American art, carrying it in the last three decades of the 19th century to what may have been its highest achievement. With his mastery of mechanical drawing, perspective, and anatomy, Eakins realistically depicted the physical world and the beings who inhabit it. But more importantly, he sought and captured the inner reality of scenes and individuals, expressing in memorable images his understanding of the world in which he lived.

**Early life and first works.** Thomas Eakins was born on July 25, 1844, in Philadelphia. Except for one extended study trip abroad and a brief trip to the West, virtually his entire life was spent in that city. From his father, a writing master, Eakins inherited not only the manual dexterity and sense of precision that characterizes his art but also the love of outdoor activity and the commitment to absolute integrity that marked his personal life. Young Eakins did well in school, especially in science and mathematics. As his interest in art developed, he studied at the Pennsylvania Academy of Fine Arts. Concerned particularly with the human figure, he reinforced his study of the live model at the academy by attending lectures in anatomy at Jefferson Medical College and eventually witnessing and participating in dissections.

Eakins went to France in 1866. He enrolled at the École des Beaux-Arts and studied with the leading academic painter Jean-Léon Gérôme for over three years. Unaffected by the avant-garde painting of the Impressionists, Eakins absorbed a solid academic tradition with its emphasis on drawing. After completing his study, Eakins went to Spain late in 1869, where he was greatly influenced by the 17th-century paintings of Diego Velázquez and Jusepe de Ribera. Perhaps reacting against the

Thomas Eakins, self-portrait, oil on canvas, 1902; in the National Academy of Design, New York.  
BY courtesy of the National Academy of Design, New York

rigours of his academic training, he preferred artists who used paint and brush boldly to express their sense of life, creating what he called "big work." In Spain, his student days behind him, Eakins undertook his first independent efforts at oil painting.

Eakins returned to Philadelphia in the summer of 1870. His earliest artistic subjects were his sisters and other members of his family and the family of his fiancée, Katherine Crowell. Redolent with the character of each individual in an intimate and personal domestic setting—pensive young ladies at the piano, children engrossed with toys scattered on the floor, Katherine playing with a kitten in her lap—these rich, warm portraits seem to express in colour and mood the essence of what Lewis Mumford called "the Brown Decades." Close family ties were important to Eakins, and the intimate harmony of his home life was seriously disrupted and saddened by the death, first of his mother, and, later, of Katherine Crowell.

Eakins resumed the vigorous outdoor life of his earlier years—hunting, sailing, fishing, swimming, rowing. These activities, like his family circle, provided him with subject matter for his art. A candid realist, Eakins simply painted the people and the world that he knew best, choosing his subjects from the life that he lived. Like the poetry of his aged friend Walt Whitman, who lived across the Delaware River in Camden, New Jersey, Eakins' art was autobiographical, "a song of himself." Eakins, in fact, often included himself as an observer in his own paintings—sculling in the background behind his friend in "Max Schmitt in a Single Scull," peering intently at a surgical operation in "The Agnew Clinic," or treading water next to his setter dog Harry and watching a group of students swimming nude in "The Swimming Hole." Each of the early outdoor scenes, natural and informal at first glance, was, in fact, carefully composed on a perspective grid, with each object precisely located in pictorial space. Each image is further informed by Eakins' personal knowledge of the scene depicted. Thus colour, composition, and the play of lights and darks subtly convey to the viewer a fuller understanding of and feeling for the concentrated energy of a sculler propelling his boat through the water, or the taut equilibrium of the moment when a hunter standing in his boat balances himself, sights his target, and slowly squeezes the trigger.

In 1875 Eakins, who had yet to become well known, decided to paint a major picture for the Centennial Exposition to be held in Philadelphia the following year. Eakins took as his subject a scene that had become familiar to him—Samuel Gross of Jefferson Medical College operating in his clinic before his students. Gross was a magnetic teacher and one of the country's greatest

Eakins' master-piece

New Orleans navigation channel

Study in France and travel in Spain

surgeons. Eakins often selected moments that reveal multiple aspects of a scene and in this picture depicts Gross as both surgeon and teacher. Gross stands in the centre of a sombre amphitheatre, starkly top-lighted by a flood of cool daylight cascading down from a skylight above; he is dressed in black street clothes. He has opened an incision in the leg of the anesthetized male patient stretched out before him. While his assistants probe the wound, the doctor turns, one hand holding a scalpel covered with blood, to tell his students what he has done and what he will do next. At the left a seated woman, perhaps the patient's mother, flings an arm across her face, shielding her eyes from the scene, her fingers clawing the air in anguish. Her emotion and the note of pain and suffering inherent in the subject contrast strikingly with the cool professionalism of Gross, whose calm features reflect assurance and determination as well as compassion. The painting objectively records a realistic drama of contemporary life, full of feeling but free of sentimentality. "The Gross Clinic" is generally agreed to be Eakins' masterpiece.

**Rejection by critics and public.** To Eakins' dismay "The Gross Clinic" was rejected for the art exhibition at the Centennial Exposition, and he had to exhibit it in a medical section. Critics and public alike responded to the painting unfavourably. While they could accept historical scenes of grisly martyrdoms or bloody massacres without qualm, "The Gross Clinic" represented blood and pain and suffering as immediate facts in Philadelphia. That was offensive and unacceptable. Viewers could not appreciate a picture that was neither entertaining nor ennobling but simply a frank statement of contemporary reality. The rejection of the painting was the first of many rebuffs Eakins was to receive from Victorian contemporaries who shared his world but not his values.

From his earliest student days, Eakins had been primarily interested in studying and portraying the human figure. His early sculling scenes displayed the musculature of athletic men, and "The Gross Clinic" dealt directly with the subject of human anatomy. But Eakins found few subjects in contemporary Philadelphia that afforded opportunities for portraying the undraped human figure, especially females. He circumvented this by painting repeatedly a partly imaginary scene of William Rush, a much earlier Philadelphia sculptor, carving his statue of the "Nymph with Bittern" from a naked female model in the presence of a chaperon, which provided him with a pictorial pretext for portraying a nude woman.

In the late 1870s Eakins began to teach at the Pennsylvania Academy of Fine Arts, where he became professor of drawing and painting in 1879. A popular and influential teacher, Eakins stressed anatomy and drawing from live, nude models as opposed to the study of plaster casts of antique sculpture. The fame of the Pennsylvania Academy as a centre for the best art instruction in the country spread among young artists. Yet notoriety accompanied repute, and objections were voiced increasingly from outside the academy to Eakins' unrestrained use of nude models in front of mixed classes. The suspicious were unable to accept Eakins' assurance that the relationship between artist and model was as innocent, objective, and professional as that between doctor and patient. Eakins continued to insist on the importance of teaching from nude human models and was finally forced to resign in 1886. Teaching had become a major part of his life, and this was another severe blow. He continued to teach sporadically at the newly formed Art Students League in Philadelphia and at the National Academy of Design in New York, and his personal relationships with young artists remained close. One bright moment during these difficult years occurred in 1884, when he married one of his pupils, Susan Macdowell.

As a corollary to his interest in anatomy, Eakins was fascinated with locomotion—human and animal figures in motion. A commission in 1879 to paint Fairman Rogers driving his four-in-hand coach through Fairmount Park in Philadelphia (Philadelphia Museum of Art) led him to an intensive study of horse anatomy, and he made a number of sculpted wax sketches of horses in

motion. He developed a serious interest in sculpture, an aspect of his art that only became appreciated much later. His interest in locomotion led to familiarity with the experiments in sequential photography being made in California by Eadweard Muybridge. By 1884 Eakins himself was experimenting with multiple-image photography of moving athletes and animals. And in later years his interest in the human figure in motion led him to make a series of impressive paintings of boxing scenes.

Eakins' interests ranged widely—sports, anatomy, locomotion, music, sculpture, photography—in directions often reminiscent of his great French contemporary Edgar Degas but without that artist's innovative stylistic concerns. There is no evidence, however, that Eakins was aware of the work of Degas. Eakins' art does demand comparison with that of Winslow Homer, the contemporary he most admired and his principal rival claimant to the title of the greatest American artist of the 19th century. Homer, also an objective realist, was similarly interested in outdoor sports and such sporting subjects as hunting, canoeing, and fishing. He also had a similar love for and identification with a specific place—in Homer's case, Prouts Neck, Maine. Homer's art is cool, detached, impersonal, and ultimately pessimistic in its view that man is at the mercy of a deterministic universe. Eakins' art, although often sad in its reflection of the buffeting each human receives in the course of his years, still is ultimately optimistic in its humanism, in its message that man, through his individual actions—a doctor with a knife, a sculler with an oar, a hunter with a gun, a boxer with his gloved fist, a musician with his instrument, a singer with her voice, a chess player with his pieces, a scientist with his instruments—can act, do things, have an effect in this world. Despite the wide variety of his subject matter, almost all of Eakins' art is portraiture, images of real people whom he knew and loved or respected. In his representations of the physical world, Eakins combined a technical ability to depict the external aspect of things with a probing for the essence of each scene. In his portraits of individuals, he similarly combined the faithful representation of the external and anatomical realities of each person with a deeper probing into the subject's inner being and character. The people he portrays have lived, and often their experiences are etched on their faces. The wear and tear of years is not glossed over but celebrated in staring eyes, wrinkles, and slumping torsos.

**Significance and influence.** Although always respected for his ability, Eakins remained throughout his years something of an outcast. His contemporaries, rather than allow themselves to be shaken by his frank statements of the human condition and his joyous appreciation of the human body, ignored him. He sold few pictures, but fortunately a small private income matched his modest needs. Unfettered by the demands of clients, Eakins was free to paint what and, more importantly, whom he wished. His art was never compromised by the need to flatter patrons or sitters, and honesty was his only policy. Good friends and faithful followers rather than fame and fortune were his lot. Not until the year of his death (June 25, 1916) was one of his paintings acquired by a museum ("Pushing for Rail," Metropolitan Museum of Art), and the first major exhibition of his work was held the following year (Metropolitan Museum of Art). But Eakins' art had its long-range effect, serving as a model and an impetus for the burst of realism in American painting during the early years of the 20th century, especially in the work of George Bellows and the group called the Ashcan School of painters. And despite the increasing dominance of abstract art during the middle years of the 20th century, a pervasive and stubborn sub-stream of realism surfaced periodically—Regionalism, Pop art, the figurative work of artists such as George Segal and Leonard Baskin—to manifest the continuing debt of American art to the achievement of Thomas Eakins.

## Ear and Hearing, Human

The ear is an organ capable of receiving and responding to sound—that is, to the minute vibratory disturbances of the air molecules. Not only does the ear detect even faint sounds and noises, so that it can serve as a sentinel, but it also analyzes them. After the mechanical energy of vibration has been converted in that portion of the inner ear called the cochlea (see below) to an electrochemical form (the process of conversion is known as transduction), the ear sends to the brain coded information about the frequency, intensity, and complexity of the sounds. The sensations evoked are those of pitch, loudness, and timbre, all of which contribute to the recognition of the particular kind of sound heard. Equally important in the processing of sound stimuli, especially those of speech, is the ear's accurate recording of their temporal sequence, undistorted by fatigue, adaptation, or afterimages.

The ears are remarkably sensitive to minute differences in the intensity of a sound and the time of its arrival at each ear. This fine discrimination makes it possible not only to localize a source of sound with considerable accuracy but also to attend to certain sounds while ignoring or suppressing others that are of less interest or significance.

The inner ear also contains, in addition to the cochlear transducer, a second set of sense organs that make up the vestibular system. This system is concerned with equilibrium—i.e., with balancing the body by adjustments of the position of the head and the posture. From a functional point of view, equilibrium is more closely

related to vision than to hearing, despite its intimate anatomical relationship to the cochlea and the similarity of the sensory cells in the two sets of organs.

The present article contains a description of the structure of the ear and the physical relations of its parts, including both the cochlea and the vestibular organs; an account of the transmission of sound waves to the cochlea and to its sensory elements contained in the organ of Corti; and a description of the auditory nerve and the auditory pathways of the central nervous system. Tests of hearing are briefly surveyed. The article concludes with sections on the role of the vestibular system and on the tests used to detect disturbances of vestibular function.

## Structure of the ear

The human ear, like that of other mammals, has three distinguishable parts: the external, the middle, and the inner ear. The external ear consists of the portion projecting from the side of the head, called the auricle or pinna, and the external auditory canal, which ends blindly at the eardrum. The middle ear is a narrow, air-filled space within the temporal bone, separated from the outside by the tympanic (eardrum) membrane and crossed by a chain of three tiny bones, the auditory ossicles. The inner ear is a complicated system of fluid-filled passages and cavities, deep in the rock-hard petrous portion of the temporal bone. It contains the sensory organs of hearing and equilibrium, the specialized endings of the auditory, or eighth cranial, nerve (Figure 1).

## EXTERNAL EAR

The most striking differences between the ear of man and that of many other mammals are seen in the auricle itself. In man the auricle is an almost rudimentary, usually immobile shell, more or less closely applied to the side of the head. It consists of a thin plate of yellow fibrocartilage covered by closely adherent skin. The cartilage is molded into the characteristic shape with clearly defined hollows, ridges, and furrows, forming an irregular, shallow funnel (Figure 2). The deepest depression, leading directly to the external auditory canal, or meatus, is called the concha. It is partly covered by two small projections, the tongue-like tragus in front and the anti-tragus behind. Above the tragus, a prominent ridge, the helix, arises from the floor of the concha and continues as the incurved rim of the upper portion of the auricle. An inner, concentric ridge, the antihelix, surrounds the concha and is separated from the helix by a furrow, the scapha (also called the fossa of the helix). In some ears

Figure 2: Structure of the outer ear.

a little prominence, Darwin's tubercle, is seen along the upper, posterior portion of the helix, the vestige of the folded-over point of the ear of a remote prehuman ancestor. The lobule, the fleshy, lower portion of the auricle, is the only part of the external ear that contains no cartilage. The auricle also has several small rudimentary muscles, which connect it to the skull and scalp. They are usually without function but in some persons are capable of limited movements.

The external auditory canal is a slightly curved tube, extending inward from the floor of the concha and ending blindly at the tympanic membrane. In the outer third the wall consists of cartilage; in the inner two-thirds, of bone. The entire length of the passage (24 millimetres, or almost one inch) is lined with skin, which also covers the surface of the eardrum membrane. Fine hairs directed outward and modified sweat glands producing earwax, or cerumen, discourage insects from entering the canal.

#### TYMPANIC MEMBRANE AND MIDDLE EAR

**Tympanic membrane.** The tympanic membrane lies obliquely across the end of the external canal in the form of a flattened cone with its apex directed inward. Its edges are attached to a ring of bone, the tympanic annulus. The diameter of the membrane is about nine millimetres (about one-third inch). The appearance and mobility of the membrane are important for the diagnosis of middle-ear disease. The healthy membrane is pearl gray; sometimes it has a pinkish or yellowish tinge.

The drum membrane is made up of three layers. The outer layer is continuous with the skin of the external canal; the inner with the mucous membrane lining the middle ear. Between them is a layer of circular and radial fibres that give the drum its stiffness and tension. It is well supplied with blood vessels and with sensory nerve fibres that make it acutely sensitive to pain.

**The cavity, including the eustachian tube.** The cavity of the middle ear is a narrow, air-filled space. A slight constriction divides it into two chambers, the tympanum (eardrum) proper, or atrium below, and the epitympanum, or attic above. Its outer wall is formed largely by the tympanic membrane, its inner wall by the bony capsule of the inner ear. Its roof and floor are thin plates of bone separating it from the cranial cavity and the brain above and from the carotid artery and the jugular vein below. Its posterior bony wall has an opening leading to a second air space, the tympanic antrum, and to the small air cells of the mastoid process, the portion of the temporal bone directly in back of the external auditory canal. In the narrow anterior wall is the opening of the eustachian or auditory tube.

