Magnetic surveys at sea have revealed patterns of stripes denoting high and low values of magnetic intensity. Especially noteworthy is a survey south of Iceland, where the stripes run parallel to the rift zone at the crest of the Mid-Atlantic Ridge. Moreover, the rift divides the pattern into mirror-image halves. This is thought to have been caused by upwelling of molten material at the rift followed by sideward spreading. The stripes of uniform magnetic intensity are like time lines and their magnetic contrast with adjacent bands is ascribed to repeated reversals of the Earth's magnetic field. It is noteworthy that the first few stripes adjacent to the Mid-Atlantic rift have widths in proportion to the corresponding epochs of the paleomagnetic time scale. When time from the scale is combined with the widths from the magnetic pattern, the result is a velocity of about two centimetres (0.8 inch) per year. On the premise that spreading has been constant at two centimetres per year, distance from the Mid-Atlantic rift becomes a direct indicator of age. Thus, some 80 magnetic bands spanning 1,600 kilometres (1,000 miles) are interpreted as 80 polar reversals in the past 80,000,000 years.

An independent check on the foregoing reasoning has resulted in dramatic confirmation. Deep-sea drilling has brought up complete sediment cores at various places in the Atlantic Ocean. If sea-floor spreading is real, bottom sediment in each core was deposited at the time the underlying basalt began spreading outward from the rift. Thus, index microfossils in basal sediment should increase in age the farther a core was taken from the rift. This is exactly what is found. Furthermore, absolute ages of the microfossils agree with ages based on a spreading rate of two centimetres per year (see further SEA-FLOOR SPREADING).

**Lunar history.** Before man set foot on the Moon, its history had been a matter of study for a number of years. Photographs through telescopes and later from Ranger and Orbiter unmanned spacecraft are still the source for most of the raw data from which astrogeologists, as they are known, seek to determine lunar events and their sequence. Their relative dating techniques are the tried and true principles of superposition and cross-cutting. Lunar seas appear to be great lava flows that lap over the base of adjacent highlands and almost bury certain craters, thus being younger than both. Rilles, steep-walled valleys resembling Grand Coulee in the state of Washington, are clearly younger than the rock through which they cut. So are escarpments that appear to be faults in the lunar crust. At places there are over-

lapping craters, the younger having removed a rim section from the older. Giant rays of light-coloured material radiate out from a number of fresh-appearing craters and so must be younger than the features they lie across. Moreover, craters run a continuum from very sharp to very subdued and thus provide relative ages for the surfaces on which they have formed.

Gradually, astrogeologists have been able to piece together the sequence of inferred events for much of the lunar face that perpetually is toward the Earth. Like their geological forbears, they have proposed a relative time scale complete with names such as Imbrian, Eratosthenian, and Copernican, terms originated in accord with the geographic tradition of Earth-based stratigraphy. Maps of most of the Moon's front face are presently available to show the different rock units, their presumed origins, and their relative ages.

Without an atmosphere, lunar history is clearly different from that on Earth. Meteorite impact is inferred to be the main agent of change, excavating in one place and dispersing the material outward in all directions. Volcanism is thought to be the agent responsible for some craters and domes as well as sheets that end in lobate forms typical of lava flows. Weathering is a fact on the Moon, but so far its complete nature is beyond full understanding. Micrometeoroid bombardment as well as cosmic radiation may be significant in this regard.

The rocks obtained from the Moon are very old. Basalts from Apollo 11 show potassium-argon and rubidium-strontium ages of approximately 3,700,000,000 years. The Apollo 12 basalts are about 400,000,000 years younger. Certain materials from both Apollo 11 and 12 give ages approximating 4,600,000,000 years, however. Rocks from the Fra Mauro region collected on the Apollo 14 mission have been dated at 3,800,000,000 years, whereas the so-called genesis rock of Apollo 15 gave an age of 4,200,000,000 years. Although it is far too early to understand the full meaning of lunar rock ages, one thing is clear: most of the events that brought the Moon to its present state occurred within the first 1,000,000,000 years of its history. The history of the Moon is slowly emerging through the application of the relative and absolute dating principles developed in studying the earth. There is no reason why they will not succeed in unlocking the secrets of Mars, and perhaps of other planets as well.

**BIBLIOGRAPHY.** The range of topics treated in this article is great, encompassing several kinds of dating methodology and several areas of applicability—e.g., archaeology, the geological sciences, and astrogeology. Accordingly, a diverse array of books of relevance must be cited here. The titles are largely self explanatory.

## Daudet, Alphonse

Remembered today chiefly as an outstanding short story writer and the author of sentimental tales of provincial life in the south of France, Alphonse Daudet was chiefly known in his own day as a dramatist and novelist. Although usually classed with the Naturalist school of writers in his documentation of the 19th-century contemporary scene, particularly among the lower classes of soci-

ety, Daudet is distinguished from other members of the school by his more sensitive approach and by his impressionistic description.

H. Roger-Viollet

Daudet.

He was born at Nîmes, France, on May 13, 1840, the son of a silk manufacturer. In 1849 his father was obliged to sell his factory and to move to Lyon where Alphonse was at first repelled by the damp-laden atmosphere but soon found compensations in escapades and in the life of the Rhône. He wrote his first poems and his first novel at the age of 14. In 1857 his parents lost all their money, and Daudet had to give up his hopes of matriculating. His work as an usher at a school at Alès for six unhappy months culminated in his dismissal but later furnished the theme, with embellishments and omissions, for his semi-autobiographical novel *Le Petit Chose* (1868). At the end of the year he went to join his elder brother, Ernest, in Paris.

Daudet now threw himself into writing and began to frequent literary circles, both Bohemian and fashionable. A handsome young man, he formed a liaison with a model, Marie Rieu, to whom he dedicated his only book of poems, *Les Amoureuses* (1858). His long and troubled relationship with her was to be reflected, much later, in his novel *Sapho* (1884). He also contributed articles to the newspapers, in particular to *Figaro*. In 1860 he met Frédéric Mistral, the leader of the 19th-century revival of Provençal language and literature, who awakened his enthusiasm for the life of the south of France, which was regarded as inherently passionate, artistic, and sensuous as opposed to the moral and intellectual rigour of the north. In the same year he obtained a secretarial post under the duc de Morny.

His health undermined by poverty and by the venereal disease that was eventually to cost him his life, Daudet spent the winter of 1861–62 in Algeria. One of the fruits of this visit was *Chapatin le tueur de lions* (1863), whose lion-hunter hero can be seen as the first sketch of the author's future Tartarin. Daudet's first play, *La Dernière Idole*, made a great impact when it was produced at the Théâtre de l'Odéon in Paris in 1862. His winter in Corsica at the end of 1862 is recalled in passages of his *Lettres de mon moulin* (1869; "Letters from My Mill"). His full social life over the years 1863–65 (until Morny's death) provided him with the material that he analyzed mercilessly in *Le Nabab* (1877). In January 1867 he married Julia Allard, herself a writer of talent, with whom he was deeply in love and who gave him great help in his subsequent work. They had two sons, Léon and Lucien, and a daughter, Edmée.

In the Franco-German War, which had a profound effect on his writing (as can be judged from his second volume of short stories *Les Contes du lundi*, 1873; "Monday Tales"), Daudet enlisted in the Army, but he fled from Paris during the terrors of the Commune of 1871. His *Les Aventures prodigieuses de Tartarin de Tarascon*

(1872) was not well received, though its adventurous hero is now celebrated as a caricature of *naïveté* and boastfulness. His play *L'Arlésienne* was also a failure (although its 1885 revival was acclaimed). His next novel, *Fromont jeune et Risler aîné* (1874), which won an award from the Académie Française, was a success, and for a few years he enjoyed prosperity and fame—though not without some hostile criticism.

In his last years Daudet suffered from an agonizing ailment of the spinal cord caused by his venereal disease. *La Douleur* (not published until 1931) represents his attempt to alleviate his pain by investigating it. With admirable self-control he continued to write books of all sorts and to entertain Parisian literary and musical society. He was a kindly patron of younger writers—for instance, of Marcel Proust. In 1895 he visited London and Venice. He died suddenly on Dec. 16, 1897.

Psychologically, Daudet represents a synthesis of conflicting elements, and his actual experience of life at every social level and in the course of travels helped to develop his natural gifts. A true man of the south of France, he combined an understanding of passion with a view of the world illuminated by Mediterranean sunlight and allowed himself unfettered flights of the imagination without ever relaxing his attention to the detail of human behaviour. All his life he recorded his observations of other people in little notebooks, which he used as a reservoir of inspiration: a novel, he held, should be "the history of people who will never have any history." Yet there was nothing unfeeling in his approach (he has even been accused of sentimentality), and he was free from preconceived ideas: unlike his fellow naturalists, he believed that the world in its diversity was misrepresented by novelists who concentrated only on its uglier aspects.

At the same time his objective interest in external detail went hand in hand with the expression of an extraordinarily compassionate personality and a reverence for the mystery of things and of individuals. Everything in his world had an inner reality that he reproduced no less faithfully than he did the material phenomena. Finally, he saw passion as endowed with something like the force of destiny, and this conception, which bore fruit in many of his writings, tempers his satire with pity and brings him into kinship with Dickens as well as with Maupassant.

Daudet's work as a whole reveals not so much a continuous evolution as an episodic process in which various literary tendencies found expression successively. Even so, the antiromantic irony of *Tartarin de Tarascon* gave place to a realism akin to that of the Pointillist and Impressionist painters in *Lettres de mon moulin*, which was followed by the tragic tone of *L'Arlésienne* as a corrective to his earlier mockery of southern characteristics; also there is more sympathy and anxiety than irony in *Le Petit Chose* and *Les Contes du lundi*. As he grew older Daudet became more and more preoccupied with the great conflicts in human relationship: *Jack* (1876) presents a woman torn between physical and maternal love; *Numa Roumestan* (1881), the antagonism between the northern and the southern character in man and woman; *L'Évangéliste* (1883), filial affection struggling against religious fanaticism; and *La Petite Paroisse* (1895), the contrarities of jealousy. In *Sapho* (1884), underlying the moral issue, there is Daudet's evaluation of a whole generation of young men, together with a statement of the age-old dilemma of the lover who must choose between freedom and pity for the girl he leaves. *Le Tre'sor d'Arlatan* (1897), *Notes sur la vie*, and *Nouvelles notes* show Daudet as a bold psychologist, anticipating Freud in his analysis of complexes. Truth and fantasy, merciless delineation and poetry, clear-sighted seriousness and a sense of humour, irony, and compassion, all the contrasting elements of which man's dignity is made up are to be found harmonized in Daudet's best work.

#### MAJOR WORKS

VERSE *Les Amoureuses* (1858).

PLAYS: *La Dernière Idole* (1862); *Les Absents* (1863); and *L'Oeillet blanc* (1865), three plays written with E. L'Épine; *Le Frère aîné* (1867; Eng. trans., 1930); *Le Sacrifice* (1869);

#### Evaluation

*L'Arlésienne* (1872); *Lise Tavernier* (1872; Eng. trans., 1890); *La Lutte pour la vie* (1890); *L'Obstacle* (1891), with L. Hennique; *La Menteuse* (1892).

NOVELS AND SHORT STORIES: *Le Roman du Chaperon-Rouge* (1862); *Le Petit Chose* (1868; *My Brother Jack*, 1877; *The Little Good-for-Nothing*, 1878; *The Little Weakling*, 1917); *Lettres de mon moulin* (1869; *Letters from My Mill*, 1880); *Lettres à un absent* (1871); *Aventures prodigieuses de Tartarin de Tarascon* (1872; *The New Don Quixote or the Wonderful Adventures of Tarascon*, 1875; the first of several English translations); *Contes du lundi* (1873; *Monday Tales*, 1927; another Eng. trans., 1950); *Les Femmes d'artistes* (1874; *Artists' Wives*, 1890); *Fromont jeune et Risler aîné* (1874; *Fromont the Younger and Risler the Elder*, 1880); *Robert Helmont* (1874; Eng. trans., 1888); *Jack* (1876; Eng. trans., 1877); *Le Nabab* (1877; *The Nabob*, 1878); *Les Rob en exil* (1879; *Kings in Exile*, 1880); *Numa Roumestan* (1881; Eng. trans., 1884); *L'Évangéliste* (1883; Eng. trans., 1883); *Sapho* (1884; Eng. trans., 1886; one of several translations); *Tartarin sur les Alpes* (1885; *Tartarin on the Alps*, 1887); *La Belle-Nivernaise* (1886; Eng. trans., 1887); *L'Immortel* (1888); *Port-Tarascon* (1890; Eng. trans. by Henry James, 1891); *Rose et Ninette* (1892; Eng. trans., 1892); *La Petite Paroisse* (1895); including *L'Enterrement d'une étoile*, *La Fédor* (1896); *Le Trésor d'Arlatan* (1897); *Soutien de famille* (1898; *The Hope of the Family*, 1898).

MEMOIRS: *Souvenirs d'un homme de lettres* (1888; *Recollections of a Literary Man*, 1889); *Trente ans de Paris* (1888; *Thirty Years of Paris and of My Literary Life*, 1888); *Notes sur la Vie* (1899); *Premier voyage, premier mensonge* (1900; *My First Voyage, My First Lie*, 1901); *La Doulou* (1931), notebooks.

LITERARY CRITICISM: *Pages inédites de critique dramatique*, 1874–1880 (1923).

## Daumier, Honoré

Honoré Daumier, a French caricaturist and painter, is best known for his thousands of satirical lithographs that portray the society of his time as incisively as the novels of *La Comédie humaine* of his friend Honoré de Balzac. No less important, though hardly known during his lifetime, were his paintings, which helped introduce techniques of Impressionism into modern art.

**Background and early life.** Daumier was born on February 20 or 26, 1808, in Marseilles. Traits of his ancestry—a violent temperament, a generous and rather fanciful turn of mind, and an easily aroused capacity for pity—all form part of his character. His mother's family was from a village in which samples of unique ancient sculptured reliefs—fierce primitive human heads—had been found. His grandfather and father both worked in Marseilles as "glaziers"—that is to say, dealers in frames (or passe-partout pictures) and decorative tableaux that they painted themselves. His godfather was a painter. When Daumier was seven, his father abandoned his business in order to go to Paris and, like so many Provençals, seek his fortune as a poet. He was presented

"Self-Portrait," painting by Honoré Daumier. In the Musée Calvet, Avignon, France. Giraudon

to the king, Louis XVIII; but his swift fall from favour—he was famous only for a fortnight—unbalanced him mentally. After apparently being confined for many years, he died in the Charenton asylum.

Daumier received a typical lower middle class education, but he wanted to draw, and his studies did not interest him. His family therefore placed him with an old and fairly well-known artist, Alexandre Lenoir. Lenoir, a student and friend of Jacques-Louis David, a leading classicist painter, was more an aesthete than a painter. He had a pronounced taste for Rubens, one of whose works he kept in his collection. A connoisseur of sculpture, he had saved the most beautiful medieval and contemporary sculptures from the Revolutionaries, which inspired a lasting interest in Daumier.

Daumier was then not at all the uncultured, self-taught genius that most art historians of the late 19th and early 20th centuries have depicted. He did not rise from an artistic void—he was the child of artists, however modest and unsuccessful they had been in making a name. Added to the advantage of this ancestry, he also benefited from a more interesting artistic education than his contemporaries.

At the age of 13 his father's breakdown forced Daumier to seek paying work. He first became a messenger boy for a bailiff and, from this experience, acquired his familiarity with the world of the lawcourts. He worked next as a bookseller's clerk at the Palais-Royal. The Palais-Royal, with its arcades surrounding the garden, was one of the busiest spots in Paris, and there Daumier saw, parading before his employer's window, all the characters of the *Comédie humaine*, about whom he would later talk with his friend Balzac: not only men and women of fashion, intellectuals, and artists but also "captains of industry," or swindlers, as they were commonly called—all of them picturesque personalities that lent themselves to caricature.

Daumier's development was thus complete at that moment when, about 1825–28, he decided to give up everything to embark on the artistic career of which he had dreamed so long. He was a young man of about 18 or 20, from a family of painters, who had had an opportunity to admire Rubens, had learned to analyze sculpture, and had been able to observe the appearance and behaviour of different classes of society.

Physically he was ugly, at least according to the taste of his time. Heavily set like Balzac, although probably smaller, he had small but lively eyes and a large nose. He always kept a pipe in his mouth, in order to mask his Provençal accent and the frequent lisp of his native region.

Daumier could not, of course, live from painting or from sculpture as he had set out to do. He therefore accepted commissions for lithographs: portraits and, at a

Sources  
for his  
caricatures

very early age, cartoons of morals and manners (*caricatures de mœurs*), the first of these dating from 1822, when he was scarcely 15 years old and was just beginning to produce lithographs. Although some of his first works were signed, many others were not: they were portraits of celebrities that were signed by another native of Marseilles, Zéphirin Belliard, Daumier's elder by ten years and the author of a lavish *Zonographie des contemporains*. For the most part these portraits were mediocre, modelled on another artist's style, but they constituted an excellent apprenticeship for someone interested in the human physiognomy.

His life, devoted entirely to his work, was to be divided into two parts: from 1830 to 1847, he was a lithographer, cartoonist, and sculptor; and, beginning in 1848 and lasting until 1871, he was an Impressionist painter whose art was reflected in the lithographs he continued to produce. Constant work was not a burden to him; while producing 4,000 lithographs and 4,000 illustrative drawings, he sang sentimental songs whose foolishness made him laugh, and, "unconcerned with his works, he was always out drinking cheap wine with barge captains."

Satirical lithographs. In 1830 Daumier began his satirical work: his busts lampooning certain contemporary types and his many lithographs. He enjoyed the company of grandiloquent men and mainly associated with men of the left. It was at this time that Charles Philipon, a liberal journalist who had founded the opposition journal *La Caricature*, invited him to become a contributor.

King Louis-Philippe generally tolerated jokes at his expense, but, when unduly provoked, rather than bring suit against a paper, he preferred to seize it, a procedure that meant ruin for its staff and financial backers. Only once during his reign did he deal severely with an offender—with Daumier in 1832, and then only after the second of the artist's most violent attacks. Sentenced to six months in prison, Daumier spent two of them in the state prison and four in a mental hospital, the King apparently wanting to show that one had to be mad to oppose and caricature him.

After his release in February 1833, Daumier was never again indicted, even though in his cartoons he continued to attack a regime, a form of society, and a concept of life that he scorned, while at the same time creating unforgettable characters. Daumier's types were universal: businessmen, lawyers, doctors, professors, and petits bourgeois. His treatment of his lithographs was sculptural, leading Balzac to say about him that he had a bit of Michelangelo under his skin.

Daumier's sculptures have still not been sufficiently studied. The 15 or so small busts that he modelled in clay for the window of the satirical journal for which he worked and that remained there some 30 years occupy an important place in the history of sculpture. Scarcely differing from official busts, but with the accentuation of a detail that made them caricatures, they constitute an unforgettable gallery of the politicians of the July monarchy. The complete series has not been preserved: it included a Louis-Philippe, which Daumier hid, and other pieces that were broken in moving. A few copies of the busts were cast in bronze in the 20th century, and their originality is the more striking when they are compared with similar pieces by other sculptors of that period.

Daumier's only close friends were sculptors, all of them romantic, poor, and ardent left-wingers. Although intimate with these few friends, Daumier did not form part of any of the many artistic or literary coteries of the time. He did not consort with the painters Eugène Delacroix and Gustave Courbet and the writer Victor Hugo and was not inclined to frequent salons, or even saloons. When he went to a *café*, it was with his neighbours on the Île Saint-Louis, where he lived between 1833 and approximately 1850 in a studio on the quay d'Anjou. This old studio still exists, at the top of a house overlooking a world of roofs and open windows, behind which his models lived. Nor did his wife, to whom he was very attached, his dear "Didine" (Léopoldine), mix in artistic circles; she was a dressmaker.

In 1848 Daumier believed the era of social justice for which he had militantly fought for 20 years had arrived, and he took part in the official competition for the representation of the republic that was to replace the portrait of the King in all the municipal buildings of France. His rough sketch was beautiful, and, had he agreed to complete the painting, he would have received the prize.

Impressionist techniques. He did not do so, however, for he had become preoccupied with new technical studies; earlier than others, he had discovered Impressionism—faces and bodies devoured by the surrounding light and becoming one with the atmosphere. He painted a great deal, and the more so as his studies in the new technique did not interest the satirical journals to which he now submitted drawings devoid of humorous meaning. He was supported by Charles Baudelaire and by that poet's friends. The two men had met in 1845 and saw each other more frequently after 1848. Baudelaire, who "adored him," wrote in 1857 the only significant article on Daumier to appear in the painter's lifetime.

Daumier was indeed the first of the Impressionists. As early as 1848, his lithographs show contours effaced by light. Two factors, however, prevented this fact from being noticed: the lack of interest in his lithographs shown by historians of painting and the lack of research to establish the exact dates of the lithographs. These dates were not necessarily those of their appearance. It has been shown, for instance, that the Impressionist lithographs, which appeared around 1860, had been rejected by journals in 1848 as being too bold, too modern. Because of this lack of demand, Daumier's Impressionist lithographs are not very numerous, but his painting shows that he was won over to Impressionism. The paintings, also, were too few in number to assign him his true place in the history of Impressionism—before Manet and Monet, both of whom admired him greatly.

The dating of Daumier's paintings has given rise to controversy. Nineteenth-century art historians and those prior to 1938 dated them largely in relation to the paintings of his contemporaries. But it now seems more reasonable to date them from his lithographs, for it is not likely for an artist who changes styles frequently to work differently when drawing on a lithographic stone than when painting on canvas. When Daumier imagined a form, he would fashion and refashion it numerous times in his lithography. It is not likely that he would wait four to six years after he had stopped dealing with it in his lithographs to treat it in his painting. The question may be studied again, but not on the basis of documents of the period, for Daumier's notebooks were too abbreviated, and critiques by his contemporaries were rare, since he seldom showed his works, and they went largely unnoticed.

Daumier's paintings are highly original, both in their style and in the subjects they present. He created the painting of morals and manners (*la peinture de mœurs*); he shows the everyday life on the Île Saint-Louis and its quays, such as children playing in the water, one of them brought back to its parents after an accident; horses leaving a water trough; washerwomen wearily returning up the stairs from the river or fighting against the wind, their bundles in their arms; drinkers in a pub; masons on a scaffold. He was stirred by the theatre, then by railroads, which he used as a means of showing galleries of faces as powerful in their impact as those of the "Ventre législatif" ("Legislative Belly" or "Vile Body of the Legislature"). Earlier, the Palais de Justice had provided him with the opportunity of drawing his dramatically impressive lawyers. Then he went to Valmondois, on the outskirts of Paris, and depicted rustic scenes. Much of his painting was devoted to artists' studios—not studios of a studied picturesqueness but those where artists were concerned with creating works of art.

These subjects are found again in his lithographs, together with topical subjects, such as seaside resorts, hunting, and winter scenes, all of which, having been commissioned, seemed to inspire him less. Thus he transposed into his painting what had until then belonged to the domain of the caricatures of morals and manners.

Impressionist lithographs

Imprisonment by King Louis-Philippe

Daumier's sculptures

Paintings of morals and manners

Daumier was not often inspired by religious subjects, except for the image of Christ, insulted and ridiculed, in which there appears to be personal allusion—that of a man who each day hoped to draw his last cartoon so that he could devote himself to painting. On the other hand, mythology excited him during his Rubens period under Lenoir; but in this case, obviously, the subject was only a prop for the painting.

On several occasions Daumier painted historical subjects. He painted "Camille Desmoulins," the Revolutionary leader, rousing the crowd in 1789; and his "Emigrants" of 1857 is an allusion to the authoritarian empire of Napoleon III, a painting that echoes the words of the proscribed Victor Hugo: "It is not I who am proscribed, it is liberty; it is not I who am exiled, it is France."

The types that Daumier created did not always survive him. He created a Louis-Philippe, but above all Robert Macaire (the typical businessman of Louis-Philippe's reign). His "Bons Bourgeois" probably served as a reference for the French middle class up to the '40s. In any case, his "Lawyers" remain up-to-date.

Following tradition, Daumier took pupils who learned their craft by copying and imitating his works. Two of them are known by name: Boulard and Gill. Their works are known—incorrectly—as *faux Daumier*, for works are only false when one is unable to see that they are the exercises of pupils.

Less solitary than he is said to have been, and admired by the new school, notably by Manet, Daumier grew old: sadly, for he would have liked to give up his lithographic work in favour of painting, but he could not do so. But he was happy in the knowledge that his lithographs preserved their force, as Hugo said in 1870 when Daumier symbolized his great satirical poem *Les Châtiments* by a crucified eagle.

In 1871, Daumier, who had discreetly refused to be decorated by the empire, became a member of the leftist Paris Commune. After 1871, Daumier, now almost blind, lived on until February 11, 1879. His drawings, like those of Edgar Degas, gained a magnificent wholeness. He had one last joy, an exhibition at the Durand-Ruel Gallery in 1878. People began to say that his paintings were at least as good as his lithographs, though it was more the republican than the artist that they wished to celebrate.

As a cartoonist, Daumier enjoyed a wide reputation, although as a painter he remained unknown. His fame was not based, any more than it is today, on critical appreciations but, rather, on the smiling or laughing admiration of those who read the satirical journals.

#### MAJOR WORKS

**PAINTINGS:** "Three Lawyers in Conversation" (c. 1843–46; Phillips Collection, Washington, D.C.); "Les Noctambules" (c. 1843–48; National Museum of Wales, Cardiff); "The Republic" (c. 1848; Louvre, Paris); "The Miller, His Son, and the Ass" (c. 1849; Museum and Art Gallery, Glasgow); "Nymphs Pursued by Satyrs" (c. 1849–50; Montreal Museum of Fine Arts); "The Drinkers" (c. 1856; Metropolitan Museum of Art, New York); "The Melodrama" (c. 1856–60; Neue Pinakothek, Munich); "The Print Collector" (c. 1857–60; Musée du Petit Palais, Paris); "Crispin and Scapin" (c. 1858–60; Louvre); "The Horsemen" (c. 1860–62; Museum of Fine Arts, Boston); "The Washerwoman" (c. 1860–62; Louvre); "The Third-Class Carriage" (c. 1862; Metropolitan Museum of Art, New York); "The Painter at His Easel" (c. 1866; Phillips Collection); "Don Quixote" (c. 1868; Neue Pinakothek).

**LITHOGRAPHS:** "The Legislative Belly" (1834); "Rue Transnonain, April 15, 1834" (1834); "Freedom of the Press" (1834); "Pygmalion" (1842); "Pardon Me, Sir, If I Bother You a Bit" (1844); "The Orchestra During the Performance of a Tragedy" (1852); "The Muse of the Beer Parlour" (1864).

**DRAWINGS:** "Two Men Looking Toward the Left" (c. 1840; Louvre); "Connoisseurs" (c. 1858; Cleveland Museum of Art); "Soup" (c. 1860–62; Louvre); "Clown" (c. 1868; Metropolitan Museum of Art, New York).

**SCULPTURE:** "The Refugees" (1848–49; National Gallery of Art, Washington, D.C.); "Ratapoil" (1850; National Gallery of Art, Washington, D.C.).

**BIBLIOGRAPHY.** There is no definitive work on Daumier. Nineteenth-century studies include DURANDY, "Daumier," in

*Gazette des beaux-arts*, 17:429–433 (1878); EUGENE MONTROSIER, "Honoré Daumier," in *L'Art*, 2:25–32 (1878); GUSTAVE GEFFROY, "Daumier," in *Revue de l'Art*, 9:229–250 (1901); and the only nearly contemporary book, written thanks to some testimonies, including those of his widow: ARSENE ALEXANDRE, *Honoré Daumier: l'homme et l'oeuvre* (1888; reissued as *Daumier*, 1928). Twentieth-century works, particularly recommended, are PAUL VALÉRY, *Daumier* (1938); HENRI FOCILLON, "Visionnaires—Balzac et Daumier," in *Essays in Honor of Albert Feuillerat* (1943); JEAN ADHEMAR, *Honoré Daumier* (1954; Eng. trans., *Daumier: Drawings and Watercolors*, 1954), an exhaustive study; KARL E. MAISON, *Honoré Daumier: Catalogue raisonné of the Paintings, Watercolours, and Drawings*, 2 vol. (1968); HOWARD P. VINCENT, *Daumier and His World* (1968); and BERNARD LEMANN, "Daumier and the Republic," *Gazette des beaux-arts*, 27:105–120 (1945). On the sculpture of Daumier, see MAURICE GOBIN, *Daumier sculpteur: 1808–1879* (1952); and JEANNE L. WASSERMAN, assisted by JOAN M. LUKACH and ARTHUR BEALE, *Daumier Sculpture: A Critical and Comparative Study* (1969), a very good exhibition catalog and study from the Fogg Art Museum.

(J.Ad.)

## David

David, second of the Israelite kings, established a united kingdom over all Israel with Jerusalem as its capital. Through his political and religious leadership, he founded a national identity and unity that survived later political divisions and disasters. In Jewish tradition he became the ideal king, the founder of an enduring dynasty, around whose figure and reign clustered messianic expectations of the restoration of the city and the people of Israel. Since he was a symbol of fulfillment in the future, the New Testament writers emphasized that Jesus was of the lineage of David. He is also held in high esteem in the Islamic tradition. For ancient Israel, it has been said, his role was second only to that of Moses.

**Political career.** The youngest son of Jesse (grandson of Boaz and Ruth), David was born in Bethlehem. He began his career as an aide at the court of Saul, Israel's first king, and became a close friend of Saul's son and heir, Jonathan, and the husband of Saul's daughter Michal. He so distinguished himself as a warrior against the Philistines that his resultant popularity aroused Saul's jealousy and a plot was made to kill him. He fled into southern Judah and Philistia, on the coastal plain of Palestine, where, with great sagacity and foresight, he began to lay the foundations of his career.

Beginning as an outlaw, with a price on his head, he led the life of a Robin Hood on the desert frontier of his country (Judah). He became the leader and organizer of other outlaws and refugees; and, according to the Bible, "... everyone who was in distress, and everyone who was in debt, and everyone who was discontented, gathered to him; and he became captain over them." This group progressively ingratiated itself with the local population by protecting them from other bandits or, in case they had been raided, by pursuing the raiders and restoring the possessions that had been taken. Though sometimes dependent upon the Philistine kings of Gath for protection from the pursuit of King Saul, David managed to retain his status as a patriot in the eyes of his own people in Judah and, even as one who had, indeed, been an innocent and loyal servant of the demented Saul. He also won the favour of many Judaeans elders by various politic gestures. Thus, by biding his time, he eventually had himself "invited" to become king, first by Judah in Hebron and later by all Israel, not as a rebel against Saul but as his true successor.

This opportunity emerged when Saul and Jonathan were slain in battle against the Philistines on Mount Gilboa. David entered Hebron, where he was proclaimed king. He had to struggle for a few years against the contending claim and forces of Ishbaal, Saul's surviving son, who had also been crowned king, but the civil war ended with the murder of Ishbaal by his own courtiers and the anointing of David as king over all Israel (including tribes beyond Judah). He proceeded to conquer the walled city of Jerusalem, held by the alien Jebusites, which he made the capital of the new united kingdom,

Rise to power

and to which he moved the sacred ark of the Covenant, the supreme symbol of Israelite religion. He defeated the Philistines so thoroughly that they were never again a serious threat to the Israelites' security, and he annexed the coastal region. He went on to establish an empire by becoming the overlord of many small kingdoms bordering on Israel, including Edom, Moab, and Ammon. Beginning about 1000 BCE (before the Common Era—BC), David's reign lasted for about 40 years (until 962 BCE).

David's great success as a warrior and empire builder was marred by family dissensions and political revolts, which were interrelated. To tie together the various groups that constituted his kingdom, David took wives from them and created a harem. The resultant family was an extreme departure from the family in the consanguinal context, the traditional clan structure. David's wives were mostly completely alien to one another, and his children were without the directing support of established social patterns that provided precedents for the resolution of conflict or for establishing the rights of succession. Thus, David's third son, Absalom, murdered the eldest son, Amnon, for the latter's rape of Tamar, the former's sister and the latter's half sister. After a period of exile and then of reconciliation with King David, Absalom used the favour he had gained among the people and some courtiers to launch a rebellion that sent his father fleeing across the Jordan and that made him master of Jerusalem and the royal harem for a time. Eventually, Absalom's forces were defeated, and he was killed by Joab, David's general, and it was Solomon, born of David's union with Bathsheba, who became the King's eventual heir.

The authors of the biblical accounts (in books I and II Samuel) of David's political career display a deep insight into his character. David was a man who could make an indelible personal impression in a specific situation. His doubling of the bride price set by Saul for Michal illustrates this capacity for imaginative action and dramatic publicity. Coupled with this ability to exploit the immediate situation in the service of his momentary requirements, he possessed the knack of making his conduct in particular situations serve his persistent and long-range aims. For example, the two versions of his refusal to assassinate King Saul when he had it in his power to do so (in I Samuel 24 and 26) do not simply present an inspiring example of gallantry in a moment of dramatic confrontation; they also contribute to the enduring reputation of David as a man who, even in his years as an outlaw, had a deep respect for established institutions, especially for the sacred office of the king ("the Lord's anointed"). Later, after the death of Saul and Jonathan, David again confirmed this point at a moment in which it was crucially important for him to do so for the sake of his own career. A young Amalekite who came to report Saul's death to David intimated that he had had a share in it. He thought that as the bearer of good news he would be rewarded, but his miscalculation cost him his life. David sensed that in an hour of national disaster the differences between him and Saul were of no importance. He had the Amalekite slain for having laid hands on the Lord's anointed, and with his men he performed the mourning rites for Saul and Jonathan, memorializing them in a deeply moving elegy. Somewhat later, after David had become king in Hebron, he learned that the men of Jabesh-Gilead, a town across the Jordan that had been fanatically attached to King Saul, had recovered the bodies of Saul and Jonathan to give them honourable burial. David sent the town a message commending it for its act of reverent loyalty, which had been undertaken at great risk. His action in this episode, also, was both political and sincere; and it was eminently suited to the situation in which the conciliation of all Israelites was of the greatest importance for both the career of David and the survival of the nation.

In the case of Absalom's rebellion, a poignant conflict took place between parental love and political power. When the news of his son's slaying came to him he broke down into deep grief and lamented, "O my son Absalom,

my son, my son Absalom! Would I had died instead of you . . .!" But he was rebuked by his general Joab (who had ignored the King's direct order and had the young rebel killed) as showing more concern for his enemies than his supporters and risking the loss of public esteem and so of his rule. Thereupon he returned with his old energy and wile to the task of uniting and reconciling the various factions in Israel, including putting down another revolt, this time by Sheba, the son of Bichri, of the tribe of Benjamin.

**Nation builder: David's political achievement.** David was Israel's first successful king. He united all of the Israelite tribes, became the effective ruler over all, and was the founder of an enduring dynasty. Thus, he succeeded where King Saul had failed and attained a unique place in Israel's history and tradition. II Samuel 9–20 and I Kings 11–22 provide the primary source for knowledge of his reign and of the succession. It is generally agreed that this "history" was written very soon after the reign of David; as such, it is perhaps the oldest piece of historiography in the Western world. Known as the "Family History of David," and also as "The Succession History," it is an especially clear mirror in which to study the problems David faced in displacing charismatic political leadership and authority with hereditary monarchy.

For centuries before David's rise to kingship, Israelites had been held together in loose tribal confederacies. The northern confederacy, with its centre at Shechem, is the best known. It was dominated by the tribe of Ephraim. A tribe was a collection of clans; and a clan was simply an expanded family. The consanguinal and familial character of Israelite society is a basic feature of Semitic tradition and is today still intact in the Arab society of the peninsula of Arabia. There the founding of the Sa'ūdī dynasty in the present century offers close and instructive parallels to David's problems and accomplishments 3,000 years ago. For example, both the revolt of Absalom, which necessitated David's exile for a time, and the grasp of the eldest surviving son, Adonijah, for the succession, in competition with the sponsors of Solomon, very nearly succeeded because they appealed to traditions of local and tribal authority, winning the support of many who were disillusioned with the swift centralization of power that had accompanied the establishment of the Davidic empire. In II Samuel 15, for example, Absalom, in his bid for support, says that he would like to exercise judgment in the premonarchic manner, as an elder in the gate. Ironically, he was attempting to displace his father by the same means by which David had so successfully risen to power; *i.e.*, appealing to local clans. Later, after Solomon's reign had ended, the united kingdom broke up when these tribalistic traditions again reasserted themselves. The relentless movement of social evolution made impossible the re-establishment of a tribal society; but the vitality of the tribal heritage was still very strong, both in David's day and later. Thus, there was a basic instability in his position; he faced the problem of winning consent for and establishing the legitimacy of his office, for it was an imported novelty in the social structures and traditions of Israel, on the model of the ancient Near Eastern kingships.

David's position in the tribal units that made up Judah was secure, for he had united them and had risen to authority over Judah through his adroit use of the indigenous social and political instruments of its clan structures. Therefore, Judah accepted his legitimacy and never disowned his dynasty. He sought to win the consent of all Israel, first, by the decisively successful war against the Philistines, which made the whole land secure; and then by establishing the city of Jerusalem as the centre both of Israel's political power and of its worship. On the political level this effort was not enough, for the kingdom was divided after the death of Solomon; but on the religious and cultic level it did eventually succeed, for Jerusalem, the "city of David," became the Holy City for all Jews, and the messiah, "the anointed one" of the house of David, a sign of the relationship between the God of Israel and his people.

From  
tribalism  
to mon-  
archism

Messianic symbol: David's religious role and significance. In Israel's religious tradition the royal line, or "house," of David became a primary symbol of the bond between God and the nation; the king was the mediator between the deity and his people. As in many ancient traditions, the king was thought of as both divine and human. The English word messiah is derived from *ha-meshiach* ("the anointed one"), the title of the kings of the line of David. Thus, in later times of disaster, Israel began to wait for a messiah, a new mediator of the power of God that would redeem the people and its land. By designating Jesus as the son of David, Christianity dramatized its conviction that this hope had been fulfilled. David lived in the memory of his people in a double way: as the great founder of their political power and as the symbol of a central facet of their religious faith.

The process by which David achieved this status for himself, his house, and his city may be traced in II Samuel 5–8. When David took Jerusalem, he assumed the rule over its inhabitants and their religious institutions with the cult centred on Mt. Zion. The previous (Jebusite) ruler had been both king and high priest, and played the role of mediator between the city and its deity. There was no precedent for such a mediative and priestly role of kings in Israelite religion, nor of walled cities as the seat of government and worship. Apparently, David simply took over the Jebusite cult on Zion and adapted it to his own (and Israelite) use. Beginning with David and throughout the entire period of the monarchy, for about four centuries, Israel's worship on Zion gave a central place to the king, not simply as officiant but substantively, as the figure who in his office and person embodied the relationship between God and the nation. In contrast, the premonarchic worship of Israel, at Shechem and elsewhere, had featured a covenant between God and the people, through their tribal heads, as the bond in the relationship. By taking over and adapting Jerusalem's ancient cult, David provided Israel with a new worship, one that featured his own status and its sacral significance.

Israel's God was named Yahweh. David made this name the supreme name for deity in Jerusalem (previously perhaps "Salem"), to indicate his conquest of the city. All former names and titles of deity became attributes or titles of Yahweh, the God of Israel, the conqueror; for example, El 'Elyon (God Most High). While the Israelite name for God displaced all others, the substance of the worship remained similar: Yahweh had created the world and ruled the nations; he had established kingship as the sign and means of his universal rule; and Zion was the seat of his chosen king, David, his anointed. Yahweh himself was enthroned on Zion, and his king sat at his right hand as his regent. David thus continued the line of king-priests that had reigned in Jerusalem from the founding of the city, and, according to a legend that may have developed in this context, the patriarch Abraham had been blessed by Melchizedek, an earlier representative of the line, when he had presented tithes to him.

Having adopted the ancient cult of Jerusalem as a means of giving sacral significance to his royal status and having renamed it the cult of Yahweh, by whose power he had conquered, David also made an important move to make the new shrine and its worship relate to the premonarchic experience of Israel. He brought the ark to Jerusalem and established it as the central object of the cult. According to tradition, it had travelled with Israel in the wilderness and led the way into the land. It was a rectangular wooden box, originally without a cover, that established and located the presence of Yahweh with the people of Israel. So close was the connection that the ark could be addressed as Yahweh. The ark was carried into battle to demonstrate that Yahweh fought for Israel; and it was carried in the wilderness, to show that he travelled with his people. In worship, it was apparently carried in procession in the pilgrimages that were features of the annual feasts. It was a sign and even the embodiment of Yahweh's presence. David could have chosen no better way of making premonarchic Israelites accept the royal cult on Zion than by incorpo-

rating the ark, with all its ancient associations, into the new ceremonial.

David's adaptation of the Zion cult, with its understanding of kingship as the substance and means of the presence of God on earth, was to have momentous consequences for the religious history of mankind, notably for the experience of the entire Western world. Because of it Jerusalem became the Holy City, and David became the prototype of an awaited messiah. As symbol of the Messiah, the return of David, or the coming of David's "son" stood for the reassertion of the divine rule and presence in history: to judge it, to redeem it, to renew it. David thus became the symbol of a fulfilment in the future, final peace.

In the apocalyptic developments in Judaism that mark the last two pre-Christian centuries, the symbolic role of David stressed his status as divine mediator. The son of David became more emphatically a heavenly figure, the son of God enthroned to rule over the nations of the world. This was the matrix for the rise of Christianity. The new faith interpreted the career of Jesus by means of the titles and functions assigned to David in the mysticism of the Zion cult, in which he served as priest-king and in which he was the mediator between God and man.

**BIBLIOGRAPHY.** R.A. CARLSON, *David, the Chosen King* (Eng. trans. 1964), provides a most complete analysis of the development of the traditions about David now embedded in biblical materials. JUAN BOSCH, *David: Biografía de un rey* (1963; Eng. trans., *David: The Biography of a King*, 1966), is a realistic account of the actual dynamics of the political career of the King. Two works on the role of David as a mystical figure in the religious mythology and imagination of ancient Israel are AAGE BENTZEN, *Messiah-Moses Redivivus-Menschensohn* (1948; Eng. trans., *King and Messiah*, 1955); and HELMER RINGGREN, *The Messiah in the Old Testament* (1956). The former stresses that he was the subject of messianic expectations that clustered around hopes for a political deliverance and national re-establishment. The latter connects the King with the "Suffering Servant" of Isaiah 53, which is used to illustrate the theme of vicarious suffering in the New Testament's interpretation of the career of Jesus.

(J.C.Ry.)

## David, Jacques-Louis

In compartmented histories of European art, the French painter Jacques-Louis David appears as a principal exponent of the late-18th-century Neoclassical reaction against the pretty, feminine, allegedly decadent Rococo style and in favour of a return to the supposedly more manly, more virtuous styles of ancient Rome and Athens. But David cannot be easily assigned to a single historical category. He was the most talented delineator of the aspirations and the tragedy of the French Revolution, and he then became the chief celebrator in paint of the pomp of the Napoleonic empire. In his work and his doctrines can be found not only Neoclassicism but also the seeds of later Romanticism, Realism, and Academicism. His reputation, after a sharp decline under charges of dryness, frigidity, and theatricality, has been rising steadily during the second half of the 20th century.

Formative years. David was born in Paris on August 30, 1748, a year when new excavations at the ash-buried ruins of Pompeii and Herculaneum were beginning to encourage a stylistic return to antiquity (without being, as was long supposed, a principal cause of that return). His father, a small but prosperous dealer in textiles, was killed in a duel in 1757, and the boy was subsequently raised, reportedly not very tenderly, by two uncles. After classical literary studies and a course in drawing, he was placed in the studio of Joseph-Marie Vien, a history painter who catered to the growing Greco-Roman taste without quite abandoning the light sentiment and the eroticism that had been fashionable earlier in the century. At 18 the obviously gifted budding artist was enrolled in the school of the *Académie Royale de Peinture et de Sculpture*. After four failures in the official competitions and years of discouragement that included an attempt at suicide (by the stoic method of avoiding food), he finally obtained, in 1774, the Prix de Rome, a government scholarship that not only provided a stay in Italy

but practically guaranteed lucrative commissions in France. His prize-winning work, "Antiochus and Stratonice," reveals that at this point he could still be influenced slightly by the Rococo charm of the painter François Boucher, who had been a family friend.

In Italy there were many influences, including those of the dark-toned 17th-century Bolognese school, the serenely classical Nicolas Poussin, and the dramatically realistic Caravaggio. David absorbed all three, with an evident preference for the strong light and shade of the followers of Caravaggio. For a while he seemed determined to fulfill a prediction he had made on leaving France: "The art of antiquity will not seduce me, for it lacks liveliness. . . ." But he became interested in the Neo-classical doctrines that had been developed in Rome by, among others, the German painter Anton Raphael Mengs and the art historian Johann Joachim Winckelmann. In the company of Quatremère de Quincy, a young French sculptor who was a strong partisan of the return to antiquity, he visited the ruins of Herculaneum, the Doric temples at Paestum, and the Pompeian collections at Naples. In front of the ancient vases and columns, he felt, he said later, that he had just been "operated on for cataract of the eye."

**Rise to fame: 1780–94.** Back in Paris in 1780, he completed and successfully exhibited "Bélisaire demandant l'aumône" ("Belisarius Asking Alms"), in which he combined a nobly sentimental approach to antiquity with a pictorial technique reminiscent of Poussin. In 1782 he married the rather plain but spirited Marguerite Pécoul, whose father was a wealthy building contractor and the superintendent of construction at the Louvre—a position that carried considerable influence. From this date David prospered rapidly. The pathos and painterly skill of "Andromache Mourning Hector" brought him election to the Académie Royale in 1784; and that same year, accompanied this time by his wife and studio assistants, he returned to Rome with a commission to complete a painting that appears to have been originally inspired by a Paris performance of Pierre Corneille's *Horace*. The result, finally not based on any of the incidents in the play, was the "Oath of the Horatii." The subject is the solemn moment, charged with stoicism and simple courage, when the three Horatii brothers face their father and offer their lives to assure victory for Rome in the war with Alba; the pictorial treatment—firm contours, bare cubic space, sober colour, frieze-like composition, and clear lighting—is as austere non-Rococo as the subject. Exhibited first in David's studio in Rome and then, following his return to France, in the official Paris Salon of 1785, the picture created a sensation; it was regarded as a manifesto for an artistic revival (the term Neoclassicism was not yet in use) that would cure Europe of the lingering addiction to dainty curves and boudoir themes. Even-

tually, it came to be regarded, although such was almost certainly not the first intention, as a manifesto for an end to the corruption of an effete aristocracy and for a return to the stern, patriotic morals attributed to republican Rome.

David became a culture hero; he was even referred to in some quarters as a messiah. He added to his fame by producing in 1787 the morally uplifting "Death of Socrates," in 1788 the less uplifting but archaeologically interesting "Amours de Paris et d'Hélène" ("Paris and Helen"), and in 1789 another lesson in self-sacrifice "Les Lictteurs rapportent à Brutus les corps de ses fils" ("The Lictors Bringing to Brutus the Bodies of His Sons"). By the time the "Brutus" was on view, the French Revolution had begun, and this picture of the patriotic Roman consul who condemned his traitorous sons to death had an unanticipated political significance. It also had, through its presumably accurate reconstitution of the details of everyday Roman life, an effect that was perhaps equally unexpected, for with it David began the long and extensive influence he was to have on French fashions. Up-to-date homes began to display imitations of his Roman furniture; men cut their hair short in the Roman style; and women adopted the dresses and the coiffures of Brutus' daughters. Later on, even the flimsy Sabine dress, which left the breasts exposed, was adopted by the ultramodern.

In the early years of the Revolution, David was a member of the extremist Jacobin group led by Robespierre, and he became an energetic example of the politically committed artist. He was elected to the National Convention in 1792, in time to vote for the execution of Louis XVI. By 1793, as a member of the art commission, he was virtually the art dictator of France and was nicknamed "the Robespierre of the brush." He preached moral and aesthetic sermons to the Convention:

The artist must be a philosopher. Socrates the skilled sculptor, Jean-Jacques [Rousseau] the good musician, and the immortal Poussin, tracing on the canvas the sublime lessons of philosophy, are so many proofs that an artistic genius should have no other guide except the torch of reason.

Guided supposedly by the torch of reason and perhaps also by bitter memories of his many unsuccessful attempts to win the Prix de Rome, he succeeded in abolishing the Académie Royale and with it much of the old regime's system for training artists and providing them with patronage. The Académie was replaced briefly by a body called the Commune des Arts, then by a group called the Popular and Republican Society of the Arts, and then, finally, in 1795, after David was out of power, by the beginning of the system—a combination of the Institut de France and the École des Beaux-Arts—that dominated French artistic life during most of the 19th century.

As an artist during these years of his dictatorship, David was frequently busy with revolutionary propaganda. He had commemorative medals struck, set up obelisks in the provinces, and staged national festivals and the grandiose funerals the new government gave its martyrs. Some of his projects for paintings at this time were never completely carried out: one of these is the unfinished "Joseph Bara," which is a tribute to a drummer boy shot by the royalists, and another is the sketched "Oath of the Tennis Court" (Louvre, Musée National de Versailles et des Trianons, and the Fogg Art Museum, Cambridge, Massachusetts), which was to commemorate the moment in 1789 when the Third Estate (the commoners) swore not to disband until a new constitution had been adopted. The "Death of Lepeletier de Saint-Fargeau," painted to honour a murdered deputy and regarded by David as one of his best pictures, was eventually destroyed. The result of all this is that the artist's Jacobin inspiration is represented principally by "The Dead Marat," painted in 1793 shortly after the murder of the revolutionary leader by Charlotte Corday. This "pietà of the Revolution," as it has been called, is generally considered David's masterpiece and an example of how, under the pressure of genuine emotion, Neoclassicism could turn into tragic Realism.

Political activities

Italian influences on David

Arrest  
and im-  
prisonment

Later years: **1794–1825.** In 1794, after his friend Robespierre had been sent to the guillotine, David was arrested. At his trial he is said to have defended himself badly, mumbling that in the future he intended to attach himself "to principles and not to men." He was imprisoned twice, for four months in 1794 and for two more the next year, apparently most of the time in the not uncomfortable Palais du Luxembourg in Paris. He was consoled by being allowed to paint and also by the fact that his wife, who had divorced him two years earlier for having voted for the death of the King, now loyally returned in his hour of trouble and remarried him, on this occasion for good. During his first period in prison, he painted from his window his only landscape, the "Vue du jardin du Luxembourg à Paris" ("View of the Luxembourg Gardens"). While he was held temporarily in another Paris building, he did an unfinished "Self-Portrait." At 46 he appears as a boyish young man with romantically disheveled hair, brown eyes, and a generally aggressive, if worried, look; a cheek tumor from which he suffered all of his adult life and which is said to have impeded his speech gives his face a slight twist.

Even during his imprisonment, he had retained three studios in the Louvre, and, after the amnesty of 1795, he devoted to teaching the same energy he had been devoting to revolutionary politics. Eventually, between the "Oath of the Horatii" and the Battle of Waterloo, he was responsible for the training and indoctrination of hundreds of young painters from all over Europe, among them such future masters as Baron François Gérard, Antoine-Jean Gros, and Jean-Auguste-Dominique Ingres. The indoctrination began with the premise that the basis of art was the contour, and so it can be held partly responsible for the excessive emphasis on drawing that characterized European academic painting in the 19th century. But David himself, as his works show, was not always hostile to rich chromatic effects; as late as 1860 he could be called, by no less a colorist than Eugène Delacroix, "the father of the whole modern school."

Mastery of  
portraiture

Neoclassicism was in theory inclined to scorn portraiture, since a contemporary sitter normally lacked both the universality and the nudity of an ancient statue. David, however, had done portraits, remarkable for their psychological individuality and their look of solid flesh, since the beginning of his career: in 1782–83 his sitter had been Alphonse Leroy, a Paris medical professor; in 1784 Mme Pécoul, his mother-in-law; in 1788 the chemist Antoine-Laurent Lavoisier, with Mme Lavoisier. In 1795 the freed artist portrayed his pretty, elegant sister-in-law, Mme Sériziat, and her dandyish husband. In the last year of the century, he produced his famous period piece, "Portrait de Mme Récamier," which he left unfinished because the sitter, then at the start of her career as a reigning Paris beauty, proved unreliable about hours for posing.

But David was not a man for the life of a mere teacher and portraitist. In 1799 he made a spectacular re-entry into public notice with a new giant canvas, "Les Sabines" ("The Intervention of the Sabine Women"). The picture, often mistakenly referred to as "The Rape of the Sabines," represents the moment, a few years after the legendary abduction, when the women, now contented wives and mothers, halt a battle between their Roman husbands and the Sabine men who have come on an unwanted rescue mission; in the middle of the melee stands the lovely Sabine woman Hersilia, appealing with one arm toward the Roman Romulus and the other toward the bearded Sabine Tatius. The artist had said that his aim was to move away from the allegedly crude Roman manner of the "Oath of the Horatii" into a more graceful Greek manner, and he did win enthusiastic applause for the elegance of his figures. He also won some approval for his supposed intention to preach conciliation after 10 years of bloodletting in France. But he attracted perhaps the most attention with the nakedness of his ancient warriors; having ceased to be the Robespierre of the brush, he now became, in a popular jingle, "the Raphael of the sans-culottes" ("without breeches"; the radical Republicans).

Napoleon admired "The Intervention of the Sabine Women" and saw possibilities for self-aggrandizement in the talent displayed. Soon David, without acquiring political office, was again a government painter, first under the Consulate and then, after 1804, under the Empire. He was not, however, the only prominent Frenchman to move from the Jacobin left to the Bonapartist right, and he had evidently always been a worshipper of historical heroes. His most important Napoleonic work is the huge "Coronation" of 1805–08, sometimes called "Napoleon Crowning the Empress Josephine"; in it Neoclassicism gives way to a style that combines the official portraiture of the old French monarchy with overtones—and occasional straight imitation—of the masters of the Italian Renaissance. This picture was followed in 1810 by the large "Napoleon Distributing the Eagles" and in 1812 by "Napoleon in His Study," a sharply perceptive portrait notwithstanding its conspicuously propagandistic intention.

After the fall of Napoleon in 1815, David was exiled to Brussels. Cut off from the excitement and stimulus of the great events he had lived through, he lost much of his old energy. Toward the end of his life, he executed, probably with considerable help from a Belgian pupil, François-Joseph Navez, one more remarkably convincing portrait: the "Les Trois Dames dites de Gand" ("Three Women of Ghent"). He died in Brussels on December 29, 1825.

#### MAJOR WORKS

"Combat de Minerve contre Mars" (1771; Louvre, Paris); "The Death of Seneca" (1773; Musée du Petit Palais, Paris); "Antiochus and Stratonice" (1774; École des Beaux-Arts, Paris); "Bélisaire demandant l'aumône" ("Belisarius Asking Alms," 1780; Musée Wicar, Lille); "Portrait of Pierre Desmaisons" (1782; Albright-Knox Art Gallery, Buffalo); "Andromache Mourning Hector" (1783; Louvre); "Oath of the Horatii" (1784; Louvre); "Portrait de Charles-Pierre Pécoul" (1784; Louvre); "Portrait of Mme Pécoul" (1784; Louvre); "The Death of the Ugolino" (1786; Musée des Beaux-Arts et d'Histoire Naturelle, Valence); "The Death of Socrates" (1787; Metropolitan Museum of Art, New York); "Les Amours de Paris et d'Hélène" ("Paris and Helen," 1788; Louvre); "Portrait of Lavoisier and His Wife" (1788; Rockefeller University, New York); "Les Licteurs rapportent à Brutus les corps de ses fils" ("The Lictors Bringing to Brutus the Bodies of His Sons," 1789; Louvre); "Self-Portrait" (1790; Louvre); "Le Serment du Jeu de Paume" ("The Oath of the Tennis Court," 1791; Louvre); "Portrait of Devienne" (1792; Musée Royaux des Beaux-Arts de Belgique, Brussels); "Portrait de Mme Trudaine" ("Portrait of Mme Chalgrin," 1792; Louvre); "The Dead Marat" (1793; Musée Royaux des Beaux-Arts de Belgique); "Vue du jardin du Luxembourg à Paris" ("View of the Luxembourg Gardens," 1794; Louvre); "Joseph Bara" (1794; Musée Calvet, Avignon); "Self-Portrait" (1794; Louvre); "Les Sabines" ("The Intervention of the Sabine Women," 1794–99; Louvre); "Portrait de Mme Sériziat" (1795; Louvre); "Bonaparte Crossing Mount St. Bernard" (1800; Musée National de Versailles et des Trianons); "Portrait de Mme Récamier" (1800; Louvre); "Sacre de l'empereur Napoleon Ier et couronnement de l'impératrice Joséphine dans la cathédrale Notre-Dame de Paris, le 2 décembre 1804" ("Coronation," "Napoleon Crowning the Empress Josephine," 1805–07; Louvre); "Portrait du Pape Pie VII" (1805; Louvre); "Sappho and Phaon" (1809; Hermitage, Leningrad); "Napoleon Distributing the Eagles" (1810; Musée National de Versailles et des Trianons); "Napoleon in His Study" (1812; National Gallery of Art, Washington, D.C.); "Lionidas aux Thermopyles" (1814; Louvre); "Les Trois Dames dites de Gand" ("Three Women of Ghent," c. 1815; Louvre); "Cupid and Psyche" (1817; private collection, Paris); "Mars and Venus" (1824; Musée Royaux des Beaux-Arts de Belgique).

**BIBLIOGRAPHY.** E.J. DELECLUZE, *Louis David, son école et son temps* (1855), is a primary source of information by one of the artist's pupils. Standard modern biographies are D.L. DOWD, *Pageant-Master of the Republic: Jacques-Louis David and the French Revolution* (1948); and LOUIS HAUTECOEUR, *Louis David* (1954). General histories of style containing perceptive analyses of David's work are WALTER FRIEDLAENDER, *Von David bis Delacroix* (1930; Eng. trans., *David to Delacroix*, 1952); ROBERT ROSENBLUM, *Transformations in Late Eighteenth Century Art* (1967); and HUGH HONOUR, *Neoclassicism* (1968).

## Davis, Jefferson

Jefferson Davis, whose truly unique place in world history is that of the first and only president of the Confederate States of America (1861–65), served in the United States Congress as representative and senator from Mississippi and was outstandingly successful as secretary of war under Pres. Franklin Pierce. After the death of John C. Calhoun in 1850, Davis was generally recognized as the foremost Southerner in Washington, and until 1861 he was admired by both the North and the South as a "virtuous and resolute man."

By courtesy of The Library of Congress, Washington, D.C.

Davis.

Jefferson Davis was born in western Kentucky, in what is now Fairview, on June 3, 1808, the tenth and last child of Samuel Emory Davis, a Georgia-born planter of Welsh-ancestry who was also an American Revolutionary War veteran. When he was three his family settled on a plantation called Rosemont at Woodville, Mississippi. At seven he was sent for three years to a Dominican boys' school in Kentucky, and at 13 he entered Transylvania College. He later spent four years at the United States Military Academy, graduating in 1828.

Davis served as a lieutenant in the Wisconsin Territory and afterward in the Black Hawk War under the future president, then Col. Zachary Taylor, whose daughter Sarah Knox he married in 1835. According to a contemporary description, Davis in his mid-20s was "handsome, witty, sportful, and altogether captivating." He stood five feet eleven inches; his eyes were blue gray; his hair, gold.

In 1835 Davis resigned his commission and became a planter near Vicksburg, Mississippi, on land given him by his rich eldest brother, Joseph. Within three months his bride died of malarial fever. Grief-stricken, Davis stayed in virtual seclusion for seven years, creating a plantation out of a wilderness and reading prodigiously in constitutional law and world literature.

In 1845 Davis was elected to the United States Congress and, in the same year, married Varina Howell, a Natchez aristocrat who was 18 years his junior. He resigned his seat in Congress to serve in the war with Mexico and became a national hero for winning the Battle of Buena Vista with tactics that won plaudits even in the European press. After returning, severely wounded, he entered the Senate and shortly became chairman of the Military Affairs Committee. Pres. Franklin Pierce made him secretary of war in 1853. Davis enlarged the army, strengthened coastal defenses, and directed three surveys for railroads to the Pacific.

During the period of mounting intersectional strife, Davis spoke widely in both North and South, urging harmony between the sections. When South Carolina withdrew from the Union in December 1860, Davis still opposed secession, though he believed that the constitution gave a state the right to withdraw from the original com-

pact of states. He was among those who believed that the newly elected Pres. Abraham Lincoln would coerce the South and that the result would be disastrous.

Twelve days after Mississippi seceded, Davis made a moving farewell speech in the Senate and pleaded eloquently for peace between brothers. He had hardly got back to his Brierfield plantation when the Confederate convention in Montgomery, Alabama, chose him provisional president. Inaugurated on February 18, 1861, his first act was to send a peace commission to Washington to prevent an armed conflict. Lincoln refused to see his emissaries and made secret preparations to send armed ships to Charleston, South Carolina, to "relieve" Ft. Sumter. When Lincoln called for 75,000 volunteers, four more states, including Virginia, promptly seceded.

Davis faced a dire crisis. A president without precedent, he had to mold a brand-new nation in the midst of a war. With few resources except cotton and courage, with a white population only one-quarter that of the North, and with a small fraction of the North's industrial power, with inferior railroads, no powder mill, no navy, and no shipyard, the agricultural South was in no condition to stand an invasion. Davis dispatched agents to Europe to buy defensive arms and ammunition and sent representatives to try to secure recognition from England and France.

The Confederate capital was moved from Montgomery, Alabama, to Richmond, Virginia, in June 1861. On July 21 an invading Federal army was defeated at Manassas, Virginia, and retreated in disorder to the Potomac.

Davis had innumerable troubles, including a squabbling Congress, a dissident vice-president, two state governors who opposed the conscription law, and a few virulent newspapers, which, as a matter of principle, he refused to censor. Despite military defeats, unrelieved tensions, an appalling lack of manpower and armament, and skyrocketing inflation, Davis remained resolute, with Gen. Robert E. Lee in agreement by his side. In September 1864, a Northern writer wrote in *The Atlantic Monthly*:

Our interview with him explained why, with no money and no commerce, with nearly every one of their important cities in our hands, and with an army greatly inferior in numbers and equipment to ours, the Rebels have held out so long. It is because of the sagacity, energy, and indomitable will of Jefferson Davis.

When General Lee surrendered to the North without Davis' approval, Davis and his Cabinet moved south, hoping to reach the trans-Mississippi area and continue the struggle until better terms could be secured from the North. At dawn on May 10, 1865, Davis was captured near Irwinville, Georgia. Imprisoned in a damp casemate on the moat at Ft. Monroe, Virginia, Davis was put in leg-irons. Two guards paced up and down his cell night and day, and a lamp was kept continually burning by his bedside. Though outraged Northern public opinion brought about his removal to healthier quarters, Davis remained a prisoner under guard for two more years. Finally, in May 1867, he was released on bail and went to Canada to regain his shattered health. Several notable Northern lawyers offered their free services to defend him in a treason trial, which Davis longed for. The government, however, never forced the issue, many believe because it feared that such a trial might establish that the original Constitution gave the states a right to secede. The case was finally dropped on December 25, 1868.

Davis made five trips to Europe in an effort to regain his health and to find employment as an agent for some British firm. In the United States, he was offered the presidency of three southern colleges, but the salaries were insufficient to support his wife and his four remaining children. For a few years he served as president of an insurance company in Memphis, Tennessee. In 1877, he retired to Beauvoir, a small Gulf-side estate near Biloxi, Mississippi, which a patriotic admirer provided for him. There he wrote his *Rise and Fall of the Confederate Government*. Though pressed to enter the United States Senate, he declined to "ask for amnesty," for he felt he had done nothing wrong, and he never regained his citizenship. He remained the acknowledged leader of the South.

President of the Confederacy

Capture and imprisonment

Dedicated to the principles of democracy, Davis by nature was a benevolent aristocrat. Though diplomatic to a degree, he did not possess the pliancy of the professional politician. Austere in his dignity, he was really the warmest of men. Idolized by his family and relatives, he was said to be beloved even by onetime slaves. Through the fratricidal conflict he kept his old friends in the North. Many public men spoke and wrote unabashedly of their love for Jefferson Davis. Though he did not become a church member until he was past 50, when he joined the Episcopal Church, he was sustained throughout his life by a simple faith in the grace of God. Known from youth for his beautifully modulated voice, which profoundly influenced legislators and troops, in his old age he eloquently urged reconciliation with the North.

On December 6, 1889, at 81, Davis died in New Orleans of a complicated bronchial ailment. At his temporary interment he was accorded the greatest funeral the South has ever known. On May 31, 1893, he was buried permanently in Hollywood Cemetery in Richmond, Virginia.

**BIBLIOGRAPHY.** The first biography of Jefferson Davis was by one who knew and understood him, FRANK E. ALFRIEND, *The Life of Jefferson Davis* (1868). VARINA DAVIS, *Jefferson Davis, Ex-President of the Confederate States of America: A Memoir by His Wife*, 2 vol. (1890), is rich in family anecdotes as well as information about his public career. Two good short biographies are LONDON KNIGHT, *The Real Jefferson Davis* (1906); and MORRIS SCHAFF, *Jefferson Davis: His Life and Personality* (1922). A thoroughly sound appraisal is WILLIAM E. DODD, *Jefferson Davis* (1907). Of somewhat lesser value are H.G. ECKENRODE, *Jefferson Davis: President of the South* (1923); and ROBERT MCHROY, *Jefferson Davis: The Real and the Unreal*, 2 vol. (1937). In 1923, DUNBAR ROWLAND, after prodigious researches, published in ten volumes his invaluable compilation with notes: *Jefferson Davis, Constitutionalist: His Letters, Papers and Speeches*. R.W. PATRICK, *Jefferson Davis and His Cabinet* (1944), is sound throughout. HUDSON STRODE, *Jefferson Davis*, 4 vol. (1955-66), is the most up-to-date appraisal. The author had access to more than 1,000 hitherto unknown holograph letters owned by the Davis' grandson.

(Hu.S.)

## Davy, Sir Humphry

A brilliant English chemist and exponent of the scientific method, inventor of the miner's safety lamp, and discoverer of the elements sodium and potassium. Humphry Davy was born in Penzance, Cornwall, on December 17, 1778, the elder son of middle class parents with an estate nearby. He was educated at the grammar school in Penzance, and, in 1793, at Truro. In 1795, a year after the death of his father, Robert, he was apprenticed to a surgeon and apothecary, and he hoped eventually to qualify in medicine. An exuberant, affectionate, and popular lad, of quick wit and lively imagination, he was fond of composing verses, sketching, making fireworks, fishing, shooting, and collecting minerals. He loved to wander, one pocket filled with fishing tackle and the other with rock specimens; he never lost his intense love of nature and, particularly, of mountain and water scenery.

While still a youth, ingenuous and somewhat impetuous, Davy had plans for a volume of poems, but he began the serious study of science in 1797, and these visions "fled before the voice of truth." He was befriended by Davies Giddy (later Gilbert; president of the Royal Society, 1827-30), who offered him the use of his library in Tradea and took him to a chemistry laboratory that was well equipped for that day. There he formed strongly independent views on topics of the moment, such as the nature of heat, light, and electricity and the chemical and physical doctrines of A.-L. Lavoisier. In his small private laboratory, he prepared and inhaled nitrous oxide (laughing gas), in order to test a claim that it was the "principle of contagion," that is, caused diseases. On Gilbert's recommendation, he was appointed (1798) chemical superintendent of the Pneumatic Institution, founded at Clifton to inquire into the possible therapeutic uses of various gases. Davy attacked the problem with characteristic enthusiasm, evincing an outstanding talent for experimental inquiry. He investigated the composition of the oxides and acids of nitrogen, as well as ammonia, and persuaded

Davy, oil painting after Sir Thomas Lawrence (1769-1830). In the National Portrait Gallery, London.

his scientific and literary friends, including Samuel Taylor Coleridge, Robert Southey, and P.M. Roget, to report the effects of inhaling nitrous oxide. He nearly lost his own life inhaling water gas, a mixture of hydrogen and carbon monoxide sometimes used as fuel. The account of his work, published as *Researches, Chemical and Philosophical* (1800), immediately established his reputation, and he was invited to lecture at the newly founded Royal Institution of Great Britain in London, where he moved in 1801, with the promise of help from the British-American scientist Sir Benjamin Thompson (Count von Rumford), the British naturalist Sir Joseph Banks, and the English chemist and physicist Henry Cavendish in furthering his researches; e.g., on voltaic cells, early forms of electric batteries. His carefully prepared and rehearsed lectures rapidly became important social functions and added greatly to the prestige of science and the institution. In 1802 he became professor of chemistry. His duties included a special study of tanning: he found catechu, the extract of a tropical plant, as effective as and cheaper than the usual oak extracts, and his published account was long used as a tanner's guide. In 1803, he was admitted a fellow of the Royal Society and an honorary member of the Dublin Society and delivered the first of an annual series of lectures before the board of agriculture. This led to his *Elements of Agricultural Chemistry* (1813), the only systematic work available for many years. For his researches on voltaic cells, tanning, and mineral analysis, he received the Copley Medal in 1805. He was elected secretary of the Royal Society in 1807.

Davy early concluded that the production of electricity in simple electrolytic cells resulted from chemical action and that chemical combination occurred between substances of opposite charge. He therefore reasoned that electrolysis, the interactions of electric currents with chemical compounds, offered the most likely means of decomposing all substances to their elements. These views were explained in his Bakerian lecture of 1806, "On Some Chemical Agencies of Electricity," for which, despite the fact that England and France were at war, he received the Napoleon Prize from the Institut de France (1807). This work led directly to the isolation of sodium and potassium from their compounds (Bakerian lecture, 1807) and of the alkaline-earth metals from theirs (1808). He also discovered boron (by heating borax with potassium), hydrogen telluride, and hydrogen phosphide (phosphine). He showed the correct relation of chlorine to hydrochloric acid and the untenability of the earlier name (oxymuriatic acid) for chlorine: this negated Lavoisier's theory that all acids contained oxygen. He explained the bleaching action of chlorine (through its liberation of oxygen from water) and discovered two of its oxides (1811 and 1815), but his views on the nature of chlorine were disputed. He was not aware that chlorine is a chem-

Lectures  
at the  
Royal  
Institution

Contribu-  
tions to  
chemical  
theory

ical element, and experiments designed to reveal oxygen in chlorine failed.

In 1810 and 1811, he lectured to large audiences at Dublin (on agricultural chemistry, the elements of chemical philosophy, geology) and received £1,275 in fees, as well as the honorary degree of LL.D., from Trinity College. In 1812 he was knighted by the Prince Regent (April 8), delivered a farewell lecture to members of the Royal Institution (April 9), and married Jane Apreece, a wealthy widow well-known in social and literary circles in England and Scotland (April 11). He also published the first part of the *Elements of Chemical Philosophy*, which contained much of his own work; his plan was too ambitious, however, and nothing further appeared. Its completion, according to a Swedish chemist, J.J. Berzelius, would have "advanced the science of chemistry a full century."

His last important act at the Royal Institution, of which he remained honorary professor, was to interview the young Michael Faraday, later to become one of England's great scientists, who became laboratory assistant there in 1813 and accompanied the Davys on a European tour (1813–15). By permission of Napoleon, he travelled through France, meeting many prominent scientists, and was presented to the empress Marie Louise. With the aid of a small portable laboratory and of various institutions in France and Italy, he investigated the substance "X" (later called iodine), whose properties and similarity to chlorine he quickly discovered; further work on various compounds of iodine and chlorine was done before he reached Rome. He also analyzed many specimens of classical pigments and proved that diamond is a form of carbon.

Shortly after his return, he studied, for the Society for Preventing Accidents in Coal Mines, the conditions under which mixtures of firedamp and air explode. This led to the invention of the miner's safety lamp and to subsequent researches on flame, for which he received the Rumford medals (gold and silver) from the Royal Society and, from the northern mine owners, a service of plate (eventually sold to found the Davy Medal). After being created a baronet in 1818, he again went to Italy, inquiring into volcanic action and trying unsuccessfully to find a way of unrolling the papyri found at Herculaneum. In 1820 he became president of the Royal Society, a position he held until 1827. In 1823–25 he was associated with the politician and writer John Wilson Croker in founding the Athenaeum Club, of which he was an original trustee, and with the colonial governor Sir Thomas Stamford Raffles in founding the Zoological Society and in furthering the scheme for zoological gardens in Regent's Park, London (opened in 1828). During this period, he examined magnetic phenomena caused by electricity and electrochemical methods for preventing salt-water corrosion of copper sheathing on ships by means of iron and zinc plates. Though the protective principles were made clear, considerable fouling occurred, and the method's failure greatly vexed him. But he was, as he said, "burned out." His Bakerian lecture for 1826, "On the Relation of Electrical and Chemical Changes," contained his last known thoughts on electrochemistry and earned him the Royal Society's Royal Medal.

Davy's health was by then failing rapidly; in 1827 he departed for Europe and, in the summer, was forced to resign the presidency of the Royal Society, being succeeded by Davies Gilbert. Having to forgo business and field sports, Davy wrote *Salmonia: Or Days of Fly Fishing* (1828), a book on fishing (after the manner of Izaak Walton) that contained engravings from his own drawings. After a last, short visit to England, he returned to Italy, settling at Rome in February 1829—"a ruin amongst ruins." Though partly paralyzed through stroke, he spent his last months writing a series of dialogues, published posthumously as *Consolations in Travel, or the Last Days of a Philosopher* (1830). He suffered a further stroke and died in Geneva on May 29, 1829.

**BIBLIOGRAPHY.** J.A. PARLIS, *The Life of Sir Humphry Davy* (1831), for more than a century the standard work on Davy's life; J. DAVY, *Memoirs of the Life of Sir Humphry Davy*

(1836), a biographical work with emphasis on social conditions in early 19th-century Britain; T.E. THORPE, *Humphry Davy: Poet and Philosopher* (1896), primarily an analysis of the scientist's literary work; A. TRENEER, *The Mercurial Chemist: A Life of Sir Humphry Davy* (1963), chiefly concerned with the development of Davy as a scientist; SIR H. HARTLEY, *Humphry Davy* (1966), an extremely useful account of Davy's life that complements Paris' biography, but with changed emphases resulting from the passage of 135 years.

(F.W.G.)

## Dead Sea

The Dead Sea, actually not a sea at all but a landlocked lake between Israel and Jordan, is the lowest body of water on earth, at approximately 1,296 feet (395 metres) below sea level. Its northern half belongs to Jordan; its southern half is divided between Jordan and Israel. After the 1967 Arab–Israeli War, however, the Israeli Army remained in occupation of the entire west shore. The Dead Sea, Hebrew Yam ha-Melah ("Salt Sea"), Arabic al-Baḥr al-Mayyit ("Sea of Death") or Buhayrat Lūt ("Sea of Lot"), lies between the hills of Judaea to the west and the Transjordanic plateaus to the east. The Jordan River flows from the north into the Dead Sea, which is 50 miles long and attains a width of 11 miles. Its surface area is 405 square miles (1,049 square kilometres), and its maximum depth is 1,300 feet (400 metres). The peninsula of al-Lisān (the "tongue") divides the lake on its eastern side into two unequal basins; the northern basin measures 294 square miles and reaches a depth of 1,250 feet; the southern basin is smaller (99 square miles) and shallower (20 feet on the average). During biblical times and up to the 8th century AD, only the northern basin was inhabited, and the lake was 130 feet below its level of the early 1970s. It then rose to reach its highest level (34 to 36 feet above the 1970s level) around 1890 to 1900. In the 20th century its level has fallen; e.g., 12 to 13 feet between 1935 and 1963. (For an associated physical feature, see JORDAN RIVER; for further historical aspects, see NEAR EAST, ANCIENT; SYRIA AND PALESTINE, HISTORY OF.)

*Historical and religious associations.* The name Dead Sea can be traced back at least to the Hellenistic epoch (323 to 30 BC). It has been associated with biblical history since the time of Abraham (progenitor of the Hebrews) and the destruction of Sodom and Gomorrah (the two cities, according to the Old Testament, that were destroyed by fire from heaven because of their wickedness; the city sites are now submerged in the southern part of the Dead Sea). The desolate rivers of the lake offered refuge to David (king of Israel) and later to Herod I the Great, king of Judaea, who at the time of the siege of Jerusalem by the Parthians in 40 BC barricaded himself in a fortress at Masada. Masada was the scene of a three-year siege that culminated in the mass suicide of its Jewish Zealot defenders and the destruction of the fortress by the Romans in AD 73. The Jewish sect that left the biblical manuscripts known as the Dead Sea Scrolls, took shelter in caves to the northwest of the lake. (P.Sa.)

*Physiography and geology.* The Dead Sea occupies the lowest part of the 350-mile-long Jordan–Dead Sea trench, which is a northern extension of East Africa's rift valley. It is a sunken block confined by two parallel geological faults. The eastern fault, along the edge of the Moab Plateau, is more readily visible from the lake than is the western fault, which marks the gentler Judaeian upfold.

In the Cretaceous and Jurassic periods (from 65,000,000 to 190,000,000 years ago), before the creation of the trench, an extended Mediterranean Sea covered Syria and Palestine. During the Miocene Epoch (from 7,000,000 to 26,000,000 years ago), upheaval of the sea bed produced the upfolded structures of the Transjordan highlands and the central range of Palestine, causing the fractures that formed the Dead Sea depression. At that time, the Dead Sea was probably the same size as now. During the Pleistocene Epoch (from about 10,000 to 2,500,000 years ago) it rose to a height of about 700 feet above its modern level, forming a vast inland sea, stretching 200 miles from the 'Emeq Hula (Huleh Valley) area

Dead Sea

Public  
service

in the north to 40 miles beyond its present southern limits. The Dead Sea did not spill over into the Gulf of Aqaba because it was blocked by a 100-foot rise in the highest part of ha-'Arava (WBdi al-'Arabah), a seasonal watercourse that flows along an eastern extension of the central Negev highlands.

About 2,500,000 years ago or less, heavy stream flow into the lake deposited thick sediments of shale, clay, sandstone, rock salt, and gypsum. Later strata of clay, marl, soft chalk, and gypsum were dropped upon layers of sand and gravel. With the water evaporating faster than it was replenished by precipitation over the last 10,000 years, the lake gradually shrank to its present form. In so doing, it bared deposits that cover the Dead Sea Valley to a thickness of from one to four miles.

Al-Lisān and Mt. Sedom are formations that resulted from movements of the earth's crust. Mt. Sedom's (historically Mt. Sodom) steep cliffs rise up from the southwestern shore. Al-Lisān is formed of strata of clay, marl, soft chalk, and gypsum interbedded with sand and gravel. Both al-Lisān and beds made of similar material on the western side of the Dead Sea Valley dip to the east. It is assumed that the uplifting of Mt. Sedom and al-Lisān formed a southern escarpment for the Dead Sea. Later, the sea broke through the western half of this escarpment to flood what is now the shallow southern end of the Dead Sea. (S.B.Co.)

**Climate.** The Dead Sea is situated in a desert. Rainfall is scanty and irregular. Al-Lisān has about 2.5 inches (six centimetres) of rain a year and Sedom (near historical Sodom) only about two inches. Because of the very low altitude and the sheltered location, winter temperatures are mild and pleasant, averaging 63° F (17° C) at Sedom and 58° F (14° C) at the northern end in January; freezing temperatures are unheard-of. Summer, on the other hand, is very hot, averaging 93° F (34° C) in August at Sedom, with a maximum temperature of 124° F (51° C). Evaporation of the lake's waters—estimated at 55 inches (140 centimetres) a year—often creates a thick mist above the lake. On the rivers the atmospheric humidity varies from 45 percent in May to 62 percent in October. Local winds, which are relatively constant, blow off the lake in all directions in the morning and toward the centre of the lake at night.

**Hydrology.** The inflow from the Jordan River, whose high waters occur in winter and spring, averages 19,000,000,000 cubic feet per year. Four modest but perennial streams descend from Jordan on the east through deep gorges: WBdi al-'Uzaymi, WBdi Zarqā' Mā'in, Wadi al-Mawjib, and WBdi al-Hasā. Down numerous wadis (seasonal watercourses) streams flow spasmodically and briefly from the neighbouring heights as well as from the depression of ha-'Arava. Thermal sulfur springs also feed the rivers. Evaporation in summer and the intake of water, especially in winter and spring, cause seasonal variations in the level of the lake of from 12 to 24 inches.

**Salinity.** The waters of the Dead Sea are extremely saline, and the concentration of salt increases toward the bottom. In effect, two different masses of water exist in the lake. Down to a depth of 130 feet, the temperature varies from 66° to 98° F (19° to 37° C), the salinity is slightly less than 300 parts per thousand, and the water is particularly rich in sulfates and in bicarbonates. After a zone of transition located between 130 and 328 feet, the lower waters have a uniform temperature of about 72° F (22° C) and a higher degree of salinity (approximately 332 parts per thousand); they contain hydrogen sulfide and strong concentrations of magnesium, potassium, chlorine, and bromine. The deep waters are saturated with sodium chloride, which is precipitated to the bottom. The lower waters are fossilized (*i.e.*, being very salty and dense, they remain permanently on the bottom); the upper waters date from a few centuries after biblical times.

The water is saline and has a high density. Bathers float on it easily. The fresh water of the Jordan stays on the surface; in the spring its muddy colour can be traced across the lake as far as 30 miles south of the point where the river empties into the Dead Sea.

The extreme salinity excludes any animal or vegetable life except bacteria. Fish, which are carried in by the Jordan or by smaller streams when in flood, die instantly. Apart from the vegetation along the rivers, the only plant life is discontinuous and consists mainly of halophytes (plants that grow in salty or alkaline soil).

**Resources.** The Dead Sea constitutes an enormous salt reserve. In particular, salt deposits occur in the mountains of Sedom along the southwest shore. The salt has been exploited on a small scale since antiquity. In 1929 a potash factory was opened near the mouth of the Jordan at Kālīyā. Subsidiary installations were later built at Sedom. During the 1948-49 Arab-Israeli War, the factory at Kālīyā was destroyed. A factory was opened in Sedom in 1955 by the Dead Sea Works Ltd., producing potash, magnesium, and calcium chloride. Another plant produces bromine and other chemical products.

Because its situation has been on the contested Jordan-Israeli frontier, the Dead Sea has not been used to a great extent for navigation. The river shores are deserted, and permanent establishments are rare. Exceptions are the factory at Sedom, a few hotels and spas at Kālīyā, and, in the west, a kibbutz (an Israeli agricultural community) in the region of 'En Gedi. Small cultivated plots are also occasionally found on the lakeshore.

**Prospects.** The establishment of the kibbutz at 'En Gedi has demonstrated that the soil of the region can be cultivated if it is desalted and certain precautions taken. The savage grandeur of the site and the extreme mildness of the winters favour the development of tourism and the establishment of health resorts. Mineral exploitation is expected to increase, with the factory at Sedom—which has been enlarged—producing more potash as well as other chemical products. For its part, Jordan envisages the eventual exploitation of potash and its shipment by rail to the Gulf of Aqaba. (P.Sa.)

## Deak, Ferenc

The wise guidance of the Hungarian statesman Ferenc Deák during the negotiations that led to the establishment of the dual monarchy of Austria-Hungary in 1867 earned for him the sobriquet "the sage of the country." He was born on October 17, 1803, at Söjtör, in West Hungary, where his father owned substantial estates. After graduating in law, he entered the administrative service of his county of Zala, which in 1833 sent him to represent it in the Hungarian Diet, in place of his brother, who had resigned his mandate. At that Diet and those of 1839 and 1841, Deák made his mark as a leader of the growing reform movement for the political emancipation and internal regeneration of Hungary. Although re-elected in

layers

1843, he declined his mandate in protest against the scandalous manner in which the election had been conducted, but by this time his unimpeachable integrity, his unvarying good sense, and his encyclopaedic knowledge of the law had made him the most generally respected figure in his camp. In was he who, in 1847, drafted for the "national opposition" its program of reform for the Diet of 1847. Ill health prevented him from seeking election to that body, but when, in March 1848, the crown sanctioned the establishment of an independent Hungarian ministry, the new minister president, Count Lajos Batthyány, insisted on his taking the portfolio of justice.

Drafting  
of the  
April  
Laws,  
1848

As minister of justice, Deák was mainly responsible for the drafting of the reforming "April Laws" sanctioned by the Monarch on April 11. During the next months, he took part in most of the negotiations between the Hungarian government and its opponents. He ceased to be minister when Batthyány resigned on September 28, and he refused reappointment, but in January 1849 he was a member of another mission that sought to intervene with Alfred, Fürst zu Windischgratz, commander of the Austrian armies that had occupied Buda. Prevented from rejoining the Diet, he retired to his family estates, where he lived quietly for some years, unmolested by the Austrian authorities, who had decided that his activities had not been treasonable, but refusing all invitations to collaborate with a regime that he condemned as illegal. In 1854 he sold his estates—donating the bulk of the proceeds to his sister—and moved to Pest, taking up quarters in the Hotel Angol Királyné ("Queen of England"), which remained his home until his last illness.

In Pest, Deák became the oracle of all those who sought a practical and honourable way out of Hungary's political impasse. He maintained unwaveringly that the April Laws were legally valid, and that any regime that did not recognize this was itself illegal and was to be treated as such. His inflexible insistence on this principle in the Diet of 1861 caused the Monarch to dissolve the Diet and to reimpose an absolutist regime. But Deák also maintained that the laws were entirely compatible with the integrity of the monarchy and could be made the basis of a settlement satisfactory alike to the crown and the nation—further, that such a settlement was a vital interest of both parties. As his international difficulties gradually convinced Emperor Francis Joseph of the need of reconciliation with Hungary, Deák, in private conversations and public utterances, notably his famous "Easter Article" of April 16, 1865, put forward Hungary's conditions in terms that presently led to the "Compromise" (*Ausgleich*) of 1867, by which the dual monarchy was established.

Dehk was beyond question the father of the Compromise. The machinery that it embodied was not all of his devising, but it was his faith that a constitutionally satisfied Hungary and a strong monarchy could and must co-exist, that made the agreement possible; nor could agreement have been reached without his sagacity, resolution, and integrity, and the faith that these qualities inspired in both camps.

His adherents during the negotiations had styled themselves the "Deak Party," and they retained the name during the next years, when they formed the government. Deák, however, never looked on himself as a party man nor acted as a party leader. He left questions of party organization to the minister president of the day (he had again declined all ministerial office for himself), and while helping to complete the legislation deriving from the Compromise and defending it in Parliament when necessary, he thought and spoke only as guardian of the nation's interests, sometimes taking sides against the Deak Party itself on secondary issues. His interventions grew fewer as his health failed. His last public speech was made in November 1873. He died on the night of January 28–29, 1876.

The Compromise was the crowning achievement of Dehk's life work, but there was hardly a field of public life in which he did not exercise his influence and always on the side of humanity, reasoned reform, and good sense. He was a foremost fighter for the reform of the conditions of the Hungarian peasantry, setting the example on his own estates. Other fields in which he took keen interest included penal reform and interfaith relations. His moderation and sense of rectitude made him a regular choice when delicate questions had to be negotiated. He was a singularly modest man, avoiding all publicity and refusing all honours and offices, except in 1848, when his portfolio was pressed on him. His speeches were unemotional but carried conviction through their lucidity and their impeccable reasoning. His private life was entirely unpretentious. He never married.

**BIBLIOGRAPHY.** Deák destroyed all his papers before his death. His speeches and some of his letters were published (with an excellent introduction) by M. KONYI, *Deák Ferencz beszédei*, 6 vol. (1882–98). The only adequate biography of him is that by Z. FERENCZI, *Deák élete*, 3 vol. (1904).

(C.A.M.)

## Death

Death, often defined simplistically as the absence of life, has always been viewed with mystery, superstition, and fascination by man. That definition is faulty, for it presents a negative: death is not life. What it is, however, can only be conjectured. It is the supreme puzzle of poets, the concern only of humankind, and the inevitable fate of all things living. This article attempts to summarize briefly and primarily in human terms the significance of death, the signs of death, and the responses to death. Statistics on death rate and other actuarial aspects of death are found in the article POPULATION.

### THE CONCEPT OF DEATH

Man knows that things die. He witnesses their deaths and sometimes even executes them. These traumatic deaths are easy to understand. A complex living system is quickly and radically destroyed, and it ceases functioning. Natural death, the main subject of this article, is much more difficult to grasp.

Perhaps when man first discovered that certain slumbers were irreversible, he questioned the difference between that profound sleep and the daily slumbers he experienced. Manifest in ritual, symbol, and philosophical perspective are countless efforts throughout history to rationalize this final reality, the philosophical "why" of which still defies explanation, but the biomedical "how" of which is yielding to investigation.