The eustachian tube, about 45 millimetres (1.75 inches) in length, leads downward and inward from the tympanic cavity to the nasopharynx, the space that is behind and continuous with the nasal passages and above the soft palate. At its upper end the tube is rather narrow and surrounded by bone. Toward the pharynx it widens and becomes cartilaginous. Its mucous lining is continuous with that of the middle ear. The cilia (small motile hair-like projections) that cover it help to speed the drainage of mucous secretions from the middle ear to the pharynx.

The major function of the tube is to ventilate the middle ear and thus maintain equal air pressure on both sides of the drum membrane. The tube is closed at rest and opens during swallowing, so that minor pressure differences are adjusted without conscious effort. During a dive or a rapid descent in an airplane the tube may remain tightly closed. The discomfort that is felt inside the ear as the atmospheric pressure increases outside can usually be overcome by attempting a forced expiration while the mouth and nostrils are held tightly shut. This manoeuvre, which raises the air pressure in the pharynx and causes the tube to open, is named for the Italian anatomist Antonio Maria Valsalva (1666–1723), who recommended it for clearing pus from an infected middle ear.

**Auditory ossicles.** Three auditory ossicles with somewhat fanciful names form a short chain crossing the middle ear. From the outside inward, they are the malleus (hammer), the incus (anvil), and the stapes (stirrup). In appearance the malleus more nearly resembles a club, and the incus a premolar tooth with widely spreading roots. The stapes, on the other hand, is unmistakably a stirrup.

The head of the malleus and the body of the incus lie in the attic above the upper margin of the drum. The two small bones have a tightly fitting joint between them. The handle of the malleus is firmly attached to the upper half of the drum membrane. Its head is anchored to the walls and roof of the attic by three small ligaments. Another ligament fixes the short process (projection) of the incus in a slight depression in the rear wall of the cavity. Its long process is bent near its lower end and carries a small bony knob that forms a loose joint with the head of the stapes. This last, the smallest and lightest of the ossicles, is about three millimetres (about 0.1 inch) in height and weighs scarcely three milligrams (0.0001 ounce). It lies almost horizontally, at right angles to the long process of the incus. Its footplate fits nicely in the oval window, one of the two openings in the wall of the bony labyrinth, where it is held in place by a ring-like ligament called the annular ligament.

Two minute muscles are found in the middle ear. One, the slender muscle called the tensor tympani, emerges from a bony canal just above the opening of the eustachian tube, runs backward, changes direction as it passes over a pulley-like projection, and attaches to the upper part of the handle of the malleus. Its contractions tend to pull the malleus inward and thus increase the tension of the drum membrane. The other, called the stapedius, rises in the posterior wall and sends its minute tendon forward to attach to the neck of the stapes. Its contractions tend to pull the footplate out of the oval window by tipping the stapes backward.

When the healthy tympanic membrane is examined with the otoscope (an instrument designed for visual inspection of the interior of the ear), through the membrane the handle of the malleus is clearly seen projecting from above downward and backward and dividing the upper portion of the membrane into two almost equal parts. Behind and parallel to it, the long process of the incus can sometimes be made out. Above the malleus is a small triangular area in which the membrane is thin and slack. Behind this area, called the pars flaccida (as opposed to the pars tensa, which makes up the much larger portion of the membrane), lies the bare chorda tympani, a slender branch of the facial nerve that passes through the middle ear on its way to join the lingual nerve. It carries important secretory fibres to the parotid (salivary) gland, and sensory fibres to the taste buds of the tip of the tongue.

#### INNER EAR

**Structure as a whole.** The inner ear is enclosed in a bony case called the otic capsule, a part of which forms the inner wall of the middle ear. There, two openings between the middle and inner ear are found: the oval window above, which is filled by the footplate of the stapes, and the round window, which is covered by a thin membrane, sometimes referred to as the secondary

External  
auditory  
canal

The  
eustachian  
tube and its  
function

tympenic membrane. Between them is a bulge called the promontory.

Because of its complicated galleries and chambers, the inner ear as a whole is referred to as the labyrinth. There are, in fact, two labyrinths, one inside the other. The passages hollowed out in the otic capsule constitute the bony labyrinth. In it is suspended a delicate system of ducts and sacs that constitutes the membranous labyrinth (Figure 3).

Figure 3: The membranous labyrinth, within the bony labyrinth. The stapes has been removed from the oval window.

The bony labyrinth

The bony labyrinth consists of a central chamber called the vestibule, the three semicircular canals, and the spirally coiled cochlea. The last strongly resembles the shell of a snail, and its name is derived from the Greek word for a snail. The canals are designated, according to their position, superior, lateral, and posterior. The superior and posterior canals are in diagonal vertical planes that intersect at right angles. The lateral canal is often referred to as the horizontal because it lies approximately in that plane. Each canal has an expanded end, the ampulla, which opens into the vestibule. The ampullae of the lateral and superior canals lie close together, just above the oval window, but the ampulla of the posterior canal opens on the opposite side of the vestibule. The other ends of the superior and posterior canals join to form a common stem, or crus, which also opens into the vestibule. Nearby is the mouth of a canal called the vestibular aqueduct, which opens into the cranial cavity. The lateral canal has an independent opening at its opposite end. Thus the vestibule, in effect, completes the circle for each of the semicircular canals.

The cochlea, a tube consisting of two and one-half spiral turns around a hollow central pillar, the modiolus, forms a cone approximately nine millimetres (0.4 inch) in diameter at its base and five millimetres (0.2 inch) in height. The tube is approximately 30 millimetres (1.2 inches) in total length, tapering from a width of two millimetres (0.08 inch) where the basal coil joins the vestibule and ending blindly in the cupula at the apex. The hollow centre of the modiolus is a spiral canal, containing the fibres and ganglion cells of the cochlear nerve; this enters the base of the modiolus through an opening in the petrous portion of the temporal bone called the internal meatus. A thin bony shelf, the osseous lamina, winds around the modiolus like the thread of a screw. It projects about half way across the cochlear canal, partly dividing it into two ramps, or galleries, the scala vestibuli above and the scala tympani below. The round window is in the wall of the scala tympani at its basal end. Nearby is the opening of the narrow cochlear aqueduct, through which passes the perilymphatic duct, connecting the interior of the cochlea with the posterior cranial fossa (the rear portion of the floor of the cranial cavity).

Suspended in the bony labyrinth, the membranous labyrinth occupies only a fraction of the available space. Each of the semicircular canals contains a narrow membranous semicircular duct, which by no means fills the channels or lumen of the canal, with a rounded expansion, the ampulla, at one end. In the same way that the semicircular canals communicate with the vestibule, the semicircular ducts open into an elongated tubular sac, the utricle, located in the upper part of the vestibule. The utricle is also connected, through a narrow duct, with a similar structure, the saccule, which occupies the lower part of the vestibule. The cochlear duct is a coiled, tapered tube, suspended between the scala vestibuli and scala tympani of the cochlea, ending blindly at both its basal and its apical ends. It communicates with (opens into) the saccule through a narrow connecting duct (the ductus reuniens) near the basal end. The duct that unites the utricle and the saccule is also connected to another narrow channel, the endolymphatic duct, which passes through the vestibular aqueduct and ends in a pouch on the cranial surface of the petrous bone, the endolymphatic sac.

The space within the bony labyrinth that is not occupied by the various parts of the membranous labyrinth is filled with a watery fluid, the perilymph, which in composition closely resembles the cerebrospinal fluid, the aqueous humour of the eye, and other extracellular fluids of the body tissues. Like them, it is apparently formed locally from the blood plasma by ultrafiltration through the walls of the minute blood vessels called capillaries. Since it is possible for cerebrospinal fluid to enter the cochlea by way of the perilymphatic duct, a portion of the perilymph may come from that source.

The membranous labyrinth is filled with a second watery fluid of different composition, the endolymph. Chemical analysis has shown that perilymph is like most other extracellular fluids, being high in its concentration of sodium ions (about 150 milliequivalents per litre) and low in its concentration of potassium ions (about five milliequivalents per litre), but that endolymph is unique among the extracellular fluids in that it has potassium as the dominant ion (about 140 milliequivalents per litre), with a much reduced concentration of sodium (about 15 milliequivalents per litre). Contrary to the statement sometimes found in textbooks, mammalian endolymph is not a viscous fluid. Recent studies indicate that its viscosity is approximately that of water.

The process of formation of the endolymph and the maintenance of the difference in composition between it and perilymph is not yet completely understood. The tissue known as the stria vascularis, in the wall of the cochlear duct, is thought to play an important role in its secretion, but other tissues of the cochlea and the vestibular organs are probably also involved. Since the membranous labyrinth is a closed system, the question of removal of the endolymph is also of interest. Reabsorption is thought to occur from the endolymphatic sac, but this is probably only part of the story. In all probability other tissues also have important roles in regulating the inner-ear fluids.

**Parts of the inner ear.** Vestibule. The vestibule includes the utricle and saccule, each of which contains a single sensory patch called a macula. In the utricle the macula projects from the anterior wall as an oval spot on a small rounded shelf. In the saccule, the macula lies against the medial (inner) wall of the vestibule directly overlying the bone. It is more elongated than the utricular macula and somewhat resembles the letter J in shape. Each macula is covered by neuroepithelium. This covering consists of sensory cells—called hair cells because of their hairlike projections—and supporting cells. The cells are separated by a basement membrane from the underlying connective tissue. Fibres from the vestibular branch of the vestibulocochlear (eighth cranial, or auditory) nerve enter the macula and pierce the basement membrane to end either at the base of the hair cells or as cuplike formations called calyces surrounding their cell bodies. The hair cells are thus the essential sensory receptor elements of the macula. Each hair cell

Perilymph and endolymph

Utricle and saccule

is topped by a bundle consisting of about 100 fine, non-motile "hairs" (stereocilia) of graded lengths and a single motile hairlike projection called a kinocilium. Covering the entire macula is a delicate acellular structure, the otolithic (or statolithic) membrane, which is often described as gelatinous although it has a distinct fibrillar (minute-fibre-like) pattern. The surface of the membrane is covered by a blanket of rhombohedral crystals, the otoconia (or statoconia), consisting of calcium carbonate in the form of calcite. These crystalline particles, which range in length from one to 20 microns (there are about 25,000 microns in an inch), have a specific gravity almost three times that of the membrane itself and thus add considerable mass to it. The hair cells of the maculae are of two types. One type has a rounded body enclosed by a nerve calyx, the other a cylindrical body with nerve endings at its base. The surfaces of the utricle and saccular maculae show characteristic organization and orientation of the two types of cells in definite mosaic patterns. The larger, rounded cells tend to have a curvilinear arrangement near the centre of the macula, with the cylindrical cells around the periphery. The significance of these patterns is poorly understood, but they are presumed to favour increased directional sensitivity to movements of the head (Figure 4).

From H.H. Lindeman, "Studies on the Morphology of the Sensory Regions of the Vestibular Apparatus," *Ergebnisse der Anatomie und Entwicklungsgeschichte*, vol. 42,1 (1969); Springer-Verlag, New York

Figure 4: Structure of the macula of the utricle.

The utricle and saccule with their maculae are often referred to as otolith organs. Because they respond to gravitational forces, they are also called gravity receptors.

Sensory end organ of semi-circular duct

**Semicircular canals.** The sensory end organ of each semicircular duct is located in the expanded end, or ampulla. It consists of a saddle-shaped ridge of tissue covered with a sensory epithelium containing the same types of cells as do the maculae. The ridge, called the crista, extends across the ampulla from side to side, at right angles to the direction of the duct (Figure 5). It

From H.H. Lindeman, "Studies on the Morphology of the Sensory Regions of the Vestibular Apparatus," *Ergebnisse der Anatomie und Entwicklungsgeschichte*, vol. 42,1 (1969); Springer-Verlag, New York

Figure 5: Ampulla of semicircular duct, showing hair cells and cupula.

is covered by a gelatinous structure, the cupula, which extends to the roof of the ampulla immediately above it, dividing the interior of the ampulla into two approximately equal parts. On each of the hair cells of the sensory epithelium of the crista there are about 100 stereocilia, or "hairs," anchored in the dense cuticular plate. The single kinocilium springs from a small area at one side of the surface of the cell, where it is covered

Figure 6: The organ of Corti and related structures as shown in a cross section through the cochlear duct of a guinea pig (see text).

From C.H. Best and N.B. Taylor, *The Physiological Basis of Medical Practice*, 8th ed. (© 1966); Williams and Wilkins Co., Baltimore

only by the thin plasma membrane. The stereocilia stand straight, in orderly rows. The longest are those nearest the kinocilium, which is motile. The height of the others decreases in stepwise fashion away from the kinocilium. Together with the longest stereocilia, the kinocilia extend well up into the substance of the cupula, occupying fine parallel channels. The cupula is thus attached at its base to the crista, but is free to move in either direction in response to pressure in the endolymph toward or away from the utricle. Its motion is transmitted to the hairs, causing them to bend just above the cuticular plate. This bending is the stimulus to the hair cells and elicits impulses in the vestibular fibres of the auditory nerve. Each macula and each crista is supplied by fibres from the vestibular nerve, one of the two parts of the vestibulocochlear (auditory, or eighth cranial) nerve.

**Cochlea.** The interior of the cochlea is divided longitudinally into three spiral ramps or scalae: the scala vestibuli, which communicates with the vestibule; the scala tympani, which ends blindly at the round window; and the scala media, or cochlear duct, which lies between the other two scalae and ends blindly both at the round window and at the apex. The scala vestibuli and scala tympani communicate at the apex, through an opening called the helicotrema (Figure 3).

In cross section the scala media resembles a right triangle. Its base is formed by a thin bony shelf, the spiral osseous lamina, and by the basilar, or supporting, membrane, which separate it from the scala tympani, and its side by two important tissues lining the bony wall of the cochlea, the delicate stria vascularis and the tough, fibrous spiral ligament. The hypotenuse is formed by the thin membrane of Reissner, consisting of only two layers of flattened cells. A low ridge, the spiral limbus, rests on the margin of the osseous lamina. Reissner's membrane stretches from the inner margin of the limbus to the upper border of the stria, behind which it is inserted (Figure 6).

Upon the surface of the basilar membrane the sensory cells are arranged in more or less orderly rows. Together with their supporting cells they form a complex neuroepithelium called the basilar papilla or organ of Corti, named after the Italian microscopist, the Marchese Al-

The scala media

fonso Corti, who first described it, in 1851. Viewed in cross section its most striking feature is the arch, or tunnel, of Corti, formed by two rows of pillar cells, or rods. The pillar cells furnish the major support of Corti's organ. They separate a single row of larger, more or less pear-shaped inner hair cells on the inner side of the tunnel from three or more rows of smaller, cylindrical, outer hair cells on the outer side. The inner hair cells are supported and enclosed by the inner phalangeal cells, which rest on the thin outer portion, called the tympanic lip, of the spiral limbus. On the inner side of the inner hair cells and the cells that support them is a curved furrow called the inner sulcus. This is lined with more or less cuboidal cells.

Each outer hair cell is supported by a cell known as a phalangeal cell of Deiters, which holds the base of the hair cell in a cup-shaped depression. From each Deiters cell a projection extends upward to the stiff membrane, the reticular lamina, that covers the organ of Corti. The top of the hair cell is firmly held by the lamina, but the body is suspended in fluid that fills the so-called space of Nuel and the tunnel. Although this fluid is sometimes referred to as the cortilymph, it appears to have the same composition as the perilymph. Beyond the hair cells and the cells of Deiters are epithelial cells of three other types, usually called the cells of Hensen, Claudius, and Bottcher, after the 19th-century microscopists who first described them. Their function has not been established, but they are assumed to help in maintaining the composition of the endolymph by secretory and absorptive activity.