**Biological death.** In the economy of nature one generation succeeds another, living its span, then yielding to the next. Those organisms survive that are best adapted to the prevailing environmental conditions. When those conditions change, the organisms least adapted may no

of Deák's  
achievements

The  
biological  
signifi-  
cance of  
death

longer be capable of surviving and may migrate to more favourable surroundings or may die. But nature is not shortsighted. Organisms are often very productive before their death and in some cases appear to die in a frenzy of reproductive activity, as when plants, grown on poor soil or during a period of drought, flower and fruit, seemingly in a last effort to provide successors to carry on the line. Among those offspring may be many new sorts potentially capable of surviving under a variety of conditions hostile to the parental organisms. In this manner nature clears the way for innovation. Death moves exhausted organisms to another phase of the cycle of nature and allows potentially more successful combinations of genes to supplant them. Death, therefore, is one of nature's ways of improving life; it provides a changing stage on which natural selection can try new experiments in evolution.

Human death. Primitive man lived in a world beset by death, to the degree that fertility and other life symbols often were the focal point of his worship. He did not deny death's reality but interpreted death as a transition from one phase of life to another. Burial, then, became a rite of passage similar to puberty, from one mode of participation in life to another. The contents of early tombs bear witness to this view of death among prehistoric cultures.

In later times, the afterlife was envisioned in more ethereal and spiritual terms, as exemplified in early religions. The Judeo-Christian tradition distinguishes itself from others in terms of its historicity, emphasizing the entrance of God's revelation as events (*e.g.*, Passover, crucifixion, resurrection) that at one and the same time establish temporality and future possibility.

Much serious misunderstanding exists relative to the biblical understanding of death and resurrection, upon which much of the view of Christianity is said to rest, and with which modern natural science ostensibly is said to be in conflict. The most obvious misunderstanding is in the notion of physical resuscitation of the body, or belief in the physical conquest of death. Theologians have sought to reinterpret the concept of resurrection in language that simultaneously affirms and denies the exclusiveness of flesh or spirit as the biblical understanding of resurrection. Saint Paul, in the earliest writings on resurrection, uses the Greek term *sōma* (body), which would correspond much more closely to modern terms such as identity, ego, or even gestalt than to either flesh or spirit. The biblical witness stresses, therefore, a real but not a physical conquest over death. Later, as theology developed historically and particularly as folk religion struggled to come to terms with the agnostic and Eastern religions, the emphasis often shifted to either a purely physical phase change or a total spiritualizing of the death event. Contemporary theology seems to be developing a more profound yet realistic conception of death as the foreclosure of life, a point at which God calls man into the future. Thereby hope becomes the alternative to unempirical despair.

#### THE BIOMEDICAL ASPECTS OF DEATH

There is little argument about the determination of the natural death of a subhuman animal. Its heart fails or it ceases breathing and is pronounced dead. A loved pet may, of course, be given extraordinary medical care to keep it alive, but not for long. It is only the human value of the level of life that dictates the criteria for determining the moment that life ends. For this reason a precise definition of human death is required.

Although death as a concept continues to elude the philosopher and the theologian, its physical signs are yielding to codification by the biologist and the physician. Except for immediate death by overwhelming injury or accident, higher organisms die gradually, from their cells and tissues to their organs and vital systems, ending finally in collapse of the entire body.

Among lower organisms, the commonly accepted criteria of life, which include such functions as respiration, transfer of vital substances (*e.g.*, water, ions, metabolites), and reduplication, are not manifest at all times. Viruses

outside of a host cell, for example, fail to show any of these criteria and can therefore be regarded as dormant proteinaceous particles containing ribonucleic acid (RNA) or deoxyribonucleic acid (DNA). When introduced into a host cell, the virus is capable of reproduction and renewed life. Under unfavourable environmental conditions, fungi and bacteria are able to assume an arrested stage wherein the criteria of the living cell are absent. These periods of dormancy offer no information about death as such; they simply suggest that the traditional criteria for determining death are not adequate.

Death of cells and tissues. Death at the cellular level is as obscure as death of the whole organism, but arbitrary signs have been generally agreed upon to judge the limits of life.

The cell appears to be the smallest functioning unit of all many-celled organisms. It is a membrane-bound mass of cytoplasm containing a membrane-bound nucleus. It has the ability to grow, assimilate, and undergo division, reproducing itself under normal conditions. The cell can, therefore, be regarded as a two-phase system. The nucleus, directing cell growth, development, and division, represents one phase. The cytoplasmic mass, representing the second phase, controls the absorptive, secretory, and transport functions of the cell. With the exception of nerve cells, all cells of the body are constantly being replaced, some more rapidly than others. Death of certain tissues or localized areas, from a variety of causes, may lead to death of the body as a whole. But the point at which the cell's self-regulatory, or homeostatic, mechanism undergoes irreversible damage, with subsequent death of the cell, continues to evade discovery. What is injurious to one cell may be of little or no consequence to another cell in the same organ or in other organs. Chloroform, for example, affects the more centrally positioned cells of the lobes of the liver, while phosphorus affects the peripheral cells of those lobes. Nerve cells show a selective vulnerability to brief periods of oxygen deprivation (hypoxia). The nerve cells of a part of the hippocampus (Sommer sector of the Ammon's horn) and the Purkinje cells of the cerebellum swell initially when deprived of oxygen but undergo irreversible shrinkage degeneration if hypoxia is prolonged. The nerve cells of the medulla or spinal cord will show little or no changes unless the hypoxic episode is very severe and sustained. The point at which the cell undergoes the irreversible change and begins to die is unknown.

In certain tissue culture preparations, injured cells lose protein from both the cytoplasm and nucleus. The degree of protein loss often appears to be proportional to the degree of injury. The mechanism controlling this loss remains unknown. The injured cells also exhibit a reduction in cell division but show little initial change in structure. These findings suggest that one pathway leading to cell death would be interference with protein synthesis, resulting in eventual protein deficiency.

At the electron microscopic level, initial cell damage is seen early, in contrast with light microscopic observation in which several hours may pass before structural changes can be recognized. The fine structures of the cell swell and become disrupted, leading to death via several processes. The cell, after swelling, may rupture, extruding its contents into the surrounding tissue (cytolysis). The nucleus alone may swell and rupture (karyolysis), fragment (karyorrhexis), or shrink (pyknosis).

Death of the entire organism. From the earliest days it was known that death of all parts of a multicellular organism did not occur simultaneously. Since the heart was considered to be the central organ, its cessation of function was used to mark the beginning of death for other vital organs. Historically, clinical death has been based on the absence of the heartbeat (and therefore the peripheral pulse) and the absence of breathing (with resultant bluing of the extremities, mouth, and lips). A lack of certain reflexes of the eye is also noted when death is further advanced, with absolute signs, such as algor, rigor, and livor mortis, finally becoming apparent. Algor mortis represents the fall of body temperature to that of the environment. Rigor mortis is the rigidity of skeletal

Death  
versus  
dormancy

The  
traditional  
definition  
of clinical  
death

muscles. Finally, livor mortis is the purple-red discoloration of parts of the body as a result of the settling of blood.

The essential components of most mammalian organisms include nervous, circulatory, respiratory, gastrointestinal, excretory, endocrine, and supportive organ systems. In general, parts of one or more of these systems may be injured for variable periods of time without causing irreversible changes. There is a hierarchy, however, *i.e.*, some of these systems are much more essential than others. Large portions of bone, for example, may be lost forever, and a kidney may cease functioning for several hours; but if organs such as the heart or the lungs stop working for only a few minutes, irreparable damage may occur. Cardiac or even respiratory standstill does not, however, automatically mean the onset of clinical death. Through the use of respirators, pacemakers, and other sophisticated apparatus life can be extended greatly. It is therefore possible to sustain the function of both the heart and the lungs even in the face of total loss of brain activity. Life of a sort may continue, but it is not life as the term is normally understood. It would appear that the definition of death should be more closely related to the determination of brain (cerebral) death, or at least to the condition of irreversible coma (see *The determination of death*, below).

#### THE PROSPECT OF DYING

The awareness of death is difficult to study objectively. The reality of death for the individual is not dwelt upon but is usually—and thankfully—of momentary concern. Although each person may be reminded of death frequently enough, the personal reality of it is often remote. Studies on patients with terminal illnesses who face death imminently have revealed much of interest and psychosocial value regarding the personal response to the approach of death.

The stages of **dying**. Terminally ill patients often go through a series of five stages in accepting the reality of their own finiteness and oncoming death. Most patients initially respond with temporary shock and a mental denial to the first awareness of a fatal, or potentially fatal, illness. Informed about the diagnosis, a patient may not be able to "hear" it and may go from hospital to hospital in an attempt to find someone who will reassure him that his condition is not serious. Eventually, he will face the reality, but often only for brief periods of time, to provide a last will and perhaps make arrangements for dependents.

Sooner or later, however, he will drop his denial and enter the second stage, the stage of anger, during which he complains about any service anyone renders and is difficult to deal with; thus he is often avoided, which only increases his rage. This is the stage at which he no longer says "no, not me" but instead "why me?" His anger is displaced to the nurse, the physician, the family members, in fact to all the people around him who represent life, energy, and functioning—the very qualities the patient is in the process of losing. The anger also includes God, who "is not listening" to the patient's pleas for help and good health. Patients who are not made to feel guilty or ungrateful during this difficult time—who are encouraged to express their anger—will soon proceed to the third stage, the stage of bargaining.

Bargaining  
for life

With the realization that he is to die soon, the patient offers a token in exchange for prolongation of life, usually in form of prayers: "if you give me one more year of life, I will become a good Christian," or "I will go to the Synagogue every day," or "I will make a pilgrimage. . . . This is the time of truce, psychologically speaking. The patient is not at peace, though he is more comfortable emotionally and believes that he has a certain extension of life, no matter how brief. He will say "yes, it is me, but . . .," and only when the bargaining time is up will he enter the fourth stage, one of depression. He now faces that certainty that it is truly his life that is coming to an end. He has responded already to the losses he has experienced (an organ perhaps, a job, being home with the family) and gradually descends

into deep and silent depression called the preparatory grief. This is the time when he faces the impending loss of everybody and everything he has ever loved. He begins to separate from the living and finally wants only the next of kin by his side. When he has finished all his business, has ventilated his anger and expressed his grief, he will be able to reach the final stage, of acceptance.

A patient who has no moral support and help during this crucial period of his life or who is isolated in a hospital or nursing home will often remain merely resigned to death. He is bitter, unhappy, and often complains, frequently to the very end of life. By contrast a patient in a true stage of acceptance is almost void of feelings; he may say simply: "My time comes very close and it is all right." If no extraordinary means are employed to prolong his life at this time, the patient is prepared to die with peace and dignity.

Three basic requirements are necessary to assist chronically ill patients to reach this final stage of equanimity: (1) excellent nursing care with adequate pain relief, (2) a flexible management in order to gratify simple needs (lifting severe restrictions against food, drink, and cigarettes), and (3) a hospital staff and a family who themselves accept the reality that this patient is dying and who can openly talk about it, if and when the patient expresses a desire to talk about it.

The patient's hope, originally associated with cure, treatment, or prolongation of life, is then diverted to hope for God's acceptance, for maintaining a sound mind to the end, or simply for the well-being of the children or family left behind.

A patient with a genuine faith (of whatever religion, including those that do not believe in an afterlife) dies with less turmoil than one who lacks belief. A person raised in a rural environment or in a non-death-denying society faces death with more equanimity than a person who grew up in an urban environment, where death occurs in hospitals, where children are "protected" from sharing this experience in a community, and where mortuaries attempt to disguise the reality of death with heavy makeup and other forms of denial.

Family members and attending staff also proceed through these five stages, when personally involved in the care of a dying patient. Parents of dying children and anyone who loses a loved one suddenly and unexpectedly may go through this adjustment after the death occurs—often in a prolonged manner and requiring more time to reach a true stage of acceptance. Widows and widowers often die soon after the death of the spouse, during their own grief process, which apparently renders them more vulnerable to death, often without reaching the stage of acceptance.

A patient is often able to convey his awareness of impending death and will communicate this knowledge to those around him if they are listening. He may use verbal or nonverbal communication. He may comment simply: "My time is very close now and I am ready." He may use symbolic language: "I had this fantasy of a train running rapidly down the hill toward the end of the tracks and I had an argument with the trainmaster. I demanded that he stop the train 1/10th of an inch short of the end." This patient's request for a tenth of an inch represented his bargaining for a very short extension of time to complete some unfinished business. When he accomplished his goal, he died very peacefully a few days later. It is not known exactly how patients realize the moment of impending death, but it is a fact that many of them are able to postpone death psychologically or to hasten it (without committing suicide) when they no longer desire to struggle for life.

Awareness  
of  
impending  
death

The fear of death. The fear of death is universal and consists of two parts. Consciously, people may be afraid of the pain and suffering associated with dying, the separation from the living, or simply the state of non-being or nothingness. Fear of the unknown is frequently mentioned as the most outstanding fear. Much more significant, however, is a fear heavily repressed and often revealed through dream material or, in the case of children through play or in drawings. The often-repressed

fear of death is seen as a fear of catastrophic destructive force bearing down and leaving the victim with a sense of utter helplessness, impotence, and rage. It is the fear of a traumatic annihilation that can be seen in children even before they have an empirical knowledge of death. Perhaps this fear originates in attitudes formed during the infantile stage that precede those attitudes imposed by culture or religion. Whether anxiety of death is an inherent property or not, it seems clear from clinical evidence that the early mother-child relationship is an essential source of the death complex in its catastrophic aspects.

Historically, a catastrophic death was also seen in the form of epidemics, which men attempted to conquer. Since death is still popularly conceived of not as a natural ending here on earth but simply as being killed, man learned to kill rather than be killed. He conquered diseases, added years to his life-span, learned to transplant organs, and is now on the verge of actually creating life. In his fear of death, however, man also created weapons of mass destruction (the atomic bomb, chemical and bacteriological warfare) and, for the first time in the history of mankind, created a concrete reality of what he associates with the fear of death—a catastrophic destructive force that hurls from nowhere and against which there is no defense. This is most likely a contributing factor to the extreme death denial of the current society.

Individuals as well as societies believe "death will happen to you and to you, but not to me." Thus man is able to function and plan for the future despite the fact that his own weapons of mass destruction may be used against him. With increased availability of such devices, the anxiety increases, the denial of his own finiteness becomes harder to maintain, and the psychological and financial expenses multiply in order to maintain a sense of security (distant wars, antiballistic missile systems). The "generation gap" may be based not upon father-son differences on matters of progress in science and technology, but on weapons of mass destruction and death denial.

#### THE DETERMINATION OF DEATH

**The medical aspects.** Is a patient alive who has only his vegetative functions and no consciousness of his being? Is not a patient virtually dead who has no brain activity whatsoever? And if he is in irreversible coma, can his organs be removed for transplantation into a conscious body? These questions and even more vexing ones (regarding possible future brain transplants) have raised a host of legal, ethical, moral, and religious considerations that require resolution.

A standardized diagnosis of clinical death is vitally needed. One such definition holds that death is equated with irreversible coma. In the late 1960s several medical conferences met with the primary purpose being to define irreversible coma as a new criterion for death. It was recommended by these groups that a comatose patient be regarded as dead if he has a permanently nonfunctioning brain, nonreceptive to external stimuli and showing no spontaneous respirations, muscular movements, or cephalic reflexes. An examination that reveals no brain waves (a flat electroencephalographic recording) lends further confirmatory support. Subsequent investigators have added the requirement of the presence of the so-called agonal angiogram, another examination that reveals a markedly diminished blood circulation. The Ad Hoc Committee of the Harvard Medical School further noted that the conditions previously described must be present for 24 hours. Despite the growing list of signs that must be present before a person can be judged dead, a danger still remains, as noted by the committees that seek to define death. In certain cases these criteria of death do not apply, as in patients who exhibit marked hypothermia (body temperatures below 90° F or 32.2° C) or marked central nervous system depression as a result of drug overdose. Furthermore, the notion of irreversibility is not easily agreed upon. Conditions thought to be irreversible in the 19th century are not invariably so today. Will an irreversible coma become reversible sometime in the future because of biomedical advances?

**The legal aspects.** Since individual tissues die at differ-

ent times, and even cerebral death has to be observed over a defined period of time, it is often difficult to speak of a moment of death. An exact time of death is sometimes necessary, however, in order to ensure that an organ is being removed from a donor who is clinically dead. Aside from these medical implications, an unambiguous moment of death is often important to establish for legal purposes. In the death of a couple, it may be necessary to know whose death occurred first. It may be important to know the exact time of death in civil and criminal liability as well as in inheritance of property, insurance, or survivor's benefits. Unfortunately, current legal concepts appear inconsistent with the revised definition of death, which is gaining wide medical acceptance.

With technological advances and the increasing demand for organs for use in transplants, it becomes mandatory that more than one physician verify the death of a potential donor; it is especially recommended that a verifying physician not be involved in any later effort to transplant organs or tissues from the deceased individual. This lessens the appearance of self-interest by the physicians involved and obviates later legal disputes. A declaration of death is generally made before disconnecting a life-sustaining machine such as a respirator, thus relieving physicians and hospitals of possible future legal entanglements. A physician—and a hospital—otherwise may become liable for suit and accused of euthanasia, or "mercy killing."

Laws concerned with gifts or bequests of organs are becoming more common. Many include the principle of the "separation of powers," meaning a complete separation of authority and responsibility between the physicians who care for the prospective donor and those who care for the potential recipient of the organs or tissues of the donor. Many localities with anatomical and tissue gift acts have specific forms and provide for procedures before death to make transplantation more effective. A patient can also bequeath his body to a medical school, but such provisions are not binding on the family.

A death is usually registered with a governmental department established for maintaining records of births and deaths. In many cases the body cannot be removed or disposed of until such certification of death has been made with the local authority.

In many countries a person legally can be presumed dead after an unexplained absence of seven years. Specific laws relating to the presumption of death and to the disposition of property of a person presumed dead, however, vary widely. Similarly, legal regulations concerned with the disposition of human remains are too diverse to consider here. In every age, however, and in every culture, such disposition complies with prevailing public interest, moral values, and cultural tradition.

Laws relating to organ donations upon death

The revised definition of death

## Death and Gift Taxes

Death and gift taxes are levies imposed on gratuitous transfers of property—that is, transfers made without compensation in either money or its equivalent. In this respect they differ from sales taxes imposed on transfers made in exchange for something of value and from property taxes and capital levies that are based on the mere ownership or possession of property and from income taxes levied on earnings.

**Death taxes.** Death taxes are of two kinds: those imposed on the property left at death are known as "estate" taxes and those imposed on the acquisition of property from a person who has died are known as "inheritance" taxes. The two kinds of death taxes are sometimes both used in the same system.

Inheritance taxes generally discriminate on the basis of relationship: there may, for example, be larger exemptions or lower rates for spouses and children. Inheritance taxes are in the nature of "accessions" taxes, a tax on receiving rather than giving. Even the United States estate tax, which is primarily a tax on the estate rather than its acquisition, takes some account of who benefits; anything left to a spouse is tax-free up to one half of the estate, and anything left to charity is entirely exempt.

**Gift taxes.** Levies on gratuitous transfers between living persons are known as "gift" taxes. These may be integrated with death taxes to make a single structure of taxation applicable to gratuitous transfers. Death and gift taxes are closely related in France, Germany, and Sweden. A complete "accessions" tax would cumulatively combine both inheritance and gifts received. Japan had such a tax in the 1950–53 period. Italy and Colombia have partial accessions taxes.

**Origin and history.** Death in most countries is considered to be a "taxable event," one that prompts the imposition of a levy by the state. Such imposts at death predate general income and sales taxes. Even the Romans imposed a tax on inheritances. Though a death tax was levied in the United Kingdom in 1694, the present structure dates back to 1779–80, and the prevailing estate duty was introduced in 1894. Death taxes are widely employed in both developed and developing countries.

In the United States there were several short-lived death taxes before the present tax was introduced at the federal level in 1916. Many of the states already had death taxes. In an attempt to reduce the lack of uniformity in the inheritance taxes of the various states and to protect them from federal incursion, the federal government of the United States gives credit for state inheritance taxes against the estate tax up to a certain point. But the lack of uniformity persists. A comparison of death duties in Great Britain, Canada, Australia, and the United States discloses some interesting differences in federal–state relationships. In all these nations, except Great Britain, death taxes are imposed by subnational units (state or provincial governments), as well as by the central government. Canada and the United States have a generally higher federal tax and allow substantial credits for the subnational taxes. In Australia, however, the state taxes are significant in themselves.

**The controversy about death and gift taxes.** *Arguments for.* Death taxes can be supported on both legal and social grounds. Legally, the tax may be considered a fee for the privilege of passing property on after death. A traditional argument is that the state is permitting and facilitating the transfer of property. Even where the property is transferred by operation of law—as in an insurance policy or a joint bank account with survivorship rights—it is the legal system and its enforcement power that makes the transfer possible. Socially, the tax tends to reduce inequalities in the distribution of wealth and provides an opportunity to break up large estates. The heavy death taxation in England has had such a result. Substantial economic benefits may derive from the resulting reduction in the concentration of economic power.

*Arguments against.* The main argument against large death taxes rests on their possible negative effects on incentives. In this regard, the argument is that the person

building up an estate will be less inclined to do so if he knows a large part of it will never go to his heirs. An economic limit to the usefulness of death taxes may be said to exist when the accumulation of wealth is discouraged to the point of hampering the growth of the economy. For the heirs, hardship may also result if forced sales must be made to obtain liquid resources with which to pay taxes. In the case of a family business there is a danger that the business will have to be sold quickly below its actual value or that strangers will be brought in to supply funds, with a resulting loss of family control.

The negative arguments may be countered to some degree. It may be that a person who seeks to provide a certain estate for his heirs will have an incentive to work harder, since he will want to leave a large enough estate to absorb the taxes. The problem of cash requirements may be taken care of in various ways, such as provisions allowing the tax to be paid over a period of years or allowing various insurance arrangements that make liquidation of a business unnecessary.

**Economic importance.** Death and gift taxes are of greater symbolic than practical significance. Of all taxes, they are among the least productive of revenue in both absolute and percentage terms, and their relative importance has dwindled with the growth of income, sales, and excise taxes. The tax-rate structure alone is misleading, since the many deductions, exemptions, exclusions, and allowances generally reduce the yield drastically. Moreover, most people have no taxable estate whatever and are never subject to the gift tax. The exact yield varies from year to year, but some generalizations may be made. In the United States the federal estate tax generally has produced less than 2 percent of federal tax revenues. In the Irish Republic the percentage is about the same. In Canada the figure has been closer to 1 percent, with the federal government paying 75 percent of the federal estate tax revenue to those provinces that do not levy succession duties. The Australian national estate duty has also produced less than 1 percent of the total national revenue. A similarly small percentage has held in Sweden. Even in Great Britain, where death duties are high, the yield has been only about 3 percent of total tax revenues.

A comparison of the actual burden of the tax on the taxpayer is difficult because of the innumerable differences in provisions, but it has been attempted for Great Britain, Canada, Australia, and the United States. Where there is no applicable family relationship, Australian rates on the small estates are heavier than on the large ones. In the middle ranges, Australian and British rates are loosely comparable, as are those of Canada and the United States; but the former two are roughly double those of the latter. In the higher ranges, Great Britain and the United States both take more than Australia and Canada, the key difference being that the top rates are higher and are reached sooner in Great Britain than in the United States. These differences are accentuated when closeness of family relationship is taken into account. In general, it may be said that Great Britain's tax is substantially heavier than the others in the middle and higher ranges. The maximum rates that have prevailed in several countries in recent years are suggestive of the burden at the top (figures are percent): United States, 77; Canada, 54; Netherlands, 54; Germany, 60; Japan, 70; Belgium, 72.6. Italy and the United Kingdom have had a maximum effective rate of 80 percent, and Austria and France have had a maximum effective rate of 60 percent. These are variously "marginal," "bracket," or "overall" rates.

**Economic effects.** The economic effects of death taxes are, in a word, unimportant by the usual criteria. There is little reason to believe that a person will alter his consumption patterns because of the prospect of death taxes. Those who might consume more quickly to avoid leaving an estate and paying an estate tax are likely to be offset by those who consume less and save more in order to leave enough to their heirs after taxes. The main effect of death and gift taxes is to encourage estate planning and the employment of legal devices to minimize taxes rather than to change behaviour.

The person receiving property after estate taxes will

Discrimination on basis of relationship

Legal and social basis

Burden on the taxpayer

have less to consume, but the inheritance will generally be of a windfall nature and may have few enduring effects on the heir's lifetime pattern of consumption. In any case, the effect on consumption in the economy as a whole is trivial. Death and gift taxes do tend to achieve a more equal distribution of wealth, but the magnitude of the effect is small in most countries.

Effect on  
business  
structure  
and  
practices

A significant effect that is often overlooked is that on business structure and practices. This stems from two problems that exist in death taxation. One of these is that of setting a valuation on the estate for tax purposes. Another is the problem of liquidity; *i.e.*, getting the cash with which to pay the taxes.

The valuation of an estate suffers from the same problems as the valuation of any property. There may not be an active market in the various assets involved. The assets may be unique in some sense. There may be a problem of "blockage": a large block of stock may actually be worth more than the apparent market value of the individual shares. A family-owned business may be particularly difficult to evaluate. Appraisers may be called in to set a value on the property, but their evaluations may vary widely. These problems introduce an element of uncertainty into estate planning inasmuch as an individual cannot foresee what value will be placed on various assets he might be holding, especially if they are assets for which there is no active market. It is therefore difficult for him to make adequate preparation for the taxes that may have to be paid. To some extent it also complicates the problem of deciding how much to leave to whom.

Even if there were certainty in the valuation of an estate, there remains the problem of paying the taxes. The gravity of this problem depends partly on the nature of the assets in the estate. If they are shares of stock that are traded on a national stock exchange there is relatively little difficulty. If a family-owned business or a major portion of any business is involved, serious losses, including a change of control of the business, may result from attempts to liquidate the ownership interest in order to obtain cash. Thus the problem of liquidity presents a major consideration in estate planning.

In spite of all efforts to mitigate the impact of estate taxes, there is a strong temptation for an owner to convert his assets into a highly marketable, easily evaluated form while he is alive. This may require their sale to another company, either for cash or for nationally traded securities. The result is a merger or absorption of the smaller company and an increase in the concentration of economic power.

**Avoidance of death taxes.** On the books, death taxes look highly progressive: the rates of taxation approach 100 percent in the highest brackets in some countries. In fact, however, the opportunities for avoidance are so great that death taxes often have little impact on the enjoyment and use of property passing from one generation to the next.

It is significant that most people do not incur any death or gift taxes at all. But those who are required to pay are liable to pay substantial taxes if advance plans are not made to prevent it. As a result the avoidance of death taxes is a major preoccupation of lawyers and accountants. Refined economic calculation and modern systems analysis techniques may be employed in estate and gift tax planning to minimize the total tax by selecting the optimal estate or will. Efforts at avoidance are highly successful and present a serious problem of equity.

Techniques  
used to  
avoid the  
tax

**Family bequests.** The best way to reduce death and gift taxes generally is to leave property to a spouse. Under the prevailing United States laws, all that goes to a husband or wife, up to half the total estate, is tax-free; and half of any lifetime gift to a spouse is similarly tax-free. Under inheritance taxes, bequests to a spouse and children are also given preferential treatment. In Canada, under a bill passed in 1969, all gifts and bequests to a spouse are exempt.

**Trusts and life estates.** A common technique of avoidance is to skip a generation. Rather than leave everything to one's wife, the device is to leave the property to children, with the wife to enjoy the income from the property

during her lifetime. The total tax is then generally less than if the estate passed entirely to the wife and from her to the children. Probate of a will is also avoided, since the property passes by virtue of the trust deed—though avoidance of probate does not in itself provide any assurance of avoidance of death taxes.

A wife may have title to the property for life—*i.e.*, a "life estate," which gives her the right to use and enjoy the property for her lifetime. A trust deed is simply a document that provides for putting the property in the hands of trusted persons, such as a bank, a friend, or a lawyer, with instructions to use the property to benefit certain persons (the "beneficiaries"). The trust device is peculiarly an Anglo-American instrument, but comparable devices have arisen under other systems of law.

**Gifts between living persons.** An obvious way to avoid death taxes is to give one's property away before death. Precisely for this reason, death taxes sometimes take account of "gifts made in contemplation of death" in totaling up the estate for death-tax purposes. Gifts made during life may also be subject to tax at the time they are made. In the United States the gift tax has large exemptions and carries lower rates than the estate tax. Each person has a federal lifetime exemption of \$30,000 and can give \$3,000 tax-free each year to as many individuals as he wishes. If a spouse joins in the gifts, the annual exemptions are effectively doubled. Those gifts that are taxable are subject to rates that are three-quarters of the estate-tax rates. A few other cases may be noted. The United Kingdom has no gift tax. Canada's gift tax **was** first introduced in 1935, prior to the federal succession duties of 1941, primarily to preserve the progressivity of income taxes. The Swedish gift and succession taxes both impose their liability on the recipient, and at the same rates. The German tax generally treats all gratuitous transfers alike. France imposes a death and gift duty on the value received by the beneficiary.

**Charitable and other contributions.** Gifts to charitable, religious, and educational institutions are generally exempt from death and gift taxes. This fact is sometimes used, not only to reduce taxes but to ensure maintenance of family control of a business that would pass to strangers if a large portion of the stock must be sold to pay death taxes. Since charitable contributions are exempt from death and gift taxes, a gift of stock to a charitable foundation can reduce or eliminate the gift or estate tax. The donated stock may be a nonvoting variety, leaving control in the hands of the owners of a small amount of voting stock. The controlling trustees of the foundation may even be members of the family or their agents, hence the family has lost little if anything by this manoeuvre. It has presumably retained **sufficient** assets after taxes to yield the income it actually needs; for the rest, it has retained family control of the assets and has ensured perpetuation of family control through trustees. It has lost some of the incidents of ownership, but none that really affect its current standard of living or its economic power.

**Change of residence.** An effective way to avoid death taxes is to move to a "tax haven," a jurisdiction that has no death taxes. Nevada is the only state in the United States without death taxes; but a resident of Nevada is still subject to federal death taxes. There is always a problem of establishing residence, however, and in the case of a wealthy decedent several jurisdictions are likely to claim a tax.

**Present trends.** Despite their relative unimportance for revenue, death and gift taxes are under constant review for improvement, the main purpose being to achieve equity. The assumption is that glaring inequity jeopardizes the tax system as a whole.

**Modification of the estate tax.** The death levy has long been regarded as a unique type of impost, to be studied apart from the rest of the tax structure. The current trend is to consider this levy in relation to other taxes, especially those imposed on gifts, income, and capital gains. In this view, any tax that is imposed at death is only one of a series of taxes imposed on the decedent during his life and later to be imposed on the inheritor with respect to the same property.

Solving  
problems  
of  
valuation  
and  
liquidity

The problems mentioned above (uncertainty of valuation and need for liquid resources) have led to numerous legal provisions and private arrangements that may have significant economic consequences. The problem of liquidity can be solved by giving an estate a period of time, say ten years, to pay the taxes. Even long-term loans, with an appropriate interest charge, may be desirable. As for valuation, various expedients are possible. The estate may be given some choice in the date of valuation, thereby avoiding a particularly unfavourable market condition. There could be an arrangement whereby the estate-tax authorities commit themselves to particular property valuations on a year to year basis, while the owner is living. In partnerships, fixed prices of ownership interests may be set by agreement. These prices are persuasive, even if not necessarily binding on the authorities. Life insurance can be provided to generate funds to buy out the interests of the decedent. This will give his estate enough cash for taxes and prevent ownership interest from passing into the hands of a stranger. A possible modification is to acknowledge some of these private arrangements more fully in the administration of death taxes.

**Proposals to reduce avoidance.** The first step in reducing avoidance is a fuller integration of death and gift taxes. The present requirement in the United States is that only "gifts made in contemplation of death" be included in the estate for tax purposes. This involves knowing what was in the mind of a dead person for a specified period before death. Complete integration of death and gift taxation, whether or not further integrated with income taxation, would eliminate such areas of dispute and litigation. A single schedule applying to all gifts, whether during life or after death, would cover the problem. A plan of this sort was enacted in Canada in 1969. Some other instances of integration may be noted. In Italy all gifts that are made after a certain date are included in the estate. Taxes that have been paid on the gifts are credited against the estate tax, the amounts paid as gift tax being cumulative. In Colombia, the taxable estate includes all gifts, but no credit is allowed for any gift tax that has been paid. Germany has a tax on the recipient of gifts and inheritances that allows for a limited degree of cumulation.

It is also necessary to limit the use of the trust device and of gifts to controlled charitable foundations. The latter abuse may be curtailed by stricter surveillance of foundations, including a requirement that the donor retain no control whatever, directly or indirectly. The trust instrument could still be used as a legal method of separating legal ownership and control from a beneficiary. For tax purposes, however, the treatment might be the same as if no trust existed. There would then be a tax both at the death of the original decedent and at the death of the person who enjoys the income for life.

**Integration with other taxes.** A serious problem in death taxation is the treatment of capital gains at death. In the United States, gains on appreciated property that remains in an estate are forever free of the capital gains tax. The estate does not pay a capital gains tax if it sells the property at the same value it is given for estate tax purposes. Anyone who inherits the property takes it at the appreciated basis for all future capital gains taxes. If the decedent had sold the appreciated property just before he died, he would have had to pay a tax on the gain; the proceeds would then have appeared in his estate and been subject to the estate tax. This appears to represent a pointless inequality of treatment, despite the fact that the full value of the appreciated property will be subject to the estate tax. The large exemptions and deductions in the estate tax may still leave the appreciation free of tax, and the capital-gains-tax rates are very different from the estate-tax rates. Countries that do not have a capital gains tax are not faced with this problem.

One argument against taxing capital gains at death is essentially the one that is used against taxing any capital gains; such gains result from price fluctuations and not from the production of income. Another argument against doing so is that an even greater cash burden would be imposed at death. The introduction of a capital

gains tax in Great Britain has created new problems for the family company because it has to make provision for postponed tax liabilities in addition to the provision for death duties. A solution to this lies in making allowance for the capital gains tax liability in computing the amount of death tax due.

The gift tax provisions solve a similar problem by requiring the person who receives the gift to take the donor's initial value as his own. Any appreciation that occurs from the time the original donor acquired the property is subject to the capital gains tax when the property is first sold. A similar idea has been proposed as an alternative to the taxation of capital gains at death. This proposal, currently under discussion in the United States, would impose a capital gains tax on the sale (rather than the acquisition) of inherited property.

An ultimate modification would be the complete integration of income, capital gains, death, and gift taxes. The accretion in one's economic power (*i.e.*, the increase in the value of one's property, including income) would be evaluated and taxed each year. In the extreme form of this plan, the year of death would just be another year, and the disposition of property would itself have no tax consequences or benefits. But the practical problems of valuation throw doubt on the wisdom of any such approach. A recent proposal of the Canadian government would require an evaluation of property every five years for purposes of a capital gains tax.

**Exemptions and rate structure.** The existing exemptions and rate structure are an expression of social policy toward (1) institutions that are to be favoured, including marriage, schools, charities, and churches, and (2) redistribution of wealth and income. Exemptions or low rates on gifts and bequests to spouse and children represent a social policy in favour of the family unit. This notion is carried to its limit in a proposal recently considered in Canada that all transfers among members of a family unit be tax-free; only when a person leaves the family unit, as by marriage or setting up housekeeping on his or her own, would a tax be assessed. All gifts and bequests would be treated as increasing the economic power of the recipient. Taxation would thus be rationalized in the same way as income taxes. Existing estate and gift taxes would be repealed and all gifts would be brought into the recipient's comprehensive income tax base and taxed at full progressive rates in the same way as wages and other income. All gifts and bequests within the "family tax unit"—husband, wife, and dependent children—would be exempt. Essentially the tax would be imposed on gifts and bequests into and out of the family unit. Provisions for averaging would prevent an excessive tax in a particular year.

Canada in 1969 actually exempted from tax the transfer of property by gift or inheritance between a husband and his wife but raised taxes significantly on transfers to children and others.

Provisions, in tax laws that favour educational, religious, and charitable organizations reflect a desire to encourage private support of these institutions. The social cost of this policy is sometimes very high, and in some instances it is possible for a taxpayer to make a tax-free profit through the donation of appreciated property.

Tax exemptions and rate structure also serve as an instrument for redistributing wealth and income. But, as in the case of the income tax, the methods of avoidance must be considered before any conclusion is drawn concerning the actual impact of death and gift taxes on the distribution of wealth and income.

**BIBLIOGRAPHY.** Death and gift taxes in various countries are covered in the HARVARD LAW SCHOOL, INTERNATIONAL PROGRAM IN TAXATION, "World Tax Series" (Australia, 1958; Brazil, 1957; Colombia, 1964; France, 1966; Federal Republic of Germany, 1969; India, 1960; Italy, 1964; Mexico, 1957; Sweden, 1959; United Kingdom, 1957; United States, 1963). A comparison of practices in the United Kingdom, Canada, and Australia is G.S.A. WHEATCROFT (ed.), *Estate and Gift Taxation: A Comparative Study* (1965). The subject has been much discussed in Canada; particularly useful are vol. 3 of the *Report of the Royal Commission on Taxation* (1966); and *Studies of the Royal Commission on Taxation*, especially

Treatment  
of capital  
gains at  
death

no. 11, *Death Taxes*, by JOHN G. SMITH, D.B. FIELDS, and E.J. MOCKLER (1967); and no. 13, *Gift Tax*, by E.J. MOCKLER and D.B. FIELDS (1966).

## Death Rites and Customs

Man is the only creature known to bury his dead. The fact is of fundamental significance. For the practice was not originally motivated by hygienic considerations but by ideas entertained by primitive peoples concerning human nature and destiny. This conclusion is clearly evident from the fact that the disposal of the dead from the earliest times was of a ritual kind. The Paleolithic peoples not only buried their dead but they provided them with food and other equipment, thereby implying a belief that the dead still needed such things in the grave. In such provision for the dead, Paleolithic man had been anticipated, inevitably in a cruder manner, by his predecessor, the so-called Neanderthal or Mousterian man, so that this very significant practice can be traced back to an even greater antiquity, possibly to about 50,000 BC.

The ritual burial of the dead, which is thus attested from the very dawn of human culture and which has been practiced in most parts of the world, stems from an instinctive inability or refusal on the part of man to accept death as the definitive end of human life. Despite the horrifying evidence of the physical decomposition caused by death, the belief has persisted that something of the individual person continues to survive the experience of dying. In contrast, the idea of personal extinction through death is a sophisticated concept that was unknown until the 6th century BC, when it appeared in the metaphysical thought of Indian Buddhism; it did not find expression in the ancient Mediterranean world before its exposition by the Greek philosopher Epicurus (341–270 BC).

The belief that human beings survive death in some form has profoundly influenced the thoughts, emotions, and actions of mankind. The belief occurs in all religions, past and present, and decisively conditions their evaluations of man and his place in the universe. Mortuary rituals and funerary customs reflect these evaluations; they represent also the practical measures taken to assist the dead to achieve their destiny and sometimes to save the living from the dreaded molestation of those whom death had transformed into a different state of being.

### RELEVANT CONCEPTS AND DOCTRINES

**Life and death.** The evidence of Paleolithic burials shows that already, in that remote age, various ideas were held about death and the state of the dead. The provision of food, ornaments, and tools in the graves implies a general belief that the dead continued to exist, with the same needs as in this life. Other customs, however, indicate the currency of a variety of notions about the post-mortem existence, particularly about the potentialities and destiny of the dead. Thus, the presence of red ochre in some burials suggests the practice of contagious magic: the corpse had possibly been stained with the colour of blood in order to revitalize it. The fact that, in Paleolithic burials, the skeleton has often been found lying on its side, in a crouched position, has been interpreted by some prehistorians as evidence of belief in rebirth, in that the posture of the corpse imitated the position of the child in the womb. In some crouched burials, however, there is reason for suspecting a more sinister motive; for the limbs are sometimes so tightly flexed that the bodies must have been bound in that position before rigor mortis set in. Such treatment of the corpse was doubtless prompted by fear of the dead, for similar customs have been found

among later peoples. Preventive action of this kind has a further significance, for it implies a belief that the dead might be malevolent and had power to harm the living.

That death was sometimes regarded as transforming those who experienced it into a state of being balefully different from that of those living in this world is evident in later mortuary rites and customs. Indeed, the proper performance of funerary rites was deemed essential by many peoples, to enable the dead to depart to the place and condition to which they properly belonged. Failure to expedite their departure could have dangerous consequences. Many ancient Mesopotamian divinatory texts reveal a belief that disease and other misfortunes could be caused by dead persons deprived of proper burial. The fate of the unburied dead finds expression in Greek and Roman literature. The idea that the dead had to cross some barrier that divided the land of the living from that of the dead also occurs in many religions: the Greeks and Romans believed that the dead were ferried across an infernal river, the Acheron or Styx, by a demonic boatman called Charon, for whose payment a coin was placed in the mouth of the deceased; in Zoroastrianism, the dead cross the Bridge of the Requirer (Činvato Paratu); bridges figure also in Muslim and Scandinavian eschatologies (speculations concerning the end of the world and the afterlife)—the Širāt bridge and the bridge over the Gjoll River (Gjallarbrú)—and Christian folklore knew of a Brig o' Dread, or Brig o' Death.

It is significant that in few religions has death been regarded as a natural event. Generally, it has been viewed as resulting from the attack of some demonic power or death god: in Etruscan sepulchral art a fearsome being called Charun strikes the deathblow, and medieval Christian art depicted the skeletal figure of Death with a dart. In many mythologies death is represented as resulting from some primordial mischance. According to Christian theology, death entered the world through the original sin committed by Adam and Eve, the progenitors of mankind.

**Human substance and nature.** The conception of death in most religions is closely related to the particular view held about the constitution of human nature. Two major traditions of interpretation have provided the basic assumptions of religious eschatologies and have often found expression in mortuary rituals and funerary practice. The more primitive of these interpretations has been based on an integralistic evaluation of human nature. Thus, the individual person has been conceived as a psychophysical organism, of which both the material and nonmaterial constituents are all essential for a properly integrated personal existence. From such an evaluation it has followed that death is the fatal shattering of personal existence. Although some constituent element of the living person has been deemed to survive this disintegration, it has not been regarded as conserving the essential self or personality. The consequences of this estimate of human nature can be seen in the eschatologies of many religions. The ancient Mesopotamians, Hebrews, and Greeks, for example, thought that after death only a shadowy wraith descended to the realm of the dead, where it existed miserably in dust and darkness. Such a conception of man, in turn, has meant that, where the possibility of an effective afterlife has been envisaged, as in ancient Egyptian religion, Judaism, Zoroastrianism, Christianity, and Islām, the idea of a reconstitution or resurrection of the body has also been involved; for it has been deemed essential to restore the psychophysical complex of personality. In Egypt, most notably, provision was made for the reconstitution in an elaborate mortuary ritual, which included the mummification of the corpse to preserve it from disintegration.

The alternative view of human nature may be termed dualistic. It conceives of the individual person as comprising an inner essential self or soul, which is nonmaterial, and a physical body. In many religions based on this view of human nature, the soul is regarded as being essentially immortal and as existing before the body was formed. Its incarnation in the body is interpreted as a penalty incurred for some primordial sin or error. At

Early  
practices

Two  
dominant  
traditions  
concerning  
human  
nature

death, the soul leaves the body, and its subsequent fate is determined by the manner in which it has fulfilled what the particular religion concerned has prescribed for the achievement of salvation. This view of human nature and destiny finds most notable expression in Hinduism and, in a subtly qualified sense, in Buddhism; it was also taught in such mystical cults and philosophies of the Greco-Roman world as Orphism (an ancient Greek mystical movement with a significant emphasis on death), Gnosticism (an early system of thought that viewed spirit as good and matter as evil), Hermeticism (a Hellenistic esoteric, occultic movement), and Manichaeism (a system of thought founded by Mani in ancient Iran).

**Forms of survival.** The conception of human nature held in any religion has, accordingly, determined the manner or mode in which postmortem survival has been envisaged. Where the body has been regarded as an essential constituent of personal existence, belief in a significant afterlife has inevitably entailed the idea of the reconstitution of the decomposed corpse and its resurrection to life. In turn, a dualistic conception of human nature, which regards the soul as intrinsically nonmaterial and immortal, envisages postmortem life in terms of the disembodied existence of the soul. This dualistic conception, in many religions, has also involved the idea of rebirth or reincarnation. In Hinduism, Buddhism, and Orphism this idea has inspired a cyclical view of the time process and produced esoteric explanations of how the soul becomes reborn into a physical body, whether human or animal.