The basilar membrane consists of two zones, the pars arcuata under the arch, and the pars pectinata extending from the feet of the outer pillars to the spiral ligament. The fibres of the membrane are fine and inconspicuous in the pars arcuata. Under the feet of the outer pillars the membrane splits into two distinct layers, the upper one containing stout, parallel, radial fibrils that give the membrane its stiffness. These fibrils decrease in calibre and increase in length from the basal end of the cochlea to the apex, so that the basilar membrane as a whole decreases in stiffness as it increases in width from base to apex.

Beneath the fibrillar layer is the acellular ground substance of the membrane, which is covered in turn by a single layer of mesothelial cells forming the tympanic lamella on the tympanic surface.

Capillary blood vessels are found beneath the tympanic lip of the limbus and, in many species, beneath the tunnel. These vessels, called spiral vessels, do not enter the organ of Corti but are thought to furnish the major part of the supply of oxygen and nutrients to its various cells, including the hair cells. Although the outer spiral vessel is seldom found in adult animals of certain species such as the dog and cat and is somewhat irregularly distributed in man, it is always present during fetal development. To judge by its size in the fetus, it plays a major part in bringing blood to the rapidly differentiating organ of Corti.

Each hair cell is capped by a plate, which bears the stereocilia or hairs. On the inner hair cells 40 to 60 stereocilia are arranged in two or more irregularly parallel rows. On the outer hair cells approximately 100 stereocilia form a W pattern. Below the notch of the W the plate is incomplete. At this point is the base of the kinocilium, although the motile "hair" is absent.

The stereocilia are about three to five microns in length and extend upward from the cuticular plate to the underside of the tectorial membrane. This is an acellular, gelatinous structure that covers the top of the limbus spiralis as a thin layer and extends outward over the inner sulcus and the reticular lamina. Its fibrils extend radially and somewhat obliquely to end in finger-like projections at its free margin; these make contact with the stereocilia of the outermost hair cells.

The myelinated (sheathed) fibres of the vestibulocochlear nerve fan out in spiral fashion from the modiolus to pass into a channel near the root of the osseous lamina called the canal of Rosenthal. There, the bipolar cell

bodies of these neurons, or nerve cells, are located, forming the spiral ganglion. Beyond the ganglion their dendrites extend radially outward in the lamina beneath the limbus to pass through the small pores of a structure called the habenula perforata, directly under the inner hair cells. At this point the fibres abruptly lose their multilayered coats of myelin and continue as thin, naked, unmyelinated fibres into the organ of Corti. They form a longitudinally directed bundle running beneath the inner hair cells and another at the foot of the inner pillars just inside the tunnel. The majority of the fibres end beneath the inner hair cells, but some of them cross the tunnel to form longitudinal bundles beneath the outer hair cells, on which they eventually terminate.

The endings of the nerve fibres beneath the hair cells are of two distinct types. The larger and more numerous endings contain many minute vesicles (liquid-filled sacs), which are related to impulse transmission at neural junctions. As described below these endings belong to a special bundle of nerve fibres arising in the brainstem and constituting an efferent system or feedback loop. The smaller and less numerous endings contain few vesicles or other cell structures (organelles). They are the terminations of the afferent fibres of the cochlear nerve, transmitting impulses from the hair cells to the brainstem.

The outer membranous wall of the cochlear duct is lined, as has been mentioned above, by the stria vascularis, a dense cellular layer containing a network of capillary blood vessels. The surface cells of the stria, called dark cells, are of secretory type. Interspersed among the dark cells is an intermediate layer of cells called light cells. Several layers of flat basal cells bound the stria and separate it from the spiral ligament.

Reissner's membrane is inserted at the upper margin of the stria. At the lower margin of the stria is the spiral prominence, a low ridge containing its own set of longitudinally directed capillary vessels. Below the prominence is a depression called the outer sulcus, the floor of which is lined by cells of epithelial origin that send long projections into the substance of the spiral ligament. Between these so-called root cells, capillary vessels descend from the spiral ligament. This region appears to have an absorptive rather than a secretory function, and it may be concerned with the removal of waste materials from the endolymph.

The spiral ligament lies between the stria vascularis and the bony wall of the cochlea. Extending above the attachment of Reissner's membrane, it is there in contact with the perilymph in the scala vestibuli; and extending below the insertion of the basilar membrane, it is there in contact with the perilymph in the scala tympani. It contains many stout fibres that anchor the basilar membrane, and numerous cells, mainly connective tissue cells (fibrocytes). Behind the stria the structure of the spiral ligament is denser than near the upper and lower margins.

Like the stria, the spiral ligament is well supplied with blood vessels. It receives the radiating arterioles that pass outward from the modiolus in bony channels of the roof of the scala vestibuli. Branches from these vessels form a network of capillaries above Reissner's membrane that is thought to be largely responsible for the formation of the perilymph as an ultrafiltrate of the blood plasma. Other branches enter the stria, and still others pass behind it to the spiral prominence and the floor of the outer sulcus. From these separate capillary networks, which are not interconnected, venules (small veins) descending below the attachment of the basilar membrane collect the blood and deliver it to the spiral vein in the floor of the scala tympani.

Viewed from above, the organ of Corti with its covering, the reticular lamina, forms a well-defined mosaic pattern. In man the arrangement of the outer hair cells in the basal turn of the cochlea is quite regular, with three distinct and orderly rows; but in the higher turns of the cochlea, it becomes increasingly irregular, as scattered cells appear representing incomplete fourth and fifth rows. The spaces between the outer hair cells are filled by the oddly shaped extensions (phalangeal plates)

The spiral  
vessels

The spiral  
ligament

of the supporting cells. The double row of head plates of the inner and outer pillar cells cover the tunnel and separate the inner from the outer hair cells. The reticular lamina extends from the inner border cells near the inner sulcus to the Hensen cells but does not include either of these cell groups. When a hair cell degenerates and disappears as a result of injury, its place is quickly covered by the adjacent phalangeal plates, which form an easily recognized "scar."

The  
basilar  
membrane

The length of the basilar membrane (and of the organ of Corti that covers it) is about 35 millimetres (about 1.4 inches) in man. Its width varies from less than 0.001 millimetre near its basal end to 0.005 millimetre near the apex. The membrane is not under tension but decreases remarkably in stiffness from the base to the apex of the cochlea. Furthermore, at the basal end the osseous lamina is broader, the stria vascularis wider, and the spiral ligament stouter than at the apex. The mass of the organ of Corti, on the other hand, is least at the base and greatest at the apex. These considerations indicate that there is a certain degree of "tuning" provided in the structure of the cochlear duct and its contents. With greater stiffness and less mass, the basal end is more attuned to the higher frequencies of vibrations. Decreased stiffness and increased mass render the apical end more responsive to the lower frequencies.

The total number of outer hair cells in the cochlea has been estimated at 12,000, and the number of inner hair cells at 3,500. Although there are almost 30,000 fibres in the cochlear nerve, there is considerable overlap in the innervation of the outer hair cells. A single fibre may supply endings to many hair cells, which thus share a "party line." Furthermore, a single hair cell may receive nerve endings from many fibres. The actual distribution of the nerve fibres in the organ of Corti has not been worked out in any detail, but the inner hair cells appear to receive the lion's share of the afferent fibre endings (fibres bearing impulses to the brain), with less of the overlapping and sharing of fibres that are characteristic of the outer hair cells.

## Functions of the ear

### TRANSMISSION OF SOUND WAVES

**Transmission to the inner ear.** Air conduction. The auricle, or visible portion of the outer ear, because of its small size and virtual immobility in man, has lost most of the importance that it has in many animals as an aid in sound gathering and direction finding. For airborne sounds of relatively short wavelength—*i.e.*, those above 3,000 hertz (cycles per second)—the concha serves as a funnel, directing them into the canal. The canal itself contributes little of acoustic importance apart from a broad resonance centred at 3,800 hertz, which helps to determine the frequencies to which the ear is most sensitive.

Acoustic  
impedance

Sounds reaching the drum membrane are in part reflected and in part absorbed. Only that portion of the sound that is absorbed is effective in setting the drum membrane and the ossicles in motion and thus eventually reaching the inner ear. This tendency of the ear to oppose the passage of sound is called its acoustic impedance. The magnitude of the impedance depends upon the mass and stiffness of the drum membrane and the ossicular chain and on the frictional resistance that they offer. Direct or indirect measurement of the impedance of the ear in hard-of-hearing patients can give important information about the condition of the middle-ear mechanism.

The central portion of the drum membrane vibrates as a stiff cone in response to sound, at least at frequencies below 2,400 hertz. Its motion is transmitted to the handle of the malleus, the tip of which is at the umbo, or centre, of the membrane. At higher frequencies the motions of the drum membrane are no longer simple, and transmission to the malleus may be somewhat less effective. The malleus and incus are suspended by small elastic ligaments and are finely balanced, so that their masses are evenly distributed above and below their common axis of rotation. The head of the malleus and the body

of the incus are tightly bound together, with the result that they move in and out as a unit with the movements of the drum membrane. At moderate sound pressures the stapes follows them, and the whole ossicular chain vibrates as a single mass. There may, however, be considerable freedom of motion and some loss of energy at the joint between the incus and the stapes because of the relatively loose coupling. The stapes itself does not move in and out, however, but rocks about the lower pole of its footplate as it transmits the vibrations to the perilymph that fills the vestibule. Its motion thus resembles that of a bell-crank lever rather than that of a piston (Figure 7).

Adapted from S.S. Stevens and H. Davis. *Hearing: Its Psychology and Physiology* (1938); John Wiley and Sons, Inc.

Figure 7: Mechanics (diagrammatic) of the drum membrane and ossicular chain (see text).

The acoustic problem solved by the middle-ear mechanism of drum membrane and ossicular chain is that of transmitting sound from the air to the watery perilymph of the inner ear. Because of the great difference in density between the gas and the liquid, there is a serious mismatch of impedance between them. Ordinarily, this mismatch causes 99.9 percent of airborne sound striking a water surface to be reflected, so that only 0.1 percent passes into the water. In the ear this would represent a transmission loss of 30 decibels, enough to seriously limit its performance, were it not for the transformer action of the middle ear. The matching of impedances is accomplished in two ways, primarily by the reduction in area between the drum membrane and the stapes footplate and secondarily by the mechanical advantage of the lever formed by the malleus and incus. Although the total area of the drum membrane is about 69 square millimetres (0.1 square inch), the area of its central portion that is free to move has been estimated at about 43 square millimetres (0.07 square inch). All of the sound that causes this area of the membrane to vibrate is transmitted and concentrated in the 3.2-square-millimetre (0.005-square-inch) area of the stapes footplate. Thus the pressure (*i.e.*, force per unit area) is increased at least 13 times over. The mechanical advantage of the ossicular lever, because the handle of the malleus is longer than the long projection of the incus, amounts to about 1.3. The total increase in pressure at the footplate is, therefore, not less than 17-fold, depending upon the area of the drum membrane actually vibrating. At frequencies in the range of 3,000 to 5,000 hertz, to which the ear is most sensitive, the increase may be even greater because of the resonant properties of the ear canal as a closed tube.

The ossicular chain not only concentrates sound in a small area but also applies sound preferentially to one window of the cochlea—*i.e.*, to the oval window, in which the footplate fits so neatly. If the oval and the round windows were equally exposed to airborne sound

Matching  
of im-  
pedances

crossing the middle ear, the vibrations in the perilymph of the scala vestibuli would be opposed by those in the perilymph of the scala tympani, and little effective movement of the basilar membrane would result. As it is, sound is delivered selectively to the oval window, and the round window moves in reciprocal fashion, bulging outward in response to an inward movement of the stapes footplate and vice versa. The passage of vibrations through the air across the middle ear from the drum membrane to the round window is of negligible importance.

Thanks to these mechanical features of the middle ear, the hair cells of the normal cochlea are able to respond at the threshold of hearing to vibrations of the tympanic membrane no greater than one angstrom unit (0.000001 millimetre) in amplitude. On the other hand, when the ossicular chain is immobilized by disease, as in **otosclerosis**, which causes the stapes footplate to become fixed in the oval window, increase in the threshold of hearing of as much as 60 decibels is common. Bypassing the ossicular chain through the surgical creation of a new window, as in the so-called fenestration operation, can restore hearing to within 25 or 30 decibels of the normal. Only if the stapes is removed and replaced by a tiny artificial stapes can normal hearing be approached. Fortunately, defects of the middle ear causing so-called conductive impairment can often be corrected by surgical means so that useful hearing is restored.

#### Action of middle-ear muscles

The muscles of the middle ear, the tensor tympani and stapedius, can influence the transmission of sound by the ossicular chain. Contraction of the tensor tympani pulls the handle of the malleus inward and, as the name of the muscle suggests, tenses the drum membrane. Contraction of the stapedius tends to pull the stapes footplate outward from the oval window and thereby reduces the intensity of sound reaching the cochlea. The stapedius responds reflexly with quick contraction to sounds of high intensity applied either to the same ear or to the opposite ear. The reflex has been likened to the **eyeblink** or constriction of the pupil in response to light and is thought to have protective value. Unfortunately, the contractions of the middle-ear muscles are not instantaneous, so that they do not protect the cochlea against damage by sudden intense noise, as of gunfire. They also fatigue rather quickly and thus offer little protection against injury by sustained high level noise, as in industry. Because dangerously intense noises are rare in nature, it has been argued that the chief biological significance of the aural reflex is not protection of the inner ear but selective high pass filtering of sound. In other words, since the contractions stiffen the ossicular chain, they favour the transmission of the higher frequencies. These carry more information than the lower frequencies, whether in the consonant sounds of human speech or in the rustle of leaves and the snap of a twig that may signal the approach of an enemy in the wild. At the same time, they reduce the transmission of the lower frequencies, which may otherwise mask those of greater significance for survival. The intra-aural muscle reflexes may also have a role in listening and attention, but this function is by no means fully understood.

**Bone conduction.** There is another route by which sound can reach the inner ear—that is, by conduction through the bones of the skull. When the handle of a vibrating tuning fork is placed on a bony prominence such as the forehead or the mastoid process behind the ear, its note is clearly audible. Similarly, the ticking of a watch held between the teeth can be distinctly heard. When the external canals are closed with the fingers, the sound becomes louder, indicating that it is not entering the ear by the usual channel. Instead, it is producing vibrations of the skull that are passed on to the inner ear, either directly or indirectly.

The higher audible frequencies cause the skull to vibrate in segments, and these vibrations are transmitted to the cochlear fluids by direct compression of the otic capsule, the bony case inclosing the inner ear. Since the round window membrane is more freely mobile than the stapes footplate, the vibrations set up in the perilymph

of the scala vestibuli are not cancelled out by those in the scala tympani, and the resultant movements of the basilar membrane can stimulate Corti's organ. This type of transmission is known as compressional bone conduction.

At lower frequencies—*i.e.*, 1,500 hertz and below—the skull moves as a rigid body. The ossicles, because of their inertia and because they are suspended in the middle-ear cavity and only loosely coupled to the skull, are less affected and move less freely than the cochlea and the margins of the oval window. The result is that the oval window moves with respect to the footplate of the stapes, which gives the same effect as if the stapes itself were vibrating. This form of transmission is known as inertial bone conduction. The fixed stapes in otosclerosis interferes with this type of bone conduction, but not with compressional bone conduction.

In the presence of middle-ear disease, hearing aids with special vibrators are sometimes used to deliver sound to the mastoid process (the part of the temporal bone that is behind the ear) and then by bone conduction to the inner ear. Bone conduction is also the basis of some of the oldest and most useful tests in the repertory of the **otologist**, those employing tuning forks to distinguish between a conductive impairment affecting the middle ear and amenable to surgery and a sensorineural impairment—that is, an impairment affecting the inner ear and the cochlear nerve—for which surgery is usually not indicated. In the Rinne test the sounding tuning fork is placed on the mastoid process, and the person being tested is asked to report when he can no longer hear it. The examiner then removes the fork quickly and holds the prongs close to the open ear canal. The normal ear continues to hear it for about 45 seconds, and this "positive" result occurs also with incomplete sensorineural impairment of hearing. When the result is "negative" and the fork is heard longer by bone conduction than by air conduction, a conductive type of deafness is present. In the Schwabach test the presence of a sensorineural impairment is indicated when the patient is unable to hear the bone-conducted sound as long as the examiner with normal hearing can. The patient with a conductive hearing loss, on the other hand, can hear the fork longer than can the examiner because the conductive lesion excludes the extraneous masking noise of the surroundings. A bone-conduction audiometer would give the same result.

For the Weber test, the fork is simply placed on the patient's forehead, and the examiner asks in which ear he hears it. If a sensorineural lesion is present in one ear, the patient will localize the sound in the opposite, or "better," ear. If a conductive lesion is present, he will localize it in the "worse" ear—*i.e.*, in the one that is protected from interference by extraneous sounds. This simple test is a valuable aid in the diagnosis of otosclerosis.

**Transmission through liquid of inner ear to organ of Corti.** The vibrations of the stapes footplate at the oval window are transmitted through the perilymph of the vestibule and that of the scala vestibuli to the cochlear duct. Normally, they do not affect the semicircular canals, the utricle, or the saccule. Only the cochlear fluids and the membranes of the cochlear duct are free to vibrate in response to alternating pressures at the oval window, because only the cochlea has the round window as a "relief valve."

What takes place in the cochlea is both an analysis or sorting out of the frequencies of a complex sound and a transduction of the mechanical vibrations into nerve impulses for transmission to the brainstem by the fibres of the cochlear nerve. The analysis occurs because the cochlea is a tuned structure, different parts of which vibrate in response to different frequencies; the transduction because the hair cells of Corti's organ are capable of changing minute amounts of mechanical energy into an electrochemical form that stimulates the endings of the nerve fibres.

The idea of the inner ear as a resonant structure was proposed by several authors in the 17th and 18th centuries but received its most explicit statement just over a

Hearing aids for conduction deafness

The ear's  
analysis of  
complex  
sounds

century ago by the German physicist and physiologist Hermann von Helmholtz. Inspired by the anatomical studies of Corti, Helmholtz postulated in the cochlea a series of resonators capable of analyzing complex sounds into their component frequencies. After considering various other structures, he concluded that the transverse fibres of the basilar membrane, which increase in length and decrease in stiffness from the basal end to the apex, were the resonators he sought. Although Helmholtz' resonance theory in its original form is no longer accepted, much experimental and clinical evidence supports the closely related "place theory," which holds that sounds of different frequency activate different regions of the basilar membrane and organ of Corti, there being an orderly progression from the basal end, where the highest tones are effective, to the apical end, where the lowest tones are received.

From the experiments of Georg von Békésy (for which he was awarded the Nobel Prize for Physiology or Medicine in 1961) it is clear that the frequency analysis performed by the cochlea occurs not because of a series of separate tuned resonators as postulated by Helmholtz but because the basilar membrane and organ of Corti vary continuously in stiffness and mass from base to apex, stiffness decreasing and mass increasing as the width of the basilar membrane increases. Vibrations reaching the basal end through the perilymph can be shown to proceed as travelling waves, attaining a maximum amplitude at a certain point along the membrane and then rapidly subsiding. The higher the frequency of the sound imposed, the shorter is the distance that the waves travel. Since the hair cells are arrayed in orderly ranks on the basilar membrane and the nerve fibres fan out in orderly fashion to innervate them, a tone of a given frequency causes a certain "place" on the basilar membrane to vibrate, the hair cells overlying it are stimulated, and the corresponding nerve fibres convey impulses to the brain. The brain can recognize the place on the basilar membrane and thus the pitch of the stimulating tone, depending upon the particular group of nerve fibres activated. For the lower frequencies the rate of stimulation is also an important indicator of pitch because the frequency of the nerve impulses tends to follow the frequency of the tone. For the higher frequencies, place alone seems to be decisive. The intimate nature of the events that occur at the hair cells when they are stimulated by movements of the basilar membrane is by no means fully understood. The up-and-down movements of the basilar membrane are thought to be converted into shearing movements between the reticular lamina and the tectorial membrane, which overlies it. The stereocilia, or hairs of the hair cells, in contact with the tectorial membrane are displaced or bent by the shearing forces, and it is this bending of the stereocilia that triggers the electrochemical events in the hair cells that excite the endings of the cochlear nerve fibres. Present understanding of the events occurring in the cochlea is based in part on von Békésy's experiments with cochlear models, in part on his direct microscopic observations by stroboscopic illumination of vibratory patterns in the human cochlea removed from the body after death and subjected to intense sound. Important insights have also been obtained through the study of the small electrical potentials that are produced by the living cochlea in response to sound. These alternating current potentials, first reported in 1929, reproduce the frequency and wave form of the stimulating sound and can be picked up by means of two electrodes, one of which is placed in contact with the round window membrane or with the bony wall of the cochlea. The potentials were shown to consist of two separate components, the microphonic potentials, which appear to be related to the transduction process at the hair cells, and the action potentials, which represent the nerve impulses in the terminal fibres of the cochlear nerve. There is also a direct current potential difference, the endocochlear potential of some 80 millivolts between the endolymph in the cochlear duct and the perilymph in the scala tympani. The alternating current potentials depend upon an intact organ of Corti, the

Electrical  
potentials  
of the  
cochlea

direct current potential upon the stria vascularis. All require an adequate supply of oxygen to the cochlea and soon disappear when oxygen is lacking. When the organ of Corti is damaged by drugs or by intense sound, the potentials are diminished or abolished. In young children suspected of congenital deafness, the cochlear potentials can give important information about the state of the inner ear.

#### THE COCHLEAR NERVE AND THE CENTRAL AUDITORY PATHWAYS

The vestibulocochlear (acoustic, or eighth cranial) nerve consists of two anatomically and functionally distinct parts, the cochlear nerve, distributed to the organ of hearing, and the vestibular nerve, distributed to the organs of equilibrium. The fibres of the cochlear nerve have their peripheral terminals around the bases of the inner and outer hair cells and their central terminals in the groups of nerve cells called the dorsal and ventral cochlear nuclei, in the medulla oblongata, at the base of the brain. The cell bodies of these neurons (nerve cells), numbering some 30,000 in all, fill the spiral canal of Rosenthal at the root of the osseous lamina of the cochlea. Their peripheral, dendritic portions extend radially in the lamina to the habenula perforata, beneath the inner hair cells. At this point they lose their myelin sheaths and enter the organ of Corti as thin, unmyelinated fibres. The greater number are distributed as radial fibres directly to the inner hair cells, whereas others cross the tunnel either as radial fibres supplying a few outer hair cells or as spiral fibres that turn to run for relatively long distances and make contact with many outer hair cells. The central or axonal portions of the bipolar cochlear neurons unite to form the cochlear nerve trunk, the fibres of which are twisted like the strands of a rope. Leaving the modiolus through the internal meatus or passageway, they pass directly to the medulla. There each fibre divides into two, sending one branch to the dorsal and the other to the ventral cochlear nucleus.

The central auditory pathways extend from the medulla to the cerebral cortex and consist of a series of nuclei (groups of nerve cell bodies) connected by fibre tracts made up of their axons. They form a more or less direct route for relaying acoustic information, encoded in the form of nerve impulses, directly to the highest cerebral levels in the cortex. At lower levels information as to pitch, loudness, and localization of sounds is processed, and appropriate responses, such as contractions of the intra-aural muscles, turning of the eyes and head, or movements of the body as a whole, are initiated.

Some fibres from the ventral cochlear nucleus pass across the midline to the cells of the superior olivary complex, whereas others make connection with the olivary complex of the same side. Together, these fibres form the trapezoid body. Fibres from the dorsal cochlear nucleus cross the midline to end on the cells of the nuclei of the lateral lemniscus. There they are joined by fibres from the ventral cochlear nuclei of both sides, and from the olivary complex. The lemniscus is a major tract, most of the fibres of which end in the inferior colliculus, the auditory centre of the midbrain, although some fibres may by-pass the colliculus and end at the next higher level, the medial geniculate body. From the medial geniculate there is an orderly projection of fibres to a portion of the cortex of the temporal lobe.

In man and other primates the primary acoustic area in the cerebral cortex is in the superior transverse temporal gyrus, a ridge in the temporal lobe, on the lower edge, or lip, of a cleft known as the sylvian fissure.

Because about half of the fibres of the auditory pathways cross the midline while others ascend on the same side, each ear is represented in both the right and the left cortex. For this reason both ears can continue to function normally, even if the auditory cortical area of one side is destroyed. Impaired hearing due to bilateral cortical injury involving both auditory areas has been reported, but it is extremely rare.

Parallel with the pathway ascending from the cochlear nuclei to the cortex is a pathway descending from the

Central  
auditory  
pathways

cortex to the cochlear nuclei. In both pathways some of the fibres remain on the same side, while others cross the midline to the opposite side of the brain. There is also evidence of a "spur" line ascending from the dorsal cochlear nucleus to the cerebellum and another descending from the inferior colliculus, the auditory centre of the midbrain, to the cerebellum. The significance of these cerebellar connections is not clear, but they may antedate the development of the cerebral cortex. In general, the descending fibres may be regarded as exercising an inhibitory function by means of a sort of "negative feedback." They may also determine which ascending impulses shall be blocked and which shall be allowed to pass on to the higher centres of the brain.

From the olivary complex, a region in the medulla oblongata, there arises also a fibre tract called the olivocochlear bundle. It constitutes an efferent system or feedback loop, by which nerve impulses, thought to be inhibitory in nature, reach the hair cells. This system, which apparently utilizes acetylcholine as a chemical synaptic transmitter, is presumably involved in sharpening the analysis that is made in the cochlea.

Evidence of an orderly spatial representation of the organ of Corti at the lower levels of the auditory pathway has been reported by many investigators. Such a pattern would seem to be required by the place theory of cochlear analysis of sound.

Physiological evidence of "tuning" of the auditory system has also been obtained by recording the electrical potentials from individual neurons at various levels by means of microelectrodes. Most neurons of the auditory pathway show a "best frequency"—*i.e.*, a frequency to which the individual neuron responds at minimal intensity. With each increase in the intensity of the sound stimulus, the neuron is able to respond to a wider band of frequencies, thus reflecting the broad tuning of the basilar membrane. With sounds of lower frequency, the rate of response of the neuron tends to reflect the stimulus frequency. Increased intensity of stimulation causes a more rapid rate of responding. In general, pitch tends to be coded in terms of the neurons that are responding, loudness in terms of the rate of response and the total number of active neurons.

Auditory  
function of  
the cortex

Although extensive studies have been made of the responses of single cortical neurons, the data do not yet fit any comprehensive theory of auditory analysis. Experiments in animals have indicated that the cortex is not even necessary for frequency recognition, which can be carried out at lower levels, but that it is essential for the recognition of temporal patterns of sound. It appears likely, therefore, that in man both pitch and loudness are distinguished at lower levels of the auditory pathways and that the cortex is reserved for the analysis of more complex acoustic stimuli, such as speech and music, for which the temporal sequence of sounds is equally important.

Presumably it is also at cortical levels that the "meaning" of sounds is recognized and behaviour is adjusted in accordance with their significance. Such functions were formerly attributed to an "auditory association area" immediately surrounding the primary area, but such a term might equally well be interpreted as embracing the entire cerebral cortex, thanks to the multiple interconnections between the various areas.

The localization of sounds is known to depend upon the recognition of minute differences in intensity and in the time of arrival of the sound at the two ears. A sound that arrives at the right ear a few microseconds sooner than it does at the left or that sounds a few decibels louder in that ear is recognized as coming from the right. In a real-life situation the head may also be turned to pinpoint the source of sound by maximizing these differences. For low-frequency tones a difference in phase at the two ears is the criterion for localization, but for higher frequencies the difference in loudness caused by the sound shadow of the head becomes all-important.

Each cochlear nucleus receives impulses only from the ear of the same side. A comparison between the responses of the two ears first becomes possible at the su-

perior olivary complex, which receives fibres from both ears. Electrophysiological experiments in animals have shown that some units of the accessory nucleus of the olivary complex respond to impulses from both ears. Others respond to impulses from one side exclusively, but their response is modified by the simultaneous arrival of impulses from the other side.

The  
superior  
olivary  
complex

This system appears to be capable of making the extraordinarily fine discriminations of time and intensity that are necessary for sound localization. By virtue of such complex neural interconnections in the brain, the two ears together can be much more effective than one ear alone in picking out a particular sound in the presence of a background of noise. They also permit attention to be directed to a single source of sound, such as one instrument in an orchestra or one voice in a crowd. This is the basis of the "cocktail-party effect," whereby a listener with normal hearing can attend to different conversations in turn or concentrate on one speaker despite the surrounding babble. Whether the muscles within the ear play a part in filtering out unwanted sounds during such selective listening has not been established.

#### HEARING TESTS: AUDIOMETRY

Before the development of electroacoustic equipment for generating and measuring sound, the tests of hearing at the disposal of the otologist gave approximate answers at best. A patient's ability to hear could be specified in terms of whether he could distinguish the ticking of a watch or the clicking of coins or at what distance he could understand a whispered voice. Alternatively, the examiner might note the length of time a patient could hear the gradually diminishing note of the tuning fork, comparing the performance with his own. Other specialized tuning fork tests have been described above.

The electronic audiometer, introduced in the 1930s, makes it possible to measure the patient's threshold of hearing for a series of pure tones ranging from a lower frequency of 125 hertz to an upper frequency of 8,000 or 10,000 hertz. This span includes the three octaves between 500 and 4,000 hertz that are most important for speech.

The audiometer consists of an oscillator or signal generator, an amplifier, a device called an attenuator, which controls and specifies the intensity of the tones produced, and an earphone. The intensity range is usually 100 decibels in steps of five decibels. The "zero dB" level represents "normal hearing" for young adults under favourable, noise-free laboratory conditions and was established in 1964 as an international standard.

For pure-tone audiometry, the patient wears the earphone and is asked simply to indicate when he hears a tone. The examiner proceeds to determine the lowest intensity for each frequency at which the patient reports that he is just able to hear the tone 50 percent of the time. If, for example, he hears 4,000 hertz only at 40 decibels, he is said to have a 40-decibel hearing level for that frequency—*i.e.*, a threshold 40 decibels above the normal threshold. A graph showing the hearing level for each frequency is called an audiogram. The shape of the audiogram for a hard-of-hearing patient can give the otologist or audiologist important information for diagnosing the nature and cause of the defective hearing. (The otologist is concerned with diseases of the ear; the audiologist focusses his attention on the measurement of hearing impairment.)

With the Békésy automatic recording audiometer, the patient himself controls the level of the tone presented. He is required to press a button so long as he is able to hear the tone, which is automatically reduced in intensity as the button is pressed. When it is released the intensity increases until the patient again signals that he hears it by pressing the button. In this way the patient's threshold is "tracked." At the same time the frequency is slowly increased and a graphic recording is made. Thus a complete, continuous audiogram can be obtained in less than ten minutes.

A calibrated bone conduction vibrator is usually furnished with the audiometer so that hearing by bone con-

Compo-  
nents of an  
audiometer

duction can also be measured. In the presence of otosclerosis or other conductive defect of the middle ear, there may be a sizable difference between the air-conduction and bone-conduction audiograms, the so-called "air-bone gap." This difference is a measure of the loss in transmission across the middle ear and indicates the maximum improvement that may be obtained through successful corrective surgery. When the defect is confined to the organ of Corti, the bone-conduction audiogram shows a loss similar to that for air conduction. In such cases of sensorineural impairment, surgery is seldom if ever capable of improving the hearing, but a hearing aid may prove useful.