**The ultimate destiny of the dead.** Belief in postmortem survival has been productive also of a variety of images concerning the destiny of the dead. This imagery is closely related to the conception of man that is held in each religion. Thus, the magical resuscitation of the dead in ancient Egypt was designed to enable them to live forever in their well-furnished tombs; according to Christian and Islamic belief, God will ultimately raise the dead with their physical bodies and assess their merits for eternal bliss in heaven or everlasting torment in hell; the Buddhist concept of Nirvana (Enlightenment) is achieved only when the individual has eradicated all desire for existence in the empirical world.

#### PATTERNS OF MYTH AND SYMBOL

**Geography of the afterlife.** Inhumation naturally prompted the idea that the dead lived beneath the ground. The mortuary cults of many peoples indicate that the dead were imagined as actually residing in their tombs and able to receive the offerings of food and drink made to them; e.g., some graves in ancient Crete and Ugarit (Ras Shamra) were equipped with pottery conduits, from the surface, for libations. Often, however, the grave has been thought of as an entrance to a vast, subterranean abode of the dead. In some religions this underworld has been conceived as an immense pit or cavern, dark and grim (e.g., the Mesopotamian *kur-nu-gi-a* ["land of no return"], the Hebrew *Sheol*, the Greek *Hades*, and the Scandinavian *Hel*). Sometimes it is ruled by an awful monarch, such as the Mesopotamian god *Nergal* or the Greek god *Hades*, or *Pluto*, or the *Yama* of Hindu and Buddhist eschatology. According to the view of man's nature and destiny held in a particular religion, this underworld may be a gloomy, joyless place where the shades of all the dead merely survive, or it may be pictured as a place of awful torments where the damned suffer for their misdeeds. In those religions in which the underworld has been conceived as a place of postmortem retribution, the idea of a separate abode of the blessed dead became necessary. Such an abode has various locations. In most religions it is imagined as being in the sky or in a divine realm beyond the sky (e.g., in Christianity, Gnosticism, Hinduism, and Buddhism); sometimes it has been conceived as the "Isles of the Blessed" (e.g., in Greek and Celtic mythology) or as a beautiful garden or paradise, such as the *al-firdaws* of *Islām*. Christian eschatology, which came to conceive of both an immediate judgment and a final judgment, developed the idea of a purgatory, where the dead expiated

their venial sins in readiness for the final judgment. Although the dead suffered there in a disembodied state, because their bodies would not be resurrected until the last day, the purifying flames of purgatory were usually regarded as burning in a physical sense, as Dante's *Purgatorio* vividly shows. The idea of a postmortem purgatory had been adumbrated in the 1st and 2nd centuries BC in Jewish apocalyptic literature (*I Enoch* 22:9–13). The ten hells of Chinese Buddhist eschatology may be considered as purgatories, for in them the dead expiated their sins before being incarnated once more in this world.

**Means of approach to the afterworld.** The idea that the dead had to make a journey to the otherworld, to which they belonged, finds expression in many religions. The oldest evidence occurs in the Egyptian Pyramid Texts (c. 2375–c. 2200 BC). The journey is conceived under various images. The dead pharaoh flies up to heaven to join the sun-god *Re*, in his solar boat, on his unceasing voyage across the sky, or he joins the circumpolar stars, known as the "Imperishable Ones," or he ascends a ladder to join the gods in heaven. Later Egyptian funerary texts depict the way to the next world as beset by awful perils: fearsome monsters, lakes of fire, gates that cannot be passed except by the use of magical formulas, and a sinister ferryman whose evil intent must be thwarted by magic. The idea of crossing water en route to the otherworld, which first appears in Egyptian eschatology, occurs in the eschatological topography of other religions, as was noted above. Many mythologies describe journeys to the underworld; they invariably reflect the fear felt for the grim experience that was believed to await the dead. Ancient Mesopotamian literature records the visit of the goddess *Ishtar* to the realm of the dead, the way to which was barred by gates. At each gate the goddess was deprived of some article of her attire, so that she was naked when she finally came before *Ereshkigal*, the queen of the underworld. It is possible that this successive stripping of the celestial goddess was meant to symbolize the stripping away of the attributes of life that the dead experienced as they descended into the "land of no return." An 8th-century Japanese text, the *Koji-ki*, tells of the first contact with death experienced by the primordial pair, *Izanagi* and *Izanami*. When his wife died, *Izanagi* descended to *Yomi*, the underworld of darkness, to bring her back. His request was granted by the gods of *Yomi*, on condition that he did not look at her in the underworld. Impatiently he struck a light and was horrified to see her as a decomposed corpse. He fled in terror and disgust. Blocking the entrance to *Yomi* with a great rock, he then sought desperately to purify himself from the contagion of death.

Such myths doubtless reflect an instinctive feeling that death works an awful change in those who experience it. The dead cease to belong to the world of the living and become uncanny and dangerous: hence, their departure to the world of the dead must be expedited. To assist that grim journey, various aids have been provided. Thus, on some Egyptian coffins of the 11th dynasty, a plan of the "Two Ways" to the underworld was painted, and from the New Kingdom period (c. 1567–1085 BC), copies of the Book of the Dead, containing spells for dealing with perils encountered en route, were placed in the tombs. Orphic communities in southern Italy and Crete provided their dead with directions about the next world by inscribing them on gold laminae deposited in the graves. Advice about dying was given to medieval Christians in a book entitled *Ars moriendi* ("The Art of Dying") and to Tibetan Buddhists in the *Bardo Thodol* ("Book of the Dead"). Chinese Buddhists were informed in popular prints of what to expect as they passed after death through the ten hells to their next incarnation. More practical equipment for the journey to the next world was provided for the Greek and Roman dead: in addition to the money to pay *Charon* for their passage across the *Styx*, they were provided with honey cakes for *Cerberus*, the fearsome dog that guarded the entrance to *Hades*.

**Forms of final determination.** Those religions that have taught the possibility of a happy afterlife have also

The journey after death

The underworld and heaven

Judgment  
of the dead

devised forms of postmortem testing of merit for eternal bliss. Ancient Egypt has the distinction of conceiving of a judgment of the dead of an essentially moral kind. This conception finds graphic expression in the vignettes that illustrate the Book of the Dead. The heart of the deceased is represented as being weighed against the symbol of Maat (Truth) in the presence of Osiris, the god of the dead. A monster named Am-mut (Eater of the Dead) awaits an adverse verdict. The judgment of the dead as conceived in other religions (*e.g.*, Christianity, Islām, Zoroastrianism, Orphism) is basically a test of orthodoxy or ritual status, although moral qualities were included to varying degrees. The Last Judgment, as presented in Jewish apocalyptic literature, was essentially a vindication of Israel against its Gentile oppressors. Religions that held no promise of a significant afterlife (*e.g.*, those of ancient Mesopotamia and classical Greece) had no place for a judgment of the dead.

## DEATH AND FUNERARY RITES AND CUSTOMS

Before and at death. The process of dying and the moment of death have been regarded as occasions of the gravest crisis in many religions. The dying must be especially prepared for the awful experience. In China, for example, the head of a dying person was shaved, his body was washed and his nails pared, and he was placed in a sitting position to facilitate the exit of the soul. After the death, relatives and friends called the soul to return, possibly to make certain whether its departure from the body was definitive. Muslim custom decrees that the dying be placed facing the holy city of Mecca. In Catholic Christianity, great care is devoted to preparing for a "good death." The dying person makes his last confession to a priest and receives absolution; then he is anointed with consecrated oil: the rite is known as "anointing of the sick" (formerly called extreme unction). According to medieval Christian belief, the last moments of life were the most critical, for demons lurked about the deathbed ready to seize the unprepared soul as it emerged with the last breath.

Modes of preparation of the corpse and attendant rites. After death, it has been the universal custom to prepare the corpse for final disposal. Generally, this preparation has included its washing and dressing in special garments and sometimes its public exposure. In some religions this preparation is accompanied by rites designed to protect the deceased from demonic attack; sometimes the pur-

pose of the rites has been to guard the living from the contagion of death or the malice of the dead; for it has often been believed that the soul continues to remain about the body until burial or cremation. The most elaborate known preparation of the dead took place in ancient Egypt. Because the Egyptians believed that the body was essential for a proper afterlife, a complex process of ritual embalmment was established. This process was intended not only to preserve the corpse from physical disintegration but also to reanimate it. The rites were based upon the belief that, because the dead body of the god Osiris had been preserved from decomposition and raised to life again by the gods, the magical assimilation of a dead person to Osiris and the ritual enacting of what the gods had done would achieve a similar miracle of resurrection. One of the most significant of these ritual transactions was the "opening of the mouth," which was designed to restore to the mummified body its ability to see, breathe, and take nourishment.

Mummification in cruder forms has been practiced elsewhere (notably in Peru), but not with the same complex motives as in Egypt. The preparation of the corpse has also frequently included the placing on or in it of magical amulets; these were variously intended to protect or vitalize the corpse. Evidence found in tombs of the Shang dynasty (*c.* 1766–*c.* 1122 BC) suggests that the Chinese placed life-prolonging substances, such as jade, in the orifices of the corpse. Crosses or crucifixes are frequently placed upon the Christian dead, and sometimes in the Middle Ages the consecrated bread of the Eucharist (the Lord's Supper) was buried with the body. It has also been a Christian custom to furnish a dead priest with a chalice and paten, the instruments of his sacerdotal office.

Modes of disposal of the corpse and attendant rites. The form of the disposal of the dead most generally used throughout the world in both the past and present has been burial in the ground. The practice of inhumation (burial) started in the Paleolithic era, doubtless as the most natural and simplest way of disposal. Whether it was then prompted by any esoteric motive, such as the return to the womb of Mother Earth, as has been suggested, cannot be proved. Among some later peoples, who have believed that primordial man was formed out of earth, it may have been deemed appropriate that the dead should be buried—the idea found classical expression in the divine pronouncement to Adam, recorded in Genesis 3:19: "You are dust, and to dust you shall return." There is evidence that in ancient Crete the dead were believed to serve a great goddess, who was the source of fertility and life in the world above and who nourished and protected the dead in the earth beneath.

The mode of burial has varied greatly. Sometimes the body has been laid directly in the earth, with or without clothes and funerary equipment. It may be placed in either an extended or crouched position: the latter posture seems to have been more usual in prehistoric burials. Sometimes evidence of a traditional orientation of the corpse in the grave can be distinguished, which may relate to the direction in which the land of the dead was thought to lie. The use of coffins of various substances dates from the early 3rd millennium BC in Sumer and Egypt. Intended probably at first to protect and add dignity to the corpse, coffins became important adjuncts in the mortuary rituals of many religions. Their ritual use is most notable in ancient Egypt, where the mummies of important persons were often enclosed in several human-shaped coffins and then deposited in large, rectangular wooden coffins or stone sarcophagi. The interiors and exteriors of these coffins were used for the inscription of magical texts and symbols. Sarcophagi, elaborately carved with mythological scenes of mortuary significance, became fashionable among the wealthier classes of Greco-Roman society. Similar sarcophagi, carved with Christian scenes, came into use among Christians in the 4th and 5th centuries and afford rich iconographic evidence of the contemporary Christian attitude to death.

In the ancient Near East, the construction of stone tombs began in the 3rd millennium BC and inaugurated a tradition of funerary architecture that has produced such

Inhumation

diverse monuments as the pyramids of Egypt, the Tāj Mahal, and the mausoleum of Lenin in Red Square, Moscow. The tomb was originally intended to house and protect the dead. In Egypt it was furnished to meet the needs of its magically resuscitated inmate, sometimes even to the provision of toilet facilities. Among many peoples, the belief that the dead actually dwelt in their tombs has caused the tombs of certain holy persons to become shrines, which thousands visit to seek for miracles of healing or to earn religious merit; notable examples of such centres of pilgrimage are the tombs of St. Peter in Rome, of Muhammad at Medinah, and, in ancient times, the tomb of Imhotep at Šaqqārah, in Egypt.

The funeral

The disposal of the corpse has been, universally, a ritual occasion of varying degrees of complexity and religious concern. Basically, the funeral consists of conveying the deceased from his home to the place of burial or cremation. This act of transportation has generally been made into a procession of mourners who lament the deceased, and it has often afforded an opportunity of advertising his wealth, status, or achievements. Many depictions of ancient Egyptian funerary processions graphically portray the basic pattern: the embalmed body of the deceased is borne on an ornate sledge, on which sit two mourning women. A priest precedes the bier, pouring libations and burning incense. In the cortege are groups of male mourners and lamenting women, and servants carry the funerary furniture, which indicates the wealth of the dead man. Ancient Roman funerary processions were notable for the parade of ancestors' death masks. In Islāmic countries, friends carry the corpse on an open bier, generally followed by women relatives, lamenting with dishevelled hair, and hired mourners. After a service in the mosque, the body is interred with its right side toward Mecca. In Hinduism the funeral procession is made to the place of cremation. It is preceded by a man carrying a firebrand kindled at the domestic hearth; a goat is sometimes sacrificed en route, and the mourners circumambulate the corpse, which is carried on a bier. Cremation is a ritual act, governed by careful prescriptions. The widow crouches by the pyre, on which in ancient times she sometimes died. After cremation, the remains are gathered and often deposited in sacred rivers.

Christian funerary ritual reached its fullest development in medieval Catholicism and was closely related to doctrinal belief, especially that concerning purgatory. Hence,

the funerary ceremonies were invested with a sombre character that found visible expression in the use of black vestments and candles of unbleached wax and the solemn tolling of the church bell. The rites consisted of five distinctive episodes. The corpse was carried to the church in a doleful cortege of clergy and mourners, with the intoning of psalms and the purificatory use of incense. The coffin was deposited in the church, covered with a black pall, and the Office of the Dead was recited or sung, with the constant repetition of the petition: "Eternal rest grant unto him, O Lord: and let perpetual light shine upon him." Next, requiem mass was said or sung, with the sacrifice especially offered for the repose of the soul of the deceased. After the mass followed the "Absolution" of the dead person, in which the coffin was solemnly perfumed with incense and sprinkled with holy water. The corpse was then carried to consecrated ground and buried, while appropriate prayers were recited by the officiating priest. Changes in these rites, including the use of white vestments and the recitation of prayers emphasizing the notions of hope and joy, began to be introduced into the Catholic liturgy only following the second Vatican Council (1962–65).

In some societies the burial of the dead has been accompanied by human sacrifice, with the intention either to propitiate the spirit of the deceased or to provide him with companions or servants in the next world. A classic instance of such propitiatory sacrifice occurs in Homer's *Iliad* (xxiii:175–177): 12 young Trojans were slaughtered and burnt on the funeral pyre of the Greek hero Patroclus. The royal graves excavated at the Sumerian city of Ur, dating c. 2700 BC, revealed that retinues of servants and soldiers had been buried with their royal masters. Evidence of a similar Chinese practice has been found in Shang dynasty graves (12th to 11th centuries BC), at An-yang. In ancient Egypt, models of servants, placed in tombs, were designed to be magically animated to serve their masters in the afterlife. A particular type of these models, known as an *ushabti* ("answerer"), was inscribed with chapter VI of the Book of the Dead, commanding it to answer for the deceased owner if he were required to do service in the next world.

The custom has also existed among some peoples of dismembering the body for burial or subsequently disinterring the bones for storage in some form. There is Paleolithic evidence of a cult of skulls, which suggests that the rest of the body was not ritually buried. The Egyptians removed the viscera, which were preserved separately in four canopic jars. The Romans observed the curious rite of the *os resectum*; after cremation a severed finger joint was buried, probably as a symbol of an earlier custom of inhumation. In medieval Europe, the heart and sometimes the intestines of important persons were buried in separate places: e.g., the body of William the Conqueror was buried in St. Étienne at Caen, but his heart was left to Rouen Cathedral and his entrails for interment in the church of Chalus. To be noted also is the Zoroastrian and Parsi custom of exposing corpses on dakhmas ("towers of silence") to be devoured by birds of prey, thus to avoid polluting earth or air by burial or cremation.

The alternative use of inhumation or cremation for the disposal of the corpse cannot be interpreted as generally denoting a difference of view about the fate of the dead. In India, cremation was indeed connected with the fire god Agni, but cremation does not necessarily indicate that the soul was thus freed to ascend to the sky. Burial has been the more general practice, whether the abode of the dead be located under the earth or in the heavens.

**Post-funerary rites and customs.** Funerary rites do not usually terminate with the disposal of the corpse either by burial or cremation. Post-funerary ceremonies and customs may continue for varying periods; they have generally had two not necessarily mutually exclusive motives: to mourn the dead or to purify the mourners. The mourning of the dead, especially by near relatives, has taken many forms. The wearing of old or colourless dress, either black or white, the shaving of the hair or letting it grow long and unkempt, and abstention from

Dismemberment of the body

amusements have all been common practice. The meaning of such action seems evident: grief felt for the loss of a dear relative or friend naturally expresses itself in forms of self-denial. But the purpose may sometimes have been intended to divert the ill humour of the dead from those who still enjoyed life in this world.

The purification of the mourners has been the other powerful motive operative in much post-funeral action. Death being regarded as baleful, all who came in contact with the corpse were contaminated thereby. Consequently, among many peoples, various forms of purification have been prescribed, chiefly by bathing and fumigation. Parsis are especially intent also on cleansing the room in which the death occurred and all articles that had contact with the dead body.

In some post-funeral rituals, dancing and athletic contests have had a place. The dancing seems to have been inspired by various but generally obscure motives. There is some evidence that Egyptian mortuary dances were intended to generate a vitalizing potency that would benefit the dead. Dances among other peoples suggest the purpose of warding off the (evil) spirits of the dead. Funeral games would seem to have been, in essence, prophylactic assertions of vitalizing energy in the presence of death. It has been suggested that the funeral games of the Etruscans, which involved the shedding of blood, had also a sacrificial significance.

Another widespread funeral custom has been the funeral banquet, which might be held in the presence of the corpse before burial or in the tomb-chapel (in ancient Rome) or on the return of the mourners to the home of the deceased. The purpose behind these meals is not clear, but they seem originally to have been of a ritual character. Two curious instances of mortuary eating may be mentioned in this connection. There was an old Welsh custom of "sin eating": food and drink were handed across the corpse to a man who undertook thereby to ingest the sins of the deceased. In Bavaria, *Leichennudeln*, or "corpse cakes," were placed upon the dead body before baking. By consuming these cakes, the kinsmen were supposed to absorb the virtues and abilities of their deceased relatives.

Chastisement of the Tomb

A remarkable post-funeral custom has been observed in Islām; it is known as the Chastisement of the Tomb. It is believed that, on the night following the burial, two angels, Munkar and Nakir, enter the tomb. They question the deceased about his faith. If his answers are correct, the angels open a door in the side of the tomb for him to pass to repose in paradise. If the deceased fails his grisly interrogation, he is terribly beaten by the angels, and his torment continues until the end of the world and the final judgment. In preparation for this awful examination the roof of the tomb is constructed to enable the deceased to sit up; and, immediately after burial, a man known as a *faqī* (or *faqih*) is employed to instruct the dead in the right answers.

#### CULTS AND MEMORIALS OF THE DEAD

**Commemorative rites and services.** The attitude of the living toward the dead has also been conditioned by the particular belief held about the human nature and destiny. Where death is regarded as the virtual extinction of the personality, the dead should logically have no more importance beyond that which their memory might stir in those who knew them. Even in the negative eschatologies of ancient Mesopotamia and Greece, however, the dead were thought of as still existent and capable of malevolent action if food offerings were not made to them. In those religions that have envisaged a more positive afterlife, the *tendance* of the dead has been developed in varying ways. In Egypt, it led to the building and endowment of mortuary temples or chapels, in which portrait images preserved the memory of the dead and offerings of food and drink were regularly made. In China, an elaborate ancestor cult flourished. The ancestral shrine contained tablets, inscribed with the names of ancestors, which were revered and before which offerings were made. The number of tablets displayed in the shrine was determined by the social status of the family.

When the tablet of a newly deceased member was added to the collection, the oldest tablet was deposited in a chest containing still older ones: offerings to the remoter ancestors were made collectively at longer intervals. In India, three generations of deceased ancestors are venerated at the monthly *śrāddha* festival, at which mortuary offerings were made.

The Christian cult of the dead found early expression in the catacombs, where mural paintings and inscriptions record the names of those buried there and the hopes of eternal peace and felicity that inspired them. Special chapels were made where the bodies of martyrs were entombed, and the anniversaries of their martyrdoms were commemorated by the celebration of the Eucharist (the Lord's Supper). The development of cults of martyrs and other saints in the medieval church centred on the veneration of their relics, which were often divided among several churches. The introduction of the doctrine of purgatory profoundly affected the postmortem care devoted to the ordinary dead. It was believed that the offering of the sacrifice of the mass could alleviate the sufferings of departed souls in purgatory. Consequently, the celebration of masses for the dead proliferated, and wealthy Christians endowed monasteries or chantry chapels where masses were said regularly for the repose of their own souls or those of their relatives. Prayers for the well-being of the dead have an important place in Mahāyāna Buddhism, and so-called "masses for the dead" were celebrated by Chinese Buddhists, influenced originally perhaps by the practice of the Nestorian Christians, who entered China in the 7th century AD.

In many religions, in addition to private cults of the dead, periodic commemorations of the dead have been kept. The oldest of the Hindu sacred texts, the *R̥gveda*, records the practice of the ancient Aryan invaders of India. The sacred beverage called soma was set out on "the sacred grass," and the ancestors were invited to ascend from their subterranean abode to partake of it and to bless their pious descendants. A similar ceremony, called the Anthesteria, was held in ancient Athens. On the day concerned, the souls of the dead (*kēres*) were believed to leave their tombs and revisit their former homes, where food was prepared for them. At sundown they were solemnly dismissed to the underworld with the formula: "out, *kēres*, the Anthesteria is ended." Buddhist China kept a Feast of Wandering Souls each year, designed to help unfortunate souls suffering in the next world. The Christian All Souls Day, on November 2, which follows directly after All Saints Day, commemorates all the ordinary dead: requiem masses are celebrated for their repose, and in many Catholic countries relatives visit the graves and place lighted candles on them. After World War I the public commemoration of the fallen was instituted on November 11, the day of the armistice in 1918, in many of the countries concerned: the memory of the dead was solemnly recalled in a two-minute silence during the ceremony. The body of an unknown soldier, killed in the fighting, was also buried in the capital cities of many countries and has become the accepted focus of national reverence and devotion.

Periodic commemorations

**Cult of the dead.** Among many peoples it has been the custom to preserve the memory of the dead by images of them placed upon their graves or tombs, usually with some accompanying inscription recording their names and often their achievements. This sepulchral iconography began in Egypt, the portrait statue of King Djoser (second king of the 3rd dynasty [c. 2686–c. 2613 BC]), found in the serdab (worship chamber; from the Arabic word for cellar) of the Step Pyramid being the oldest known example. The Egyptian images, however, had a magical purpose: they not only recorded the features of the deceased but also provided a locus for his *ka*, the mysterious entity that constituted an essential element of the personality. The sculptured gravestones of classical Athens deserve special notice, for they are among the noblest products of funerary art. They are expressive of a restrained grief for those who had departed to the virtual extinction of Hades. The deceased are often shown performing some familiar act for the

Images of the dead

last time. The inscriptions are very brief and usually record only the name and parentage; sometimes the word farewell is added. Etruscan mortuary art is characterized by the effigy of the deceased, sometimes with his wife, represented as reclining on the cover of the casket. These images are obviously careful portraits, but whether they had some magical use as substitute bodies or are only commemorative is unknown. Roman funerary images seem to have been essentially commemorative, as were those of Palmyra.

Christianity has provided the richest legacy of funerary monuments. In the catacomb art of the 4th and 5th centuries, the deceased was sometimes depicted on the plaster covering of the niche in which his body was laid. From the early Middle Ages onward, the more affluent dead were represented in sculptured effigy or engraved in outline on stone or brass. In this tomb iconography they are shown in a variety of postures: lying, kneeling, seated, standing, and sometimes on horseback. They are generally presented in the dress most appropriate to their office or social standing: kings wear crowns, knights their armour; bishops are in copes and mitres, and ladies are in the fashionable attire of the day. This iconography is patently commemorative of the appearance in life, the achievements, and the status of the persons concerned. In the later Middle Ages, however, there was a remarkable innovation in this funerary art, which was designed to emphasize the horror and degradation of death. In what are known as memento mori tombs, below the effigies of the deceased as they were in life, there were placed effigies of their naked decaying corpses or skeletons. Such tomb sculpture reflected a contemporary obsession with the corruption of death.

#### PSYCHOLOGICAL AND SOCIOLOGICAL ASPECTS OF DEATH

The Paleolithic burials reveal that the pattern of man's reaction to the fact and phenomena of death has been set from the dawn of culture. Unlike the other animals, man has been unable to ignore the mysterious cessation of activity and lapse of consciousness that cause his body to decay and befall members of his own kind. Death has, accordingly, constituted a problem for man, and he has felt impelled to take special action to cope with it. The pattern of his reaction has been twofold: confronted with the deaths of his companions, he has recognized an obligation to attend to their needs as he has conceived them, believing that they continue to exist in some form, either in the grave or in an underworld to which the grave gave access. But man's concern with death has not been confined to his tendance of the dead; for in the deaths of his fellows he has seen a presage of his own demise. This anticipation on the part of the living of the experience of dying has been a factor of immense psychological and social import. It is essentially a human characteristic; it stems from a consciousness of time, of which the immense cultural significance is only now beginning to be properly evaluated.

Awareness of time in its three categories of past, present, and future has decisively contributed to man's success in the struggle for existence. For it has enabled him to draw upon past experience in the present to anticipate his future needs. Thus, from the making of the first stone tools to the complex structure of modern technological civilization, man has sought by planning, to render himself economically secure and to improve his standard of living. But his time consciousness, which has made this immense achievement possible, is an ambivalent endowment. Although it has enabled man to win economic security, it has also made him acutely aware of his own mortality and the inevitability of his own demise. Hence, his anticipation of death presents him with a profound emotional challenge—a challenge unknown to other species. The repercussions of this challenge can be traced in almost every aspect of his social and cultural life; but it is in his religions that man's reaction to death finds its most significant expression. All religion is concerned with post-mortem security—with linking mortals to an eternal realm—whether through ritual magic, divine assistance, or mystic enlightenment.

#### MODERN NOTIONS OF DEATH

*Continuation of traditional responses.* Religious rites and customs continue to be practiced, because of conservatism, long after the ideas and beliefs that originally inspired them may have been forgotten or abandoned. This is especially true with regard to those rites and customs that pertain to death. It is difficult to assess the extent to which the traditional eschatologies are still effectively held in the more sophisticated societies of the modern world. Although a general skepticism obviously manifests itself toward the medieval imagery of death and judgment, of purgatory, heaven, and hell, modern modes of thinking have not lessened the mystery of death and its impact on the emotions. Indeed, in modern society, where expectation of life has been prolonged and standards of living have been raised, the negation of death is probably felt more keenly and also more hopelessly than in any other age.

*Avowed secular inattention and unconcern.* The reaction to death most apparent among those having no effective religious faith is that of seeking to treat it as a disagreeable happening that must be dealt with as quickly and unobtrusively as possible. Funerals are no longer elaborately organized, mourning attire is rarely worn, and graveyards are landscaped, thus discreetly removing the earlier memorials of death. The increasing use of cremation facilitates this disposition to reduce the social intrusion of death and banish the traditional grave as a reminder of human mortality.

*Rites and customs among secular materialists.* It is significant, however, that, even where secularist principles are consciously professed, the dead are rarely disposed of without some semblance of ceremony. A deeply rooted feeling prompts most people to treat a dead human body with a respect that is not felt for a dead animal. It is significant that Communists make pilgrimages to the graves of Lenin and Marx; and, in the modern State of Israel, great effort is made to record in the shrine of Yad va-Shem the names of those who died in the persecution of the Jews in Germany during the Nazi regime of Adolf Hitler in the 1930s and '40s and, if possible, to bring their ashes there. In the United States morticians strive to preserve the features of the dead as did the embalmers of ancient Egypt, though for somewhat different motives. Finally, as further evidence of modern preoccupation with death, it may be noted that, in Western societies, Spiritualism indicates a widespread desire to communicate with the dead, and in England there has even been a recrudescence of necromancy.

## Death Valley

One of the most remarkable natural features of North America, Death Valley not only is the driest and hottest area of that continent but also contains the lowest point in the Western Hemisphere. In some years there is no measurable rainfall, and the summer daytime temperature often exceeds 120° F (49° C). Its extreme environment is of considerable scientific interest.

Death Valley lies in southeastern California near the Nevada border. It is bounded on the west by the Panamint Range and on the east by the Black, Funeral, and Grapevine mountains of the Amargosa Range. The valley extends generally north-south, with a length of nearly 140 miles (225 kilometres) and a width of between five and 15 miles (eight and 24 kilometres). Geologically it is an elongated structural depression forming part of the southwestern portion of the Basin and Range Province—a physiographic subdivision of the western United States. It is similar in area and overall form to other structural basins of the region but unique in its depth. Parts of the great salt pan that forms the floor of part of the valley form the lowest dry land areas of the Western Hemisphere. The lowest point is 282 feet (86 metres) below sea level and is found 4.75 miles (7.64 kilometres) west of Badwater, California.

**The physical environment.** For several decades after its christening in 1849 by a hapless party of immigrants who endured intense suffering while crossing it, Death Valley was little known except to the Indians who lived in the area and to prospectors searching the surrounding mountains.

**History of geological study.** The first scientific notice of the valley seems to have been a brief note published in 1868 by California's state geologist. Mining activities, especially after the borax discoveries of the 1880s, drew the attention of other geologists. Reconnaissance reports began to appear around the turn of the century, but little detailed geological work was done until after the establishment of Death Valley National Monument in 1933. Since that time, under the auspices of the National Park Service, the U.S. Geological Survey, and the State of California Division of Mines and Geology, the central and southern parts of the valley and the adjacent mountains have been studied in detail. Information on the northern part of the valley, especially the area outside the National Monument, is still relatively scanty.

**Geology.** The mountain walls of Death Valley are composed largely of marine sedimentary rocks, deposited over a span of time from Late Precambrian (more than 600,000,000 years ago) to Triassic (about 200,000,000 years ago) in a great trough, the Cordilleran Geosyncline, which occupied much of what is now western North America. In places the sedimentary rocks can be seen to rest upon a base of much older, metamorphic (heat-altered) and granitic rocks. In Middle Mesozoic time (180,000,000 years ago) compressive forces deformed and uplifted the rocks that had accumulated in the geosyncline, converting much of the former seaway into a mountain belt.

In Late Mesozoic or Early Cenozoic time (about 100,000,000 years ago) the Earth's crust in the region of Death Valley was broken by a series of fractures, some of

them forming flat-lying surfaces along which great plates of rock moved over one another, sometimes for many miles. This process of thrust faulting, accompanied by folding, seems to have continued for many millions of years. The complexity of the results is suggested by the use of the term chaos to describe the structure of some of the thrust plates, which form a jumble of blocks of rock of various ages, with dimensions ranging from a few feet to thousands of feet. In places the fault planes have been exposed, either by erosion or by later sliding of the thrust plates from their tilted surfaces. Some of these form domed hills, referred to as turtle backs. Many questions about the mechanism of thrust faults in general, and about their part in the history of Death Valley, remain unanswered.

Magma from deep within the Earth followed some of the fractures toward the surface. In two of the areas in the Panamint Range the magma domed up the overlying rocks and then cooled and crystallized at depth to form masses of granite. Elsewhere it broke through the surface to form volcanoes. Volcanic activity continued into recent geological times in the northern end of the valley, where explosive eruptions blasted out the Ubehebe Craters and scattered volcanic ash that still blankets the surface of the land.

Another type of fault activity, block faulting, in which the movement is dominantly vertical, began to form the contemporary Death Valley in Middle Tertiary time (40,000,000 years ago). Remains of early Oligocene mammals are preserved in sediments that accumulated in one of the basins thus formed, now exposed in Titus Canyon on the east side of Death Valley. The sinking of a series of crustal blocks to form the great trough of Death Valley and the uplift of other blocks to form the adjacent mountain ranges progressed gradually through the rest of the Cenozoic Era. As the valley sank, sediments eroded from the surrounding hills accumulated, along with the products of the intermittent volcanic activity. Later fault movements tilted and exposed some of the older Cenozoic sediments along the east side of the valley; their subsequent erosion formed the spectacular badlands near Furnace Creek. In the central part of the valley the bedrock floor is buried beneath as much as 9,000 feet (2,750 metres) of sediment.

Right lateral displacement, a third type of fault activity, moved the west side of the valley to the northwest. The magnitude of this movement is still a matter of controversy: it may be as much as 50 miles (80 kilometres).

The tilting and sinking of the valley floor has continued to the present. Recent faults have affected alluvial fans in many parts of the valley perimeter. The shoreline of a lake that existed 2,000 years ago is now 20 feet (six metres) lower on the east side than it is on the west, while changes in surveyed elevations suggest that parts of the valley floor have subsided several inches during the 20th century.

**Climate and hydrology.** The floor of Death Valley is noted for its extremes of temperature and aridity. A record North American high shaded air temperature of 134° F (57° C) was recorded in 1913, and summer temperatures often exceed 120° F (49° C). Ground temperatures as high as 190° F (88° C) have been reported.

Winter minimum temperatures rarely fall to the freezing point. For a 50-year period in the 20th century the average annual rainfall at Furnace Creek was only 1.66 inches (4.22 centimetres); the maximum annual rainfall was 4.5 inches (11.4 centimetres), and two years passed with no measurable rainfall. High temperatures, low humidity, and fairly constant air movement contribute to an exceptionally high evaporation rate, averaging about 150 inches (381 centimetres) per year.

Most of the surface water in Death Valley is in the saline ponds and marshes around the salt pan, but freshwater springs and seeps are less rare than in adjacent desert areas. The Amargosa River brings some water into the southern end of the valley from the desert areas to the east, but most of its flow is underground. Salt Creek, draining the northern arm of the valley, also has only short stretches of perennial surface flow. Water emerging

Faulting  
and  
volcanic  
activity

at major springs in Furnace Creek Wash may follow fault zones from a source far to the east.

At times in the past much more water reached Death Valley. During the Wisconsin Glacial Age of the Pleistocene Epoch, perhaps about 50,000 years ago, a body of water (Lake Manly) filled the valley to a depth of as much as 600 feet (180 metres). Wave-cut terraces on Shoreline Butte near the south end of the valley record its fluctuations. The source of this water is uncertain: drainage from much of the eastern slopes of the Sierra Nevada may have flowed into Death Valley by way of Owens and Panamint valleys, but some evidence points to the Mojave Desert area as a more probable source. More recently, perhaps 2,000 to 5,000 years ago, a shallow lake occupied the floor of the valley, its evaporation producing the present salt pan.

**Plant and animal life.** Lack of water makes Death Valley a desert, but it is by no means devoid of life. Plant life above the microscopic level is absent from the salt pan, but salt-tolerant pickleweed, saltgrass, and rushes grow around the springs and marshes at its edges. Introduced tamarisks provide welcome shade around some of the springs and in the inhabited areas at Furnace Creek. Mesquite flourishes where less saline water is available. Creosote bush dominates the gravel fan surfaces around most of the valley, giving way to desert holly at the lowest elevations. Cactus is rare in the lowest part of the valley but abundant on the fans farther north. Spring rains bring out a great variety of desert wildflowers.

Wildlife in  
the valley

Animal life is varied, although nocturnal habits conceal many of the animals from visitors to the valley. Rabbits and several types of rodents, including antelope squirrels, kangaroo rats, and desert wood rats, are present and are preyed upon by coyotes, kit foxes, and bobcats. The largest native mammal in the area, and perhaps the best studied member of the fauna, is the desert bighorn sheep. Small herds of sheep are most commonly found in the mountains surrounding Death Valley but at least occasionally visit the valley floor. Wild burros, descendants of animals lost or abandoned by prospectors and miners, have become so numerous as to threaten, through overgrazing, the natural vegetation and other animals dependent upon it.

Visitors may gain the impression that the only birds present are the raucous and numerous ravens, but the first biological survey of the valley, in the 1890s, reported 78 species of birds, and nearly three times that number are now known to inhabit or visit the area. Lizards are numerous, snakes comparatively rare. Even native fish are to be found in Death Valley—several forms of desert pupfish of the genus *Cyprinodon* live in Salt Creek and other permanent bodies of water. Their ancestors apparently entered Death Valley during one of the past periods of high rainfall and permanent streamflow into the valley.

## Debussy, Claude

The works of Achille Claude Debussy have been a seminal force in the music of the 20th century. He developed a highly original system of harmony and musical structure that expressed in many respects the ideals to which the Impressionist and Symbolist painters and writers of his time aspired. As a man he was enigmatical, saturnine, and unsocial. He shunned the limelight and resented having to make his living by writing music. Debussy hated everything grandiloquent and rejected all

the trappings, pleasant and unpleasant, that eventually came to him through fame. Born of humble parents on August 22, 1862, at Saint-Germain-en-Laye, near Paris, Claude Debussy showed a gift as a pianist by the age of nine. He was encouraged by Madame Mauté de Fleuryville, who was associated with the Polish composer Frédéric Chopin, and in 1873 he entered the Paris Conservatoire, where he studied the piano and composition, eventually winning in 1884 the Grand Prix de Rome with his cantata *L'Enfant prodigue* (*The Prodigal Child*).

Giraudon

Debussy, painting by Marcel-André Baschet, 1884. In the Musée de Versailles.

Debussy's youthful years were spent in circumstances of great turbulence. He was almost overwhelmed by situations of great extremes, both material and emotional. While living with his parents in a poverty-stricken suburb of Paris, he unexpectedly came under the patronage of a Russian millionairess, Nadezhda Filaretovna von Meck, who engaged him to play duets with her and her children. He travelled with her to her palatial residences throughout Europe during the long summer vacations at the Conservatoire. In Paris during this time he fell in love with a singer, Blanche Vasnier, the beautiful young wife of an architect; she inspired many of his early works. It is clear that he was torn by influences from many directions; these stormy years, however, contributed to the sensitivity of his early style.

This early style is well illustrated in one of Debussy's best known compositions, *Clair de lune* (*Moonlight*), from his *Suite bergamasque*. The title refers to a folk song that was the conventional accompaniment of scenes of the love-sick Pierrot in the French pantomime; and indeed the many Pierrot-like associations in Debussy's music, notably in the orchestral work *Images* (1912) and the *Sonata for Cello and Piano* (1915; originally titled *Pierrot fâché avec la lune*), show his connections with the circus spirit that also appeared in works by other composers, notably the ballet *Petrushka* (1911) by Igor Stravinsky and *Pierrot Lunaire* by Arnold Schoenberg.

As a holder of the Grand Prix de Rome, Debussy was given a three-year stay at the Villa Medici, in Rome, where, under what were supposed to be ideal conditions, he was to pursue his creative work. Most composers who were granted this state scholarship, however, found life in this magnificent Renaissance palace irksome and longed to return to simpler and more familiar surroundings. Debussy himself eventually fled from the Villa Medici after two years and returned to Blanche Vasnier in Paris. Several other women, some of doubtful reputation, were also associated with him in his early years. At this time Debussy lived a life of extreme indulgence. Once one of his mistresses, Gabrielle ("Gaby") Dupont, threatened suicide. His first wife, Rosalie ("Lily") Texier, a dressmaker, whom he married in 1899, did in fact shoot herself, though not fatally; and, as is sometimes the case with artists of passionate intensity, Debussy himself was haunted by thoughts of suicide.

The main musical influence in Debussy's work was the

Early style

Influence  
of Wagner  
on Debussy

work of Richard Wagner and the Russian composers Aleksandr Borodin and Modeste Moussorgsky. Wagner fulfilled the sensuous ambitions not only of composers but also of the Symbolist poets and the Impressionist painters. Wagner's conception of *Gesamtkunstwerk* ("total art work") encouraged artists to refine upon their emotional responses and to exteriorize their hidden dream states, often in a shadowy, incomplete form; hence the more tenuous nature of the work of Wagner's French disciples. It was in this spirit that Debussy wrote the symphonic poem *Prélude à l'après-midi d'un faune*, (1894; *Prelude to the Afternoon of a Faun*). Other early works by Debussy show his affinity with the English Pre-Raphaelite painters; the most notable of these works is *La Damselle élue* (1888), based on "The Blessed Damsel" (1850), a poem by the English poet and painter Dante Gabriel Rossetti. In the course of his career; however, which covered only 25 years, Debussy was constantly breaking new ground. Explorations, he maintained, were the essence of music; they were his musical bread and wine. His single completed opera, *Pelléas et Mélisande* (first performed 1902) demonstrates how the Wagnerian technique could be adapted to portray subjects like the dreamy nightmarish figures of this opera who were doomed to self-destruction. Debussy and his librettist, Maurice Maeterlinck, declared that they were haunted in this work by the terrifying nightmare tale of Edgar Allan Poe, "The Fall of the House of Usher." The style of *Pelléas* was to be replaced by a bolder, more highly coloured manner. In his seascape *La Mer* (1905; *The Sea*) he was inspired by the ideas of the English painter J.M.W. Turner and the French painter Claude Monet. In his work, as in his personal life, he was anxious to gather experience from every region that the imaginative mind could explore.

In 1905 Debussy's illegitimate daughter, Claude-Emma, was born. He had divorced Lily Texier in 1904 and subsequently married his daughter's mother, Emma Bardac. Repelled by the gossip and scandal arising from this situation, he sought refuge for a time at Eastbourne, on the south coast of England. For his daughter, nicknamed Chouchou, he wrote the piano suite *Children's Corner* (1908). Debussy's spontaneity and the sensitive nature of his perception facilitated his acute insight into the child mind, an insight noticeable particularly in *Children's Corner*, a French counterpart to Moussorgsky's song cycle *The Nursery*; in the *Douze Préludes* (first book, 1910; second book 1913) for piano; and in the ballet *La Boîte à joujoux* (*The Bow of Toys*; first staged 1919).

In his later years, it is the pursuit of illusion that marks Debussy's instrumental writing, especially the strange, other-worldly *Cello Sonata*. This noble bass instrument takes on, in chameleon fashion, the character of a violin, a flute, and even a mandolin. Debussy was developing in this work ideas of an earlier period, those expressed in a youthful play he had written, *Frères en art* ("Brothers in Art"), where his challenging, indeed anarchical, ideas are discussed among musicians, painters, and poets. (He had in fact published in one of the anarchist journals poems that he had written and that he later set to music in the song cycle *Proses lyriques* [1893].)

Debussy's music marks the first of a series of attacks on the traditional language of the 19th century. He did not believe in the stereotyped harmonic procedures of the 19th century, and indeed it becomes clear from a study of mid-20th-century music that the earlier harmonic methods were being followed in an arbitrary, academic manner. Hence his formulation of the "21-note scale" designed to "drown" the sense of tonality, though this system was never adhered to in the inflexible manner of the 12-note system of Schoenberg. Debussy's enquiring mind similarly challenged the traditional orchestral usage of instruments. He rejected the traditional dictum that string instruments should be predominantly lyrical. The pizzicato scherzo from his *String Quartet* (1893) and the symbolic writing for the violins in *La Mer*, conveying the rising storm waves, show a new conception of string colour. Similarly, he saw that wood-

winds need not be employed for fireworks displays; they provide, like the human voice, wide varieties of colour. Debussy also used the brass in original colour transformations. In fact, in his music, the conventional orchestral construction, with its rigid woodwind, brass, and string departments, finds itself undermined or split up in the manner of the Impressionist painters. Ultimately, each instrument becomes almost a soloist, as in a vast chamber-music ensemble. Finally, Debussy applied an exploratory approach to the piano, the evocative instrument *par excellence* since notes struck at the keyboard are, by the nature of the piano mechanism, neither eighth notes, quarter notes, nor half notes, but merely illusions of these notes.

During the latter part of his life Debussy created an alter ego, "Monsieur Croche," with whom he carried on imaginary conversations on the nature of art and music. "What is the use of your almost incomprehensible art?" Monsieur Croche asks. "Is it not more profitable to see the sun rise than to listen to the Pastoral Symphony of Beethoven?" Elsewhere Monsieur Croche supports the cause of the musical explorer: "I am less interested in what I possess than in what I shall need tomorrow."

Debussy died in Paris of cancer on March 25, 1918, while the city was being bombarded by German guns. In his last works, the piano pieces *En blanc et noir* (1915; *In Black and White*) and in the *Dortze Etudes* (1915), Debussy had branched out into modes of composition later to be developed in the styles of Stravinsky and the Hungarian composer Béla Bartók. It is certain that he would have taken part in the leading movements in composition of the years following World War I had his life not been so tragically cut short.

In a sense Debussy's influence on 20th-century music has increased since his death; and yet, paradoxically, it has also diminished. Wagner, said Debussy, was a wonderful sunset that had been mistaken for a dawn. As one looks back on the music of the last century this seems a remarkably shrewd observation. It was true of Wagner, of course, but it is now seen to be more true of Debussy himself. The fact is that there comes a time when the peak, the zenith of a civilization is reached. Critics have frequently noted this evolutionary stage in the music of Wagner, Debussy, or in one of their followers. A quintessential spirit is presented by these composers; and it seemed at the time that they could never be surpassed. But of course it is at this very stage that a decline in musical values sets in. Hence the paradoxical element in Debussy's stature. Undoubtedly, he was aware of this duality in his achievement, as may be gathered from his searching, hesitant letters. Sensitive to sham in every sphere and also a child of his environment, he not only perceived this dual aspect of his work but also realized the extent to which he himself was caught up in this vast evolutionary transformation.

Debussy's work cannot be judged on the musical level alone. "One must seek the poetry in his work," said his friend the French composer Paul Dukas. There is not only poetry in his music; there is often an inspiration from painting. "I love painting [*les images*, a generic term that might apply to the whole of Debussy's work] almost as much as music itself," he told the Franco-American composer Edgard Varèse. This association of the arts is a theme that runs through the whole of the 19th century—it originated with the theories of the German short-story writer E.T.A. Hoffmann—but for Debussy it was a theory more sensitively expressed in the tales of Poe. Throughout his life Debussy planned to set "The Fall of the House of Usher" in the form of an opera—the shadow of the tale never having been realized in *Pelléas et Mélisande*—and actually signed a contract for the production of this work at the Metropolitan Opera in New York, but it was never completed. The fact is that the hero of the tale, Roderick Usher, was a hypersensitive being like Debussy himself—a poet, a painter, and a musician. Moreover, the reputation of Poe was, during Debussy's life and after, almost entirely a French reputation. The French poets translated his works, and the French painters appreciated his genius;

Debussy's  
influence

Unique  
quality of  
Debussy's  
music

and it was therefore only natural that a French musician should similarly have reflected the nature of his appeal. Debussy's adaptation of Poe's work, published only in the form of an opera libretto, is a clear indication of the cast of his artistic mind.

#### MAJOR WORKS

##### Piano music

SOLO PIANO: *Deux Arabesques* (1888); *Suite bergamasque* (1890–1905); *Estampes* (1903); *Images*, two sets (1905 and 1907); *Children's Corner* (1908); *Douze Préludes*, two books (1910 and 1913); *Douze Etudes*, two books (1915).

TWO PIANOS: *En blanc et noir* (1915).

##### Orchestral music

*Le printemps*, *Le midi d'un jeune* (completed 1894); *Nocturnes* (1899); *La Mer* (1905); *Images* (1912).

##### Ballet

*Jeux* (first performed 1913).

##### Vocal music

OPERA: *Pelléas et Mélisande*, on a text by Maeterlinck (first performed 1902).

CANTATA: *L'Enfant prodigue* (1884), awarded Grand Prix de Rome; *La Damselle éeue* (1888), text by Dante Gabriel Rossetti, trans. by Gabriel Sarrazin.

INCIDENTAL MUSIC: *Le Martyre de Saint-Sébastien* (first performed 1911), to the mystery play by Gabriele D'Annunzio.

UNACCOMPANIED CHOIR: *Trois Chansons de Charles d'Orléans* (1908).

SONGS: Over 50 songs, including: *Ariettes oubliées* (1888), text by Verlaine; *Fêtes galantes*, two sets (1892 and 1904), texts by Verlaine; *Proses lyriques* (1892–93); *Chansons de Bilitis* (1897), text by Pierre Louÿs; *Le Promenoir des deux amants* (1904–10); *Trois Ballades de François Villon* (1910); *Trois Poèmes de Stéphane Mallarmé* (1913).

##### Chamber music

*String Quartet* (1893); *Syrinx* (1912), for unaccompanied flute; *Sonata for Cello and Piano* (1915); *Sonata for Flute, Viola and Harp* (1915); *Sonata for Violin and Piano* (1917).

**BIBLIOGRAPHY.** EDWARD LOCKSPEISER, *Debussy: His Life and Mind*, 2 vol. (1962–65), a biographical, aesthetic, and psychological investigation, contains details of the ten publications of Debussy's correspondence and a discussion of Debussy's critical articles and librettos. LEON VALLAS, *Claude Debussy et son temps* (1932; Eng. trans., *Claude Debussy: His Life and Works*, 1933), is the first and most reliable of the early source books on Debussy. On individual works, see ALFRED D. CORTOT, "La Musique pour piano de Claude Debussy," *La Revue musicale* (1920; Eng. trans., *The Piano Music of Claude Debussy*, 1922); and MAURICE EMMANUEL, *Pelléas et Mélisande de Claude Debussy* (1926, reprinted 1950).

(E.L.)

## Decapoda

Decapods comprise a moderately large group of specialized, usually aquatic crustaceans commonly known as shrimp, lobsters, crayfish, hermit crabs, and crabs. More than 8,500 Recent species are known, the total number approaching one-third of all known crustaceans. The name decapod refers to the presence of five pairs of thoracic legs (pereiopods), usually modified for grasping, digging, walking, or swimming; the first pair of legs is usually modified into a pincher, or chela (cheliped).

Some decapods are among the more common animals of the seashore, and, because of their abundance and occurrence in many habitats, they have been known to man since earliest times. A few species of decapods, including many lobsters, some shrimps, and a few crabs, form the basis for economically important commercial fisheries. Many other species are sought for food locally but have limited economic value. Most of the known decapods are too small or rare to have any potential economic importance, but some of the smaller species are important as food items of higher animals. A few decapods serve as secondary hosts for parasites of man and other animals.

Decapods exhibit an enormous range of size as adults, from shrimps and crabs one centimetre long (less than one-half inch) to the giant spider crab of Japan (*Macrocheira kaempferi*), which measures almost 400 cm (12 ft) between the tips of its outstretched claws and may measure 45 cm (18 in.) across its body, making it the largest living arthropod (the phylum including inverte-

brates such as insects, arachnids, and crustaceans). An Australian crab, *Pseudocarcinus gigas*, may span 41 cm (16 in.) across the body and may weigh more than 13.5 kilograms (about 30 pounds). The American lobster (*Homarus americanus*) may attain a weight of 20 kg (44 lb), although individuals that size are rare.

Figure 1: Diversity among decapods.

Members of this order exhibit great diversity in structure. Two basic body types can be recognized, the macrurous and the brachyurous. In the macrurous, or shrimp-like, type of body organization, the body is elongate, often compressed laterally, with a long abdomen and a well-developed tail fan. The legs, usually two or more pairs of the anteriors, may be chelate and are often long and slender. In the brachyurous, or crablike, body organization, found in a few decapod groups, the body is flattened and laterally expanded, the abdomen folded beneath the carapace, and the tail fan reduced. The legs are often stout and short, and only the anteriors have claws.

Decapods are primarily marine animals, occurring in all oceans, from the intertidal zone to a depth of about 5,500 metres. In terms of numbers of species, they are most abundant in shallow waters and in warm tropical environments. Although the majority of decapods are marine, perhaps as many as 10 percent of the known species occur in freshwater or terrestrial habitats. Members of the caridean families (crustaceans in which the lateral plate

of the second abdominal segment overlaps the first) Atyidae and Palaemonidae, the macruran families (crustaceans with well-developed abdomens) Astacidae, Parastacidae, and a few relatives, the anomuran family (crustaceans with abdomens more or less reduced) Aeglididae, and the brachyuran family (crustaceans with greatly reduced abdomens) Potamidae, occur in fresh water. Many of these forms are restricted to freshwater habitats. Decapods utilizing terrestrial habitats are less numerous and include members of the anomuran family Coenobitidae as well as crabs of the families Ocypodidae, Gecarcinidae, and Grapsidae.

#### IMPORTANCE TO MAN

Some decapods form the basis for economically important commercial fisheries in areas around the world.

Species of shrimps and crabs, and many of the lobsters of the families Nephropidae and Palinuridae are caught in commercial quantities in both the Atlantic and Pacific oceans. The American lobster supports a small but valuable fishery off the northeastern United States, and the related *Homarus gammarus* and *Nephrops norvegicus*, are fished extensively in European waters. *Nephrops norvegicus*, known as the dublin prawn, scampi, and langostino, is a well-known commercial lobster.

Locally, burrowing decapods may have deleterious effects on farming and fishing. The land crab (*Cardisoma guanhumi*), from southern Florida and the Caribbean Sea, will eat young plants and is particularly destructive during spawning migrations, when local populations move as a unit. In Asia the mud shrimp *Thalassina anomala*, as well as a number of freshwater crabs, can seriously affect farming activities, not only by their burrowing activities but also by feeding on crop plants. The large swimming crab *Scylla serrata*, of the Pacific Ocean, is known to cause extensive damage to oysters but may itself be a locally important commercial species.

Although most decapods are edible, at least when thoroughly cooked, there are a few scattered references to poisonous crabs. In Hawaii, S.W. Tinker reports that the crab *Dromidiopsis dormia*, is regarded as poisonous by some people, but others are known to eat it. The 18th-century naturalist G.E. Rumpf (Rumphius) reported that a xanthid crab, *Eriphia sebana*, from Indonesia had caused two deaths. In a review of crab poisoning, L.B. Holthuis suggests that no species is poisonous, but that individual crabs might be toxic after ingesting toxic substances; he attributes some reports of poisonous crabs to other factors, including appearance, poor flavour, and allergic reactions by some people. Scientific evidence indicates that there are at least three species of poisonous crabs in the Ryukyu and Amani islands, Japan.

Although most decapods are not harmful when properly cooked, several of the Asian freshwater crabs serve as intermediate hosts for such parasites as the lung fluke. Although the flukes can be transmitted to a person eating the crab, they can be destroyed by cooking. In Africa, an eye disease, onchocerciasis, is caused by a nematode that can be transmitted by a fly, *Simulium*. Control of the disease was thwarted for many years until it was learned that fly larvae which had eluded medical entomologists for years, lived attached to the backs of river crabs.

#### NATURAL HISTORY

**Life cycle.** Most decapods brood their eggs. Only the shrimp of the section Penaeidea shed the eggs directly into the water. In the remainder of the decapods, the eggs are cemented to the abdominal appendages and carried until hatched. In crabs the abdomen, normally tightly appressed to the underside of the thorax, serves as a brood pouch. In shrimps a more open pouch is formed by the lateral extensions of the sides of the abdomen.

Most decapods hatch as free-swimming larvae, of which several basic kinds can be recognized. Although many different names have been applied to larval forms of different groups within the decapods, there are four basic larval types, each characterized partly by its mode of locomotion: the nauplius, with three pairs of appendages (antennules, antennae, and mandibles); the protozoea (from "stage preceding the zoea"), with three pairs of anterior appendages, as well as first and second maxillae and first and second maxillipeds; the zoea, with the remainder of the thoracic appendages; and the postlarva, in which the abdominal appendages are developed. Several molts can take place during each of these stages, with the appendages appearing in succession at each molt. The nauplius is believed to be the most primitive larval form, occurring in the section Penaeidea and in some other crustacean groups. The postlarva is a transitional stage between the pelagic larval stages and the juvenile stages in the life cycle. In benthic decapods, the postlarva is the first benthic stage; earlier stages are free-swimming.

In development, larvae undergo fundamental changes in methods of propulsion. In the nauplius and protozoea stages, propulsion is provided by the antennae, whereas in the zoeal stages it is by the thoracic appendages, as in some adult decapods of the open ocean. Only in the postlarval stage are the abdominal appendages developed enough to be used for locomotion.

In most groups the larva hatches in an advanced form, the zoea or an equivalent stage (mysis or phyllosoma). In relatively few species, the larval forms are completely suppressed or greatly reduced in number and the larvae pass through their metamorphic stages before hatching.

The commercially important pink shrimp (*Penaeus duorarum*) of the southeastern United States has a complicated life history, which may serve as an example of decapod development. Off the southwestern coast of Florida, adult shrimps are common in a large area with a depth of around 15–35 m (50 to 120 ft). Following copulation, the shrimp release their eggs in the open sea. The larvae hatch 13–14 hours later and make their way to the shallow, protected waters of the estuary in Everglades National Park. During their journey, the larvae pass through five naupliar, three protozoal, three mysis, and three postlarval stages. Young shrimps spend up to seven months in the estuary and grow to a length of 7–10 cm (3–4 in.). At this size they begin a return migration to the spawning grounds, which may take as long as two months. In general, the shrimps travel and are active only at night. During the day they burrow into the bottom. The remainder of their life is spent in the area of the spawning grounds.

**Behaviour.** Complicated behaviour patterns are known in many decapods but perhaps are best known in some of

Figure 2: Life cycle of the pink shrimp.

the fiddler crabs of the genus *Uca*, which generally inhabit areas on the shore exposed at low tide. In *U. maracoani*, a series of six phases of activity patterns have been observed. In the underground phase, during high tide, the animals remain in their burrows. As the tide recedes, the maintenance activity phase begins, devoted primarily to feeding and burrow repair. Next, in the nonaggressive wandering phase, the animals appear to move at random and feed, exhibiting, as in the previous phase, no defensive or aggressive behaviour. This phase may be transformed into an aggressive wandering phase in which males may attack other males and pursue females. Preliminary courtship behaviour occurs during this phase. Then, in the territorial phase, the male occupies and defends a burrow. Finally, in the display phase, the male displays in the vicinity of his burrow. Display behaviour (beckoning) by males of *Uca* is intensified by the approach of a female. During this behaviour, the large claw is extended slowly to the side, opened and raised slowly, and then retracted rapidly. In *Uca*, the display pattern known as beckoning is distinctive in each species. All of the known fiddler crabs can be classified into two large groups based on their beckoning patterns. These patterns are correlated with the shape of the carapace (dorsal shell). Species with a broad front on the carapace share similar display patterns that distinguish them from species with the narrow front. In *Uca*, perhaps more than in any other group of decapods, studies on behaviour, ecology, and morphology have combined to yield a great deal of information on the natural affinities and the classification of the animals.

A variety of activities relating to cleaning the body have been observed in decapods. In the shrimps, the second and third pereiopods are used to clean other appendages and the body; occasionally other legs are used also. The cleaning claws are often equipped with brushlike tufts of setae (bristles). The pleopods (abdominal appendages) are thoroughly cleaned before egg laying. For cleaning the eyes, fiddler crabs may use the small claw, the large claw, and the third maxillipeds, which may also clean the antennules and antennae.

Various forms of masking or camouflage behaviour are known in hermit crabs and in several groups of brachyuran crabs as well. The former are specially adapted to inhabit empty snail shells. The hermit crabs *Pagurus pri-deauxii* and *Dardanus arrosor* find a sea anemone, detach it from its normal substratum, and attach it to the gastropod shell that is used to protect the soft abdomen of the animal. As the crabs grow they change shells, selecting a larger one with each molt, and the anemone is transferred to the new shell. Many brachyuran crabs practice camouflage behaviour. Some spider crabs select pieces of algae or colonies of hydroids or bryozoans and attach

these to the dorsal surface of the carapace. Often the crabs are ornamented with small, hooked hairs to which algae and other foreign objects can be attached. The sponge crab *Dromia*, however, shapes a piece of sponge, which it carries on its back using the fifth pereiopods. This crab has been observed to use a variety of mechanisms for placing the sponge on its back. Other crabs carry half of the shell of a bivalve mollusk instead of a sponge.

**Locomotion.** Adult decapods utilize two basic types of locomotion, swimming and crawling, and different appendages may be used for each type. Most pelagic shrimps swim by means of long, fringed exopods on the thoracic appendages or by the pleopods. Crabs of the family Portunidae have the fifth pair of pereiopods modified into swimming paddles. In benthic decapods, all or most of the pereiopods, including the chelipeds, may be used in walking.

In the various stages of the life history of a given species, the individual may use different types of locomotion, involving different appendages, body orientation, and neuromuscular control. A swimming portunid crab hatches as a zoea and swims with its anterior end down and its dorsal surface forward, using the thoracic appendages for propulsion. As a postlarva, or megalops, it swims forward with the pleopods and may also walk sideways with four pairs of legs. As an adult it may walk sideways, utilizing three pairs of legs, or swim sideways utilizing the paddle-shaped fifth legs.

The macruran decapods share one mode of locomotion that they use as an escape mechanism. By strongly flexing the abdomen under the thorax, these animals can dart backward rapidly. Many of the thoracic appendages may be extended anteriorly, achieving a streamlined effect. The animals may use a few rapid flips of the abdomen to move short distances, but some, including lobsters of the genus *Panulirus*, may flex the abdomen many times and move for considerable distances. *Panulirus* has been reported to move 0.9–1.2 metres per second utilizing this mechanism.

Decapods use a variety of techniques for burrowing. Burrows may be excavated by digging motions with the thoracic legs. Some shrimps burrow by rapidly beating the pleopods, and the mole crab *Emerita* uses its uropods. To transport material from the burrow the pereiopods may be used, but the mud shrimp *Callinassa* uses the third maxillipeds. *Uca* carries out mud or sand utilizing pereiopods on the side with the small chela, and these same legs may be used to push the mud pellet away from the mouth of the burrow. Several forms, including the mole crab, have basic modifications of the body, in addition to those of the appendages, as adaptations to a burrowing existence.

**Reproduction.** The sexes are separate in the majority of decapods. Protandrous hermaphroditism, in which the animal spends a period of its life as a male then reverses its sex to become a female, is known among a few species of shrimps of the families Hippolytidae and Pandalidae. One species of thalassinid shrimp, *Calocaris macandreae*, is a functional hermaphrodite. In other decapods, paired testes or ovaries usually lie in the thorax but may extend into the abdomen; in hermit crabs the gonads are abdominal and may be located on the left side only. Paired male genital openings are on the ventral surface of the eighth thoracic somite; paired female openings are on the sixth thoracic somite.

Sperm is usually passed from the male to the female in spermatophores formed in the terminal portion of the male genital ducts (vasa deferentia). Each vas deferens is modified into an ejaculatory duct that opens on the coxa, or between the coxa and the basis, of the fifth leg. Rarely, the male genital openings are sternal in position. The first, and often the second, pleopods are modified in males as gonopods for transmission of spermatophores. In many crabs and in the crayfishes, the form and ornamentation of the gonopod is unique for each species. The female is grasped by the male, and spermatophores are attached to the ventral surface of the female or, more often, are

Display  
behaviour  
of fiddler  
crabs

Burrowing  
techniques

placed by the male in a seminal receptacle or spermatheca of the female.

In most macrurous decapods, as well as in some crab groups (gymnopleurans and dromiaceans), the oviducts open on the coxae of the third pereopods and the spermathecae are sternal; in these groups fertilization is external. In the other crab groups, the female genital openings are on the thoracic sternum, the spermathecae are enlargements of the oviducts, and fertilization is internal.

There are several different patterns of mating activity, many of which apparently are linked to the molting cycle. Crabs of the genus *Maia* undergo a molt of puberty at a relatively large size and do not molt again after becoming sexually mature. In *Carcinus*, which may molt and grow indefinitely, the copulatory appendages appear and the animal reaches sexual maturity after the molt of puberty. In both *Carcinus* and *Maia* there may be a definite prepuberal molt. In the shrimp *Lysmata seticaudata*, many individuals of which are protandrous hermaphrodites, a molt of prepuberty precedes that of puberty by about six months. At the molt of puberty each individual becomes a male, but 18 months later the animal undergoes a critical molt during which the male appendages are shed. The shrimp may then be a sterile intersex (a temporary condition) or a functional female, depending on its level of food reserves.

Male decapods can copulate only when their exoskeleton is fully hardened, but in the crabs, at least, females need not be fully hardened. In the Cancridae, Portunidae, and some Majidae, the females can mate only following a molt, when they are soft. In other majids, *Hyas coarctus* and *Maia squinado*, the females may be either hard or soft. In crabs of the families Xanthidae, Grapsidae, and Ocypodidae most mating females are hardened. R.G. Hartnoll suggests that soft-female mating, correlated with a simple vagina structure, is the primitive condition, and from this, on several occasions, hard-female mating evolved, correlated with a more complex vagina structure.

**Ecology.** Although most decapods, in terms of major groups and numbers of species as well, have adapted to a benthic existence, members of some shrimp groups are well adapted to life in the open ocean. Among these are shrimps of the penaeidean families Penaeidae and Sergestidae, as well as some caridean shrimps, principally of the families Oplophoridae, Pasiphaeidae, Pandalidae, and Bresiliidae. These shrimps are generally streamlined and relatively soft bodied, usually with a very thin, membranous integument, although in some oplophorids the carapace may be quite hard. The swimming appendages are well developed. In most groups the thoracic legs are provided with functional exopods and the pleopods are also strongly developed.

Shrimps living near the surface are usually unpigmented, clear in colour, or with some pigment in scattered chromatophores; those living just below the surface may show more pink coloration. Mesopelagic shrimps (free-swimming in midwater) are usually red, sometimes quite dark. In some species of *Notostomus* the abdomen is scarlet and the carapace darker, almost black. Some of these shrimps live to a depth of 5,000 m (about three miles), but below 500–1,000 m the red pigment appears black, for the red rays of sunlight are filtered out by the surface waters.

Some deep-sea shrimps possess light organs (photophores); particularly species of *Sergestes* and representatives of two genera of Oplophoridae, *Systellaspis* and *Oplophorus*. *Sergestes* may have 125 to 150 photophores, which in *S. prehensilis* are thought to light up in succession from head to tail. The photophores may occur on the eyestalks, the margin of the carapace, the roof of the branchial chamber, on the abdomen, or on the legs of the thorax and abdomen. There appears to be a correlation between photophore development and eye size, suggesting that the photophores aid in feeding or species recognition. Some oplophorids are able to discharge clouds of luminescent material from glands near the mouth.

Pelagic shrimps undergo daily vertical migrations, pos-

sibly in response to changes in light intensity and food concentrations. Shrimps living between 200 and 1,200 metres in the sea have been found to undergo vertical migrations of 200 to 600 in a 24-hour period. *Acanthephyra purpurea* has been found at 800 m at noon and at 200 m at midnight, a journey of 600 m in 12 hours or a speed of vertical movement of some 50 m per hour.

Decapods have also taken advantage of one specialized open-ocean habitat, that afforded by the Sargassum weed, *Sargassum natans*. A portunid crab, *Portunus sayi*, the grapsid crabs *Planes minutus* and *Pachygrapsus marinus*, and several shrimps are commonly found living on the weed at sea. All are a mottled brown colour like the weed. Two of the shrimps, *Latreutes fucorum* and *Leander tenuicornis*, also occur on seaweeds in shallow waters. Species of *Planes* are also commonly found on flotsam at sea.

The terrestrial environment has been invaded by relatively few decapods. Some representatives of the anomuran family Coenobitidae, including the species of the hermit crab genus *Coenobita* and the robber crab *Birgus latro*, and true crabs of the family Gecarcinidae, are terrestrial. Ocypodid crabs, including species of the fiddler crab *Uca* and the ghost crab *Ocypode*, also live on the shore but are more dependent on the sea than the gecarcinids. In colonizing terrestrial habitats, these decapods have evolved the ability to regulate the internal concentrations of their body fluids and have accompanying mechanisms to protect against desiccation and the allied problem of overheating. In addition, they have developed methods of communication by visual and acoustic signals. According to D.E. Bliss, behavioral modifications involving primarily burrowing activity and physical movements, help to minimize water loss, aid exposure to favourable rather than extreme environmental conditions, and maintain a balance between evaporative cooling and dehydration. As a general rule, terrestrial decapods spawn in the sea.

In adult land crabs, water balance is maintained by the gills, gut, and pericardial sacs, which assimilate, store, and recirculate salts and water under the control of the central nervous system.

Respiration in terrestrial decapods has been made possible by extensive vascularization of the gill surfaces. Apparently invasion of the terrestrial environment has been accompanied by reduction in the number or the volume of the gills, vascularization of epithelial surfaces in the branchial chambers, enlargement of the gill chambers (in crabs such as *Gecarcinus* and *Uca*), or vascularization of the epithelial surfaces (in the hermit crab *Coenobita*, which apparently can survive amputation of the gills).

Most terrestrial or semiterrestrial crabs are found in the tropics, but some species of *Uca* extend northward into temperate climates. Bliss has described the zonation of *Ocypode*, *Cardisoma*, and *Gecarcinus* on Bimini, Bahama Islands. *Ocypode quadrata* remains on beaches where it can enter the ocean freely to keep its gills moist and help maintain normal concentrations of body fluids. *Cardisoma guanhumi* is only found in areas of relatively low elevation, where it constructs burrows extending into fresh water. *Gecarcinus lateralis* shows some overlap with *Cardisoma* but is found over the entire island. Its burrows do not extend into water and it can live almost independently of the aquatic environment. Among modifications developed by this crab are the highly vascularized epidermis of the branchial chambers, enormously developed pericardial sacs, which extend into the branchial chambers, and the ability to absorb water from dew or rain through tufts of hairs on the underside of the body.

In the West Indies the hermit crab *Coenobita clypeatus* also has evolved a high degree of independence from the sea. On the island of Dominica it is found some two miles from the shore and at an altitude of nearly 400 metres (1,300 feet). Like the marine hermit crabs, *Coenobita* must inhabit an empty gastropod shell to protect its uncalcified abdomen. Its relative, the robber or coconut crab of the Pacific, *Birgus latro*, is unusual among the hermit crabs in having a calcified abdomen. *Birgus* is an active

water  
decapods

crab and an agile climber, apparently omnivorous, but possibly with a preference for coconuts. It is eaten by man in areas where it still exists.

Relatively few decapod groups have successfully colonized fresh water. Those with fresh water representatives include the caridean shrimp family Palaemonidae (especially species of the genera *Macrobrachium* and *Palaemonetes*), all of the shrimps of the family Atyidae, all members of the crayfish families Astacidae (Europe, North and Central America) and Parastacidae (South America, Australia, Indo-Malaya, and Madagascar), and all species of the genus *Aegla* (the only anomurans restricted to fresh water). Among the crabs, the families Potamidae (Old World) and Pseudothelphusidae and Trichodactylidae (both New World) are exclusively freshwater. Some other crabs, including members of the family Grapsidae such as the Chinese mitten crab (*Ereiocheir sinensis*) and species of *Platycheirograpsus*, also live in fresh water. One species, *Metopaulias depressus*, lives in fresh water in West Indian plants of the bromeliad family. Although some of these species, including certain members of the genera *Macrobrachium* and *Ereiocheir*, must return to salt water to spawn, many go through their entire life cycle in fresh water. In most of those spawning in fresh water, larval development is abbreviated and the young often hatch as miniature adults.

The fresh water habitat has probably been invaded independently by several evolutionary lines. The crayfishes appear to be the oldest inhabitants of fresh water among the decapods, judged by the fact that their entire life cycle is spent there. Those species that must return to the sea to spawn are considered to be more recent invaders of the habitat.

Penetration of fresh water is dependent upon the organism's ability to maintain its blood concentration at a level different from the medium. Blood concentration of marine decapods is usually equal to the medium (isotonic), whereas in fresh water form it is much higher. In adapting for life in fresh water, decapods have developed several mechanisms, including reduction of the permeability of the body surface, development of greater tolerance for variations in blood concentrations, and the ability to transport inorganic ions in or out of the body against a concentration gradient.

Symbiosis  
and  
parasitism

Representatives of several different decapod groups have developed commensal relationships (in which the guest symbiont does not use the host tissue as food) with other animals, particularly echinoderms, mollusks, and coelenterates (cnidarians), including corals, sea anemones, and sea whips. Commensal relationships exist in more than 80 species of the palaemonid shrimp subfamily Pontoninae, certain hippolytid shrimps, some snapping shrimps, and several stenopodidean shrimps. Most anomuran decapods are free-living, but some galatheid lobsters live on crinoids and numerous porcellanid crabs live as commensals. The West Indian Porcellana sayana often is found in the shell carried by the large hermit crab *Petrochirus*. Although hermit crabs are free-living, several carry anemones or bryozoan colonies on their shells, and in some species the bryozoans dissolve the shell, the colony becoming the shelter for the crab.

Among the crabs, the dromiaceans or sponge crabs carry a live sponge or other object on their backs. Most of the brachyrynch crabs are free-living, but a few groups are commensal with sponges, coelenterates, mollusks, polychaete worms, or echinoderms. A pea crab, *Pinnotheres ostreum*, which lives in the American oyster and sometimes in other invertebrates, may be considered as a parasite, for its feeding activities on the mucous masses of the bivalve's gills leaves evidence of gill damage. Another pinnotherid, *Dissodactylus*, can be found living on echinoderms. The family Hapalocarcinidae contains the gall crabs, of which the female forms a pocket within a living coral and spends her adult life there. Relatively few of the oxyrhynch crabs are commensals, but all members of the subfamily Eurnedoninae, family Parthenopidae, are commensals of echinoderms.

Decapods may also serve as hosts of commensal ani-

mals; many of the species that form burrows act as hosts for a variety of animals. The land crab *Gecarcinus* may share its burrow with the minute fly, *Drosophila*, which lays its eggs on the crab; larval flies may be found on the mouthparts or in the gill chambers. One of the common thalassinidean shrimp from the west coast of the United States, the ghost shrimp or mud shrimp *Callinassa californiensis*, shares its burrow with no less than nine other species: a gobiid fish, three species of pea crabs, a snapping shrimp, two species of copepods, a polychaete worm, and a small clam. As many as five of these, the fish, the clam, the worm, a pea crab, and a copepod, can be found in the burrow at one time. The blue mud shrimp of the California coast (*Upogebia pugettensis*) also serves as host to a number of commensals and, in addition, may be parasitized by a pair of isopods.

Shrimps of several families in the Atlantic and Pacific oceans have developed a very specialized symbiotic relationship with fishes. An individual shrimp apparently occupies a "cleaning station" to which fish come to have parasites removed. Some fish, ordinarily predatory on crustaceans, will allow the shrimp to enter the mouth and gill chambers to search for parasites. Brightly coloured shrimps of the genera *Periclimenes* (family Palaemonidae), a genus containing many species commensal on other invertebrates, *Hippolytina* (family Hippolytidae), and *Stenopus* (family Stenopodidae) are known to exhibit cleaning behaviour.

#### FORM AND FUNCTION

All decapods share a basic body plan, in which the body is a modified tube made up of 19 distinct rings or segments, to each of which is attached one pair of appendages. Each body segment or somite comprises a dorsal portion, the tergum; a ventral portion, the sternum; and, on each side, a flap of the tergum that extends below the sternum, the pleuron. The appendages are attached to the sternum by a membrane. In addition to the 19 somites bearing appendages, there is an anterior portion of the body bearing the stalked, compound (multifaceted) eyes, and a terminal portion, the telson, through which the alimentary canal opens to the exterior via the anus; the telson lacks appendages. Decapods, like other eumalacostracan crustaceans, have three distinct body regions: head, thorax, and abdomen. In decapods the head and thorax are fused and may be referred to as the cephalothorax. One of the characteristics of decapods is the head shield, or carapace, that covers the cephalothorax dorsally and extends laterally over the gills at the bases of the thoracic appendages. There are five pairs of head appendages, eight pairs of thoracic appendages, and six pairs of abdominal appendages.

Basic  
body  
plan

Figure 3: Typical external structure of the decapod body.

**Appendages.** Decapod appendages all appear to have been modified from one basic plan, in which two branches, an inner endopod and an outer exopod, arise from a basal portion, the protopod, which is attached to the body. The protopod comprises two indistinguishably fused segments, the praecoxa and coxa, and a distinct segment, the basis. The endopod and exopod both attach to the basis. The coxa may bear a separate branch, the epipod. The endopod typically consists of five segments, the ischium, merus, carpus, propodus, and dactylus; the walking legs and chelipeds of decapods are formed by the endopod.

The anterior two pairs of head appendages, the **antennules** (first antennae) and the **antennae** (second antennae), serve sensory functions, including olfaction, touch, and balance. The antennules typically consist of a three-segmented stalk with two many-jointed whiplike flagella. In some shrimps one of the flagella may be secondarily subdivided and there may be stylocerite or antennular scale. The proximal segment of the stalk of the antennule usually contains an organ of balance, the statocyst, absent in some shrimps. The second antennae have a **five-segmented** stalk and a single flagellum. A movable, articulated exopod, the antennal scale or squama, may be present. In adult decapods, the proximal segment of the antennae each contain the opening of the excretory organ, the green gland.

Mouth-  
parts

The posterior three head appendages serve as mouthparts. The heavily calcified mandibles may have distinct molar and incisor processes and often have a three-segmented mandibular palp. The mandibles are the crushing and chewing mouthparts. The maxillules or first maxillae and the maxillae (second maxillae) are the flattened, multilobed food manipulators. The exopod of the maxilla, called the scaphognathite or gill bailer, extends over the gills and acts as a pump to help maintain a constant stream of water over the gills.

The anterior three thoracic appendages or thoracopods, called the first, second, and third maxillipeds, also serve as mouthparts. The first and second maxillipeds are leaflike, resembling the maxillae. The third maxillipeds are elongate in the shrimps, but in the crabs each is highly modified as an operculum, or cover, for the mouth and mouthparts.

The posterior five pairs of thoracic appendages are the walking legs or pereopods. They may be modified by loss of exopods and epipods, fusion of segments, development of extra segments, formation of pinching claws (chelae or subchelae) or swimming paddles. They may be reduced or even lost. In the brachyurous or crablike decapods, the first pereopods usually are modified as chelae, and the fifth pereopods may be modified into paddles, reduced in size, or absent. In many anomurans, the fifth pereopods are chelate. In the macrurous or shrimplike decapods all five pereopods may be chelate, but usually only the anterior two or three are so modified; in certain shrimps some segments of the chelae are multiarticulate.

Basically, the anterior five pairs of abdominal appendages are bilobed, leaflike swimmerets or pleopods, and, in macrurous forms, they may be used as swimming appendages. The anterior two pairs may be modified as sexual appendages, or gonopods, in males, serving in sperm transfer. They may be vestigial or even absent in females. In brachyurous forms the pleopods have lost their swimming function. In females they serve as attachments for the egg mass and in males the anterior two are modified into gonopods. The sixth or last pair of abdominal appendages are the uropods. In macrurous forms these form a tail fan with the telson, the terminal segment of the body. In brachyurous forms the uropods are usually absent, but in hermit crabs the uropods are modified into structures that help to hold the abdomen of the crab in the gastropod shell in which it lives.

**Nervous system.** The central nervous system in decapods is made up of a supraesophageal ganglion with lateral connections to a subesophageal ganglion. The ventral nerve cord may be connected to additional thoracic and abdominal ganglia. In most brachyurans the ganglia are fused into a central mass from which nerves radiate.

A variety of structures serve as sense organs. The eyes are usually well developed with a pigmented, multifaceted cornea; but they may be reduced in size, or lacking pigment, or even absent in some deep-sea and cave species. Balance organs (statocysts), which may contain a sand grain or other inclusion in a cavity lined with fine hairs (setae), are on the basal segment of the antennule. Tactile setae may be present on various parts of the body and olfactory setae are present on the antennular flagella.

Sense  
organs

**Circulatory system.** As in other crustaceans, the circulatory system is open. The heart is located to the rear of the carapace (cardiac region) above the gut. Blood flows from the heart through several arteries to various parts of the body, returns through the tissues into a ventral sinus, and passes through the gills to the pericardial sinus around the heart. The blood contains a respiratory pigment, hemocyanin.

**Respiratory system.** 4 series of gills, attached to the body wall of the thorax or to the bases of the thoracic legs, serves as respiratory organs. A variety of gills is found: podobranchs, attached to the coxae of the thoracic legs; arthrobranchs, attached to the articular membranes of the appendages; and pleurobranchs, attached to the body wall. In some cases the epipods may have a respiratory function. The number of gills present is always less than the theoretical maximum of 32 pairs. The number, position, and kind of gill are important characters for the higher taxonomic categories. Three basic gill types can be recognized: dendrobranchiate, with the main axes branched; phyllobranchiate, with the branches flattened and arranged in two series; and trichobranchiate, with the filaments arranged in series around the stem.

Water currents are maintained over the gills by the motion of the scaphognathite, the exopod of each maxilla. The current usually runs anteriorly from the bases of the legs, but it is reversed in some burrowing species.

**Digestion and excretion.** The gut or alimentary tract of decapods is basically a straight tube in which three regions can be recognized: the stomodaeum, or foregut, the mesenteron, or midgut, and the proctodaeum, or hindgut. The foregut, expanded anteriorly to form a stomach, and the hindgut have a chitinized or calcified lining; the cardiac or anterior portion of the stomach contains a movable, calcified masticatory apparatus known as the gastric mill. The midgut is ramified with numerous blind pockets or ceca and to it are attached ducts from the hepatopancreas or digestive gland. The highly ramified hepatopancreas extends through much of the cephalothorax; in the Paguroidea it extends into the abdomen.

The green gland or antennal gland, which opens on the basal segment of the antenna, is the primary excretory organ of the decapods. A maxillary gland with the same function, believed to be more primitive, is found in some decapod larvae. The opening of the antennal gland may be operculate in brachyurous forms.

#### EVOLUTION AND PALEONTOLOGY

The decapods first appeared in the Early Triassic or Late Permian periods with forms identified with peneideans (shrimps and prawns) and the fossil family Erymidae in the nephropideans. There was an expansion in the Early Jurassic Period, with representatives of fossil Nephropidea, Palinuroidea, Thalassinoidea, and Paguroidea, as well as one from the Brachyura. In the Middle and Late Jurassic, the decapods apparently adapted to the varied environments afforded by coral reefs, and a diversified crab fauna was developed, mainly with representatives of the fossil family Prosoponidae. The oldest crayfishes have been found in deposits of the Late Jurassic and Early Cretaceous periods, and in the latter period nephropids and palinurans began to outnumber the Erymidae and Glypheoidea, respectively. The crabs began to increase in numbers in the Early and Late Cretaceous, and by the Tertiary Period most modern groups were established. The Tertiary was a period of rapid diversification of the crabs, accompanied by a reduction in numbers of the reptant macrurans. Dromiaceans and raninids decreased in the Tertiary, whereas oxyrhynchs and xanthids flourished. The Tertiary also marked the appearance of freshwater shrimps and crabs.

Relatively little is known of the origin and evolution of the Decapoda, for many of the early shrimps left no fossil record, presumably because they were soft bodied. Both reptant and natant forms, the latter represented by forms similar to modern penaeideans, were established by the Triassic Period. M.F. Glaessner has pointed out that there is no evidence showing the relation between

the early penaeideans and the other decapods, but some zoologists consider the penaeideans to be the ancestral decapods. It has been suggested that the lobster-like fossil order Pygocephalomorpha or representatives of the unspecialized, shrimp-like fossil order Eocaridacea, or both, may be related to ancestral decapods.

#### CLASSIFICATION

Distinguishing taxonomic features. In classifying the Decapoda taxonomists primarily use characters based on external morphology. In the Natantia, the form of the appendages, the shape and decoration of the carapace and abdomen, and the number and kinds of gills are primary taxonomic characters. In certain Natantia and in the section Brachyura of the Reptantia the characters afforded by the male gonopod are often important at the specific level. In the Brachyura, features of the outer maxillipeds, the five pereopods, and the structure and ornamentation of the carapace are used; the position and nature of the genital openings are important distinguishing features of the higher categories.

Annotated classification. The classification given below is based primarily on the higher categories as proposed by L.A. Borradaile (1907), with modifications within the Caridea proposed by L.B. Holthuis (1955); with a few other modifications, it is used by modern taxonomists. An alternative classification, proposed by M.F. Glaessner, follows the discussion of classification below.

#### Order Decapoda

Malacostracan crustaceans in which the anterior three thoracic appendages are modified as mouthparts (maxillipeds). No more than the posterior five thoracic appendages are locomotory. Gills are arranged in several series on the thoracic appendages. Larvae hatch as a nauplius or in a more advanced stage. Marine and freshwater, a few terrestrial. More than 8,500 Recent species.

##### Suborder Natantia (shrimps)

Body usually laterally compressed; rostrum usually well-developed. First abdominal somite not markedly smaller than remainder. Male genital apertures in articular membrane. Pleopods well-developed, used for swimming. Contains about 2,000 species.

*Section Penaeidea.* Pleura of second abdominal somite not overlapping those of first somite. Third pereopods chelate, not stronger than first pair. First pleopods of male with petasma (a hooked plate). Female with thoracic thelycum (seminal receptacle). Eggs shed into water, larvae hatch as nauplius. Gills dendrobranchiate. About 325 living species.

*Superfamily Penaeoidea.* Fourth and fifth pereopods and gills not reduced. Adults benthic in shallow water or pelagic in midwater or deep water.

*Superfamily Sergestoidea.* Fourth and fifth pereopods are reduced. Gills reduced or absent. Adults pelagic.

*Section Caridea.* Pleura of second abdominal somite overlap those of first and third somites. Third legs not chelate. Males lacking petasma; second pleopod with two styliform appendices. Females lacking thelycum; second pleopod with one styliform appendix. Eggs attached to pleopods, hatching at stage later than nauplius. Gills phyllobranchiate. Over 1,600 Recent species.

*Superfamily Oplophoroidea.* Pereopods usually with exopods. First pair of pereopods chelate, usually slenderer than second, fingers of chela not unusually long. Carpus of second pereopods not secondarily subdivided. Over 200 species, pelagic in open ocean (Oplophoridae) or benthic in fresh water (Atyidae).

*Superfamily Stylodactyloidea.* Pereopods without exopods. First pair of pereopods chelate, fingers long and slender. Distal two joints of second maxilliped set side by side, at end of antepenultimate segment. One family; less than 10 species.

*Superfamily Pasiphaeidea.* First and second pereopods chelate; cutting edges of fingers pectinate. One family containing about 60 species of pelagic shrimps.

*Superfamily Bresilioidea.* First pair of pereopods chelate, usually stronger but shorter than second. About 15 species in 4 families.

*Superfamily Palaemonoidea.* Pereopods without exopods. First pair of pereopods chelate, usually slenderer than second. Carpus of second pereopods not secondarily subdivided. Over 400 species in four families; the river shrimp, *Macrobrachium*, family Palaemonidae, contains the largest living shrimps, up to 19 cm in length.

*Superfamily Psalidopodoidea.* First pair of pereopods with both fingers movable. One family with three species.

*Superfamily Alphaeidea.* Carpus of second pereopods is usually subdivided into two or more segments. First pair of pereopods with distinct chelae. Over 600 species in four families, including the snapping shrimp, family Alpheidae.

*Superfamily Pandaloidea.* Carpus of second pereopods usually subdivided into two or more segments. Chelae of first pair of pereopods small or absent. About 120 species in three families, some pelagic.

*Superfamily Crangonoidea.* First pair of pereopods subchelate. Fewer than 200 species in two families; benthic.

*Section Stenopodoidea.* Pleura of second abdominal somite not overlapping those of first. Third pereopods chelate, usually stouter than first. Males lacking petasma; females lacking thelycum. Eggs carried on pleopods by female. Gills trichobranchiate. About 20 species in one family.

##### Suborder Reptantia

Body usually depressed. Rostrum often lacking. First abdominal somite usually smaller than remainder. Male genital apertures coxal or sternal. Pleopods usually reduced or absent, not locomotory.

*Section Macrura.* First and third pereopods similar, subcylindrical or with chelae. Flagella of anterior three maxillipeds directed anteriorly. Abdomen natant-like, with well-developed pleura and broad tail fan. About 700 species in four superfamilies.

*Superfamily Eryonidea.* Carapace depressed, fused with epistome. Integument soft. Anterior four, or all five, pereopods chelate. First pleopods absent. About 40 species, blind inhabitants of deep sea.

*Superfamily Nephropidea.* Carapace usually depressed; integument hard. Rostrum present. Anterior three pereopods chelate, first usually stoutest. Includes the marine lobsters (Nephropidae) and the freshwater crayfishes. More than 300 species.