Although faint sounds may not be heard at all by the ear with a sensorineural impairment, more intense sounds may be as loud as to a normal ear. This rapid increase in loudness above the threshold level is called recruitment. When the opposite ear has normal hearing, recruitment can be measured by the alternate binaural loudness balance (ABLB) test. The subject is asked to set the controls so that the loudness of the tone heard in his defective ear matches that of the tone heard in his normal ear. By repetition of the comparison at several intensity levels, the presence or absence of recruitment can be demonstrated. When recruitment is excessive, the range of useful hearing between the threshold and the level at which loudness becomes uncomfortable or intolerable may be extremely narrow, so that the amplification provided by a hearing aid is of limited value to the patient.

Although hearing thresholds for pure tones give some indication of the patient's hearing for speech, direct measurement of this ability is of interest to the otologist. Two types of tests are most often used. In one, the speech reception threshold (SRT) is measured by presenting words of spondee pattern—words containing two syllables of equal emphasis, as in "baseball" or "cowboy"—at various intensity levels until the level is found at which the patient can just hear and repeat half of the words correctly. This level usually corresponds closely to the average of the patient's thresholds for frequencies of 500, 1,000, and 2,000 hertz. A more important measure of socially useful hearing is the discrimination score. For this test a list of selected monosyllabic words is presented at a comfortable intensity level, and the subject is scored in terms of the percentage of the words heard correctly. This test is helpful in evaluating certain forms of hearing impairment in which the sounds may be audible but words remain unintelligible. Such tests are usually carried out in a quiet, sound-treated room that excludes extraneous noise. They may give a mistaken impression of the ability of the patient with sensorineural impairment to understand speech in ordinary noisy surroundings. Because such persons often have increased difficulty in understanding speech in the presence of noise, speech tests are best carried out against a standardized noise background as well as in the quiet. A person with a conductive defect may be less disturbed by noise than may the normal subject.

For very young persons or others who are unable to cooperate in the usual audiometric tests, thresholds for pure tones may be established by electrophysiological means. A brief tone causes a small variation in the electrical potentials that can be recorded from the scalp and constitute the electroencephalogram, EEG (a recording of the brain waves). By repetition of the stimulus up to 100 times and by an averaging of the responses in a small computer, the responses can be selectively enhanced while the more or less random background of electrical activity is cancelled out. In this way auditory thresholds can be established that closely approximate those obtained in conventional audiometry. If the responses indicate impaired hearing, they give little or no indication of the site of the defect.

Another form of electrophysiological hearing test is the electrocochleogram. Electrical potentials representing impulses in the cochlear nerve are recorded from the cochlea by means of a fine, insulated needle electrode inserted through the eardrum membrane to make contact

with the promontory of the basal turn. This test gives a direct measure of cochlear function.

More elaborate tests, often involving speech or sound localization, are available for testing hearing impaired by defects of the central nervous system. The interpretation of the results is often difficult, and the diagnostic information furnished by the tests is seldom clear-cut.

A simple and objective means of testing hearing at the level of the cochlea and brainstem is supplied by impedance audiometry. Two small tubes are sealed into the external canal. Through one tube sound from a small loudspeaker is injected into the canal. The portion that is reflected from the drum membrane is picked up by the other tube and led to a microphone, amplifier, and recorder. When a sudden, moderately intense sound is applied to the opposite ear, the stapedius muscle contracts, the impedance is increased, and the recorder shows a slight excursion as more sound is reflected. This test can give valuable information not only about the condition of the cochlea and the auditory pathways of the medulla but also about the facial nerve that supplies fibres to the stapedius muscle. On the other hand, it does not give an actual measurement of the acoustic impedance of the ear, representing the state of the ossicular chain and the mobility of the eardrum. This information can be obtained by means of the acoustic bridge—a device that enables the observer to listen to a sound as reflected from the subject's eardrum and at the same time to a similar sound of equal intensity as reflected in an artificial cavity, the volume of which is adjusted to equal that of the external canal of the ear being tested. When the two sounds are matched by varying the acoustic impedance of the cavity, the impedance of the ear is equal to that of the cavity, which can be read directly from the scale of the instrument. Conductive defects of the middle ear, including discontinuity (disarticulation) of the ossicular chain and immobility of the malleus or stapes, can be recognized by the characteristic changes they cause in the impedance of the ear.

Conductive impairment of hearing can occur from so simple a cause as an excessive accumulation of wax in the external canal. It is a common result of infections of the middle ear (otitis media), especially when perforation of the drum membrane leads to an ingrowth of epithelial cells with the formation of a mass called a cholesteatoma. In such cases the ossicles may be eroded or destroyed. As previously mentioned, otosclerosis can seriously limit the transmission of sound to the cochlea by causing the stapes footplate to become sealed in the oval window.

Sensorineural impairment involving the organ of Corti and the cochlear nerve fibres of the basal turn occurs in aging and is the most common form of hearing loss in elderly persons (presbycusis). In some older patients the central auditory pathways may also be affected by a reduced blood supply to the brain. Injury to the cochlea and its nerve supply occurs also as a result of exposure to intense noise, whether in industry, military activity, sport, or entertainment. Noise levels above 90 decibels are generally recognized as dangerous to the hearing. The higher the level and the more prolonged the exposure, the greater is the risk of permanent changes in the inner ear (Figure 8).

Several well-known antibiotics, including streptomycin, kanamycin, neomycin, and gentamicin, can cause irreversible damage to the organ of Corti. Other drugs that may cause sensorineural impairment of hearing include quinine, aspirin and other salicylates in large doses, and certain diuretics and antitumour agents.

In Ménière's syndrome, variable sensorineural loss and tinnitus (noise or ringing in the ear) are associated with severe attacks of vertigo. Tumours of the vestibulocochlear nerve can affect hearing by compressing the nerve fibres and impairing their ability to transmit impulses.

Profound sensorineural deafness can occur as a result of viral and other infections, including mumps, measles, and meningitis. Rubella (German measles) in the mother during pregnancy can cause the child to be born with a severely damaged organ of Corti and profound hearing

loss. Cochlear abnormalities may be present also as a result of genetic defects. In all such cases of deafness in young children it is essential that the condition be recognized as early as possible so that special educational measures may be instituted to minimize the handicap. The newer electrophysiological hearing tests described above—*i.e.*, electroencephalographic audiometry and the electrocochleogram—offer the best possibilities for detecting such losses in infants.

#### VESTIBULAR FUNCTION

The vestibular system represents the equilibrium sense and is concerned primarily with controlling the position of the head and the posture of the body. The adequate stimulus for its end organs is acceleration: angular acceleration for the semicircular canals; linear acceleration for the utricle and saccule. Functionally these organs are closely related to the cerebellum and to the reflex centres that govern the movements of the eyes, the neck, and the limbs. The information they deliver is proprioceptive in character, dealing with events within the body itself, rather than exteroceptive, dealing with events outside the body, as in the case of the responses of the cochlea to sound. Although the vestibular organs and the cochlea are derived embryologically from the same formation, the otic vesicle, their association seems to be a matter more of convenience than of necessity. Both from the developmental and from the structural point of view, the kinship of the vestibular organs with the lateral line system of the fishes is easily recognized. This system is made up of organs located in the skin at the side of the body and contains cristae with innervated hair cells and a cupula, like those of the semicircular canals. They are sensitive to waterborne vibrations and to pressure changes.

The anatomists of the 17th and 18th centuries were impressed by the orientation of the semicircular canals in the head, in three planes more or less perpendicular to one another. Since it was generally assumed that the entire labyrinth is devoted to hearing, the suggestion was put forward that the canals must perceive the direction of sound.

The first investigator to present evidence that the vestibular labyrinth is the organ of equilibrium was a French experimental neurologist, Marie-Jean-Pierre Flourens, who, in 1824, reported a series of experiments in which he had produced abnormal head movements in the pigeon by cutting each of the semicircular canals in turn. The plane of the movements was always the same as that of the injured canal. Hearing was not affected by destroying the nerve fibres to the vestibular organs, but it was abolished by cutting the cochlear nerve.

It was almost half a century later that the significance of these experiments was appreciated and the semicircular canals were recognized as specific sense organs concerned with the position of the head. The German physi-

ologist Friedrich Goltz in 1870 suggested in his "hydrostatic concept" that the canals are stimulated by the weight of the fluid they contain, the pressure it exerts varying with the head position. Three years later the Austrian scientists Ernst Mach and Josef Breuer, and the Scottish chemist Crum Brown, working independently, proposed their "hydrodynamic concept." They held that head movements cause a flow of endolymph in the canals, which are stimulated by the fluid movement or pressure changes. A German physiologist, J.R. Ewald, showed that the compression of the lateral canal in the pigeon by a small pneumatic hammer caused endolymph movement toward the crista and turning of the head and eyes toward the opposite side. Decompression reversed both the direction of endolymph movement and the turning of the head and eyes.

Later investigators have proved that the hydrodynamic concept is correct and that the cupula is deflected by endolymph movement in response to rotation. They were able to keep track of the deflection in live fish by means of a droplet of oil injected into the canal. At the start of rotation in the plane of the canal, the cupula was deflected in the opposite direction and then returned slowly to its position of rest. At the end of rotation it was deflected again, this time in the same direction as the rotation, and then returned once more to its upright resting position. These deflections were due to the inertia of the endolymph, which tended to lag behind at the start of rotation and to continue in motion after rotation had stopped. The slow return was a function of the elasticity of the cupula itself.

Other researchers found that they could keep the labyrinth of a cartilaginous fish, the thornback ray (*Raja clavata*), active for some time after it was removed from the animal and could record from the vestibular fibres of the vestibulocochlear nerve impulses arising in one of the ampullar cristae. At rest there was a slow continuous discharge, which was increased by rotation in one direction and decreased by rotation in the other. In other words, the level of excitation rose or fell depending upon the direction of rotation. Later studies with the electron microscope showed a remarkable polarization of the hair cells of the ampullar cristae. Each hair cell of the horizontal canals has its kinocilium facing toward the utricle, whereas each hair cell of the vertical canals has its kinocilium facing away from the utricle. In the horizontal canals deflection of the cupula toward the utricle—*i.e.*, bending of the stereocilia toward the kinocilium—depolarizes the hair cells and increases the rate of discharge. Deflection away from the utricle causes hyperpolarization and decreased discharge. In the vertical canals these effects are reversed.

The relation between the two labyrinths is reciprocal. When the head is turned to the left, the discharge from the left horizontal canal is increased while that from the right horizontal canal is decreased, and vice versa. Normal posture is the result of their acting both in cooperation and in opposition. When one labyrinth is injured, the unrestrained activity of the other causes a continuous false sense of turning (vertigo) and rhythmical, jerky movements of the eyes (nystagmus), both toward the normal side. When both labyrinths are injured or destroyed, as by the action of the antibiotic streptomycin, there may be a serious disturbance of posture and gait (ataxia) as well as severe vertigo and general disorientation. In younger persons the disturbance tends to subside as reliance is placed on vision and on proprioceptive impulses from the muscles and joints to compensate for the loss of information from the labyrinth. In elderly persons, the loss of labyrinthine function may be disabling.

The two otolith organs or gravity receptors, the maculae of the utricle and saccule, are more or less perpendicular to each other. The left and right utricular maculae lie in the same approximately horizontal plane; the saccular maculae in parallel, vertical planes. Both types of receptors are stimulated by shearing forces between the otolithic membrane and the cilia of the hair cells beneath it. The otolithic membrane is covered with a layer of crystals of calcite (otoconia), which add to its weight

Endolymph and the "hydrodynamic concept"

Polarization of hair cells

Equilibrium sense

and increase the shearing forces set up in response to a slight displacement when the head is tilted. These receptors, particularly the utricle, have an important role in the righting reflexes and in reflex maintenance of tonic contraction of the muscles that keep the body in the upright position. The role of the saccule is less completely understood, and some investigators have suggested that it is responsive to vibration as well as to rectilinear acceleration of the head in the sagittal (fore-and-aft) plane. Of the two receptors, the utricle appears to be the dominant partner.

Tests of vestibular function depend mainly upon stimulation of the semicircular canals. Rotation, which can cause vertigo and nystagmus, as well as temporary disorientation and a tendency to fall, stimulates both labyrinths simultaneously. Since the otoneurologist is usually more interested in examining the right and left labyrinths separately, he usually employs warmth as a stimulant. Syringing the ear canal with warm water at 44° C (111° F) or cool water at 30° C (86° F) elicits nystagmus by setting up convection currents in the horizontal canal. The duration of the nystagmus may be timed with a stopwatch, or the movements of the eyes can be accurately recorded by picking up the direct current potentials of the eyeballs by means of electrodes pasted to the skin of the temples (a process called electronystagmography, or ENG). An abnormal labyrinth usually gives a reduced response or none.

Vertigo, the false sense of rotation, is experienced in Menière's syndrome and in many other abnormal conditions involving the labyrinth, the vestibular nerve, and the vestibular centres of the medulla oblongata. Though by no means uncommon, it can present a difficult diagnostic problem for the physician. In normal subjects, sudden movements of the head during rotation can elicit the so-called Coriolis reaction, which involves severe vertigo, disorientation, nystagmus, nausea, and vomiting. This is one of the potential hazards of daily life in a rotating space station.

**BIBLIOGRAPHY.** Reliable and readable introductory treatises are S.S. STEVENS and FRED WARSHOFKY, *Sound and Hearing* (1965); and W.A. VAN BERGEL, J.R. PIERCE, and E.E. DAVID, *Waves and the Ear* (1960). HALLOWELL, DAVIS and S.R. SILVERMAN, *Hearing and Deafness*, 3rd ed. (1970), although somewhat more technical, is also written for the non-specialist. A useful account of the anatomy of the ear may be found in WILLIAM BLOOM and D.W. FAWCETT, *A Textbook of Histology*, 9th ed. (1968). B.J. ANSON and J.A. DONALDSON, *The Surgical Anatomy of the Temporal Bone and Ear* (1967), presents the gross and microscopic structure of the ear from the point of view of the surgeon. Details of inner ear anatomy can be studied in SALVATORE IURATO, *Submicroscopic Structure of the Inner Ear* (1967); HANS ENGSTROM, H.W. ADES, and ANTON ANDERSSON, *Structural Pattern of the Organ of Corti* (1966); and HEINRICH SPOENDLIN, *The Organization of the Cochlear Receptor* (1966). For the comparative anatomy of the ear from fish to man, the illustrations in GUSTAF RETZIUS' two folio volumes *Das Gehörorgan der Wirbelthiere* (1881-84), are still unsurpassed, but available only in a few medical libraries. The physiology of hearing and of vestibular function is discussed in four chapters by JOSEPH E. HAWKINS in C.H. BEST and N.B. TAYLOR (eds.), *The Physiological Basis of Medical Practice*, 8th ed. (1966). Modern classics in the field of hearing are: S.S. STEVENS and HALLOWELL DAVIS, *Hearing* (1938, reprinted 1960), equally divided between psychological and physiological aspects of the subject; E.G. WEVER, *Theory of Hearing* (1949, reprinted 1970), including a good historical treatment of auditory theories developed through the centuries; and E.G. WEVER and MERLE LAWRENCE, *Physiological Acoustics* (1954), concerned mainly with middle-ear and inner-ear mechanics. G. VON BÉKÉSY, *Experiments in Hearing* (1960), is the best source of information about the experimental work that won von Békésy the Nobel Prize, but it is not recommended for the novice. Biochemical aspects of cochlear physiology and pathology are treated in SIGURD RAUCH, *Biochemie des Hörorgans* (1964); and in *Biochemical Mechanisms in Hearing and Deafness*, ed. by MICHAEL M. PAPARELLA (1970). I.C. WHITFIELD, *The Auditory Pathway* (1967), gives a useful summary of our imperfect knowledge of auditory processes in the central nervous system.

The measurement of human hearing is described in numerous textbooks of audiology. *Audiometry: Principles and Practices*, ed. by ARAM GLORIG (1965), gives a good overview of the

field. A thorough, sober, and factual account of studies concerning *The Effects of Noise on Man* has been written by K.D. KRYTER (1970). It is recommended as an antidote to some of the more hysterical popular writings on this controversial topic. There are few comprehensive publications devoted to vestibular function, but the symposium volume, ed. by R.J. WOLFSON, *The Vestibular System and Its Diseases* (1966), is a good source of information, as is the NASA series ed. by ASHTON GRAYBIEL, *The Role of the Vestibular Organs in Space Exploration*, 4 vol. (1965-68).

(J.E.H.)

## Ear Diseases and Hearing Disorders

The ear has two important but quite different functions: the maintenance of equilibrium and hearing. For biped locomotion, the sense of equilibrium is especially necessary; and it is even more pressing in the dark, in which the eyes cannot help to maintain balance, or on uneven terrain, where sensations from the feet do not assist in maintaining the sense of equilibrium. Hearing, which developed later than equilibrium in the process of evolution, has become, with sight, one of the senses most needed by animals for flight and survival. For civilized man, hearing is also the chief means of receiving communication by language and is so taken for granted that its importance is rarely appreciated until it is impaired or lost. Indeed, Helen Keller, who was totally blind and deaf from early childhood, wrote:

the problems of deafness are deeper and more complex, if not more important than those of blindness. Deafness is a much worse misfortune, for it means the loss of the most vital stimulus—the sound of the voice—that brings language, sets thoughts astir and keeps us in the intellectual company of man.

After a short survey of the development, structure, and functioning of the normal ear, this article deals with the more important diseases and disorders of the outer, the middle, and the inner ear. It concludes with brief sections on the causes of deafness and impaired hearing, on rehabilitation of hearing impairment and deafness, and on the social and economic implications of deafness.

### The normal ear

#### EVOLUTION AND DEVELOPMENT OF THE EAR

The complicated structure of the mechanism for hearing is best understood by considering the way in which the human ear evolved from lower forms and how it develops in the human embryo, for one of the time-honoured apothegms in biology, "ontogeny recapitulates phylogeny," applies particularly to the ear, the development of which in the human embryo (ontogeny) retraces the stages of evolution from lower forms (phylogeny).

The earliest beginning of the human ear may be seen in the three-week-old embryo as a thickening of the epithelium (primitive skin) on each side of the head. The centre of this thickened disk soon grows inward to form a pit; then the mouth of the pit closes off, leaving a rounded fluid-filled structure called an otocyst; this is destined to become the inner ear, which will contain the nerve endings of the hearing (auditory) nerve and the balancing (vestibular) nerve.

Soon after the formation of the otocyst, the outer and middle ears begin to develop. These portions of the hearing mechanism are necessary for the transmitting of airborne sound from the outer world to the fluid-filled inner ear, in which the sound vibrations can be transformed to nerve impulses.

About 260,000,000 years ago, certain fishes, man's ancestors, left the oceans and swamps to live on dry land. To extract oxygen from the air, they developed lungs. The discarded gills became transformed into their outer and middle ear by one of the most remarkable salvage adaptations of the entire process of evolution.

These earliest lung-breathing fish that crawled out onto land were comparatively deaf, for only 0.1 percent of sound energy could reach the fluid of their inner ears, 99.9 percent being reflected away by the air-water sound barrier. This barrier is familiar to an underwater swimmer, who with his head under water clearly hears faint sounds originating underwater, like two stones clicked

Formation of the outer and the middle ear

Caloric stimulation

together, but fails to hear a loud call from above water. Similarly, as a good fisherman can testify, fish are not disturbed by any but the loudest sounds produced above water, but instantly respond to sounds produced in the water, such as splashing.

To overcome the air-water sound barrier so that air-borne sound could reach the fluid-filled inner ear, the no-longer-needed first gill cleft became the external ear canal and the middle-ear cavity, with a thin membrane in between, which is the eardrum membrane. The gill that connects with the fish's throat persists as the eustachian tube from the upper part of the throat to the middle ear. On either side of each gill, cartilage grew that lent stiffness to them. Similarly, the cartilage of the first gill cleft in the human embryo grows outward to form the outer ear, which protrudes from each side of the head. The cartilage of the second gill cleft in the human embryo becomes transformed into the ossicular chain, the chain of tiny bones that carries sound vibrations from the eardrum membrane to the fluid of the inner ear. The first of these bones, the hammer (malleus), is attached to the eardrum membrane by its handle. Attached to the head of the hammer by a tiny joint is the second tiny bone, the anvil (incus). Joined to the incus by another, even tinier joint, the smallest in the body, is the smallest bone in the body, the stirrup (stapes) bone, with its footplate inserted into an oval-shaped opening called the oval window, leading to the inner ear.

The air-water sound barrier, which caused our earliest land-based ancestor to be virtually deaf, is overcome in the human embryo by the mechanical device of the eardrum membrane and ossicular chain, in the following manner:

The large area of the eardrum membrane vibrates in response to sound with movements that are fairly large, but with small force. The ossicular chain transmits these movements to the much smaller area of the footplate of the stirrup, decreasing the size of the movements but increasing their force manyfold. The ossicular chain itself adds appreciably to the force of the vibrations of the stapes by its lever effect, the handle of the hammer being longer than the anvil. As a result, sound vibrations at the footplate of the stirrup in the oval window of the human ear are made 22 times smaller—and stronger—than at the eardrum membrane.

The human ear, which develops in the embryo from two distinct beginnings, the early otocyst for perception of sound in the inner ear and the primitive gills to form the sound-transmitting outer and middle ear, is the only part of the body that reaches adult size and form long before birth. By the fifth month of fetal life, just a little beyond halfway between fertilization of the egg and birth, the otocyst, by a series of outpouchings and infolding~has fully developed into the complicated fluid-filled labyrinth of the inner ear. First to appear are three semicircular canals, one for each plane in space, and the vestibule with an elongation ending in a pouch, called the endolymphatic sac. As early as the seventh to eighth week after fertilization, the nerve endings for the vestibular nerve of equilibrium first appear, for in fishes and earlier aquatic forms equilibrium is more important than hearing. The function of hearing developed later in evolution, so that the hearing-nerve endings do not develop until the 12th week of embryonic life. By the fifth month of fetal life the entire labyrinth of the inner ear, including the semicircular canals and vestibule for balance and the snail-shaped cochlea for hearing, are fully formed and of adult size. The more recently acquired outer and middle ear for sound transmission are not fully formed and ready to function until the seventh month, two months before the infant is born.

Not only is the sense of hearing acquired later in evolution and later in the embryo than the sense of equilibrium, but the sense of hearing is more fragile and more easily injured by viruses and other infections or by blows on the head or by excessive stimulation by extremely loud noise. Thus, infants born with defective hearing generally have a well-functioning sense of equilibrium, and children and adults whose hearing nerves

have been damaged by viruses or other infections generally retain normal nerves for equilibrium.

#### STRUCTURE AND FUNCTION OF THE EAR

As noted above, the ear has three main parts, the outer ear, the middle ear, and the inner ear. The outer ear, formed of flexible, delicately curved cartilage covered by skin, includes the outer ear canal, formed partly by cartilage and partly by bone. The outer ear canal extends about three centimetres (1.2 inches) from the outer surface of the adult head to the thin, transparent eardrum membrane. The skin of the outer ear canal is supplied with hairs and with glands that secrete a waxy substance called earwax, or cerumen. Both the hairs and the earwax function to discourage insects from making their home and laying their eggs in the ear canal.

The eardrum membrane, averaging one centimetre (0.4 inch) in diameter, is semitransparent like a piece of waxed paper and is stretched tightly like the head of a drum, so that it vibrates readily in response to sound waves. The handle of the hammer is firmly embedded in it, so that vibrations of the eardrum membrane are communicated to the hammer and then to the anvil and stirrup, through the tiny joints that connect them. It is the vibratory movements of the stirrup footplate in the oval window that create vibratory motion of the fluid filling the inner ear, needed to stimulate the hearing nerve.

The middle ear is a small, air-filled cavity in bone, about the size of an aspirin tablet, separated from the outer ear canal by the eardrum membrane. The eustachian tube connects the middle ear with the upper part of the throat, above the palate. It opens with each yawn or swallow to equalize air pressure on both sides of the eardrum membrane. This function is most noticeable with rapid change in altitude as in a high-speed elevator, driving over mountains, or in an airplane. Failure of the eustachian tube to open results in a full or pressure sensation in the ear and a noticeable, although at first slight, impairment in hearing. This is more likely to happen during a head cold or an allergic reaction when the membranes of the eustachian tube are swollen. If the eustachian tube remains closed, fluid accumulates in the middle-ear cavity, replacing the air and causing an increased impairment of hearing.

Across the middle-ear cavity extends the chain of three tiny bones, mentioned earlier, the auditory ossicles. *Os* is Latin for "bone," and "ossicle" means "little bone." From the middle-ear cavity into the mastoid bone that lies behind the outer ear there extends a series of air cells, spongelike but with rigid, bony walls. These, like the air sacs in the bones of birds, are to lighten the weight of the skull. Infection of the middle-ear cavity can extend into these air cells and produce a mastoid abscess.

The inner ear, or labyrinth, consists of a complicated series of passageways embedded in rock-hard bone, the hardest bone in the body and therefore called the petrous bone, "petrous" being Latin for "rocklike." The passageways of the labyrinth are filled with fluid containing the nerve endings of the hearing nerve (auditory nerve) and the nerve of equilibrium (vestibular nerve). The vestibular nerve supplies the three semicircular canals. At one end of each canal a spherical enlargement is filled by a gelatinous caplike structure, the cupula, attached to hairlike endings of the vestibular nerve. When the head turns in the plane of a semicircular canal, inertia of the fluid within it causes the cupula to be pushed to one side, pulling on the vestibular-nerve endings and stimulating them. This stimulus travels back to the brain along the vestibular nerve, producing a sense of rotation or even vertigo. If a person is rotated slowly and steadily, as on a piano stool, the fluid within the semicircular canal begins to rotate. If the piano stool is suddenly stopped, the fluid continues to rotate, pushing the cupula to one side, stimulating the nerve of equilibrium, and causing vertigo. Strong stimulation of the vestibular nerve of equilibrium causes nausea, sometimes vomiting, as well as the sense of rotation with inability to stand and walk straight.

The vestibular nerve of equilibrium also supplies two

The outer ear

The inner ear

Vestibular and hearing nerve endings

structures in a space called the vestibule, each consisting of a gelatinous membrane in which are embedded tiny stones about the size of grains of sand that rest upon hair-like endings of the vestibular nerve. One of these membranes lies in the horizontal plane, one in the vertical plane. Pressure exerted by gravity on these tiny stones, called otoliths, pulls on the hairlike endings of the vestibular nerve. In this way, one's position in space is known even in the dark or with the eyes closed.

The labyrinth of the inner ear, in addition to the more primitive balancing mechanism of the semicircular canals and vestibule, includes the more recently acquired organ of hearing, located in the snail-shaped cochlea (Latin: "snail shell"). Within the cochlea is a marvellously contrived structure first described in 1851 by an Italian anatomist named Alfonso Corti; thus, it is known as the organ of Corti. It consists of a membrane, broad at one end of the cochlea and narrow and tightly stretched at the other end, known as the basilar membrane, on which rests a large number of hair cells containing the ends of the hearing nerve. On top of the hair cells and attached to their projecting hairs rests the tectorial membrane, similar in its gelatinous composition to the cupulas in the semicircular canals. Like the basilar membrane, the tectorial membrane is large at one end of the cochlea and tiny at the other end, with all gradations in between.

Thus, the basilar and tectorial membranes resemble the strings on a piano or harp. It has been shown that for each tone in the musical scale, from the lowest audible rumbling tone of ten vibrations per second to the shrill tone of 24,000 vibrations per second, the highest tone audible to a young human ear, a certain section of the basilar and tectorial membranes in the cochlea is set into maximum vibration. The hairlike endings of the auditory nerve at that point are pulled upon and stimulated, and the stimulus travels back to the brain, which "hears" that particular tone. There is still debate as to whether the basilar membrane or the tectorial membrane is the chief one that vibrates in response to a particular tone. Since both membranes are graduated in size, large at one end of the organ of Corti and tiny at the other end, it seems likely that a section of both membranes vibrates in response to a particular tone.

The cochlea of the inner ear with its organ of Corti not only has a wide range of response but also distinguishes minute pitch differences, as small as a quarter tone for the trained ear, and, in addition to differences in pitch, the ear can distinguish differences in loudness from the faintest audible sound to a sound vibration 1,000,000,000,000 times stronger.

The person with normal hearing has another ability, that of suppressing or ignoring a large amount of background noise and concentrating on one speaker. This requires binaural hearing with two ears of approximately equal sensitivity. Binaural hearing is also needed to determine the direction from which sound comes. One's own voice is heard, and one automatically monitors its quality and intensity, so that unconsciously the voice is raised in the presence of noise and lowered in quiet surroundings. The harsh and toneless quality of the completely or profoundly deaf is due to loss of this feedback system.

Loss of hearing on one side causes difficulty in understanding speech in the presence of noise and loss of ability to tell the direction from which sound comes. In quiet there is little handicap in one-eared hearing unless the speaker happens to be on the side of the deaf ear.

Loss of the balancing vestibular nerve on one side causes temporary imbalance that is soon compensated for in children, more slowly in adults; it may never be completely compensated for in older persons. Loss of both balancing nerves causes imbalance noticed mostly in the dark and walking on grass or a soft carpet, where the eyes and the sensations from the soles of the feet cannot assist in maintaining equilibrium. A person with such a disability walks unsteadily, with the feet and legs apart and the hands and arms partly extended ready to catch hold of supports. Children compensate quickly and well for loss of both vestibular nerves, except in the dark and

on uneven terrain, while adults compensate much more slowly and imperfectly.

## Diseases and disorders of the ear

### THE OUTER EAR

Each of the three main parts of the ear is afflicted by a particular set of diseases, according to the structure, tissues, and function of that part. Diseases of the outer ear are those that afflict skin, cartilage, and the glands and hair follicles in the outer ear canal. The sound-transmitting function of the outer ear is impaired when the ear canal becomes filled with tumour, infected material, or earwax, so that sound cannot reach the eardrum membrane. The most common diseases of the outer ear are briefly described in the following paragraphs.

**Frostbite.** The exposed position of the outer ear makes it the part of the body most frequently involved by freezing or frostbite. Humidity, duration of exposure, and, most of all, wind, in addition to degrees of temperature below freezing, predispose to occurrence of frostbite. The frozen area begins along the upper and outer edge of the ear, which becomes yellow-white and waxy in appearance, cold and hard to the touch, and numb with loss of skin sensation.

In treatment of frostbite the victim is placed as soon as possible in a warm room, but the frozen ear is kept cool until the returning blood circulation gradually thaws the frozen part from within. Massage of the frozen ear is avoided, for it is likely to injure the skin. Heat applied to the frozen area before circulation is established can result in clotting of the blood in the blood vessels. This in turn can result in death of that part of the ear, which turns black and eventually falls off, a process called dry gangrene.

**Hematoma.** Injury to the outer ear can cause bleeding between the cartilage and the skin, producing a smooth, rounded, nontender purplish swelling called hematoma. The accumulation of clotted blood is removed by a surgeon because, if it is left, it will become transformed into scar tissue and cause a permanent, irregular thickening of the outer ear commonly called cauliflower ear and seen in boxers and wrestlers whose ears receive much abuse.

**Perichondritis.** Infection of the cartilage of the outer ear, called perichondritis, is unusual but may occur from injury or from swimming in polluted water. It is due to a particular micro-organism, *Pseudomonas aeruginosa*. There is a greenish or brownish, musty or foul-smelling discharge from the outer ear canal, while the affected outer ear becomes tender, dusky red, and two to three times its normal thickness. Prompt medical treatment is necessary to prevent permanent deformity of the outer ear.