*Superfamily Scyllaridea.* Carapace depressed, integument hard. Rostrum absent. No legs chelate, except sometimes the fifth in female. Includes the spiny lobsters, Palinuridae, and Spanish or shovel lobsters, Scyllaridae; together, about 100 species.

*Superfamily Thalassinidea.* Carapace compressed, integument usually soft. First pereopods chelate or subchelate, third pereopods not chelate. Contains several anomuran-like families of uncertain position. Most of the 250 species are secretive, burrowing forms.

*Section Anomura.* Fifth pereopods always differing from third in length, size, and shape. Abdomen not natant-like; usually reduced. Uropods usually present.

*Superfamily Galatheaidea.* Abdomen recurved anteriorly, bent under carapace. First pereopods chelate. Tail fan well-developed. Includes the squat lobsters (Galatheaidea, Uroptychidae) and the porcelain crabs or rock sliders (Porcellanidae); the latter resemble true crabs but have uropods and chelate fifth pereopods. About 600 species, mostly marine; one family, Aeglididae, lives entirely in fresh water.

*Superfamily Paguridea.* Abdomen asymmetrical, usually soft and unprotected; sometimes hardened and bent under thorax. First and occasionally fifth pereopods chelate. Tail fan, if present, adapted for holding abdomen in shelter. Includes several families of marine hermit crabs, the terrestrial hermit crabs, and the king crabs; about 700 species are known.

*Superfamily Hippidea.* Abdomen symmetrical, bent under thorax. First pereopods styliform or subchelate. Not chelate. Tail fan adapted for burrowing. Two families. Includes about 60 species of marine burrowing crabs, many of which live in sand in the intertidal zone.

*Section Brachyura* (true crabs). Carapace broad, lateral margins almost always well-developed. Abdomen symmetrical, bent under thorax, tail fan absent. First pereopods chelate or subchelate. About 4,500 Recent species.

*Subsection Gymnopleura.* Carapace elongate, not covering anterior abdominal somites. First pereopods subchelate. Oviducts open on coxa. Fifth pereopods subdorsal in position. About 30 species of marine burrowing crabs in one family Raninidae; they may be related to subsection Oxystomata, below, but their position is uncertain.

*Subsection Dromiacea.* Carapace usually not elongate. First pereopods chelate. Fifth pereopods dorsal in position, modified to hold shells, sponges, and other objects over the body. Oviducts open on coxae.

*Superfamily Dromiidea.* Sternum of female with longitudinal grooves. Remnants of uropods usually present. About 175 species in three families; marine; includes sponge crabs.

**Superfamily Homolidea.** Sternum of female lacking longitudinal grooves. Uropods absent. Contains about 25 species living in deep water.

**Subsection Oxytomata.** Mouth frame triangular, produced anteriorly. Female openings usually sternal. Fifth pereopods normal or modified as in Dromioidea. Includes purse crabs (Leucosiidae), box crabs (Calappidae), and masking crabs (Dorippidae); about 500 species known, all marine.

**Subsection Brachygnatha.** Mouth frame quadrate. Female openings usually sternal. Fifth pereopods normal, not reduced or dorsal in position. Includes about 3,800 species of true crabs.

**Superfamily Brachyrhyncha.** Body not narrowed anteriorly. Rostrum reduced or absent. Orbits well developed. Includes the swimming crabs (Portunidae), mud crabs (Xanthidae), land crabs (Gecarcinidae), fiddler crabs (Ocypodidae), square back crabs (Grapsidae), pea crabs (Pinnotheridae), and several families of freshwater crabs; about 2,900 species.

**Superfamily Oxyrhyncha.** Body narrowed anteriorly. Rostrum usually present. Orbits usually poorly developed. Includes the spider crabs (Majidae) and several smaller families of crabs; about 900 species, all marine.

**Critical appraisal.** Present classifications and phylogenetic schemes suggested for the Decapoda are not accepted by all authorities, for several reasons. Evidence derived by neontologists from Recent species, based on mouthfield and mouthpart structure, gill number and position, and internal morphology, conflicts with evidence on fossil forms, based mostly on carapace morphology, presented by paleontologists. Further, evidence from studies on larval forms of Recent species also seems to be contradictory. For example, zoologists have suggested that the Brachyura arose from astacidean stock (morphology) or from thalassinidean stock (larval development), whereas the fossil evidence strongly supports the derivation of the Brachyura from the Glypheoidea, a superfamily of fossil palinurans. In 1969 M.F. Glaessner reviewed earlier classifications and the phylogeny of decapods and proposed the following classification (groups indicated by a dagger are known only from fossils):

- Order Decapoda
  - Suborder Dendrobranchiata
    - Infraorder Penaeidea
      - Superfamily Penaeoidea
      - Superfamily Sergestoidea (no fossil record)
  - Suborder Pleocyemata
    - Infraorder Stenopodidea (no fossil record)
    - †Infraorder Uncinidea
    - Infraorder Caridea
    - Infraorder Astacidea
    - Infraorder Palinura
      - †Superfamily Glypheoidea
      - Superfamily Eryonoidea
      - Superfamily Palinuroidea
    - Infraorder Anomura
      - Superfamily Thalassinioidea
      - Superfamily Paguroidea
      - Superfamily Galatheoidea
      - Superfamily Hippoidea
    - Infraorder Brachyura
      - Section Dromioidea
        - Superfamily Dromioidea
        - Superfamily Homoloidea
        - †Superfamily Dakotancroidea
      - Section Oxytomata
        - Superfamily Dorippoidea
        - Superfamily Calappoidea
        - Superfamily Raninoidea
      - Section Oxyrhyncha
      - Section Cancridea
      - Section Brachyrhyncha
        - Superfamily Portunoidea
        - Superfamily Xanthoidea
        - Superfamily Ocypodoidea

In this classification, the first eight categories (the suborder Dendrobranchiata and the suborder Pleocyemata, up to and including Caridea) correspond to the suborder Natantia of the above annotated classification. The Thalassinioidea are considered by Glaessner to be anomurans. This classification emphasizes the distinctness of the Penaeidea and provides other modifications that make the conventional classification more acceptable to the paleontologist.

## Dedekind, Richard

Highly original, the German mathematician Julius Wilhelm Richard Dedekind developed a major redefinition of irrational numbers (see below) in terms of arithmetic concepts. Although not fully recognized in his lifetime, his treatment of the ideas of the infinite and what constitutes a real number continue to influence modern mathematics.

By courtesy of the Library of the Swiss Federal Institute of Technology, Zurich

Dedekind.

Dedekind was born the son of a lawyer on October 6, 1831, in Brunswick (modern Braunschweig), Germany. While attending the Gymnasium Martino-Catharineum in 1838–47 in Brunswick, he was at first interested primarily in chemistry and physics. At the Caroline College in 1848–50, however, he turned to calculus, algebra, and analytic geometry, which helped qualify him to study advanced mathematics at the University of Gottingen under the mathematician Carl Friedrich Gauss.

After two years of independent study of algebra, geometry, and elliptic functions, Dedekind served as *Privatdozent* ("unsalaried lecturer") in 1854–58 at the University of Gottingen, where, in his lectures, he introduced, probably for the first time, the Galois (*q.v.*) theory of equations and attended the lectures of the mathematician Peter Gustav Lejeune Dirichlet. These experiences led Dedekind to see the need for a redefinition of irrational numbers in terms of arithmetic properties. By contrast, the geometric approach had led Eudoxus in the 4th century BC to define them as approximations by rational numbers (*e.g.*, a series of non-repeating decimals, as  $\sqrt{2} = 1.414213\dots$ ).

Early training

In 1858 Dedekind joined the faculty of the Zurich Polytechnikum, where he remained for five years. In 1862 he accepted a position in the Technische Hochschule in Brunswick, where he remained in comparative isolation for the rest of his life.

While teaching there, Dedekind developed the idea that both rational and irrational numbers could form a continuum (with no gaps) of real numbers, provided that the real numbers have a one-to-one relationship with points on a line. He said that an irrational number would then be that boundary value that separates two specially constructed collections of rational numbers.

Dedekind perceived that the character of the continuum need not depend on the quantity of points on a line segment (or continuum) but rather on how the line submits to being divided. His method, now called the Dedekind cut, consisted in separating all the real numbers in a series into two parts such that each real number in one part is less than every real number in the other. Such a cut, which corresponds to a given value, defines an irrational number if no largest or no smallest is present in either part; whereas a rational is defined as a cut in which one part contains a smallest or a largest. Dedekind would therefore define the square root of 2 as the unique number dividing the continuum into two collections of numbers, such that all the members of one collection are greater than those of the other; or, that cut, or division, separating a series of numbers into two parts such that one collection contains all the numbers whose squares are larger than 2, and the other contains all the numbers whose squares are less than 2.

Dedekind developed his arithmetical rendering of irrational numbers in 1872 in his *Stetigkeit und Irrationale Zahlen* (Eng. trans., "Continuity and Irrational Numbers," published in *Essays on the Theory of Numbers*, 1901). He also proposed, as did the German mathematician Georg Cantor (q.v.), two years later, that a set—a collection of objects or components—is infinite if its components may be arranged in a one-to-one relationship with the components of one of its subsets. By supplementing the geometrical method in analysis, Dedekind contributed substantially to the modern treatment of the infinitely large and the infinitely small.

While vacationing in Interlaken, Switzerland, in 1874, Dedekind met Cantor. Dedekind gave a sympathetic hearing to an exposition of the revolutionary idea of sets that Cantor had just published, which later became prominent in the teaching of modern mathematics. Because both mathematicians were developing highly original concepts, such as in number theory and analysis, which were not readily accepted by their contemporaries, and because both lacked adequate professional recognition, a lasting friendship developed.

Continuing his investigations into the properties and relationships of integers—that is, the idea of number—Dedekind published *Über die Theorie der ganzen algebraischen Zahlen* (1879; "On the Theory of Algebraic Numbers"). There he proposed the "ideal" as a collection of numbers that may be separated out of a larger collection, composed of algebraic integers that satisfy polynomial equations with ordinary integers as coefficients (see ALGEBRAIC STRUCTURES). The ideal is a collection of all algebraic integer multiples of a given algebraic integer. For example, the notation (2) represents such a particular collection, as ...-8, -6, -4, -2, 0, 2, 4, 6, 8.... The sum of two ideals is an ideal that is composed of all the sums of all their individual members. The product of two ideals is similarly defined. Ideals, considered as integers, can then be added, multiplied, and hence factored. By means of this theory of ideals, he allowed the process of unique factorization—that is, expressing a number as the product of only one set of primes, or 1 and itself—to be applied to many algebraic structures that hitherto had eluded analysis.

Dedekind died at Brunswick on February 12, 1916.

**BIBLIOGRAPHY.** There is no full-length biographical treatment of Dedekind and his work. See ERIC T. BELL, *Men of Mathematics*, ch. 27 (1937, reprinted 1961); and CARL B. BOYER, *A History of Mathematics* (1968). Recent editions of

Dedekind's publications include his *Gesammelte Mathematische Werke*, 3 vol. 1930–32, reprinted 1969), his collected mathematical writings; and *Essays on the Theory of Numbers* (1901, reprinted 1963).

(Ed.)

## Defoe, Daniel

Daniel Defoe, English novelist, journalist, and pamphleteer, is best known as the author of *Robinson Crusoe*, one of the most famous books ever written. A man of many talents and author of an extraordinary range and number of works, he has been called the father of the English novel and of modern journalism, while his political poem *The True-Born Englishman*, which appeared in 1701, is said to have been the most widely sold poem that had ever been published in English up to that time. Nevertheless, Defoe remains in many ways an enigmatic figure. A man who made many enemies, he has been accused of double-dealing, of dishonest or equivocal conduct, of venality. Certainly in politics he served in turn both Tory and Whig; he acted as a secret agent for the Tories and later served the Whigs by "infiltrating" extremist Tory journals and toning them down. But Defoe always claimed that the end justified the means, and a more sympathetic view may see him as what he always professed to be, an unswerving champion of moderation, skillfully helping those whom he advised and supported to steer a middle course. In an age of violent partisanship, he sought by his writings and his actions to modulate the bitterness of party and religious strife. At the age of 59 Defoe embarked on what was virtually a new career, producing in *Robinson Crusoe* the first of a remarkable series of novels and other fictional writings that took up much of his abundant energy over the next five years. In so doing he was able to bring together his brilliant gifts as a journalist and the accumulated experience of a lifetime of busy activity to create works of an extraordinary and vivid power.

Defoe, engraving by M. Van der Gucht (1660–1725) after a portrait by J. Taverner, first half of the 18th century.

By courtesy of the National Portrait Gallery, London

Two important circumstances helped to shape Defoe's life both as man and writer: his Nonconformist background and the fact that, from his early 30s, he was never quite clear of the shadow of debt. That he did not conform to the Church of England meant that he was always something of an "outsider," not part of the polite world of 18th-century literature; the satirist Jonathan Swift referred to him contemptuously as "that fellow who was pilloried" and affected to forget his name, and Alexander Pope, though privately able to praise Defoe's achievement as a writer, nevertheless found a place for him in his satiric poem *The Dunciad*. The second circumstance—the existence of unsatisfied creditors—meant that his enemies always had a weapon they could use against him, while his political masters could use his need for protection to keep him toeing the line. Defoe's last years were clouded by legal controversies over al-

Nonconformist background

The Dedekind cut

Dedekind's sets and "ideals"

legedly unpaid bonds dating back a generation, and it is thought that he died in hiding from his creditors. His character Moll Flanders, born in Newgate Prison, speaks of poverty as "a frightful spectre," and it is a theme of many of his books.

**Early life.** Defoe was born in London, probably in the latter half of 1660. His father, James Foe, was a hard-working and fairly prosperous tallow chandler (perhaps also, later, a butcher), of Flemish descent. By his middle 30s, Daniel was calling himself "Defoe," probably reviving a variant of what may have been the original family name. As a Nonconformist, or Dissenter, Foe could not send his son to Oxford or Cambridge; he sent him instead to the excellent academy at Newington Green kept by the Rev. Charles Morton. Here he received an education in many ways better, and certainly broader, than any he would have had at an English university. Morton was an admirable teacher, later becoming first vice president of Harvard College; and the clarity, simplicity, and ease of his style of writing—together with the Bible, the works of John Bunyan, and the pulpit oratory of the day—may have helped to form Defoe's own literary style.

Although intended for the Presbyterian ministry, Defoe decided against this and by 1683 had set up as a merchant. He called trade his "beloved subject," and it was one of the abiding interests of his life. He dealt in many commodities, travelled widely at home and abroad, and became an acute and intelligent economic theorist, in many respects ahead of his time; but misfortune, in one form or another, dogged him continually. He wrote of himself:

"No man has tasted differing fortunes more,  
And thirteen Ones I have been rich and poor."

It was true enough. In 1692, after prospering for a while, Defoe went bankrupt for £17,000. Opinions differ as to the cause of his collapse: on his own admission, Defoe was apt to indulge in rash speculations and projects; he may not always have been completely scrupulous, and he later owned himself as one of those tradesmen who had "done things which their own principles condemned, which they are not ashamed to blush for." But undoubtedly the main reason for his bankruptcy was the loss he sustained in insuring ships during the war with France—he was one of 19 "merchants insurers" ruined in 1692. In this matter Defoe may have been incautious, but he was not dishonorable, and he dealt fairly with his creditors (some of whom pursued him savagely) paying off all but £5,000 within ten years. He suffered further severe losses in 1703, when his prosperous brick-and-tile works near Tilbury failed during his imprisonment for political offenses, and he did not actively engage in trade after this time.

Soon after setting up in business, in 1684, Defoe married Mary Tuffley, the daughter of a well-to-do Dissenting merchant. Not much is known about her, and he mentions her little in his writings, but she seems to have been a loyal, capable, and devoted wife. She bore him eight children, of whom six lived to maturity, and when Defoe died the couple had been married for 47 years.

**Mature life and works.** With Defoe's interest in trade went an interest in politics. The first of many political pamphlets by him appeared in 1683. When the Roman Catholic James II ascended the throne in 1685, Defoe—as a staunch Dissenter and with characteristic impetuosity—joined the ill-fated rebellion of the Duke of Monmouth, managing to escape after the disastrous Battle of Sedgemoor. Three years later James had fled to France, and Defoe rode to welcome the army of William of Orange—"William, the Glorious, Great, and Good, and Kind," as Defoe was to call him. Throughout William's reign, Defoe supported him loyally, becoming his leading pamphleteer. In 1701, in reply to attacks on the "foreign" king, Defoe published his vigorous and witty poem *The True-Born Englishman*, an enormously popular work that is still very readable and relevant in its exposure of the fallacies of racial prejudice.

Foreign politics also engaged Defoe's attention. Since the Treaty of Rijswijk (1697), it had become increasingly probable that what would, in effect, be a world war

would break out as soon as the childless king of Spain died. In 1701, five gentlemen of Kent presented a petition, demanding greater defense preparations, to the House of Commons (then Tory-controlled) and were illegally imprisoned. Next morning Defoe, "guarded with about 16 gentlemen of quality," presented the speaker, Robert Harley, with his famous document "Legion's Memorial," which reminded the Commons in outspoken terms that "Englishmen are no more to be slaves to Parliaments than to a King." It was effective: the Kentishmen were released, and Defoe was feted by the citizens of London. It had been a courageous gesture, and one of which Defoe was ever afterward proud; but it undoubtedly branded him in Tory eyes as a dangerous man who must be brought down.

What did bring him down, only a year or so later, and consequently led to a new phase in his career, was a religious question—though it is difficult to separate religion from politics in this period. Both Dissenters and "Low Churchmen" were mainly Whigs, and the "high-fliers"—the High-Church Tories—were determined to undermine this working alliance by stopping the practice of "occasional conformity" (by which Dissenters of flexible conscience could qualify for public office by occasionally taking the sacraments according to the established church). Pressure on the Dissenters increased when the Tories came to power, and violent attacks were made on them by such rabble-rousing extremists as Dr. Henry Sacheverell. In reply, Defoe wrote perhaps the most famous and skillful of all his pamphlets, "The Shortest-Way With The Dissenters" (1702). His method was ironic: to discredit the high-fliers by writing as if from their viewpoint but reducing their arguments to absurdity. The pamphlet had a huge sale, but the irony blew up in Defoe's face: Dissenters and High Churchmen alike took it seriously, and—though for different reasons—were furious when the hoax was exposed. Defoe was prosecuted for seditious libel and was arrested in May 1703. The advertisement offering a reward for his capture gives the only extant personal description of Defoe—an unflattering one, which annoyed him considerably: "a middle-size spare man, about 40 years old, of a brown complexion, and dark-brown coloured hair, but wears a wig, a hooked nose, a sharp chin, grey eyes, and a large mole near his mouth." Defoe was advised to plead guilty and rely on the court's mercy, but he received harsh treatment, and, in addition to being fined, was sentenced to stand three times in the pillory. It is likely that the prosecution was primarily political, an attempt to force him into betraying certain Whig leaders; but the attempt was evidently unsuccessful. Although miserably apprehensive of his punishment, Defoe had spirit enough, while awaiting his ordeal, to write the audacious "Hymn To The Pillory" (1703); and this helped to turn the occasion into something of a triumph, with the pillory garlanded, the mob drinking his health, and the poem on sale in the streets.

Triumph or not, Defoe was led back to Newgate, and there he remained while his Tilbury business collapsed and he became ever more desperately concerned for the welfare of his already numerous family. He appealed to Robert Harley, who, after many delays, finally secured his release—Harley's part of the bargain being to obtain Defoe's services as a pamphleteer and intelligence agent.

Defoe certainly served his masters with zeal and energy, travelling extensively, writing reports, minutes of advice, pamphlets. He paid several visits to Scotland, especially at the time of the Act of Union in 1707, keeping Harley closely in touch with public opinion. These trips bore fruit in a different way two decades later: in 1724–26 the three volumes of Defoe's admirable and informative *Tour Thro' the whole Island* of Great Britain were published, in preparing which he drew on many of his earlier observations.

Perhaps Defoe's most remarkable achievement during Queen Anne's reign, however, was his periodical, the *Review*. He wrote this serious, forceful, and long-lived paper practically single-handed from 1704 to 1713. At first a weekly, it became a thrice-weekly publication in

1705, and Defoe continued to produce it even when, for short periods in 1713, his political enemies managed to have him imprisoned again on various pretexts. It was, effectively, the main government organ, its political line corresponding with that of the moderate Tories (though Defoe sometimes took an independent stand); but in addition to politics as such, Defoe discussed current affairs in general, religion, trade, manners, morals, and so on, and his work undoubtedly had a considerable influence on the development of later essay periodicals (such as Richard Steele and Joseph Addison's *The Tatler* and *The Spectator*) and of the newspaper press.

**Later life and works.** With George I's accession (1714) the Tories fell; but the Whigs in their turn recognized Defoe's value, and he continued to write for the government of the day and to carry out intelligence work. At about this time, too (perhaps prompted by a severe illness), he wrote the best known and most popular of his many didactic works, *The Family Instructor* (1715). Not all the writings so far mentioned, however, would have procured literary immortality for Defoe; this he achieved when in 1719 he turned his talents to an extended work of prose fiction and (drawing partly on the memoirs of voyagers and castaways such as Alexander Selkirk) produced *Robinson Crusoe*. A German critic has called it a "world-book," a label justified not only by the enormous number of translations, imitations, and adaptations that have appeared but by the almost mythic power with which Defoe creates a hero and a situation with which every reader can in some sense identify himself.

Here (as in his works of the remarkable year 1722, which saw the publication of *Moll Flanders*, *A Journal of the Plague Year*, and *Colonel Jack*) Defoe displays his finest gift as a novelist—his insight into human nature. The men and women he writes about are all, it is true, placed in unusual circumstances; they are all, in one sense or another, solitaries; they all struggle, in their different ways, through a life that is a constant scene of jungle warfare; they all become, to some extent, obsessive. They are also ordinary human beings, however, and Defoe, writing always in the first person, enters into their minds and analyzes their motives. His novels are given verisimilitude by their matter-of-fact style and their vivid concreteness of detail; the latter may seem unselective, but it effectively helps to evoke a particular, circumscribed world. Their main defects are shapelessness, an overinsistent moralizing, occasional gaucheness, and naïveté. Defoe's range is narrow, but within that range he is a novelist of considerable power, and his plain, direct style, as in almost all of his writing, holds the reader's interest.

In 1724 he published his last major work of fiction, *Roxana*, though in the closing years of his life, despite failing health, he remained active and enterprising as a writer. He died on April 24, 1731.

#### MAJOR WORKS

*An Essay upon Projects* (1697; reissued as *Essays Upon Several Projects*, 1702); "An Argument Shewing, That a Standing Army, With Consent of Parliament, Is not Inconsistent with a Free Government" (1698); "The Two Great Questions Consider'd" (1700); *The True-Born Englishman; A Satyr* (1700, for 1701); "The Shortest-Way With The Dissenters: Or Proposals For The Establishment Of The Church" (1702); "A Hymn To The Pillory" (1703); "Giving Alms no Charity, And Employing the Poor A Grievance to the Nation" (1704); "A True Relation of the Apparition of one Mrs. Veal" (1706); *The History of the Union of Great Britain* (1709); "Memoirs of the Life and Eminent Conduct Of that Learned and Reverend Divine, Daniel Williams, D.D." (1718); *The Life and Strange Surprising Adventures of Robinson Crusoe, of York, Mariner. Written by Himself* (1719); *The Farther Adventures of Robinson Crusoe; Being the Second and Last Part of his Life* (1719); *The History Of The Life and Adventures Of Mr. Duncan Campbell, A Gentleman, who, tho' Deaf and Dumb, writes down any Stranger's Name at first Sight; with their future Contingencies of Fortune* (1720); *Memoirs Of A Cavalier* (1720); *The Life, Adventures, and Pyracies, Of the Famous Captain Singleton* (1720); *Serious Reflections During The Life and Surprising Adventures of Robinson Crusoe: With His Vision Of The Angelick World* (1720); *The Fortunes And Misfortunes Of the Famous Moll Flanders* (1721, for 1722); *A Journal of the Plague*

*Year*; (1722); *An Impartial History Of The Life and Actions of Peter Alexowitz, The Present Czar of Muscovy* (1723, for 1722); *The History and Remarkable Life of . . . Col. Jacque, commonly Call'd Col. Jack* (1723, for 1722); *The Fortunate Mistress: Or, A History Of The Life And Vast Variety Of Fortunes Of Mademoiselle de Beleau . . . Being the Person known by the Name of the Lady Roxana, in the Time of King Charles II* (1724); *A Tour Thro' the whole Island of Great Britain*, 3 vol. (1724, 1725, 1726, dated 1727); *A Narrative of all the Robberies, Escapes, etc. of John Sheppard* (1724); *A New Voyage Round The World, By A Course never sailed before* (1725, for 1724); "The True and Genuine Account of the Life and Actions of the Late Jonathan Wild" (1725); *The Complete English Tradesman* (1726, for 1725); *The Political History Of the Devil, As Well Ancient as Modern* (1726); *The Four Years Voyages of Capt. George Roberts* (1726); *Mere Nature Delineated: Or, A Body without a soul. . . also a brief dissertation upon the usefulness and necessity of fools, whether political or natural* (1726); "Some Considerations upon Street-Walkers. With A Proposal for Lessening the Present Number of them" (1726); "Augusta Triumphans: Or, The Way To Make London The most flourishing City in the Universe" (1728); *A Plan Of The English Commerce* (1728); *The Memoirs of an English Officer . . . Capt. George Carleton* (1728); *The Compleat English Gentleman* (published posthumously, 1890).

**BIBLIOGRAPHY.** The fullest bibliography is J.R. MOORE, *A Checklist of the Writings of Daniel Defoe* (1960, rev. 1962). The greatest single collection of Defoe material is in the British Museum. Other important collections include the Indiana University Library, the Huntington Library (San Marino, California), the Clark Memorial Library (Los Angeles), the Bodleian Library (Oxford), the Cambridge University Library, and the Boston Public Library. No collected edition contains more than a very small portion of Defoe's works; the best general editions are *Novels and Selected Writings*, 14 vol. (Shakespeare Head edition, 1927); and *Romances and Narratives*, ed. by G.A. AITKEN, 16 vol. (1895). The *Tour* was edited by G.D.H. COLE, 2 vol. (1927; rev. and enlarged by DC. BROWNING, 1962); and the *Review* by AW. SECORD, 22 vol. (1938). *The Best of Defoe's Review*, ed. by W.L. PAYNE (1951), is a good selection. The *Letters* have been edited by GH. HEALEY (1955).

The most up-to-date and fully-documented biography is J.R. MOORE, *Daniel Defoe, Citizen of the Modern World* (1958); also recommended are JAMES SUTHERLAND, *Defoe*, rev. ed. (1950); and the pioneering study by WILLIAM LEE, *Daniel Defoe: His Life, and Recently Discovered Writings*, 3 vol. (1869). Earlier lives include those of GEORGE CHALMERS (1786) and WALTER WILSON (1830).

Critical studies include: PAUL DOTTIN, *Daniel De Foe et ses romans* (1924; Eng. trans. *Daniel Defoe and His Novels*, 1929); A.W. SECORD, *Studies in the Narrative Method of Defoe* (1924); IAN WATT in *The Rise of the Novel* (1957); M.E. NOVAK, *Economics and the Fiction of Daniel Defoe* (1962) and *Defoe and the Nature of Man* (1963); G.A. STARR, *Defoe and Spiritual Biography* (1965); and M. SHINAGEL, *Daniel Defoe and Middle-Class Gentility* (1968). There are numerous studies of individual novels, particularly *Robinson Crusoe* and *Moll Flanders*.

## De Forest, Lee

By his invention of the Audion vacuum tube and his promotion of wireless communication, Lee De Forest, prominent American inventor, substantially altered the character of 20th-century life. Among his 200 patents, secured during a professional career of more than 50 years, the Audion tube—the elementary form of the modern radio tube—exerted the most profound technological, sociological, and cultural effects. Until the invention of the transistor in 1947, followed by the development of solid-state electronics in the 1950s, the Audion remained the key component of all sophisticated radio, telephone, radar, television, and computer systems.

Lee De Forest was born on August 26, 1873, in Council Bluffs, Iowa. When he was six years old, his father, a Congregational minister, moved the family to Alabama, where he assumed the presidency of the nearly bankrupt Talladega College for Negroes. Ostracized by citizens of the white community who resented his father's efforts to educate the Negro, Lee made his friends from among the black children of the town and, together with his brother and sister, spent a happy although sternly disciplined childhood in this rural community.

De Forest, 1907.  
Culver Pictures

As a child he was fascinated with machinery and was often excited when hearing of the many technological advances during the late 19th century. By the age of 13 he was an enthusiastic inventor of mechanical gadgets such as a miniature blast furnace and locomotive, and a working silverplating apparatus.

His father had planned for him a career in the clergy, but Lee insisted on science and, in 1893, enrolled at the Sheffield Scientific School of Yale University, one of the few institutions in the United States then offering a first-class scientific education. Frugal and hardworking, he supplemented his scholarship and the slim allowance provided by his parents by working at menial jobs during his college years, and, despite a not too distinguished undergraduate career, he went on to earn the Ph.D. in physics in 1899. By this time he had become interested in electricity, particularly the study of electromagnetic wave propagation, then being pioneered chiefly by the German Heinrich Rudolf Hertz and the Italian Guglielmo Marconi. De Forest's doctoral dissertation on the "Reflection of Hertzian Waves from the Ends of Parallel Wires" was possibly the first doctoral thesis in the United States on the subject that was later to become known as radio.

His first job was with the Western Electric Company in Chicago, where, beginning in the dynamo department, he worked his way up to the telephone section and then to the experimental laboratory. While working after hours on his own, he developed an electrolytic detector of Hertzian waves similar to one that had already been patented by the Englishman Sir John Ambrose Fleming. The device was modestly successful, as was an alternating-current transmitter that he designed. In 1902 he and his financial backers founded the De Forest Wireless Telegraph Company. To dramatize the potential of this new medium of communication, he began, as early as 1902, public demonstrations of wireless telegraphy for businessmen, the press, and the military.

A poor businessman and a poorer judge of men, De Forest was defrauded twice by his own business partners. By 1906 his first company was insolvent, and he had been squeezed out of its operation. But in 1907 he patented a much more promising detector, which he called the "Audion"; it was capable of more sensitive reception of wireless signals than were the electrolytic and Carborundum types then in use. It was a thermionic grid-triode vacuum tube—a three-element electronic "valve" similar to a two-element device patented by John Ambrose Fleming in 1904. The same year De Forest was able to broadcast experimentally both speech and music to the general public in the New York City area.

A second company, the De Forest Radio Telephone Company, began to collapse in 1909, again because of some of his partners. In the succeeding legal confusion, De Forest was indicted in 1912 but later acquitted of federal charges of using the mails to defraud by seeking to promote a "worthless device"—the Audion tube.

In 1910 he broadcast a live performance by Enrico Caruso at the Metropolitan Opera in order to further popularize the new medium. In 1912 De Forest conceived the idea of "cascading" a series of Audion tubes so as to amplify high-frequency radio signals far beyond what could be accomplished by merely increasing the voltage on a single tube. He fed the output from the plate of one tube, through a transformer to the grid of a second, and the output of the second tube's plate to the grid of a third, and so forth, thereby allowing for an enormous amplification of a signal that was originally very weak. This was an essential development for both radio and telephonic long-distance communication. He also discovered in 1912 that by feeding part of the output of his triode vacuum tube back into its grid, he could cause a self-regenerating oscillation in the circuit. The signal from this circuit, when fed to an antenna system, was far more powerful and effective than that of the crude transmitters then generally employed and, when properly modulated, was capable of transmitting speech and music. When appropriately modified, this single invention was capable of either transmitting, receiving, or amplifying radio signals.

Throughout De Forest's lifetime the originality of his more important inventions was hotly contested, by both scientists and patent attorneys. In time, realizing that he could not succeed in business or manufacturing, he reluctantly sold his patents to major communications firms for commercial development. Some of the most important of these sales were made at very low prices to the American Telephone & Telegraph Company, which used the Audion as an essential amplification component for long-distance repeater circuits.

In 1920 he began to work on a practical system for recording and reproducing sound motion pictures. He developed a sound-on-film optical-recording system called phonofilm and demonstrated it in theatres between 1923 and 1927. Although basically correct in principle, its operating quality was poor, and he found himself unable to interest film producers in its possibilities. Ironically, within a few years' time the motion-picture industry converted to talking pictures by using a sound-on-film process similar to that of De Forest.

During the 1930s De Forest developed Audion-diathermy machines for medical applications and, during World War II, conducted military research for Bell Telephone Laboratories. Although bitter over the financial exploitation of his inventions by others, he was widely honoured as the "father of radio" and the "grandfather of television." He was supported strongly but unsuccessfully for the Nobel Prize for Physics.

Although he worked for many organizations during his lifetime, De Forest was fundamentally an individualist and produced most of his inventions as a free-lance worker. A complex and private kind of man, De Forest was assailed by self-doubts, indecision, and egocentricity. Divorced twice, his third marriage, to Marie Mosquini, was a happy one and endured from 1930 until his death, in Hollywood, California, on June 30, 1961.

**BIBLIOGRAPHY.** GEORGETTE CARNEAL, *A Conqueror of Space* (1930), an authorized biography that is uncritically laudatory in its appraisal of the inventor's work; LEE DE FOREST, *Father of Radio* (1950), a romantically written autobiography of his life and achievements, psychologically revealing but historically biased; ISRAEL E. LEVINE, *Electronics Pioneer: Lee de Forest* (1964), a simple, popularly-written biography; W. RUPERT MACLAURIN, *Invention and Innovation in the Radio Industry* (1949), an authoritative, economically-oriented survey of major technological contributions to the radio industry.

## Deformation and Flow

Rheology, from the Greek word *rhein* meaning "to flow," is the science of deformation and flow. Deformation is the motion of one part of the body relative to another part so that the body changes size or shape; *i.e.*, a change of distances occurs between points in the body; and flow is a continuous change of deformation with time. The section of mechanics that deals with such motions is called continuum

inventions

The  
"Audion"

Applications in technology

mechanics or the mechanics of deformable media. Many examples of deformations are observed in everyday experience: the motion of a liquid being poured, of water in a flowing river, of a flag fluttering in the wind, of water boiling, of a rubber band being stretched, and of a violin string when it is plucked.

Continuum mechanics is widely applied in technology. Structures must be designed and construction materials chosen so that neither fracture nor too much deformation will occur in use. In airplane design, the force of the air on the wings must be calculated for maximum lifting power and efficiency. Paints must be formulated so that they will flow from the brush but will not drip afterward. Pipelines must be designed with appropriate diameters so that fluids can be pumped at optimum rates.

The function of many body fluids depends on their flow characteristics. The viscosity of blood plasma increases when the organism is diseased. The synovial fluid from healthy joints has more complicated flow properties than those from rheumatoid joints.

When forces are applied to some materials they assume a deformed shape in equilibrium and return to their original shapes after the forces are removed. Such materials are called solids. Other materials can maintain an equilibrium shape only when subjected to hydrostatic pressures (the force is perpendicular to the surface). These materials, both liquid and gaseous, are known as fluids. Under other types of forces, they deform indefinitely as long as the forces are applied and do not return to their original form when these forces are removed. Such an irrecoverable deformation is called flow.

An important part of continuum mechanics is the formulation of constitutive equations—that is, relations between force and deformation—that describe the mechanical behaviour of a given material. Rheology is the part of continuum mechanics that deals with constitutive equations. Such equations provide an approximate description of behaviour over a certain range of circumstances. For example, a metal under a light load might be considered rigid; under a heavier load or with more accurate measurement of length, a linearly elastic solid; under a very large load, a plastic solid; and under a small oscillatory motion, a linearly viscoelastic solid. These three types of behaviour will be discussed later.

Two of the basic concepts of continuum mechanics are those of strain—the measure of the amount of deformation—and of stress, in units of force per unit area, as a measure of the contact force; that is, the force exerted by one part of the body on a neighbouring part.

#### HISTORY

Fracture, or breaking, was the chief subject in early work on the mechanics of solids. The notebooks of Leonardo da Vinci (1452–1519) contain a discussion of the strength of columns and beams and a sketch of a device for measuring the tensile strength of a wire to which a basket was attached, using sand as a variable load. Galileo Galilei noted in 1638 that the strength of a bar in simple tension is independent of its length and is proportional to its cross-sectional area; he was, thus, apparently the first to describe the property of a material in terms of a force per unit area.

An English scientist, Robert Hooke, in 1678, on the basis of a number of different experiments involving a wide variety of materials, concluded that the elongation of elastic materials is proportional to the force applied.

In a mathematical treatment of the shape of a loaded elastic bar, a Swiss mathematician, James Bernoulli, in 1705 was the first to state that the elastic law should be formulated as a relation between the force per unit area and the ratio of elongation to the original length. Although another Swiss mathematician, Leonhard Euler, was the first to assume in 1727 that this relation was linear, the proportionality constant is called Young's modulus, after Thomas Young, an English physicist who, in 1804, introduced it in connection with the elongation of an elastic bar. Euler also, in 1752, explicitly set forth the concept of the internal pressure in a fluid. Internal tension in solids (force acting perpendicular to the cross section) was recognized

and used by Gottfried Wilhelm Leibniz, the German mathematician and physicist, in 1684, and by James Bernoulli in 1691; and shear stresses (forces acting parallel to the cross sections) by the French mathematician Antoine Parent in 1713 and explicitly by the French physicist Charles-Augustin Coulomb in 1773. The general concept now current, that contact forces may be represented by the stress, the introduction of the stress tensor (see below), the differential equations representing the balance of force, and the application of the balance of moment of momentum were introduced by the French mathematician Augustin-Louis Cauchy in 1822. Balance of force had been recognized by another member of the famous Bernoulli family, Daniel Bernoulli, in 1727, and both balance laws by Euler in 1775.

Euler in 1775 proposed the first constitutive equation, that for a perfect fluid, based on the assumption that the force exerted by one part of the fluid on the neighbouring part is always perpendicular to the surface separating the two parts. The linearly viscous fluid is sometimes called the Newtonian fluid because Isaac Newton in his *Principia* (1687) proposed a simple case of such a material. The equations governing the motion of this fluid are called the Navier–Stokes equations after the French engineer Claude-Louis-Marie Navier (1821) and the British physicist George Gabriel Stokes (1845). Two Frenchmen, Siméon-Denis Poisson (1830) and Barré de Saint-Venant (1843), also made important contributions to the theory. The rate of efflux through narrow tubes, calculated on the basis of the Navier–Stokes equations, was found to be in good agreement with the experimental results on water obtained during the next decade or so.

Navier, on the basis of a molecular hypothesis, arrived in 1827 at a theory of elasticity of isotropic solids (solids in which elasticity is uniform in all directions) that contained only one elastic constant. Using some phenomenological concepts, Cauchy (1823), Stokes (1845), and their contemporaries produced the modern theory that involves two elastic constants, the shear modulus and bulk modulus, to be discussed later. Careful experiments confirming the modern theory were performed shortly thereafter.

In 1835 Wilhelm Weber, a German physicist, found that a load suddenly applied to a silk thread produced an immediate extension that was followed by a further lengthening with time, a behaviour called creep. Further experimental investigations of this time-dependent behaviour were performed; and in 1874 Ludwig Boltzmann, an Austrian physicist, formulated the theory of linear viscoelasticity to explain the phenomenon. That some fluids show a similar viscoelastic behaviour was exhibited on fluids of high consistency (hot glass, pitch) in 1905 and on more mobile fluids (gelatin solutions) in 1915.

Experiments around the beginning of the 20th century led to the conclusion that colloidal solutions (solutions in which one component consists of particles invisible under ordinary microscopes but thousands of times larger than ordinary molecules) do not act like Newtonian fluids in steady flow, but that their viscosity depends on the rate of deformation. The method of calculating this viscosity function from efflux experiments in the '20s greatly advanced this field of study.

The transition from the empirical approach to the development of appropriate constitutive equations has gone through several stages. Nonlinear theories proposed in the 1940s and 1950s have been superseded by theories that assume that stress depends upon the history of the strain that has been applied but not in a simple linear relationship. These latter theories explain not only nonconstant viscosity in steady flow but also time-dependent behaviour and normal stress effects, unexpected distributions of normal tractions on bounding surfaces in many experiments. Experimental work on this latter phenomenon began during World War II and is still continuing.

#### CONTINUUM MECHANICS

The study of mechanics falls in general into two parts: kinematics, which deals with the motion of particles and bodies, and dynamics, which is concerned with forces and

Introduction of stress tensor

Rheology and constitutive equations

how they effect the kinematics. In continuum mechanics, which is used to give theoretical insight into deformation and flow, the kinematics deals mainly with motions that are deformations; the dynamics, with the stress; that is, with the forces exerted on one part of the body by a neighbouring part. The detailed discrete nature of the atomic and molecular structure is ignored; it is assumed that the net effect of the atomic and molecular forces and motions can be adequately represented by the stress, the strain or rate of strain, and an appropriate constitutive relation. For a thorough understanding of continuum mechanics the use of mathematics, particularly vector and tensor analysis, is required. In the following sections the basic concepts are first presented without the use of mathematics and then a more quantitative discussion is given, using vectors and tensors only on an elementary level.

Kinematics. Before presenting the general notion of strain, some simple deformations that are commonly discussed in many branches of continuum mechanics will be defined.

1. In uniform expansion, all volume elements of the body are transformed to geometrically similar elements of greater dimensions. Such a deformation occurs when a body is uniformly deformed in all directions so that any arbitrary particle, originally having the coordinates  $(x_1, x_2, x_3)$  moves to a point whose coordinates are  $(ax_1, ax_2, ax_3)$ , in which  $a$  is a multiplicative factor (Figure 1). The displacement of the

Figure 1: The vector  $\mathbf{u}$  and its components in a Cartesian coordinate system  $X_1, X_2, X_3$  (see text).

Vector notation

particle may be represented by the vector  $\mathbf{u}$  whose components  $(u_1, u_2, u_3)$  are  $[(a - 1)x_i]$ ,  $i = 1, 2, 3$ . Any physical quantity that has direction, such as displacement, velocity, force, electric field, can be represented in magnitude and direction by a vector. The vector  $\mathbf{u}$ , for instance, can be represented by an arrow that points in the direction of the motion of the particle with the length representing the displacement or distance moved. Each component is the length of the axis intersected by lines drawn perpendicular to it from the head and tail of the vector. For example, the tail intersects the  $X_1$ -axis in the Cartesian coordinate system ( $X_1, X_2$  and  $X_3$  coordinates mutually perpendicular) at  $x_1$  and the head intersects at  $ax_1$ , so that the displacement along the  $X_1$ -axis is a component  $u_1$  of length  $ax_1 - x_1$ , or  $(a - 1)x_1$ .

2. Simple shear is usually envisaged as taking place in a material between large parallel plates and may be thought of as sheets of material sliding parallel to one another. Simple shear can be described more precisely by taking a Cartesian coordinate system with the origin  $O$  on one of the plates, say the fixed plate, the  $X_2$ -axis perpendicular to the

plates and the  $X_1$ -axis parallel to the direction of motion (Figure 2). In simple shear an arbitrary particle in the plane  $ABCD$  moves in the  $X_1$ -direction to a point in the plane  $A'B'C'D'$  by an amount proportional to its distance  $x_2$  from

Figure 2: Simple shear in a Cartesian coordinate system, showing the vector displacement  $\mathbf{u}$  of a particle from  $\mathbf{x}_1$  to  $\mathbf{x}_1 + s\mathbf{x}_2$ .

the fixed plate,  $sx_2$ , in which  $s$  is a proportionality factor; i.e., it undergoes a vector displacement with components  $(sx_2, 0, 0)$ . In simple shearing flow, each particle of the material moves with a constant velocity  $v$  in the  $X_1$ -direction, the direction of motion of the sliding plate. The components of the velocity are  $(\kappa x_2, 0, 0)$  in which  $\kappa$  is a constant called the rate of shear.