**External otitis.** Infection of the outer ear canal by molds or various micro-organisms occurs especially in warm, humid climates and among swimmers. The ear canal itches and becomes tender; a small amount of thin, often foul-smelling material drains from it. If the canal becomes clogged by the swelling and drainage, hearing will be impaired. Careful and thorough cleaning of the outer ear canal by a physician, application of antiseptic or antibiotic eardrops, and avoidance of swimming are indicated to clear up the infection.

**Boil in the ear (furuncle).** Infection of a hair follicle anywhere on the body is known as a boil, or furuncle. This can occur in a hair follicle in the outer ear canal, especially when there is infection of the skin of the canal. It always occurs because of a particular type of germ known as staphylococcus. Because the skin of the ear canal is closely attached to the underlying cartilage, a boil in the ear canal is especially painful, with swelling, redness, and tenderness but generally without fever. Heat applied to the outer ear by a hot-water bottle or electric pad helps the infection to come to a head and begin to drain. Antiseptic eardrops and careful cleaning of the outer ear canal are needed to prevent other hair follicles from becoming infected with a series of painful boils in the ear.

Infections  
of the  
outer ear

Binaural  
hearing

**Erysipelas of the outer ear.** Erysipelas is an infection in the skin caused by a particular type of streptococcus that causes a slowly advancing red, slightly tender thickening of the skin. It begins at the ear and spreads to the face and neck. Centuries ago erysipelas epidemics caused severe and often fatal infections. In AD 1089 one of the most severe epidemics was known as St. Anthony's fire; those who prayed to St. Anthony were said to recover; others, who did not, died. Today erysipelas is a rather mild and comparatively rare infection that clears up rapidly when sulfanilamide is taken by mouth or penicillin by injection.

**Leprosy.** Leprosy, seen rarely outside of the tropics today, was another scourge of ancient times that sometimes affected the outer ear. It is caused by the leprosy bacillus, *Mycobacterium leprae*, which causes a painless, slowly progressing thickening and distortion of the affected tissues. The diagnosis is made by examining a bit of the infected tissue under a microscope and finding the leprosy bacilli, which in appearance are not unlike the bacilli that cause tuberculosis. Fortunately, the antibiotics effective against tuberculosis are effective today in arresting the ravages of leprosy.

**Eczema.** Eczema of the skin of the outer ear, like eczema elsewhere, is an itching, scaling redness, sometimes with weeping of the affected skin. It is often the result of an allergy to a food or substance such as hair spray that comes in contact with the skin. The best treatment is discovery and avoidance of the causative agent.

**Impacted earwax.** The waxy substance produced by glands in the skin of the outer ear canal normally is carried outward by slow migration of the outer layers of skin. When wax is produced too rapidly it can accumulate as a hard plug, firmly filling the outer ear canal and blocking the passage of sound to the eardrum membrane, causing a painless impairment of hearing. Large plugs of earwax need to be removed by a physician. Smaller amounts may be softened by a few drops of baby oil left in the ear overnight, then syringed out with warm water and a soft-rubber baby ear syringe.

**Cancer of the outer ear.** Cancer of the outer ear occurs chiefly in areas exposed for many years to the direct sun. A small and at first painless ulcer, with a dry scab covering it, that slowly enlarges and deepens may be a skin cancer. Removal of a small bit of tissue from the edge (biopsy) and examining it under a microscope comprise the method of diagnosis. Complete removal by surgery or properly applied irradiation is needed for a cure. Cancer that begins in the ear canal is more serious, for it may deepen into the bone before it is diagnosed. It is then more difficult to cure by removal. Cancers of the ear canal are rather rare, while cancers of the skin of the outer ear are more common, as well as more readily cured by removal.

**Osteoma of the bony ear canal.** Osteoma of the bony ear canal is a bony knob that grows close to the eardrum membrane, especially in those who swim a great deal in cold water. It is not dangerous and does not need to be removed unless the bony overgrowth becomes large enough to block the ear canal.

**Cyst of the ear.** A cyst is a sac filled with liquid or semisolid material. A cyst of the ear is most often caused by a gland that lubricates the skin behind the earlobe, less often at the entrance of the ear canal. If the duct of this gland becomes stopped, the lubricating fatty material accumulates as a soft rounded nodule in the skin. Infection of the cyst causes a tender abscess to form and drain. The cyst will re-form unless it is removed completely by surgery.

Another type of cyst occurs above the ear canal, just in front of the outer ear or, rarely, in the neck behind and below the ear. This is a remnant of the primitive gill of the early embryo, a reminder of our ancient fishy ancestors. It may appear as a tiny pitlike depression that discharges a little moisture from time to time, or a cystic swelling may develop when the opening of the pit is closed, requiring surgical removal.

**Keloid of the ear.** In dark-skinned people, overgrowth of scar tissue from any skin incision or injury causes a

thickened elevation of the scar called a keloid. Having the earlobes pierced for earrings sometimes results in a large, painless nodular keloid enlargement of the earlobe, harmless but unsightly. Keloids are removed surgically (see also SKIN DISEASES).

**Absence of the outer ear.** Congenital deformity or absence of the outer ear, usually on one side, sometimes on both, is often accompanied by absence of the outer ear canal. This failure of the primitive gill structures to become properly transformed into the normal outer and middle ear is, in rare instances, hereditary. More often it occurs for no known reason. In some cases it can be traced to the damaging effects on the embryo of rubella (German measles) in the mother during the first three months of her pregnancy. Since the inner ear and nerves of equilibrium and hearing come from the otocyst, separate from the gill structure, in most cases of deformed or absent outer ear the hearing nerve is normal. Surgical construction of a new ear canal and eardrum membrane can then often improve the hearing, which has been impaired by the failure of sound conduction to reach the hearing nerve in the inner ear.

**Lop ear.** Lop ear, excessive protrusion of the ear from the side of the head, is a more frequent and less serious deformity of the outer ear. Girls easily conceal the protruding ears by their hair. Boys may desire an operation to bring the ears back to a more normal and less conspicuous position.

#### THE MIDDLE EAR

The air-filled middle-ear cavity and the air cells in the mastoid bone that extend backward from it are located a third of the distance from the side of the head toward its centre. The brain cavity lies just above and behind the middle ear and mastoid air spaces, separated from them only by thin plates of bone. The nerve that supplies the muscles of expression in the face passes through the middle-ear cavity and mastoid bone; it, too, is separated from them by only a thin layer of bone. In some instances this bony covering is incomplete, so that the facial nerve lies directly against the mucous membrane that lines the middle ear and mastoid air cells. This mucous membrane, an extension of a similar mucus-producing membrane that lines the nose and upper part of the throat, extends all the way through the eustachian tube into the middle ear and mastoid. It is subject to the same allergic reactions and infections that afflict the nasal passages. Thus, an acute head cold or other infection of the nose and throat, such as measles or scarlet fever, may extend through the eustachian tube into the middle ear and mastoid air cells. The proximity of the brain cavity to the mastoid air cells is such that an infection, if severe and untreated, may lead to meningitis (inflammation of the covering of the brain) or brain abscess. The large vein that drains blood from the brain passes through the mastoid bone on its way to the jugular vein in the neck. Infection from the middle ear can extend to this vein, resulting in "blood poisoning" (infection of the bloodstream, also called septicemia). Paralysis of the facial nerve and infection extending from the middle ear to the labyrinth of the inner ear are other possible complications of middle-ear infection. All of these possibilities spring from the particular location of the small but important middle-ear cavity.

**Acute middle-ear infection.** Fortunately, acute middle-ear infections, called acute otitis media, are nearly always due to micro-organisms that respond quickly to antibiotics. As a result, acute infection of the mastoid air cells resulting in a dangerous mastoid abscess with the possibility of meningitis, brain abscess, septicemia, infection of the labyrinth, or facial nerve paralysis, complicating an acute infection of the middle-ear cavity, have become rare. Abscess of the mastoid and the other complications of acute middle-ear infection are seen chiefly in remote regions and countries lacking adequate medical attention.

While serious and life-threatening acute infections of the middle ear and mastoid air cells have become rare, chronic infections, mentioned below, continue to occur,

Enlarge-  
ment of  
earlobe

Location  
of middle  
ear

and another type of middle-ear disease, secretory otitis media, is frequent.

*Secretory otitis media.* In secretory otitis media the middle-ear cavity becomes filled with a clear, pale-yellowish, noninfected fluid. The disorder is the result of inadequate ventilation of the middle ear through the eustachian tube. The air in the middle ear, when it is no longer replenished through this tube, is gradually absorbed by the mucous membrane, fluid taking its place. Eventually, the middle-ear cavity is completely filled with fluid instead of air. The vibratory movements of the eardrum membrane and the ossicular chain are impeded by the fluid, with a painless impairment of hearing.

The usual causes for secretory otitis media are an acute head cold with swelling of the membranes of the eustachian tube; an allergic reaction of the membranes in the eustachian tube; and an enlarged adenoid (nodule of lymphoid tissue) blocking the entrance to the eustachian tube. The condition is cured by finding and removing the cause and then removing the fluid from the middle-ear cavity, if it does not disappear by itself within a week or two. Removal of the fluid requires puncturing the eardrum membrane and forcing air through the eustachian tube to blow out the fluid. In some cases a tiny plastic tube is inserted through the eardrum membrane to aid in re-establishing normal ventilation of the middle-ear cavity. After a time, when the middle ear and hearing have returned to normal, this plastic tube is removed. The small hole left in the eardrum membrane quickly heals.

*Aero-otitis media.* The sudden change of altitude by a rapid descent in a nonpressurized or poorly pressurized plane during a head cold or allergic reaction may not permit the normal equalization of air pressure that occurs by the periodic opening of the eustachian tube on swallowing or yawning. The eardrum membrane becomes sharply retracted when the air pressure becomes less within than without, while the opening of the tube into the upper part of the throat becomes pressed tightly together by the increased air pressure in the throat, so that the tube cannot be opened by swallowing. A severe sense of pressure in the ear is accompanied by pain and a decrease in hearing. Sometimes the eardrum membrane ruptures because of the difference in pressure on its two sides. More often, the pain continues until the middle ear fills with fluid, or surgical puncture of the eardrum membrane is done. This condition occurring from airplane flights is called aero-otitis media. Usually, however, pain and hearing loss produced during a flight is of a temporary nature and disappears of its own accord.

*Chronic middle-ear infection.* Chronic infection of the middle ear occurs when there is a permanent perforation of the eardrum membrane that allows dust, water, and germs from the outer air to gain access to the middle-ear cavity. This results in a chronic drainage from the middle ear through the outer ear canal. There are two distinct types of chronic middle-ear infection, one relatively harmless, the other caused by a dangerous bone-invading process that leads, when neglected, to serious complications.

The harmless type of chronic middle-ear disease is recognized by a stringy, odourless, mucoid discharge that comes from the surface of the mucous membrane that lines the middle ear. Medical treatment with applications of antiseptic solutions and powders is all that is needed to dry up the chronic drainage. The perforation in the eardrum membrane may then be closed, restoring the normal structure and function of the ear with recovery of hearing.

The dangerous type of chronic middle-ear drainage is recognized by its foul-smelling discharge, often scanty in amount, coming from a bone-invading process beneath the mucous membrane. Such cases are usually caused by a condition known as cholesteatoma of the middle ear. This is an ingrowth of skin from the outer ear canal that forms a cyst within the middle ear and mastoid. If untreated, the cyst enlarges slowly but progressively, gradually eroding the bone until the cyst reaches the brain cavity or the nerve that supplies the

muscles of the face or a semicircular canal of the inner ear. The infected material within the cyst then produces a complication: meningitis or brain abscess, paralysis of the facial nerve, or infection of the labyrinth of the inner ear with vertigo, often leading to total deafness.

Fortunately, cholesteatoma of the middle ear is now rarely so neglected as to permit development of a serious complication. By careful examination of the eardrum-membrane perforation and by X-ray studies, the bone-eroding cyst can be diagnosed; it can then be removed surgically before it has caused serious harm. This operation is known as a radical mastoid or a modified radical mastoid operation. If at the same procedure the perforation in the eardrum membrane is closed and the ossicular chain repaired, the operation is known as a tympanoplasty, or plastic reconstruction of the middle-ear cavity.

*Ossicular interruption.* The ossicular chain of three tiny bones needed to carry sound vibrations from the eardrum membrane to the fluid that fills the inner ear may be disrupted by infection or by a jarring blow on the head. Most often the separation occurs at its weakest point, where the anvil (incus) joins the stirrup (stapes). If the separation is partial there is a mild impairment of hearing; if it is complete there is a severe hearing loss. Testing of the hearing in such a case demonstrates that the nerve of hearing in the inner ear is functioning normally but that sound fails to be conducted from the eardrum membrane to the inner ear. The separated ossicles can be brought back together by repositioning, thus restoring the conduction of sound to the inner ear. This is one of the most successful of hearing-restoring operations.

*Fixation of the stirrup by otosclerosis.* The commonest cause for progressive hearing loss in early and middle adult life is a disease process of the hard shell of bone that surrounds the labyrinth of the inner ear. This disease of bone is known as otosclerosis, a name that is misleading, for in its early and actively expanding stage the nodule of diseased bone is softer than the ivory-hard bone that it replaces. The more appropriate name otospongiosis is sometimes used, but such is the tenacity of tradition that the older name, applied before the process was well understood, has persisted and is the term generally used.

The cause for the occurrence of the nodule of softened otosclerotic bone is unknown. There is a certain familial tendency, half the cases occurring in families in which one or several relatives have the same condition. It is one-tenth as common among Negroes as among whites, and is twice as common in women as in men. The nodule of softened otosclerotic bone first appears in late childhood or in early adult life. Fortunately, in most cases it remains quite small and harmless, producing no symptoms, and is discoverable only if the ear bones are removed after death and examined under a microscope. Such evidence indicates that approximately one in ten white adult men and one in five white adult women will be found to have such a nodule of otosclerotic bone by middle adult life.

In about 12 percent of cases of otosclerosis the nodule of softened bone becomes large enough to reach the oval window containing the footplate of the stirrup. Increasing pressure caused by the expanding nodule begins to impede its vibratory movements in response to sound striking the eardrum membrane. Gradually and insidiously, such an affected person begins to lose his sharpness of hearing. First he begins to lose the ability to hear faint sounds of low pitch; next he begins to have difficulty hearing the whispered voice; then he has difficulty in hearing conversation from a distance; and finally he can hear and understand the spoken voice only when it is quite loud or close to the ear. One of the characteristics of impaired hearing due to stirrup fixation by otosclerosis is retained ability to hear over the telephone by pressing the receiver against the head so that the sound is carried to the inner ear by bone conduction. Another characteristic of this type of impaired hearing is that hearing seems to be better while one is riding in an automobile,

Dangers of neglected cholesteatoma

Diagnosis  
of stirrup  
fixation

in a plane, or on a train. The reason is that the low-pitched roar of motors causes normally hearing persons to unconsciously raise their voices, while the individual with stirrup fixation fails to hear the low-pitched roar and thus hears better and enjoys the raised voices around him.

The diagnosis of stirrup fixation by otosclerosis is made on the basis of a history of a gradually increasing impairment of hearing with absence of any chronic infection of the middle ear or of perforation of the eardrum membrane and with hearing tests showing that the nerve of hearing in the inner ear is functioning but that sound fails to be conducted properly to it. The hearing tests demonstrate that the hearing by bone conduction is better than by air conduction.

The final and conclusive diagnosis of otosclerosis is made by surgical exploration and finding that the stirrup bone (stapes) is fixed and unable to be moved because of a nodule of bone that has grown against it. A special type of X-ray of the ear called polytomography is sometimes used to demonstrate that the footplate of the stirrup bone has been invaded by otosclerosis.