3. General infinitesimal strain. In more complicated deformations, the strain is more difficult to specify. The components  $(u_1, u_2, u_3)$  represent the displacement  $\mathbf{u}$  of a particle in the body in the deformed state from its position  $(x_1, x_2, x_3)$  in the undeformed state. If the spatial derivatives (a spatial derivative is the change of a component with distance along any one of the three axes) of the displacement are small, strictly speaking, infinitesimally small, the complete description of the strain at a given point in the body may be given in terms of the six new components made up of these spatial derivatives:

$$\begin{aligned} e_{11} &= \partial u_1 / \partial x_1; \quad e_{22} = \partial u_2 / \partial x_2; \quad e_{33} = \partial u_3 / \partial x_3; \\ e_{21} &= e_{12} = \frac{1}{2} (\partial u_1 / \partial x_2 + \partial u_2 / \partial x_1); \\ e_{13} &= e_{31} = \frac{1}{2} (\partial u_1 / \partial x_3 + \partial u_3 / \partial x_1); \\ e_{23} &= e_{32} = \frac{1}{2} (\partial u_2 / \partial x_3 + \partial u_3 / \partial x_2); \end{aligned}$$

or in general,

$$e_{ij} = e_{ji} = \frac{1}{2} (\partial u_i / \partial x_j + \partial u_j / \partial x_i)$$

for  $i = 1, 2, 3$  and  $j = 1, 2, 3$ . The components  $e_{11}, e_{22}, e_{33}$  in the above equations represent relative, but not actual, elongations parallel to the  $X_1, X_2$  and  $X_3$  axes respectively; the other components, called shear components, are measures of changes of angle. It is of great importance to the theory that these components are the Cartesian components of a tensor called the infinitesimal strain tensor, or sometimes simply the strain. As a result, the powerful theorems of tensors, a well-developed area of mathematics dealing with such objects, may be exploited in continuum mechanics.

Applying the foregoing definitions to the components  $(u_1, u_2, u_3)$  of the vector  $\mathbf{u}$  for uniform expansion, one finds, if  $(a - 1)$  is small, that only three components are not zero (namely,  $e_{11} = e_{22} = e_{33} = a - 1$ , or  $e_{ii} = a - 1$  for  $i = 1, 2, 3$ ) and that the shear components are all zero. When the spatial derivative equations are applied to components  $(sx_2, 0, 0)$  of the vector  $\mathbf{u}$  for simple shear with  $s \ll 1$  ( $s$  vanishingly small), all components of strain vanish except  $e_{12} = e_{21}$ , which is equal to  $s/2$ .

4. For finite strains, the infinitesimal strain is no longer a valid measure of deformation (for example, a zero value does not necessarily mean that the material is undeformed). Many kinds of tensor relations are in current use, all of

Components of strain tensor

The flow  
of fluids

which include terms that are quadratic (squared) in the spatial derivatives of the displacement.

5. The flow of fluids is discussed in terms of the symmetric rate of deformation tensor  $D$ , with components defined as  $D_{ij} = \frac{1}{2}(\partial v_i / \partial x_j + \partial v_j / \partial x_i) = D_{ji}$ , for  $i = 1, 2, 3$  and  $j = 1, 2, 3$ —that is  $D_{11} = \partial v_1 / \partial x_1$ ;  $D_{22} = \partial v_2 / \partial x_2$ ;  $D_{33} = \partial v_3 / \partial x_3$ ;  $D_{12} = D_{21} = \frac{1}{2}(\partial v_1 / \partial x_2 + \partial v_2 / \partial x_1)$ ;  $D_{13} = D_{31} = \frac{1}{2}(\partial v_1 / \partial x_3 + \partial v_3 / \partial x_1)$ ;  $D_{23} = D_{32} = \frac{1}{2}(\partial v_2 / \partial x_3 + \partial v_3 / \partial x_2)$  in which  $v_1, v_2$ , and  $v_3$  are the components of the velocity of an arbitrary particle. Applying these equations for the components of  $D$ , to the simple shearing flow mentioned earlier, in which  $v_1 = \kappa x_2$ , the only ones that do not vanish are the components  $D_{21} = D_{12} = \kappa/2$ .

Dynamics. In continuum mechanics it is assumed that the net effect of all forces between atoms may be considered the sum of two parts: body forces, due to gravity, magnetism, and electricity; and contact forces exerted on one part of the body by a neighbouring portion. In Figure 3,

Figure 3: Stress vector  $T$  acting on an arbitrary surface  $A$  that divides the deformed body  $B$  into two parts. A vector component  $T_1$  can be decomposed along three coordinate directions,  $X_1$ ,  $X_2$ , and  $X_3$ .

$B$  is a body that is deformed and  $A$  is an arbitrary surface dividing  $B$  into two parts, with  $dA$  representing an infinitesimal portion of this area at the point  $Q$ . It is assumed that the force  $dF$  exerted by the matter on one side of the surface on that on the other is given by the equation  $dF = TdA$ , in which  $T$  is known as the stress vector. The existence of such a stress vector is one of the basic assumptions of continuum mechanics. Generally,  $T$  depends on both the position in the body and orientation of the surface  $dA$  at that point. The stress vector may be resolved into the vector sum of a normal (in this sense, perpendicular) stress that is at right angles to that surface and a shear stress parallel to that surface.

It is common to consider the stress vector across surfaces parallel to the orthogonal planes of a chosen Cartesian coordinate system (Figure 3). A plane normal or perpendicular to the  $X_1$ -direction is called an  $X_1$ -plane. At a given point  $R$  across such a plane, the stress vector  $T_1$  (not necessarily acting in the  $X_1$ -direction) may be decomposed into components ( $\sigma_{11}, \sigma_{12}, \sigma_{13}$ ) in the coordinate directions; that is, the stress vector  $T_1 = i\sigma_{11} + j\sigma_{12} + k\sigma_{13}$ , in which  $i, j$ , and  $k$  are unit vectors (vectors of given directions and unit length) in the three coordinate directions. The first number in the subscript indicates the direction of the normal or perpendicular to the plane across which the contact force acts, and the second number indicates the direction of the component of the force. A similar set of three components ( $\sigma_{21}, \sigma_{22}, \sigma_{23}$ ) may be obtained from the stress vector acting across the  $X_2$ -plane through  $R$  and ( $\sigma_{31}, \sigma_{32}, \sigma_{33}$ ) acting through the  $X_3$ -plane. The stress components with repeated index (*i.e.*,  $\sigma_{11}, \sigma_{22}, \sigma_{33}$ ) are the normal stress components; those with different indices (*e.g.*,  $\sigma_{12}$ ) are the shear stresses, or  $\sigma_{ij}$  for  $i = j$  represent normal stress components and for  $i \neq j$  represent shear stresses.

It can be shown that the set of these nine components

$$\begin{matrix} \sigma_{11} & \sigma_{12} & \sigma_{13} \\ \sigma_{21} & \sigma_{22} & \sigma_{23} \\ \sigma_{31} & \sigma_{32} & \sigma_{33} \end{matrix}$$

constitutes the components of a tensor, called the stress tensor, or simply the stress  $\sigma_{ij}$  for  $i = 1, 2, 3, j = 1, 2, 3$ , at the point with reference to the chosen Cartesian coordinate system. The stress tensor gives a complete characterization of the stress at a point. It can also be shown, as a consequence of the laws of mechanics, that the stress tensor is symmetric (*i.e.*,  $\sigma_{12} = \sigma_{21}, \sigma_{13} = \sigma_{31}$ , and  $\sigma_{23} = \sigma_{32}$  or  $\sigma_{ij} = \sigma_{ji}$  for  $i = 1, 2, 3, j = 1, 2, 3$ ). Thus, only six components are required to specify completely the stress tensor.

Stress  
tensor

#### CONSTITUTIVE EQUATIONS

Perfect fluid. In many cases, the motion of fluids such as air and water can be described to a good approximation by the equations of the perfect fluid. The concept of perfect fluid, therefore, forms the basis of much of aerodynamics, hydrodynamics, and fluid mechanics.

By definition, no shear stresses can exist in the model of perfect fluid. As a result, the stress components are given by

$$\begin{aligned} \sigma_{ii} &= \sigma_{11} = \sigma_{22} = \sigma_{33} = -p; \\ \text{and for } i \neq j, \\ \sigma_{ij} &= \sigma_{12} = \sigma_{13} = \sigma_{23} = 0, \end{aligned}$$

which are independent of the orientation of the Cartesian coordinate system. Such a stress is called an isotropic stress, and  $p$ , in the equation, is the hydrostatic pressure.

Linearly viscous fluid. The model of the linearly viscous (also called a Newtonian or a viscous) fluid describes the flow behaviour of fluids consisting of small molecules under all conditions in which the concept of a perfect fluid is not adequate (*e.g.*, near solid walls) except under extreme circumstances (*e.g.*, ultrasonic waves). It also describes the behaviour of more complex fluids, such as molten plastics at very low rates of deformation.

If a linearly viscous fluid is undergoing simple shearing flow (see definition in the section under **Kinematics**), the components of the stress with respect to the coordinate system defined above are

$$\begin{aligned} \sigma_{ii} &= \sigma_{11} = \sigma_{22} = \sigma_{33} = -p \\ \sigma_{12} &= \eta\kappa \\ \sigma_{13} &= \sigma_{23} = 0, \end{aligned}$$

in which  $\eta$  is a property known as the viscosity.

The general equation is based on the assumption that the stress is isotropic when the fluid is at rest, and is a linear function of the velocity gradients, or the partial derivatives of the velocity components with respect to the coordinates,  $\partial v_1 / \partial x_1, \partial v_1 / \partial x_2$ , etc., when it is in motion. Expressing these concepts mathematically in such a way that the constitutive equation is independent of the observer, it is found that the stress components may be expressed, for incompressible fluids, in terms of the rate of deformation tensor,  $D_{ij}$ , as:

$$\begin{aligned} \sigma_{11} &= -p + 2\eta D_{11}, \\ \sigma_{12} &= 2\eta D_{12}, \end{aligned}$$

for an arbitrary motion and arbitrary choice of Cartesian coordinate systems. The additional equations for  $\sigma_{22}$  and  $\sigma_{33}$  are analogous to that for  $\sigma_{11}$  and those for  $\sigma_{13}$  and  $\sigma_{23}$  to that for  $\sigma_{12}$ . The flow of a viscous fluid is an energy-dissipative process.

The viscosity of a fluid is commonly determined by measuring the rate of flow through a tube of small diameter when a pressure difference is applied. In the metric system the unit of  $\eta$  is called poise in honour of a French physiologist, J.-L.-M. Poiseuille. In the neighbourhood of 20°C, the viscosity of water is 0.01 poise, of air  $1.8 \times 10^{-4}$  poise, of mercury 0.016 poise, of pure glycerin 15 poise.

Linearly elastic solid. The linearly elastic (also called Hookean) solid provides a good model for the behaviour of many solids; *e.g.*, metals, salts, organic crystals, glasses, and rubber at very small strains under static conditions. The model becomes inadequate for some of these materials at elevated temperatures or for some dynamic experiments where linear viscoelasticity may prove a better description.

Stress  
vector

If an isotropic linearly elastic solid undergoes simple shear, the only nonzero components of the stress are  $\sigma_{12} = \sigma_{21} = \mu$ , where  $\mu$  is a property of the material known as the shear modulus, or the rigidity.

If a solid obeying Hooke's law is subjected to a small uniform expansion [*i.e.*,  $(a - 1) \ll 1$ ] the stress is isotropic:

$$\sigma_{11} = \sigma_{22} = \sigma_{33} = -p = 3K(a - 1),$$

in which  $3(a - 1)$  is the fractional change of volume and  $K$  is known as the bulk modulus.

The general constitutive relation between stress and strain for the isotropic linearly elastic solid is the set of equations of the form

$$\sigma_{11} = \frac{2}{3}\mu e_{11} + (K - \frac{2}{3}\mu)(e_{11} + e_{22} + e_{33})$$

for the normal stresses, and of the form  $\sigma_{12} = \frac{1}{2}\mu e_{12}$  for the shear stresses. Thus, two constants, the shear modulus  $\mu$  and the bulk modulus  $K$ , specify the properties of an isotropic linearly elastic solid. If the material is anisotropic (not uniform in all directions), as for example a crystal, up to 21 constants may be required to specify its properties.

When a stress is applied to an elastic solid, it deforms; when the stress is removed, the solid returns to its original shape. The deformation of an elastic solid is an energy-storing process.

The shear modulus  $\mu$  may be determined by measuring the torque required to twist a cylinder of the material. Sometimes an elastic modulus may be found from the speed of propagation of sound or from the natural frequency of oscillation of a mechanical system containing the material. The constants,  $\mu$  and  $K$ , for steel have values of  $8 \times 10^{11}$  and  $2 \times 10^{12}$ , respectively; for lead  $6 \times 10^{10}$  and  $4 \times 10^{11}$ ; for rubber  $7 \times 10^9$  and  $2 \times 10^{10}$ ; all in units of dynes/cm<sup>2</sup>.

**Linear viscoelastic materials.** This model provides a good description for the time-dependent behaviour of many materials under low stresses: for example, attenuation of ultrasonic waves in gases and liquids; oscillations, creep, and stress relaxation in metals, glass, rubber, plastics, and fluids containing long molecules (*e.g.* molten plastics and protein solutions).

If a shear stress  $T_0$  is suddenly applied to a viscoelastic material in simple shear and kept constant thereafter, the deformation does not increase and attain its steady-state (unchanging with time) condition at once. This type of behaviour is known as creep. The variation of the shear strain  $s(t)$  with time  $t$  is determined by the property creep compliance  $J(t)$  and is represented by the equation:  $s(t) = T_0 J(t)$ . For a viscoelastic solid, the steady state is a constant strain; for the fluid, it is a constant rate of strain.

If a shear strain  $S_0$  is suddenly imposed on a material in simple shear and kept constant thereafter, the shear stress  $T(t)$  initially is very large and then decreases to a constant value, called a steady state value, which is zero for a fluid. Such an experiment is known as a stress-relaxation experiment. This decay of stress is determined by a property of the material, the relaxation modulus  $G(t)$ , according to the equation  $T(t) = S_0 G(t)$ .

The special feature of viscoelasticity is that the stress at a given time depends on all previous values of the strain, with more recent strains having greater influence.

**Finite elasticity.** There are materials, notably various types of rubber, that can undergo very large strains and return to their original shape after the force is removed. In the theory of isotropic nonlinear elasticity, which provides a good description of the equilibrium behaviour of these materials, the stress is a nonlinear function of the deformation.

Effects arise in nonlinear theories that do not occur in linear ones. According to linear elasticity theory, torsion of a circular cylinder requires only the application of a torque. The theory of finite elasticity demands, in addition, the imposition of normal forces on the plane ends of the cylinder; otherwise the cylinder will change in length.

**Nonlinear viscoelastic fluids.** High polymers, when in solution or a melted state, show many types of deviations from the behaviour predicted by the theory of Newtonian fluids. They exhibit time-dependent behaviour—for example, creep. In steady flow, the rate of efflux from a tube of small diameter is not proportional to the pressure drop; it appears

that the viscosity decreases at the higher rates of flow. If such a fluid undergoes steady shear in the annulus between a stationary plate and a cone rotating at constant angular speed, a greater normal force (per unit area) is exerted by the fluid on the plate near the axis of rotation than at the outside. Based on the assumption that the stress is a nonlinear function of the previous history of the deformation, the theory of the nonlinear viscoelastic fluid is able to explain all of these phenomena.

Fluids exhibiting these phenomena show other technologically important deviations from Newtonian behaviour. The diameter of a stream of fluid may be considerably larger than the orifice from which it was extruded. A rotor in such a fluid may cause a completely different flow pattern from that seen in a Newtonian fluid.

**Plasticity.** When a rod composed of some solids, such as aluminum and some steels at ordinary temperature, is subjected to increasing tension, it behaves as a linear elastic solid. As extension increases, the force-elongation curve, as shown in Figure 4, deviates from proportionality at

Figure 4: Force-elongation curve.

point Y when the tensile force exceeds a value,  $F_Y$ . The ratio  $F_Y/A_0$ , in which  $A_0$  is the original cross section, is called the yield stress. The force then goes through a maximum at M before the sample finally breaks at point B. When the rod is extended beyond Y, some irrecoverable deformation, called plastic flow, takes place; the rod does not return to its original length when the force is removed.

One of the most important considerations of the engineer is that structures must be designed and materials of construction chosen so that plastic deformation does not occur to any appreciable extent. On the other hand, many fabrication processes (for example, machining, forging, and drawing) depend on the behaviour in the plastic regime.

#### FRACTURE

It is customary to classify fracture of solids into two types: brittle and ductile. Generally speaking, brittle fracture occurs when the sample behaves as a Hookean elastic solid until a critical load is reached, at which time it breaks. In ductile fracture, plastic flow precedes fracture. A given material may change its mode of fracture with varying temperature or conditions of the deformation. Thus, many metals and polymers have a brittle-ductile transition temperature that is a function of the rate of straining.

If an increasing tensile force is applied to a rod of material until it breaks in a brittle manner, the measure of the strength of the material is the tensile strength, defined as ratio of the force at break to the original cross section of the rod. Glass, cast iron, stone, and plastics under ordinary conditions exhibit this type of fracture. If the fracture took place by the simultaneous rupture of all molecular bonds in the surface of separation, the tensile strength would be ten or 100 times greater than the generally observed values for the usual brittle materials. The discrepancy is due to microscopic sharp long cracks that exist in the material.

Fracture can occur in a tensile experiment even if the stress always remains below the tensile strength. If the metal is subjected to alternating cycles of imposition and removal of stress, it may break if the number of cycles exceeds a critical number. Fatigue is the term used for this type of failure.

Creep  
behaviour

Plastic flow

Tensile  
strength

When a bar of some transparent glassy plastic (e.g., polystyrene or polymethyl methacrylate) is subjected to a tensile force, microscopic, highly reflective, planar defects form in planes normal (at right angles) to the applied tension. These defects are called crazes, which consist of microscopic voids and of polymeric material oriented in the direction of the applied force.

#### MOLECULAR THEORIES

Gases. Newton's law of viscous flow has been derived from the kinetic theory of gases. If the gas is dilute and the molecules are considered to be rigid spheres that do not attract one another, the viscosity is found to be independent of pressure. A more detailed kinetic theory calculation gives the viscosity in terms of forces between molecules. Viscosity data are now used to estimate the forces between molecules. A rigorous kinetic theory developed in 1956 shows that a rarefied gas is not strictly a Newtonian fluid; normal stress effects are to be expected.

At ultrasonic frequencies, of the order of  $10^6$  cycles per second, viscoelastic effects are indicated by changes in the velocity of propagation of the sound waves and the attenuation of their amplitude. These effects have been attributed to distortions in the distribution of velocities of the gas molecules, and in the distribution of molecules among vibrational and rotational states.

Crystalline solids. Viscoelastic effects in crystalline materials usually have been attributed to imperfections in the crystal, such as the motion of interstitial solute atoms or the slip of one crystal grain past a neighbour along a grain boundary. Plastic behaviour is understood in terms of the motion of dislocations.

Liquids. On the molecular level, the liquid is pictured as having neighbouring molecules in contact, as does the crystalline solid, but not packed together in a systematic order; hence there are many "holes" in the structure. In the liquid at rest, a molecule can move from its location into a neighbouring hole over an energy barrier if its thermal energy is high enough and the hole large enough. A shear stress induces a preferred direction for such motions and thus leads to flow.

Polymer  
behaviour

Polymer molecules in the liquid state (as a melt, rubber, or solute) are loose coils that can change their conformations readily; a barrel full of long, excited snakes has been suggested as a useful analogy. Because the molecules must move through tortuous paths to become displaced relative to one another, the viscosity is high and sensitive to the length of the chain. Viscoelastic effects occur because it takes time for the long entwined molecules to adjust to the applied force. If the temperature is lowered to the point at which large enough holes are rare, the motion becomes so restricted that the polymer acts like a glassy solid.

If a reaction is performed on a polymer (as in the vulcanization of rubber) such that the polymer chains are connected by covalent bonds and therefore cannot move past one another, flow is impossible. Because the polymer chains on the average have a coiled conformation, however, a great extensibility of a rubber sample is possible since the molecule can, with little change of internal energy, assume a greatly extended conformation. The deformation of rubber chiefly involves a change of entropy—a change to a more ordered state of about the same energy—and deformation of crystals and glassy solids, a change of internal energy.

## Degas, Edgar

Edgar Degas was one of the greatest of 19th-century French artists and a master of the human figure in movement. Though Degas was a consistent exhibitor with the Impressionists, his position mainly as a painter of closely calculated indoor figure groups places him slightly apart from his colleagues. He was, however, very much concerned with depicting the fleeting and momentary, while his subjects were those of the school that followed Gustave Courbet, and his colours, moreover, became progressively more brilliant and divided, like those of the Impressionists.

Sterling and Francine Clark Art  
Institute, Williamstown, Massachusetts

Degas, self-portrait, oil on paper applied to canvas, c. 1857–58. In the Sterling and Francine Clark Art Institute, Williamstown, Massachusetts. 26 cm x 19 cm.

**Early life and works.** Hilaire-Germain-Edgar Degas was born in Paris on July 19, 1834. He came of the powerful upper bourgeoisie, his family having banking and business connections both in Italy and the United States, and he was intended for the law, which he studied for a time after leaving the *Lycée Louis-le-Grand*. In 1855, however, he enrolled at the *École des Beaux-Arts* and entered the studio of Louis Lamothe, a pupil of the painter Jean-Auguste-Dominique Ingres, whose long-established position as defender of academic orthodoxy in draftsmanship and subject matter was being challenged by the realism of Courbet as well as by the romanticism of Eugène Delacroix.

It seems likely that as a young man Degas wished to succeed along orthodox lines as a painter of historical subjects in the grand French tradition. To further his aim he augmented his studies by visiting Florence, Assisi, Rome, and Naples and by closely observing and copying the

Early  
orthodoxy

works of Andrea Mantegna, Sandro Botticelli, Hans Holbein the Younger, and Nicolas Poussin, all notable for their scrupulousness in figure draftsmanship. Before 1860, Degas had produced some splendid family portraits in which the effect of this discipline, though clear, is heightened by a taut, alert urbanity that belongs unmistakably to the mid-19th century. The "Portrait of the Duchess of Morbilli" is typical of this group. It is broadly designed with large, simple surfaces rather flatly modelled in the manner of Ingres; the paint is solid, yet delicate, and the colours cool and restrained, with many black and neutral passages. In 1860, Degas made his debut as a painter of classical subjects with his "Young Spartans Exercising"; but here the nude figures, though arranged in balanced groups, are those of real adolescents in a natural landscape instead of idealized nudes in an Arcadian setting.

After 1861, when Degas painted "Semiramis Founding Babylon," again with academic intentions, he seems to have abandoned historical painting and begun to seek his subject matter in the fast-moving city life of Paris. In this he was probably inspired by contemporaries like Courbet and Édouard Manet (whom he met in 1862), by contemporary novelists, and by the discovery, late in the 1850s, of the astonishing formal yet documentary quality of Japanese graphic art. Nor did he overlook the brilliant work of contemporary French graphic artists such as Paul Gavarni and Honoré Daumier. It is not surprising that by 1862 he was painting the riders, their mounts, and the smart spectators at Longchamp racecourse, soon afterward beginning the portrait groups of musicians and stage subjects, which, like all subjects in which the sitters were absorbed in practiced movement, fascinated him throughout his life. Among the first of the latter is the "Mlle Fiocre in the Ballet 'La Source' ". His portraits of the 1870s show greater ease and naturalism than the very first group but are still based on a firm discipline traceable right back to Holbein and the great north Italian portraitists.

**Mature life and works.** Degas served in the artillery during the Franco-German War of 1870–71. On his return, he began to undertake ambitious figure groups, seen informally and in movement, and continued his studies of stage and orchestral groups. From these he passed to instantaneous renderings of both outdoor and indoor scenes, using displaced figure grouping and unorthodox cutting and perspective rather in the manner of a cameraman. Yet his magnificent formal sense and skill is always present to provide an equilibrium, however momentary, to these exacting subjects. The "Place de la Concorde (Vicomte Lepic and His Daughters)" is a fine example and an outdoor counterpart to the ballet subjects that gave Degas endless scope for multigure groups seen in fast intercepted movement. Degas visited the United States in October 1872, staying for five months and painting one of his best known scenes of figures in absorbed "occupational" movement. This was the "New Orleans Cotton Office" of 1873, now in the museum at Pau, France; it shows that although Degas had completely abandoned his early ambition of historical figure painting, he had nevertheless put to full use the structural principles of the formal tradition.

During the 1870s, most of Degas's figure groups were arranged against fairly extended background space, in which the figures themselves were given plenty of room. By the end of the decade, however, he was becoming interested in the pictorial possibilities of more closely juxtaposed and superimposed groups and giving more attention to the formal qualities of the voids between them. The famous "Repassseuses" ("Two Laundresses") of 1884 shows this tendency at an advanced stage, with an artificially shallow picture space and a reconciliation of solid form and surface reminiscent of Venetian mid-16th-century art in method but here applied with a documentary eye to a casual workaday subject. By this time Degas had begun to work in pastel, sometimes using a mixed technique with volatile oil mediums, and his indoor series of women at their ablutions carries on the researches mentioned above. Some of the later ones reach an astonish-

ing compromise between plasticity and surface pattern, the flesh colours being built up of strips of pure colour more closely knit than the *taches* of the Impressionists but like them, merging at a certain distance to give the illusion of solid modelling.

After 1880 Degas was practicing occasionally as a sculptor, and a group of small bronzes deriving from his models of dancers, bathing women, and horses again show his power of revealing the potentialities of the ordinary unobserved movements of human beings and animals. Degas, in fact, perhaps for the first time in history, viewed his animal and human models with the same dispassionate eye when making these studies. He was interested in photography, and there is an affinity between his vision and that of a high-speed camera. Degas's eyesight failed in later life; he became completely blind in one eye and nearly so in the other. He died September 27, 1917, leaving an important collection of the drawings and paintings of his contemporaries, and a notebook of poetic compositions, mostly in sonnet form.

#### MAJOR WORKS

**PAINTINGS:** "Portrait of the Duchess of Morbilli" (1855–56; Louvre, Paris); "Achille de Gas in the Uniform of a Cadet" (1856–57; National Gallery of Art, Washington, D.C.); "Young Spartans Exercising" (1860; National Gallery, London); "Portrait of Mme Brunet" (1860; Charles S. Payson Collection, New York); "Semiramis Founding Babylon" (1861; Louvre); "The Bellelli Family" (1860–62; Louvre); "At the Races" (1860–62; Fogg Art Museum, Cambridge, Massachusetts); "Self-Portrait" (c. 1862; National Gallery of Art, Washington, D.C.); "Portrait of a Young Woman" (1867; Louvre); "Duke and Duchess of Morbilli" (1867; Museum of Fine Arts, Boston); "Mlle Fiocre in the Ballet 'La Source' " (c. 1867–68; Brooklyn Museum, New York); "Jacques-James Tissot" (1868; Metropolitan Museum of Art, New York); "Les Musiciens à L'orchestre" (1868–69; Louvre); "Madame Camus au piano" (1869; Alfonse Kann Collection, Saint-Germain-en-Laye); "Mlle Hortense Valpinçon" (1869; Minneapolis Institute of Arts); "The False Start" (1869–72; John Hay Whitney Collection, New York); "Chevaux de courses devant les tribunes" (1869–72; Louvre); "Madame Camus" (1869–70; National Gallery of Art, Washington, D.C.); "Carriage at the Races" (1870–73; Museum of Fine Arts, Boston); "Le Foyer de la danse à l'opéra de la rue le Pelletier" (1872; Louvre); "The Dancing Class" (1872; Metropolitan Museum of Art, New York); "Mme René de Gas" (1872–73; National Gallery of Art, Washington, D.C.); "Foyer de Danse" (c. 1873; Corcoran Gallery of Art, Washington, D.C.); "New Orleans Cotton Office" (1873; Musée des Beaux-Arts, Pau, France); "Sulking (Bouderie)" (c. 1873–75; Metropolitan Museum of Art, New York); "Place de la Concorde (Vicomte Lepic and His Daughters)" (c. 1875; Gerstenberg Collection, Berlin); "Women Combing Their Hair" (1875–76; Phillips Collection, Washington, D.C.); "L'Absinthe" (1876; Louvre); "The Rehearsal" (1877; Glasgow Art Gallery); "Miss Lala at the Cirque Fernando" (1879; Tate Gallery, London); "Éventail" (1879; Louvre); "The Dancing Class" (1880; Denver Art Museum, Colorado); "Jockeys" (c. 1881–85; Yale University Art Gallery, New Haven, Connecticut); "Les Repasseuses" ("Two Laundresses," 1884; Louvre); "The Millinery Shop" (c. 1885; Art Institute of Chicago); "Ballet Scene" (1907; National Gallery of Art, Washington, D.C.).

**PASTELS:** "Woman Drying Her Foot" (c. 1866; Metropolitan Museum of Art, New York); "L'Etoile" (c. 1878; William Coxe Wright Collection, Philadelphia); "The Rehearsal on the Stage" (1878–79; Metropolitan Museum of Art, New York); "Ballet at the Opera" (1878–80; Leigh B. Block Collection, Chicago); "At the Milliner's" (c. 1882; Museum of Modern Art, New York); "Blue Dancer" (c. 1883; Charles S. Payson Collection, New York); "The Dancers" (1899; Toledo Museum of Art, Ohio).

**SCULPTURE:** "A Dancer at the Age of Fourteen" (1880; Metropolitan Museum of Art, New York); "Dancer Looking at the Sole of Her Foot" (c. 1900; Metropolitan Museum of Art, New York).

**BIBLIOGRAPHY.** Books on Degas are extremely abundant. One hundred items are included in JOHN REWALD, *The History of Impressionism*, rev. ed. (1961). The essential work is PAUL A. LEMOISNE, *Degas et son oeuvre*, 4 vol. (1946–49). Other important studies are PIERRE CABANNE, *Degas: danseuses* (1960; Eng. trans., *Degas: Dancers*, 1963), a discerning text with excellent reproductions; DOUGLAS COOPER, *Pastels by Edgar Degas* (1954), an important contribution to the study of a medium developed to a high point by Degas; FRANCOIS

Bronze sculptures

Development of figure groupings

FOSCA, *Degas* (1953), a very good treatment of his stylistic development; EDOUARD HUTTINGER, *Degas* (1959); J.B. MANSON, *The Life and Work of Edgar Degas* (1927); CAMILLE MAUCLAIR, *Degas*, rev. and enl. ed. (1941), which includes quotations from Degas' letters; MARGUERITE REBATET, *Degas* (1944), a very well-written short study with good reproductions; and JOHN REWALD, *Degas, das plastische Werk*, 2nd ed. (1957; Eng. ed., *Degas: Works in Sculpture*, 1944), a valuable study, with 141 illustrations.

*Testimony of his contemporaries:* JACQUES EMILE BLANCHE, *Propos de peintre de David à Degas*, 3 vol., with a preface by MARCEL PROUST (1919–28), informative material by a fellow artist; MARCEL GUERIN (ed.), *Lettres de Degas*, new ed. (1945; Eng. trans., *Letters*, 1948), letters to his friends that reveal a man affable, tender, sometimes gay, and sympathetic to the sufferings of others; GEORGE MOORE, "Memories of Degas," *Burlington Magazine* (July–August, 1928); DENIS ROUART (ed.), *Correspondance de Berthe Morisot* (1950); PAUL VALERY, *Degas danse dessin* (1938; Eng. trans., *Degas Dance Drawing*, 1948), rich in considerations of art in general—Valery's ideas about literature were very similar to Degas's ideas on his art.

*Catalogs:* *Catalogues des tableaux, pastels et dessins, par Edgar Degas, et provenant de son atelier* (1918), catalogs of paintings, pastels, and drawings by Degas, originating in his studio (2,290 pieces); *Degas, Musée de l'Orangerie*, Paris (1937), an excellent analysis of Degas' style, with an introduction by PAUL JAMOT; *La Peintre au Musée du Louvre* by PAUL JAMOT (1929), an explanation of Degas' techniques of painting; *Le Peintre graveur illustré* (1919), discusses 45 major etchings and 20 lithographs; *Degas*, Wildenstein Galleries, New York (1960), a distinguished general catalog; *Drawings by Degas*, City Art Museum of St. Louis (1966), an important, recent study.

(D.C.Th.)

## Dehydration

Dehydration is the loss of water from the body; it almost invariably is associated with varying kinds and degrees of disturbance of salt (sodium chloride) metabolism. Because of this, dehydration can be classified simply as follows: (1) loss of more water than sodium; (2) loss of more sodium than water; (3) isotonic (*i.e.*, proportionate) losses of sodium and water. In addition to the losses of sodium, there may be losses of other electrolytes such as potassium, as well as alterations of acid-base balance. The treatment of any form of dehydration, therefore, requires not only the replacement of the water lost from the body but also the restoration of the normal concentration and distribution of electrolytes within the body fluid.

**Causes of dehydration.** Dehydration may be caused by restriction of water intake or by excessive water loss.

**Restriction of water intake.** The commonest cause of dehydration is failure to drink. The deprivation of water is far more serious than the deprivation of food. Man loses approximately 2.5 percent of his total body water per day (about 1,200 millilitres, or 1.25 quarts) in urine, in expired air, by insensible perspiration, and from the gastrointestinal tract. If, in addition to this loss, his loss through perspiration is greatly increased—as in the case of the shipwrecked sailor in tropical seas or the traveller lost in the desert—in only a few hours he may lose so much body water that he goes into shock and dies.

When swallowing is difficult in extremely ill persons, or when people cannot respond to a sense of thirst because of age or illness or dulling of consciousness, the failure to compensate for the daily loss of body water will rapidly result in dehydration and its consequences.

**Excessive water loss.** Loss of water from the body invariably is associated with more or less loss of salt. In the following examples more water is lost than salt.

Excessive urination (diuresis) occurs when there is sugar in the urine as a result of diabetes mellitus, particularly when the blood and body fluids are abnormally low in alkalinity. It also occurs in seriously ill persons fed a high-protein diet, who cannot retain nitrogen and must excrete the urea formed by protein breakdown.

Persons with diabetes insipidus (which results from insufficiency of antidiuretic hormone) are unable to concentrate urine, and in consequence maintain the most phenomenal intake of water and excretion of urine. It has been said of these unfortunates that they "spend their lives running from the kitchen to the bathroom." The wa-

ter that they lose in this fashion has an extremely low concentration of salt. A similar clinical picture can be seen in persons whose diseased kidneys are unable to reabsorb water.

In persons with extensive burns, a large volume of water may be lost through the damaged skin. Similarly, excessive sweating without adequate water intake can produce severe dehydration. A rare cause of dehydration is loss of water from the lungs in the presence of hyperventilation—excessive rate and depth of breathing.

The second major group of diseases in which dehydration occurs are those in which there is a loss of salt which is greater than the accompanying loss of water. Such a disease is adrenal cortical insufficiency, also called Addison's disease. The hormone aldosterone, secreted by the outer substance, or cortex, of the adrenal gland, controls the reabsorption of sodium in the kidney. In Addison's disease there is lessened secretion of the hormone, with a resultant increase in excretion of sodium in the urine and a lowered level of sodium in the blood (hyponatremia). There is then increased excretion of water to restore the composition of the blood to normal. Severe dehydration is the ultimate result.

Persons whose kidneys are unable to function adequately, a condition called chronic renal insufficiency, may develop an inability to conserve salt. Such a defect may be aggravated by injudicious salt restriction to the point where the clinical state resembles adrenal cortical insufficiency.

Dehydration and hyponatremia may result from bleeding under the arachnoid, the middle layer of the brain covering, or from encephalitis, inflammation of the brain.

The normal daily turnover of fluids in the gastrointestinal tract amounts to about eight litres (slightly more than eight quarts) in 24 hours, nearly 20 percent of the total body water. In vomiting or diarrhea large volumes of water may be lost, always with an associated loss of electrolytes (*e.g.*, sodium, potassium). The exact nature of the resultant electrolyte deficit will depend in part on the site of the lesion causing symptoms, and in part on whether the ill person is receiving other fluids. In uncomplicated, untreated vomiting or diarrhea, the dehydration that results is ordinarily a balanced loss of electrolytes and water.

Short- and long-term effects of dehydration. The symptoms of dehydration depend in part on the cause, and in part on whether there is associated salt deprivation as well. Since the body is divided into a number of compartments so far as its body fluids are concerned, alterations in the water or salt content of one compartment results in rapid shifts of water or salt in an attempt to re-establish the overall balance. To further complicate matters, the electrolytes and protein are in different proportions in the blood plasma and in the cell fluid. This means that the human body must regulate not only the amount of water and the concentration of electrolytes in each compartment, but also that it must assure that each compartment contains the right kind of salt (electrolyte) for its own normal function.

When loss of water is disproportionately greater than loss of electrolytes, the osmotic pressure of the extracellular fluids becomes higher than in the cells. Since water passes from a region of lower to a region of higher osmotic pressure, water flows out of the cells into the extracellular fluid, tending to lower its osmotic pressure and increase its volume toward normal. As a result of the flow of water out of the cells, they become dehydrated. This results in the thirst that always accompanies "pure" water depletion.

In those diseases in which there is loss of salt in excess of water, the decreased concentration of sodium in the extracellular fluid and in the blood serum results in decreased osmotic pressure, and water therefore enters the cells to equalize the osmotic pressure. Thus there is extracellular dehydration and intracellular hydration—and no thirst.

A comparison of the results of water and salt (electrolyte) deprivation is given in the Table. The degree of deprivation that is present affects these results. As is already

Water loss from vomiting and diarrhea

Water loss from diabetes

apparent, it is rare for either salt or water to be depleted by itself, since compensatory mechanisms result in significant alteration in the other when the concentration of one is changed.

Comparison of Effects of Water and Salt Depletion*		
manifestation	pure water depletion	pure salt depletion
Thirst	+++	Absent
Lassitude		+++
Fainting upon standing up	Absent until late	+++
Urine volume	Scanty	Normal until late
NaCl in urine	Often +	Always absent except in Addison's disease
Vomiting	Absent	May be +
Cramps	Absent	May be +
Plasma NaCl	Slight increase or normal	Diminished +++
Plasma volume	Normal until late	Decreased +++
Blood urea	+	+++
Decrease of fluid content of blood	Not until late and slight	+++
Blood viscosity	Normal until late	Increased +
Blood pressure	Normal until late	Fall +++
Water absorption	Rapid	Slow

\* Plus signs indicate degree of severity, from slight (+) to extreme (+++).

Early and late effects of water deprivation

Gradual weight loss occurs in both types of dehydration, amounting to two to three pounds per day. Thirst is the inevitable accompaniment only of water deprivation, without concomitant salt loss. Dryness of the mouth, a craving for fluid, decreased production of saliva, and impaired swallowing all follow prolonged restriction of water intake. It is probable that thirst is the result of the subsequent intracellular dehydration and increased intracellular osmotic pressure. Experimentally, thirst can be produced when the cells have lost about one percent of their intracellular water.

As dehydration progresses, the tissues tend to shrink, the skin becomes dry and wrinkled, and the eyes become shrunken and the eyeballs soft. Fever develops, which may be mild, but may become marked as dehydration progresses. Dehydration itself probably affects the temperature regulatory centres in the brain. As dehydration and salt loss progress, however, the plasma volume and the output of the heart decrease, with consequent decrease of the blood supply to the skin. Sweating decreases and may stop completely, and the main avenue for heat loss is closed. The body temperature may then rise precipitously.

There are marked changes in the volume of the extracellular and intracellular fluids, but the blood plasma volume changes the last and the least.

Plasma volume maintained at expense of tissue fluids

The plasma volume is maintained more or less constant at the expense of the tissue fluids. When the plasma volume decreases, the concentration and the osmotic pressure of the plasma protein rise, and the venous and capillary pressures fall; these are processes that tend to maintain a normal plasma volume. If these mechanisms fail, and the plasma volume falls, the output of the heart also fails, and the pulse rate climbs, indicative of a dangerous physical state.

The renal (kidney) changes that occur in man during prolonged water depletion similarly tend to maintain a normal balance. Initially the renal blood flow is maintained and the glomerular filtration rate (the rate at which protein-free fluid containing nitrogenous waste products and other substances in solution are filtered out of the blood) may only be decreased 10–20 percent. If water deprivation continues and the plasma volume falls, however, with subsequent further decrease in the glomerular filtration rate, the output of urine will be drastically reduced. As long as urine output of over 30 millilitres (about one fluid ounce) per hour is maintained, the kidney can excrete nitrogenous and nonnitrogenous solids with maximum efficiency. Once the urine flow is decreased below this level, the kidney is unable to function efficiently, the substances are retained in the body, and their concentration in the blood rises.

The final result of prolonged dehydration is now apparent. The normal distribution of salt and water in the body is destroyed, the plasma volume decreases, and the blood viscosity increases. As a result of these changes renal function is impaired, the glomerular filtration rate falls, the urinary output falls, and waste products accumulate. Far more life-threatening, however, is decreased loss of moisture from the skin, with the subsequent rise in temperature, and the fall in cardiac output with the attendant irreversible shock.

**Prognosis and nature of the treatment.** Once renal failure occurs, about 8 percent of the total body water has been lost (four litres). When five to ten litres of body water have been lost a person is acutely and severely ill, with a contracted plasma volume, increased concentration and viscosity of the blood, renal failure and excessive urea in the blood, and a falling blood pressure. In a previously healthy adult death follows the loss of 12–15 litres of body water. In the very young, the very old, or the debilitated, death occurs at a lower level of dehydration.

Effects of degrees of dehydration

The treatment of any form of dehydration depends not only on restoring the depleted water, but also on the re-establishment of normal levels of body electrolytes (salt) and limitation of the production of nitrogenous waste products.

Before any of these therapeutic measures can be applied, however, the initiating cause must be removed. The sailor or the desert traveller must be rescued, the vomiting infant must be cured, or the underlying disease (e.g., Addison's disease) must be treated. Then, after accurate biochemical determinations of the levels of various electrolytes and other blood components have been made and the plasma volume has been measured, the physician can commence giving measured quantities of the appropriate mixtures of salt and water. Given the right amounts of salt and water, the human body will gradually restore the normal relationships between the cells, the extracellular fluid, and the plasma volume. That done, the complicated functions of the kidney will clear the circulating blood of the retained waste products, and the body will have restored its own normal balance.

Deism

Deism, as the word is customarily employed, describes an unorthodox religious attitude that found expression among a group of English writers beginning with Edward Herbert (later 1st Baron Herbert of Cherbury) in the first half of the 17th century and ending with Henry St. John, 1st Viscount Bolingbroke, in the middle of the 18th century. In general, however, it refers to what can be called natural religion, the acceptance of a certain body of religious knowledge that is inborn in every person or that can be acquired by the use of reason, as opposed to knowledge acquired through either revelation or the teaching of any church.

**Nature and scope.** Though an initial use of the term occurred in 16th-century France, the later appearance of the doctrine on the Continent was stimulated by the translation and adaptation of the English models. The high point of Deist thought occurred in England from about 1689 through 1742, during a period when, despite widespread counterattacks from the established Church of England, there was relative freedom of religious expression following upon the Glorious Revolution that

The concept of natural religion

ended the rule of James II and brought William and Mary to the throne. Deism took deep root in 18th-century Germany after it had ceased to be a vital subject of controversy in England.

At times in the 19th and early 20th centuries, the word Deism was used theologically in contradistinction to theism, the belief in an immanent God who actively intervenes in the affairs of men. In this sense Deism was represented as the view of those who reduced the role of God to a mere act of creation in accordance with rational laws discoverable by man and held that, after the original act, God virtually withdrew and refrained from interfering in the processes of nature and the ways of man. So stark an interpretation of the relations of God and man, however, was accepted by very few Deists during the flowering of the doctrine, though their religious antagonists often attempted to force them into this difficult position. Historically, a distinction between theism and Deism has never had wide currency in European thought. As an example, when encyclopaedist Denis Diderot, in France, translated into French the works of Anthony Ashley Cooper, 3rd earl of Shaftesbury, one of the important English Deists, he often rendered "Deism" as *théisme*. The term is not in current usage as a metaphysical concept, and its significance is really limited to the 17th and 18th centuries.

The historical Deists. *The English Deists*. In 1754–56, when the Deist controversy had passed its peak, John Leland, an opponent, wrote a historical and critical compendium of Deist thought, *A View of the Principal Deistical Writers that Have Appeared in England in the Last and Present Century; with Observations upon Them, and Some Account of the Answers that Have Been Published Against Them*. This work, which began with Lord Herbert of Cherbury and moved through the political philosopher Thomas Hobbes, Charles Blount, the Earl of Shaftesbury, Anthony Collins, Thomas Woolston, Matthew Tindal, Thomas Morgan, Thomas Chubb, and Viscount Bolingbroke, fixed the canon of who should be included among the Deist writers. In subsequent works Hobbes usually has been dropped from the list and John Toland included, though he was closer to pantheism than most of the other Deists were. Herbert was not known as a Deist in his day, but Blount and the rest who figured in Leland's book would have accepted the term Deist as an appropriate designation for their religious position. Simultaneously, it became an adjective of opprobrium in the vocabulary of their opponents. Bishop Edward Stillingfleet's *Letter to a Deist* (1677) is an early example of the orthodox use of the epithet.