Fixation of the stirrup bone can be corrected surgically. This was accomplished formerly by constructing a new window into the inner ear to admit sound to the hearing nerve. This operation originated in Europe in 1924 and in 1937 was brought to the United States, where it was improved and named the fenestration operation. In 1952 it was found possible to mobilize (loosen) the fixed stirrup bone in some cases, thus restoring hearing without the need of constructing a new opening. In 1956 it was found that the fixed stirrup bone could be removed and replaced by a plastic or wire substitute in cases in which it could not be mobilized. Today this operation, known as stapedectomy, is the one most often used to correct fixation of the stapes (stirrup bone) by otosclerosis.

The otosclerotic bone disease in some cases expands as far as the cochlea of the inner ear, causing a gradual deterioration of the hearing nerve. This progressive nerve deafness may precede, accompany, or follow fixation of the stapes. In some cases it may occur without fixation of the stapes.

While the exact cause for the softening of a nodule of bone known as otosclerosis is not known, it may be associated in some cases with lack of fluoride in drinking water. There is evidence, not yet conclusive, that increasing the intake of fluoride may promote hardening of the softened nodule of otosclerotic bone, thus arresting or retarding its expansion. In this way it is possible that the gradual impairment of hearing-nerve function that often occurs with fixation of the stapes may be retarded or arrested.

**THE INNER EAR**

The labyrinth of the inner ear contains the nerve endings of the vestibular nerve—the nerve of equilibrium—and the auditory nerve, or nerve of hearing. The vestibular-nerve ends supply the semicircular canals and the otolithic membranes in the vestibule. The auditory nerve supplies the cochlea (see above *Structure and function of the ear*). Diseases of the labyrinth of the inner ear may affect both the vestibular nerve and the auditory nerve; or they may affect only the auditory nerve, with loss of hearing, or the vestibular nerve, bringing on vertigo. The commoner inner-ear diseases are touched upon in the following paragraphs.

**Congenital nerve deafness.** Congenital nerve deafness, a defect of the hearing nerve in the cochlea, may be present at birth or acquired during or soon after birth. Usually both inner ears are affected to a similar degree, and as a rule there is a severe impairment of hearing, although, in some cases of congenital nerve loss the impairment is moderate in degree. Many cases of congenital nerve deafness have been caused by the rubella (German measles) virus in the mother during the first three months of her pregnancy, causing arrest of development of the otocyst. This can happen during a rubella epidemic, even when the mother has no symptoms of the infection. In most cases the vestibular nerve is not affected or is af-

fected to a lesser degree, and in most (but not all) cases the outer- and middle-ear structures are not affected. A vaccine against the rubella virus that has recently been introduced promises to result in a marked reduction in the number of cases of congenital nerve deafness if it is given to prospective mothers who have not had rubella before becoming pregnant and thus have not had an opportunity to build up immunity against infection when they are carrying a child.

Congenital nerve deafness, acquired at or soon after birth, may result from insufficient oxygen (anoxia) during a difficult and prolonged delivery or from the condition known as kernicterus, in which the baby becomes jaundiced because of incompatibility between its blood and that of the mother. In a few cases congenital nerve deafness is an inherited failure of the cochlea to develop properly. There is no medical or surgical treatment that can improve or restore hearing in cases of congenital nerve deafness. When the hearing loss is severe, speech cannot be acquired without special training. Children so afflicted must attend special classes or schools for the severely deafened, where they can be taught lipreading and speech. Electrical hearing aids can be helpful, especially during classes, to utilize the remnants of hearing usually present in such cases.

**Viral nerve deafness.** Virus infections can cause severe degrees of hearing-nerve loss in one ear and sometimes in both, at any age. The mumps virus is one of the most common causes of severe hearing-nerve loss in one ear. The measles and influenza viruses are less common causes. There is no effective medical or surgical treatment to restore hearing impaired by a virus.

**Effect of ototoxic drugs.** Ototoxic (ear-poisoning) drugs can cause temporary and sometimes permanent impairment of hearing-nerve function. Salicylates such as aspirin in large enough doses may cause ringing in the ears and then a temporary decrease in hearing that recovers when the person stops taking the drug. Quinine can have a similar effect but with a permanent impairment of hearing-nerve function in some cases. Certain antibiotics, such as streptomycin, dihydrostreptomycin, neomycin, and kanamycin, may cause permanent damage to the hearing-nerve function. The susceptibility to damage to the hearing from ototoxic drugs varies greatly among individuals. In most cases, except when streptomycin is the drug taken, the more durable and less easily damaged vestibular-nerve function is not affected. Streptomycin affects the vestibular nerve more than the auditory nerve.

**Skull fracture and concussion.** Skull fracture and concussion from a severe blow on the head can impair the functioning of the hearing nerve and of the nerve of balance in varying degrees. The greatest hearing loss arises when a fracture of the skull passes through the labyrinth of the inner ear, totally destroying its function.

**Exposure to noise.** Noise exposure, when the noise is excessive in loudness and duration, causes deterioration of the auditory nerve. A sudden explosive sound can tear the hair cells from the vibrating membranes in the organ of Corti, with a sudden, severe, permanent loss of hearing in that ear. Prolonged exposure to loud noise causes a gradually progressive impairment of auditory-nerve function, characterized by involvement first of that portion that responds to frequencies around 4,000 cycles per second. As the excessive noise exposure continues, the hearing-nerve loss increases in severity and broadens to include 2,000 and 8,000 cycles per second.

Hearing impairment after exposure to noise is especially common after gunfire explosion, in boilermakers, in stamp-press operators, in riveters, and in workers around jet engines. The critical noise level that begins to damage the hearing nerve is around 100 decibels of loudness. Below 85 or 90 decibels few if any ears will be damaged. Above 100 decibels continued exposure will cause a significant slow impairment of hearing-nerve function in most persons, with varying degrees, depending on one's susceptibility. At levels of 130 decibels or above, such as are produced by jet engines or modern powerful amplifiers often used by rock and roll bands,

Anoxia  
and kern-  
icterus

no ears are safe, and the deterioration of hearing is certain and may be rapid.

Noise-exposure deafness is preventable by avoiding exposure or by the wearing of protective earplugs or earmuffs. Cotton worn in the ears is of little help.

Causes of  
labyrinth-  
itis

**Labyrinthitis.** Labyrinthitis, an inflammation of the labyrinth of the inner ear, occurs when micro-organisms enter as a result of meningitis, syphilis, acute otitis media and mastoiditis, or chronic otitis media and **cholesteatoma**. Loss of both equilibrium and hearing occurs in the affected ear. Prompt treatment sometimes arrests the damage with the possibility of partial recovery of the function of the inner ear.

**Acoustic neuroma.** An acoustic neuroma is a benign tumour that grows on the acoustic nerve near the point where it enters the labyrinth of the inner ear. The tumour causes gradual and progressive loss of auditory- and vestibular-nerve function on one side. Eventually the tumour grows out into the brain cavity, causing headache and paralysis. If it is not removed, blindness and death may result. Fortunately, acoustic neuroma can be diagnosed early and removed before it has serious consequences.

**Ménière's disease.** Ménière's disease, also called endolymphatic hydrops, is a fairly common involvement of the labyrinth of the inner ear that affects both the vestibular nerve, with resultant attacks of vertigo, and the auditory nerve, with impairment of hearing. It was first described in 1861 by a French physician, Prosper Ménière. It is now known that the symptoms are caused by an excess of endolymphatic fluid in the inner ear. The diagnosis is made from the recurring attacks of vertigo, often with nausea and vomiting, ringing or roaring in the ear, impairment of hearing with a distortion of sound in the affected ear that fluctuates in degree, and a sense of fullness or pressure in the ear. The cause of Ménière's disease is not always known, although in many cases it results from defective functioning of the endolymphatic duct and sac, the structures that normally resorb endolymphatic fluid from the inner ear as fast as it is produced. The treatment of Ménière's disease is directed toward controlling the excess of endolymphatic fluid. If medical treatment does not relieve the repeated attacks of vertigo, surgery may be necessary.

**Presbycusis.** Presbycusis, the gradual decline of hearing-nerve function of old age, is similar to other aging processes because it affects some people more rapidly and at an earlier age than others. Usually the slow diminishing of hearing does not begin until after age 60. The affected individual notices increasing difficulty in hearing sounds of high pitch and in understanding conversation. There is no medical or surgical treatment that can restore hearing in uncomplicated presbycusis. The physician must make certain that the patient does not have a correctible impairment, such as accumulated earwax, secretory otitis media, or stirrup fixation by otosclerosis, as part of his difficulty. An electrical hearing aid is of limited help to some, while others find that a hearing aid makes voices louder but less clear and therefore is of little help. Lipreading must then be used.

#### DEAFNESS AND IMPAIRED HEARING

**Causes.** Impaired hearing is, with rare exception, the result of disease or abnormality of the outer, middle, or inner ear, located in the temporal bone of the skull. One rare exception has already been mentioned, loss of hearing, usually on one side only, caused by a tumour, acoustic neuroma, on the acoustic nerve; an even rarer exception is impairment because of a brain lesion. Since nerve fibres from each ear go to both sides of the brain, a brain tumour or stroke causing paralysis of one side of the body rarely affects hearing.

Serious impairment of hearing (deafness) at birth is nearly always of the nerve type and cannot be improved by medical or surgical treatment. Nerve deafness arising from rubella infection of the mother during the first three months of her pregnancy, from insufficient oxygen during birth, and from kernicterus have already been mentioned.

In early and late childhood the most frequent cause for impaired hearing is poor functioning of the eustachian tubes with the accumulation of a clear, pale-yellowish fluid in the middle-ear cavity, known as serous or secretory otitis media. The vibratory movements of the tympanic (eardrum) membrane and ossicular chain in response to sound are impeded by the fluid, causing a moderate loss of hearing. Since this hearing loss is due to impairment of sound conduction to the inner ear, it is known as a conductive loss. In these children, evacuation of the fluid from the middle ear and its replacement with air restores normal sound conduction and normal hearing. The enlarged adenoid or allergic swelling of the membrane lining the eustachian tube needs to be corrected to prevent recurrences of secretory otitis media.

Causes in  
childhood

In early and middle adult life the usual cause for progressive impairment of hearing is otosclerosis, the disease process of bone surrounding the inner ear that has been described above. The conductive hearing loss caused by fixation of the stirrup bone (stapes) can be relieved by surgical mobilization of the stirrup or its replacement with a fine stainless-steel wire. In some cases the otosclerotic bone nodule grows inward to the inner ear, resulting in a gradual loss of hearing-nerve function. This may occur at the same time as the fixation of the stapes; it may precede stapes fixation; or it may occur some years after fixation of the stirrup bone, whether or not the stapes has been successfully operated upon. Hearing-nerve deterioration due to otosclerosis or any other cause cannot be improved surgically or by medical treatment. The progressive loss of hearing caused by the enlarging otosclerotic nodule may stop after a time, if the nodule becomes matured and inactive. Treatment of the patient with sodium fluoride tablets taken by mouth is a promising method for promoting inactivation of an active otosclerotic process but has not yet been proved conclusively to be of value.

The usual cause of impaired hearing after the age of 60 is presbycusis, the normal aging of the hearing nerve in the inner ear, for which there is no effective medical or surgical treatment.

Other varieties of ear disease causing impaired hearing have been mentioned above in the sections on diseases of the ear. In most cases when loss of hearing is of the conductive type surgical restoration of useful hearing by correcting the defect in the outer or middle ear is a possibility. When loss of hearing is of the sound-perceiving (nerve) type, surgical restoration cannot be expected. Medical treatment for nerve types of hearing loss is helpful only in rare cases when the loss is due to syphilis and in some early cases of Ménière's disease.

More important than cure for nerve types of hearing loss is prevention. Preventable especially are cases of deafness in the newborn due to rubella in the mother. Excessive and prolonged noise-exposure nerve deafness is preventable by early detection (routine testing of the hearing of persons engaged in noisy occupations), by a change of occupation, or by the wearing of ear protectors, either specially designed earplugs or earmuffs.

The incidence of impaired hearing in the general population depends upon the degree of hearing loss defined as impaired. In 1969 approximately 40,000 children with severe nerve deafness that occurred before speech had been acquired attended preschool classes in the United States.

Incidence  
of  
impaired  
hearing

By age six, 0.2 percent of all children have impaired hearing in one or both ears sufficient to warrant consultation of an ear specialist (otologist). By age 18 the number of children with loss of hearing sufficient to require diagnostic examination reaches 2.5 to 3 percent. By age 65 the number of adults with a recognizable hearing impairment reaches 5 percent. Beyond 65 the incidence of impaired hearing rises rapidly as presbycusis, the normal aging of the hearing nerve takes its toll. In the mid-1970s at least 10,000,000 individuals in the U.S. suffered from a hearing handicap sufficient to interfere with normal communication, and at least an equal number had milder and noticeable impairment in one or both ears.

Comparable figures from Britain show that one in six

persons is estimated to have some hearing difficulty, but only a quarter of these have any real handicap, with a third of this latter group needing hearing aids and one in 20 being deaf to all speech and beyond useful help with a hearing aid. With British children, one in 1,000 is severely deaf and as high as seven per thousand estimated to have sufficient impairment to need some form of help.

**Rehabilitation.** The child born deaf or with a severe hearing impairment cannot acquire speech by the normal process. He must attend special classes or a school for the deaf to be taught speech and lipreading. Most of these children have remnants of the sense of hearing that can be utilized in their schooling by the use of aids to amplify sound. The child with a moderate or mild hearing impairment is able to acquire speech by himself but a little more slowly than the child with normal hearing, while speech-correction instruction is usually required to improve his diction.

Conductive types of hearing loss are well compensated for by an electrical hearing aid that simply amplifies sound so that it can be transmitted by bone conduction to the inner ear and the normal nerve of hearing. Nerve types of hearing loss are often associated with distortion of sound and loss of intelligibility; hence, amplification with a hearing aid may be of no value or of limited value. In certain cases of the nerve type of hearing impairment, however, the clarity and intelligibility of hearing remains good, and amplification with an electrical hearing aid is satisfactory.

**Lipreading** Lipreading, which actually entails observation of the entire facial expression rather than the movements of the lips alone, is utilized even by persons with normal hearing who, in the presence of background noise, need these visual clues to supplement hearing. As hearing begins to be impaired, lipreading, better termed speechreading, becomes increasingly valuable and important.

The hearing-impaired individual can learn lipreading skills by careful observation of the speaker at all times and by watching television with the sound volume turned down so that he needs to use his eyes to supplement his ears. Formal instruction in lipreading by a teacher individually or in classes is of additional help. The greater the loss of hearing, the more essential becomes lipreading, for which good lighting is essential.

Speech-correction instruction, needed for the young with serious degrees of impaired hearing, also becomes necessary for the adult who suddenly loses all hearing in both ears. Without the monitoring effect of hearing his

own voice, his speech begins to deteriorate and to acquire the flat, toneless quality of the profoundly deaf.

**Social and economic handicaps.** The social handicap of severe degrees of hearing impairment is particularly important to the individual and his family. An individual who has a hearing impairment can feel isolated and embarrassed by being unable to join into group conversations. He therefore tends to withdraw within himself and often develops false ideas that others are talking about him and ridiculing him. No one has more poignantly written of this isolation than Beethoven, who is generally believed to have suffered from otosclerosis. Had he lived today, his hearing might have been restored or improved through surgery. As it was, it gradually became worse until, after conducting the first performance of his ninth and last symphony, he had to be told to turn around to face the audience to acknowledge the tremendous applause because he could not hear it.

Small devices, such as installing a buzzer instead of a high-pitched door and telephone bell for the nerve-deafened person who cannot hear tones of high pitch, using an amplifier on the telephone, and being patient when communicating with the hard-of-hearing person, make life easier both for him and for those around him.

The economic handicap of impaired hearing is in proportion to the degree of loss. Nevertheless, persons with a hearing disability, while unable to engage in jobs that require keen hearing, tend to have better records of dependability and fewer days away because of illness than persons with normal hearing.