In Lord Herbert's treatises five religious ideas were recognized as God-given and innate in the mind of man from the beginning of time: the belief in a supreme being, in the need for his worship, in the pursuit of a pious and virtuous life as the most desirable form of worship, in the need of repentance for sins, and in rewards and punishments in the next world. These fundamental religious beliefs, Herbert held, had been the possession of the first man, and they were basic to all the worthy positive institutionalized religions of later times. Thus, difference among sects and cults all over the world were usually benign, mere modifications of universally accepted truths; they were corruptions only when they led to barbarous practices such as the immolation of human victims and the slaughter of religious rivals.

In England at the turn of the 17th century this general religious attitude assumed a more militant form, particularly in the works of Toland, Shaftesbury, Tindal, Woolston, and Collins. Though the Deists differed among themselves and there is no single work that can be designated as the quintessential expression of Deism, they joined in attacking both the existing orthodox church establishment and the wild manifestations of the dissenters. The tone of these writers was often earthy and pungent, but their Deist ideal was sober natural religion without the trappings of Catholicism and the High Church in England and free from the passionate excesses of Protestant fanatics. In Toland there is great emphasis on the rational element in natural religion; in Shaftes-

bury more worth is ascribed to the emotive quality of religious experience when it is directed into salutary channels. All are agreed in denouncing every kind of religious intolerance because the core of the various religions is identical. In general, there is a negative evaluation of religious institutions and the priestly corps who direct them. Simple primitive monotheism was practiced by early men without temples, churches, and synagogues, and modern men could readily dispense with religious pomp and ceremony. The more elaborate and exclusive the religious establishment, the more it came under attack. A substantial portion of Deist literature was devoted to the description of the noxious practices of all religions in all times, and the similarities of pagan and Roman Catholic rites were emphasized.

The Deists who presented purely rationalist proofs for the existence of God, usually variations on the argument from the design or order of the universe, were able to derive support from the vision of the lawful physical world that Sir Isaac Newton had delineated. Indeed, in the 18th century, there was a tendency to convert Newton into a matter-of-fact Deist—a transmutation that was contrary to the spirit of both his philosophical and his theological writings.

When Deists were faced with the problem of how man had lapsed from the pure principles of his first forebears into the multiplicity of religious superstitions and crimes committed in the name of God, they ventured a number of conjectures. They surmised that men had fallen into error because of the inherent weakness of human nature; or they subscribed to the idea that a conspiracy of priests had intentionally deceived men with a "rout of ceremonies" in order to maintain power over them.

The role of Christianity in the universal history of religion became problematic. For many religious Deists the teachings of Christ were not essentially novel but were, in reality, as old as creation, a republication of primitive monotheism. Religious leaders had arisen among many peoples—Socrates, Buddha, Muhammad—and their mission had been to effect a restoration of the simple religious faith of early men. Some writers, while admitting the similarity of Christ's message to that of other religious teachers, tended to preserve the unique position of Christianity as a divine revelation. It was possible to believe even in prophetic revelation and still remain a Deist, for revelation could be considered as a natural historical occurrence consonant with the definition of the goodness of God. The more extreme Deists, of course, could not countenance this degree of divine intervention in the affairs of men.

Natural religion was sufficient and certain; the tenets of all positive religions contained extraneous, even impure elements. Deists accepted the moral teachings of the Bible without any commitment to the historical reality of the reports of miracles. Most Deist argumentation attacking the literal interpretation of Scripture as divine revelation leaned upon the findings of 17th-century biblical criticism. Woolston, who resorted to an allegorical interpretation of the whole of the New Testament, was an extremist even among the more audacious Deists. Tindal was perhaps the most moderate of the group. Toland was violent; his denial of all mystery in religion was supported by analogies among Christian, Judaic, and pagan esoteric religious practices, equally condemned as the machinations of priests.

The Deists were particularly vehement against any manifestation of religious fanaticism and enthusiasm. In this respect Shaftesbury's *Letter Concerning Enthusiasm* (1708) was probably the crucial document in propagating their ideas. Revolted by the Puritan fanatics of the previous century and by the wild hysteria of a group of French exiles prophesying in London in 1707, Shaftesbury denounced all forms of religious extravagance as perversions of true religion. These false prophets were directing religious emotions, benign in themselves, into the wrong channels. Any description of God that depicted his impending vengeance, vindictiveness, jealousy, and destructive cruelty was blasphemous. Because sound religion could find expression only among healthy men, the argu-

Herbert's  
five fun-  
damental  
beliefs

ment was common in Deist literature that the preaching of extreme asceticism, the practice of self-torture, and the violence of religious persecutions were all evidence of psychological illness and had nothing to do with authentic religious sentiment and conduct. The Deist God, ever gentle, loving, and benevolent, intended men to behave toward one another in the same kindly and tolerant fashion.

French  
Deists

*Deists in other countries.* Ideas of this general character were voiced on the Continent at about the same period by such men as Pierre Bayle, a French philosopher famous for his encyclopaedic dictionary, even though he would have rejected the Deist identification. During the heyday of the French Philosophes in the 18th century, the more daring thinkers—Voltaire among them—gloried in the name Deist and declared the kinship of their ideas with those of Rationalist English ecclesiastics, such as Samuel Clarke, who would have repudiated the relationship. The dividing line between Deism and atheism among the Philosophes was often rather blurred, as is evidenced by *Le Rêve de d'Alembert* (written 1769; "The Dream of d'Alembert"), which describes a discussion between the two "fathers" of the *Encyclopédie*: the Deist Jean Le Rond d'Alembert and the atheist Diderot, Diderot had drawn his inspiration from Shaftesbury, and thus in his early career he was committed to a more emotional Deism. Later in life, however, he shifted to the atheist materialist circle of the Baron d'Holbach. When Holbach paraphrased or translated the English Deists, his purpose was frankly atheist; he emphasized those portions of their works that attacked existing religious practices and institutions, neglecting their devotion to natural religion and their adoration of Christ. The Catholic Church in 18th-century France did not recognize fine distinctions among heretics, and Deist and atheist works were burned in the same bonfires.

German  
Deists

English Deism was transmitted to Germany primarily through translations of Shaftesbury, whose influence upon thought was paramount. In a commentary on Shaftesbury published in 1720, Gottfried Wilhelm Leibniz, a Rationalist philosopher and mathematician, accepted the Deist conception of God as an intelligent Creator but refused the contention that a god who metes out punishments is evil. A sampling of other Deist writers was available particularly through the German rendering of Leland's work in 1755 and 1756. H.S. Reimarus, author of many philosophical works, maintained in his *Apologie oder Schutzschrift für die vernünftigen Verehrer Gottes* ("Defense for the Rational Adorers of God") that the human mind by itself without revelation was capable of reaching a perfect religion. Reimarus did not dare to publish the book during his lifetime, but it was published in 1774–78 by Gotthold Ephraim Lessing, one of the great seminal minds in German literature. According to Lessing, common man, uninstructed and unreflecting, will not reach a perfect knowledge of natural religion; he will forget or ignore it. Thus, the several positive religions can help men achieve more complete awareness of the perfect religion than could ever be attained by any individual mind. Lessing's *Nathan der Weise* (1779; "Nathan the Sage") was noteworthy for the introduction of the Deist spirit of religion into the drama; in the famous parable of the three rings, the major monotheistic religions were presented as equally true in the eyes of God. Although Lessing's rational Deism was the object of violent attack on the part of Pietist writers and the more mystical thinkers, it influenced such men as Moses Mendelssohn, a German Jewish philosopher who applied Deism to the Jewish faith. Immanuel Kant, the most important figure in 18th-century German philosophy, stressed the moral element in natural religion; moral principles are not the result of any revelation but originate from the very structure of man's reason. English Deists, however, continued to influence German Deism. Witnesses attest that virtually the whole officer corps of Frederick the Great was infected with Deism and that Collins and Tindal were favourite reading in the army.

American  
Deists

By the end of the 18th century, Deism had become a dominant religious attitude among intellectual and upper

class Americans. Benjamin Franklin, the great sage of the Colonies and then of the new republic, summarized in a letter to Ezra Stiles, president of Yale College, a personal creed that almost literally reproduced Herbert's five fundamental beliefs. The first three presidents of the United States also held Deistic convictions, as is amply evidenced in their correspondence. "The ten commandments and the sermon on the mount contain my religion," John Adams wrote to Thomas Jefferson in 1816.

(1754; also 1837 ed.), the first historical account; FRITZ MAUTHNER, *Der Atheismus und seine Geschichte im Abendlande*, 4 vol. (1921–23), a complete history; ERNST CASSIRER, *Die Philosophie der Aufklärung* (1932; Eng. trans., *The Philosophy of the Enlightenment*, 1951), a description of Deism and its philosophical background; HAROLD G. NICOLSON, *The Age of Reason* (1960), on the nature of 18th-century Rationalism and its connection with Deism; JAMES COLLINS, *God in Modern Philosophy* (1959), a full history of Deism, here called "theism," from Nicolas of Cusa to contemporary theological theories; JOHN ORR, *English Deism: Its Roots and Its Fruits* (1934); GOTTHARD V. LECHLER, *Geschichte des englischen Deismus* (1841), the first full history after the end of Deism; HERBERT OF CHERBURY, *De Veritate* (1624; Eng. trans. by MEYRICK H. CARRE, *On Truth*, 1937), the first English translation of the reputedly "first" classic expression of Deism; MARIO M. ROSSI, *La vita, le opere, i tempi di Edoardo Herbert di Chirbury*, 3 vol. (1947), and *Alle fonti del deismo e del materialismo moderno* (1942), two works that describe Herbert's life and Deistic thought against the background of the history of Deism and the attitude of the church; DAVID HUME, *Dialogues Concerning Natural Religion*, 2nd ed. with suppl. (1947), the beginning of the Deist's self-criticism; THOMAS PAINE, *The Age of Reason*, 3 pt. (1794–1811), the work most influential on the Deism of common people; JOHN S. SPINK, *French Free-Thought from Gassendi to Voltaire* (1960), on French Deism; HENRY E. ALLISON, *Lessing and the Enlightenment* (1966); IMMANUEL KANT, *Die Religion innerhalb der Grenzen der blossen Vernunft* (1793; Eng. trans., *Religion Within the Limits of Reason Alone*, 1947), the classic work of the last stage of German Deism; G.W.F. HEGEL, *Early Theological Writings*, trans. by THOMAS M. KNOX and RICHARD KRONER (1948), early writings to show Hegel's indebtedness to Deistic polemics.

(F.E.M.)

## De Kooning, Willem

Willem de Kooning is one of the most distinguished surviving painters of Abstract Expressionism, an American art movement characterized by free-associative gestures in paint and sometimes referred to as action painting. Most famous for his harsh depictions of women in the early 1950s, his work has fluctuated between figuration and abstraction since the early 1930s, when his reputation was established among his peers. His work has had substantial influence on his younger American contemporaries, especially during the late 1950s, and he enjoys a wide international reputation.

De Kooning was born in Rotterdam, Holland, April 24, 1904, the son of Leendert de Kooning and Cornelia Nobel, who were divorced about 1909. He was raised by his mother and a stepfather. In 1916 he was apprenticed to a firm of commercial artists and decorators, and about the same time he enrolled in night classes at the *Academie voor Beeldende Kunsten en Technische Wetenschappen* (Rotterdam Academy of Fine Arts and Techniques), where he studied creative and practical art for eight years. In 1920 he went to work for the art director of a large department store. During this period he became aware of modern art movements, especially the *de Stijl* group led by the painters Piet Mondrian and Theo van Doesburg, who were dedicated to geometric structure, abstraction, and simplification in art. With the exception of a few academic sketches, none of de Kooning's work from this time still exists.

In 1926 de Kooning entered the United States as a stow-away and eventually settled in Hoboken, New Jersey, where he supported himself as a house painter. In 1927 he moved to a studio in Manhattan and came under the influence of the artist, connoisseur, and art critic John Graham and the painter Arshile Gorky. Gorky became one of de Kooning's closest friends.

Early work  
in America

From about 1928 de Kooning began to paint still-life and figure compositions reflecting school of Paris and Mexican influences. By the early 1930s he was exploring abstraction, using biomorphic shapes and simple geometric compositions—an opposition of disparate formal elements that prevails in his work throughout his career. These early works had strong affinities with those of his friends Graham and Gorky and reflected the impact on these young artists of Pablo Picasso and the Surrealist Joan Miró, both of whom achieved powerfully expressive compositions through biomorphic forms.

In October 1935, de Kooning began to work on the WPA (Works Progress Administration) Federal Art Project. He was employed by this work-relief program until July 1937, when he was forced to resign because of his alien status. This period of about two years provided the artist, who had been supporting himself during the early Depression by commercial jobs, with his first opportunity to devote full time to creative work. He worked on both the easel-painting and mural divisions of the project (the several murals he designed were never executed). After he left the WPA he was commissioned to design a mural for the Hall of Pharmacy at the New York World's Fair of 1939, which was painted by professional muralists and destroyed when the fair ended. In 1940 he received a commission from the federal government's Section of Fine Arts to create a mural for the library of the U.S. President Jackson, a U.S. Navy ship. De Kooning's mural designs for the Federal Art Project were similar in style to his abstract works of the early 1930s; his murals for the World's Fair and the Section of Fine Arts were more representational.

Coloured  
abstrac-  
tions

In 1938, probably under the influence of Gorky, de Kooning embarked on a series of sad, staring male figures, such as "Two Men Standing," "Man," and "Seated Figure (Classic Male)." Parallel with these works he also created lyrically coloured abstractions, such as "Pink Landscape" and "Elegy." This coincidence of figures and abstractions continued well into the 1940s with his representational but somewhat geometrized "Woman" and "Standing Man," along with numerous untitled abstractions whose biomorphic forms increasingly suggest the presence of figures. By about 1945 the two tendencies seem to fuse perfectly in "Pink Angels." In 1946, too poor to buy artists' pigments, he turned to black and white household enamels to paint a series of large abstractions; of these works, "Light in August" and "Black

Friday" are essentially black with white elements, whereas "Zurich" and "Mailbox" are white with black. Developing out of these works in the period after his first show are complex, agitated abstractions like "Asheville," "Attic," and "Excavation," which reintroduce colour and seem to sum up with taut decisiveness the problems of free-associative composition he had struggled with for many years.

In 1938 de Kooning had met Elaine Fried, whom he married in 1943. During the 1940s and thereafter he became increasingly identified with the Abstract Expressionist movement and was recognized as one of its leaders in the mid-1950s. He had his first one-man show, which consisted of his black-and-white enamel compositions, at the Charles Egan Gallery in New York in 1948, and taught at Black Mountain College in North Carolina in 1948 and at the Yale School of Art 1950–51.

While de Kooning had painted women regularly in the early 1940s and again from 1947 to 1949, and while the biomorphic shapes of his early abstractions can be interpreted as female symbols, it was not until 1950 that he began to explore the subject of women exclusively. In the summer of that year he began "Woman I," which went through innumerable metamorphoses before it was finished in 1952. During this period he also created other paintings of women. These works were shown at the Sidney Janis Gallery in 1953 and caused a sensation, chiefly because they were figurative when most of his fellow Abstract Expressionists were painting abstractly, and because of their blatant technique and imagery. The savagely applied pigment and the use of colours that seem vomited on his canvas combine to reveal a woman all too congruent with some of modern man's most widely held sexual fears. The toothy snarls, overripe, pendulous breasts, vacuous eyes, and blasted extremities imaged the darkest Freudian insights. The "Woman" paintings II through VI are all variants on this theme, as are "Woman and Bicycle" and "Two Women in the Country." The deliberate vulgarity of these paintings contrasts with the French painter Jean Dubuffet's no less harsh "Corps de dame" series of 1950, in which the female, formed with a rich topography of earth colours, relates more directly to universal symbols.

By 1955, however, de Kooning seems to have turned to this symbolic aspect of woman; this is suggested by the title of his "Woman as Landscape," in which the vertical figure seems almost absorbed into the abstract background. There followed a series of landscapes such as "Police Gazette," "Gotham News," "Backyard on Tenth Street," "Parc Rosenberg," "Suburb in Havana," "Door to the River," and "Rosy-Fingered Dawn at Louse Point," which display an evolution from compositional and coloristic complexity to a broadly painted simplicity.

Around 1963, the year he moved permanently to the springs at East Hampton, Long Island, de Kooning returned to depicting women in "Pastorale" and "Clam Diggers." The theme is re-explored over the next years in "Woman Acabonic," "Woman and Child," and "The Visit." These paintings, as controversial as his earlier women, are satiric attacks on the female anatomy, painted with a flamboyant lubricity in keeping with the uninhibited subject matter.

Critics have charged that, compared with his paintings of the late 1940s and 1950s, his work since the 1960s seems to exploit old themes and lacks that archaeological stratification of paint surfaces so indicative of his former struggle with the processes of creation. Yet these works are not his last, and his critics' taste for more recent trends in American art may well prevent them from accepting the logical development toward freedom of a very subjective artist.

#### MAJOR WORKS

"Two Men Standing" (c. 1938; private collection, New York); "Pink Landscape" (c. 1938; Mr. and Mrs. Reuben Tam Collection, New York); "Man" (c. 1939; private collection, New York); "Elegy" (c. 1939; private collection); "Glazier" (c. 1940; private collection, New York); "Seated Figure (Classic Male)" (c. 1940; private collection); "Standing Man" (c. 1942; Wadsworth Atheneum, Hartford, Conn.); "Woman"

Variations  
on the  
theme of  
"Woman"

(c. 1943; private collection, New York); "Portrait of Max Margulis" (c. 1944; private collection); "Queen of Hearts" (1943–46; Joseph H. Hirshhorn Collection, New York); "Pink Angels" (c. 1945; Mr. and Mrs. Frederick R. Weisman Collection, Beverly Hills, California); "Light in August" (c. 1946; Elise C. Dixon Collection, Scottsdale, Arizona); "Mailbox" (1947–48; Nelson A. Rockefeller Collection, New York); "Zurich" (1947; private collection); "Painting" (1948; Museum of Modern Art, New York); "Black Friday" (1948; Mrs. H. Gates Lloyd Collection, Haverford, Pennsylvania); "Woman" (c. 1949; University of North Carolina); "Asheville" (1948–49; Phillips Collection, Washington, D.C.); "Attic" (1949; Muriel Newman Collection, Chicago); "Boudoir" (c. 1950; William Rockhill Nelson Gallery and Atkins Museum of Fine Arts, Kansas City, Mo.); "Excavation" (1950; Art Institute, Chicago); "Two Women" (1952; Art Institute Chicago); "Woman I" (1952; Museum of Modern Art, New York); "Woman II" (1952–53; Museum of Modern Art, New York); "Woman IV" (1952–53; William Rockhill Nelson Gallery and Atkins Museum of Fine Arts, Kansas City, Mo.); "Woman and Bicycle" (1953; Whitney Museum of American Art, New York); "Woman VI" (1953; Carnegie Institute, Pittsburgh, Pennsylvania); "Two Women in the Country" (1954; Joseph H. Hirshhorn Collection, New York); "Police Gazette" (1954–55; Robert C. Scull Collection, New York); "Woman As Landscape" (1955; private collection); "Gotham News" (1955–56; Albright-Knox Art Gallery, Buffalo, New York); "Easter Monday" (1956; Metropolitan Museum of Art, New York); "Backyard on Tenth Street" (1956; Baltimore Museum of Art, Baltimore, Maryland); "Parc Rosenberg" (1957; Isabel and Donald Grossman Collection, New York); "Suburb in Havana" (1958; Mr. and Mrs. Lee V. Eastman Collection, New York); "Door to the River" (1960; Whitney Museum of American Art, New York); "Rosy-Fingered Dawn at Louse Point" (1963; Stedelijk Museum, Amsterdam); "Pastorale" (1963; private collection); "Clam Diggers" (1964; private collection); "Woman Acabonic" (1966; Whitney Museum of American Art, New York); "Woman and Child" (1967; Joseph and Mildred Gosman Collection, Toledo, Ohio); "The Visit" (1967; M. Knoedler and Co., Inc.).

**BIBLIOGRAPHY.** THOMAS B. HESS has written two books entitled *Willem de Kooning*, the first in 1959 as a monograph in the "Great American Artist Series" and the second as the catalog of the Museum of Modern Art's travelling retrospective in 1968. The latter contains a basic bibliography and the text of de Kooning's three major published statements. An interpretative monograph has been written by HARRIET JANIS and RUDI BLESCH, *De Kooning* (1960); and an important article describing the creation of "Woman I" is THOMAS B. HESS, "De Kooning Paints a Picture," *Art News*, 51:30–33 (1953).

(F.V.O'C.)

## Delacroix, Eugène

Eugène Delacroix, the greatest French painter of the first half of the 19th century, possessed a powerful imagination, a subtle intelligence, and a rare (and touchy) sensitivity that made him perhaps the century's least understood artist. He wrote in 1850 in his *Journal*: "The Beautiful is found but once, at a certain appointed moment in history. Too bad for the genius who comes after." He might well have added, in view of the misunderstandings that caused him so much grief, "Too bad for the genius who comes *before*." For his genius foreshadowed the subtleties and the tragic side of modern art, which was only understood in his time by the poetic intuition of Charles Baudelaire.

With the English painter J.M.W. Turner, he was the initiator of the bold technical innovations of Impressionism and the forerunner of modern Expressionism. Auguste Renoir, Claude Monet, Paul Cézanne, Paul Gauguin, Vincent van Gogh, Odilon Redon, Georges Seurat, Henri Matisse, and Pablo Picasso all recognized their debt to him—his use of colour and skill in modelling equalled that of Titian or Rubens. Too broad an artist to be confined within one aesthetic movement, he was yet characterized, about 1830, as a Romantic. Displeased, he replied, "I am a pure Classicist." He wished to transmit through art the poetry of his being. Thus he created in each work an expressive unity, a symphony of forms, of light, and especially of colour.

**Early life.** Ferdinand-Victor-Eugène Delacroix was born on April 26, 1798, at Charenton-Saint-Maurice, the fourth child of Victoire-Oeben, a descendant of the

Delacroix, self-portrait, oil on canvas, c. 1837. In the Louvre, Paris. 65 cm X 55 cm. Girardon

Oeben-Riesener family, which had created furniture for the king and court in the 17th and 18th centuries, and of Charles Delacroix, a government official who was ambassador to Holland in 1798 and who died in 1805 while prefect of Bordeaux. One tradition attributes Eugene's true paternity to the statesman Charles-Maurice de Talleyrand-Périgord. But the childhood of the future painter was never troubled by any doubt, and he would always maintain great affection and admiration for his father. Up to the age of 17 he pursued classical studies. With in his distinguished and artistic family he found a passion for music and theatre, the manners, and the relationships that would make him a perfect dandy. In 1815 he became the pupil of a famous academic painter, Baron Pierre-Narcisse Guérin. He knew the historical painter Antoine-Jean Gros, and as a young man visited the salon of the royalist and painter Baron François Gérard. As early as 1822 he received the backing of Louis Thiers, the statesman and historian, who, as interior minister in the 1830s, put Delacroix in charge of architectural decorations.

A child of his century, Delacroix shared the melancholy that afflicted the sons and brothers of the heroes of the Napoleonic Wars. He was affected by the Romanticism of the painter Théodore Géricault, and of his friends the English painter Richard Parkes Bonington, the Polish-born composer and pianist Frédéric Chopin, and the French writer George Sand. He did not, however, take part in the battles of the Romantic movement waged by Victor Hugo, Hector Berlioz, and others.

**Development of mature style.** His first masterpiece, "Dante and Virgil in Hell," was inspired by Dante's Divine *Comedy*, but its tragic feeling is reminiscent of Michelangelo and Rubens. The dramatic contemporary event of the massacre of Greeks by Turks on the island of Chios inspired a large canvas, "The Massacre at Chios," submitted to the Paris Salon of 1824. The haughty pride of the conquerors, the horror as well as despair of the innocent Greeks, and the splendour of a vast sky create an expressive unity in which the nature of his genius is evident.

Already interested in the delicate technique of his English painter friends Bonington and the Fielding brothers (Thales, Copley, Theodore, and Newton), he also admired the English landscapes of John Constable, which were exhibited in Paris in 1824. To round out his technical and cultural education, Delacroix left for London in 1825. There, his technique, developed by contact with Turner, Constable, and Sir Thomas Lawrence, acquired the freedom and suppleness that until then he had been seeking in Rubens. Between 1827 and 1832, masterpieces came in quick succession. Paintings of historical subjects included "The Battle of Nancy" and "Bataille de Poitiers." The subjects of other paintings were taken from the English poet Byron. He also made a set of 17 lithographs illustrating a French edition of Goethe's *Faust*.

Early associations with painters

Influence of English artists

Delacroix's "Liberty Leading the People," which was inspired by the Revolution of 1830, was the last evidence of a Romanticism he finally rejected. In subsequent paintings he tried to avoid the characteristics of his earlier works: the dizzying colours of "The Death of Sardanapalus," the turmoil of massacres as in "The Assassination of the Bishop of Liège," and the gaudy trumpery of history. He did not intend to surrender to his literary penchant for dramatic expression any more than to his taste for exactitude in historical detail. He needed to confront a reality that would be a source of inner exaltation.

Moroccan  
influence

He found it on a trip to Morocco in 1832. From January to July he toured with the Comte de Momay, King Louis-Philippe's diplomatic representative to the Sultan. The sight of exuberant nature, the beauty of the horses, of the Arabs and their dress, of primitive savagery, enhanced by the light of memory, would henceforth inspire him, even in his last works. In the Moroccan people he found the noble balance of antiquity that his cultured Frenchman's soul craved, just as he would find it in 1846 in the dignity of Ojibwa (Chippewa) Indians brought to Europe from the United States by the ethnologist-painter George Catlin.

**Building decoration.** Delacroix's first commission for the decoration of a government building came in 1833. This project, a group of murals for the Salon du Roi at the Palais-Bourbon, posed problems of architectural decoration that he was to resolve through the power of colour, taking his inspiration from the Venetians, Rubens, and the work of the Renaissance Italians II Rosso and Francesco Primaticcio at Fontainebleau. He used powerfully organized colour, unifying the elements of the composition down to the last poetic detail. From then on his decorations were on a par with those of the Renaissance geniuses. Notable were his commissions for the museum of history at Versailles: "The Battle of Taillebourg" and "The Taking of Constantinople by the Crusaders." In these works he combined history, myth, philosophy, religion, and human suffering into one grandiose symphony. From 1835 to 1861 he executed many large decorations. At the Palais-Bourbon he painted allegories on the ceiling and in friezes above the doorways of the Salon du Roi; on the ceiling of the library (completed 1847), he painted two hemicycles and 20 pendentives. For the library of the Palais du Luxembourg (completed 1846), he painted the hemicycle, the cupola, and the four pendentives. At the Louvre (completed 1851) he painted the central ceiling of the Galerie d'Apollon. At the Hôtel de Ville (City Hall of Paris, burned in 1871) he painted (beginning 1849) the ceiling, eight panels, and 11 tympana of the Salon de la Paix. For the Chapel of the Holy Angels at the church of Saint-Sulpice, he painted Saint Michael on the ceiling as well as wall frescoes of Jacob and the angel and of Heliodorus (completed 1861).

Large  
decorative  
works

The task of creating these works strained his health. By 1849 he had lost all his closest relatives and friends: his nephew died in New York in 1834; his brother, Gen. Charles Delacroix, in 1845; and Chopin, in 1849. Thereafter, he lived only for the creations of his imagination. On August 13, 1863, he died in Paris in his apartment on the Place Fürstenberg, which was later made into a national museum in his honour.

#### MAJOR WORKS

**PAINTINGS:** "Dante et Virgile aux enfers" ("Dante and Virgil in Hell," 1822; Louvre, Paris); "Scenes des massacres de Scio" ("The Massacre at Chios," 1824; Louvre); "Baron Schwiter" (c. 1826-27; National Gallery, London); "The Execution of the Doge Marino Faliero" (c. 1826-27; Wallace Collection, London); "Combat Between the Giaour and the Pasha" (1827; Art Institute of Chicago); "La Mort de Sardanapale" ("The Death of Sardanapalus," 1827; Louvre); "La Grece expirant sur les ruines de Missolonghi" ("Greece Expiring on the Ruins of Missolonghi," 1827; Musée des Beaux-Arts, Bordeaux); "L'Assassinat de l'évêque de Liège" ("The Assassination of the Bishop of Liège," 1829; Louvre); "La Liberté guidant le peuple (Le 28 juillet 1830)" ("Liberty Leading the People," 1830; Louvre); "Bataille de Poitiers" ("The Battle of Poitiers," 1830; Louvre); "Arab Fantasy" (1833; Städtisches Kunstinstitut, Frankfurt am Main); "The Battle of Nancy" (1831; Musée des Beaux-Arts, Nancy); "Boissy d'Anglas at the Convention" (1831; Musée des

Beaux-Arts, Bordeaux); "Femmes d'Alger dans leur appartement" ("Women of Algiers in Their Apartment," 1834; Louvre); "Portrait de l'artiste" (c. 1837; Louvre); "La Bataille de Taillebourg" ("The Battle of Taillebourg," 1837; Louvre); "Furious Medea" (1838; Musée des Beaux-Arts, Lille); "Portrait de Frédéric Chopin" (1838; Louvre); "Portrait of George Sand" (1838; Øregård-Museum, Copenhagen); "The Return of Columbus" (1839; Toledo [Ohio] Museum of Art); "The Justice of Trajan" (1840; Musée des Beaux-Arts et de la Céramique, Rouen); "Prise de Constantinople par les Croisés, 12 avril 1204" ("The Taking of Constantinople by the Crusaders on April 12, 1204," 1840; Louvre); "Naufrage de Don Juan" ("The Shipwreck of Don Juan," 1841; Louvre); "George Sand's Garden at Nohant" (c. 1842-43; Metropolitan Museum of Art, New York City); "Muley-Abd-er-Rahmann, Sultan of Morocco" (1845; Musée des Augustins, Toulouse); "The Abduction of Rebecca" (1846; Metropolitan Museum of Art, New York City); "The Entombment" (1848; Museum of Fine Arts, Boston); "Alfred Bruyas" (1853; Musée Fabre, Montpellier); "Christ on the Sea of Galilee" (1854; Walters Art Gallery, Baltimore); "Turkish Women Bathing" (1854; Wadsworth Atheneum, Hartford, Connecticut); "View of Tangiers from the Seashore" (1858; Minneapolis [Minnesota] Institute of Art); "A Lion Hunt" (1858; Museum of Fine Arts, Boston); "L'Enlèvement de Rebecca" ("The Abduction of Rebecca," 1858; Louvre); "The Lion Hunt" (1861; Art Institute of Chicago).

**DECORATIONS:** "Orpheus Bringing Civilization"; "Attila Followed by Barbarian Hordes Tramples Italy and the Arts"; "Philosophy," "Natural Sciences," "Legislation," "Theology," and "Poetry" (commissioned in 1833, inaugurated in 1847; ceiling of library of the Chambre des Deputés, Palais-Bourbon, Paris); cupola of the library (commissioned in 1840, inaugurated in December 1846; Palais du Luxembourg, Paris); "Apollo Destroying the Serpent Python" (commissioned in 1850, inaugurated in October 1851; Galerie d'Apollon, Louvre); "The Archangel St. Michael Subduing the Demon," "Heliodorus Driven from the Temple," and "Jacob Wrestling with the Angel" (commissioned in 1849, completed in 1861; Chapel of the Holy Angels, church of Saint-Sulpice, Paris); albums of drawings and water colours from his travels in Morocco (Louvre; Musée Conde, Chantilly).

#### BIBLIOGRAPHY

**Literary works:** As an adolescent, Eugene Delacroix wished to be a poet. His early efforts in the theatre have been edited by JEAN MARCHAND, *Les Dangers de la cour*, new ed. (1960). Many important articles on aesthetics that Delacroix published were collected by his executor, E.A. PIRON, *Eugène Delacroix: sa vie et ses oeuvres* (1865); and later by ELIE FAURE in *E. Delacroix: oeuvres littéraires*, 2 vol. (1923). There are two important editions of the well-known *Journal*, indispensable to a knowledge of the psychology of the painter. The earlier edition, *Journal de Eugène Delacroix*, 3 vol. (1932), is annotated by ANDRÉ JOUBIN, and the reedition of 1960 includes a preface by J.L. VAUDOYER. A selective edition in English by HUBERT WELLINGTON, *The Journal of Eugène Delacroix* (1951), was reprinted in 1980. An important collection of Delacroix's correspondence is ANDRÉ JOUBIN (ed.), *Correspondance générale d'Eugène Delacroix*, 5 vol. (1936-38).

**Critical and biographical works:** Among 19th-century writers and critics who comprehended and analyzed the art of Delacroix, the poet CHARLES BAUDELAIRE was the most perceptive. See *Curiosités esthétiques* (1868) and *L'Art romantique* (1868). The latter includes *L'Oeuvre et la vie d'Eugène Delacroix* (Eng. trans., *Eugène Delacroix, His Life and Work*, 1947, reprinted 1979). The basic and indispensable work for any scientific study of the ensemble of paintings, drawings, engravings, and lithographs was compiled from primary sources by ALFRED ROBAUT and ERNEST CHESNEAU, *L'Oeuvre complet d'Eugène Delacroix* (1885, reprinted 1969), containing numerous sketches, addenda, and an analytical table. The memorial booklet of the Louvre exhibition that commemorated the centennial of Delacroix's death, MAURICE SERULLAZ, *Mémorial de l'exposition Eugène Delacroix* (1963), is an excellent tool for analytic study. Important sources for the history of the works are ETIENNE MOREAU-NELATON, *Delacroix raconté par lui-même*, 2 vol. (1916); RAYMOND ESCHOLIER, *Delacroix peintre, graveur, écrivain*, 3 vol. (1926-29); GEORGE P. MRAS, *Eugène Delacroix's Theory of Art* (1966); and FRANK A. TRAPP, *The Attainment of Delacroix* (1970). The pointillist painter PAUL SIGNAC, *D'Eugène Delacroix au néo-impressionnisme*, 4th ed. (1939, reprinted 1978), demonstrates the importance of Delacroix for modern art. RENE PIOT, a disciple and collaborator of Delacroix in the large decorations, has provided important details on his technique in *Les Palettes de Delacroix* (1931). RAYMOND REGAMEY, *Eugène Delacroix: l'époque de la Chapelle des Sarras-Anges, 1847-1863* (1931), analyzes the

painter's later style. JEAN CASSOU, *Delacroix* (1947), has chosen beautiful photographic details to explain the force of the "fauve" (wild beast) art. MAURICE SERULLAZ, *Les Peintures murales de Delacroix* (1963), is a systematic study of the decorations, from the classical attempts at the Abbaye de Valmont to the Chapel of Saint Sulpice. Two studies by LEE JOHNSON, a British specialist on the master, are *Delacroix* (1963), and (ed.), *The Paintings of Eugène Delacroix: A Critical Catalogue, 1816-1831*, 2 vol. (1981). RENE HUYGHE, *Delacroix* (1963), uses analytical and psychological methods in his critical technique and his *Delacroix and Greece* (Eng. trans. 1971), seeks to determine the manner in which the symbol of the liberation of Greece, through Eugene Delacroix, was of prime importance in the thought and art of the early 19th century.

(R.Hu.)

## Delaware

### Overview of the state

The first of the original 13 U.S. states to ratify the federal Constitution, Delaware occupies a small niche in the Boston-Washington, D.C., urban corridor along the Middle Atlantic Seaboard. With 2,057 square miles (5,328 square kilometres) it is the second smallest state in the nation (after Rhode Island), and with 595,000 people, by the 1980 census, it is one of the most densely populated states. Most of its people live in the north around Wilmington, where its industry is concentrated and where the major coastal highways and railways pass through from Pennsylvania and New Jersey on the north and east into Maryland on the south and west. The rest of the state comprises the northeastern corner of the Delmarva Peninsula, which it shares with Maryland and Virginia.

Historically, geographically, and economically, Delaware has its closest ties with Pennsylvania, particularly Philadelphia, where the Delaware River and other transportation arteries direct its commerce. The state's three counties—New Castle, Kent, and Sussex—had been established by 1680, and, except for periods during the Revolution and the Civil War, its history has been placid. Stability and conservatism became characteristics of Delaware, especially in the southern areas, which until 1964 had maintained a grip on political life vastly out of proportion to their population. As a result, old institutions were tenaciously preserved.

The manufacturing complex in the north makes Delaware one of the most industrialized states, especially notable for chemical research. The state is often depicted as being dominated by corporations, especially by the vast du Pont industrial empire, but the industrial wealth of the Wilmington area was balanced by the political overrepresentation of the agricultural downstate region until the mid-1960s. All factions have united to perpetuate liberal incorporation laws that encourage many U.S. businesses to make Delaware their nominal home state. Delaware ranks among the top 10 states in personal income per capita. (For information on related topics, see the articles UNITED STATES; UNITED STATES, HISTORY OF THE; and NORTH AMERICA.)

### THE HISTORY OF DELAWARE

**The colony.** The Dutch who established the first European settlement in Delaware at Lewes in 1631 were killed by Indians, and it was not until 1638 that a permanent settlement was planted—by Swedes at Ft. Christina, now Wilmington; they reputedly erected America's first log cabins in this colony of New Sweden. The Dutch from New Amsterdam (New York) conquered the Swedes in 1655, and the English seized the colony from the Dutch in 1664. Thereafter, except for a brief Dutch reconquest in 1673, Delaware was administered as part of New York until 1682, when the Duke of York, acting as proprietor, ceded it to William Penn, who wanted it so that his colony of Pennsylvania could have access to the ocean. Though he tried to unite the Delaware counties with Pennsylvania, both sides resented union. In 1704 he allowed Delaware an assembly of its own. Pennsylvania and Delaware shared a royal governor until the Revolution. Only in 1776 did the name Delaware—deriving from Sir Thomas West, 12th baron De La Warr, a governor of Virginia—become official, though it had been applied to

the bay in 1610 and gradually thereafter to the adjoining land.

**Revolution and statehood.** During the Revolution, Delaware was invaded by a British army en route to Philadelphia and was constantly menaced by British ships. The event best remembered, however, is the spectacular ride (July 1-2, 1776) of Caesar Rodney from his home to Philadelphia to break a tie in the Delaware delegation and cast Delaware's vote for independence. The proudest boast of Delaware is that its speedy ratification of the Constitution, on December 7, 1787, gave Delaware its right to be called "the first state."

As national political parties arose, Delaware became a Federalist state, adhering to the party of Alexander Hamilton and John Adams well into the 1820s. In the next period Delaware became as fervently Whig as it had been Federalist.

**Civil War and aftermath.** The advent of the Civil War did not seriously tempt Delaware to secession. Nominally, Delaware had been slave territory since its days as a Dutch colony, but the number of slaves had declined drastically, mainly through voluntary manumissions (grants of freedom), from 8,900 in 1790 to 1,800 in 1860. A more important consideration was Delaware's economic bond with Pennsylvania and the North, strengthened by the river trade and the new railroad network. Though Unionist in sentiment, Delaware never voted for Lincoln, and the Reconstruction that followed the Civil War drove many voters to the Democratic Party in sympathy with the occupied South. By the end of the 19th century, however, economic realities had regained importance, and Delaware became firmly Republican and remained such until well into the Great Depression of the 1930s.

**Economic growth.** Wilmington, meanwhile, had become a manufacturing city so populous that by 1920 it contained almost half of the state's population and at least a similar proportion of its wealth and economic energy. Diversity characterized the products of Wilmington factories, but in the 20th century the city became renowned as an administrative centre for the nation's chemical industry. Primarily, this meant E.I. du Pont de Nemours & Company and two other powder makers, Hercules Inc. and Atlas Chemical Industries, Inc., all of which transferred their major energies to basic chemicals after World War I.

### THE NATURAL AND HUMAN LANDSCAPE

With the exception of Florida, Delaware, located mainly within the Atlantic Coastal Plain, is the lowest lying state in the nation. A long sand beach forms the state's ocean front, stretching from the Maryland line, at Fenwick Island, to Cape Henlopen, at the mouth of Delaware Bay. Only one major break, Indian River Inlet, occurs along the 23-mile (37-kilometre) length of that beach. Much of the beach is a low bar between the ocean and a series of lagoons or shallow bays; but at Bethany Beach, near the southern boundary, and again at Rehoboth, near the northern end of the beach, the mainland reaches directly to the ocean.

The shoreline of Delaware Bay is often marshy. The mouths of tributary streams like the Murderkill, the Mispillion, and the St. Jones are so shallow that no good harbours exist except at Lewes, just inside Cape Henlopen, where an artificial harbour protects shipping from Atlantic storms. Farther north, on the banks of the Delaware River, spots of high, dry land appear, as at Port Penn, New Castle, and Edge Moor; but the state's main port, Wilmington, lies on the Christina River, a tributary of the Delaware.

Most of Delaware is drained by streams that run eastward to the Delaware River, Delaware Bay, and the Atlantic Ocean, but the Nanticoke River and its tributaries in southwestern Delaware flow into Chesapeake Bay. So does the Pocomoke River, which drains the Cypress Swamp, or so-called Burnt Swamp, in the extreme south of Delaware athwart the Maryland line.

Most of the coastal plain terrain is fertile and level, seldom more than 60 feet (18 metres) above sea level, but it becomes increasingly sandy to the south. Abundant wood-

19th-century political sentiments

Geographical regions and drainage

lands, streams, and freshwater ponds interrupt the monotony of the landscape. Occasionally, as at Odessa, villages appear suddenly at the side of the road, with no more warning than the sight of a church steeple.

Near its northern edge the plain is intersected by a great deep ditch, the Chesapeake and Delaware Canal, which has been deepened and straightened for ocean shipping. It shortens the water route between Philadelphia and Baltimore by several hundred miles and also brings Baltimore closer to the ocean than via Chesapeake Bay. The canal is popularly considered to be the boundary between agricultural downstate Delaware and the northern industrial region. Though the land on either side of it is strikingly similar, many Delawareans are convinced that even the weather changes at the canal.

Several high bridges over the canal, as well as the giant twin bridges crossing the Delaware River north of New Castle and the refinery stacks at Delaware City, serve as the major landmarks on the horizon below the hillier northwest corner of the state. There, north and west of a 14-mile line between Wilmington and Newark, lie the rolling hills of a section of the Piedmont extending south from Pennsylvania. The significance of this area belies its size—less than one-fifteenth of the state's total area—for within it and at its edge dwells most of Delaware's population. The highest point in the state, Elbright Road in New Castle County, is only 442 feet above sea level. Probably the most peculiar features are Iron and Chestnut hills, which protrude into the plain southwest of Newark and are scarred by open pits where iron ore once was mined.

The centre of Wilmington lies on hills sloping downward toward the intersection of the Christina and its major tributary, the Brandywine. Here, navigable water brought shipping close to falls that provided power for manufacturing. The railroads and highways, which followed this fall line along the East Coast, have kept Wilmington on major transportation routes between Philadelphia and Baltimore and have promoted the tendency for the urbanization of open land between Wilmington and other cities.

The climate of Delaware is like that of the rest of the Middle Atlantic area. August, which has the second hottest temperatures after July, is also the rainiest month, with an average precipitation of about 5½ inches (140 millimetres), whereas February has the least precipitation, an average of almost three inches. The yearly average precipitation is nearly 45 inches.

#### THE PEOPLE OF DELAWARE

Patterns of immigration. As is characteristic of the Middle Atlantic states, the colonial population of Delaware was quite varied. Swedes (and the Finns who came with them), Netherlands, and African slaves had settled in Delaware before the English, mainly in present-day New Castle County in the north. The English settlers came not only from overseas but also from Pennsylvania and Maryland. Some of the settlers from Pennsylvania were Quaker artisans and merchants; the settlers from Maryland were often planters who brought slaves with them. With the English came some Welsh settlers and, after 1715, large numbers of Irish, particularly the Presbyterians of Scottish descent known as Scots-Irish. Downstate Delaware was mainly settled by the English and by slaves.

After the Revolution a small group of French came to New Castle and Wilmington from the West Indies, and a few, including the progenitors of the du Pont family, came from France. In the mid-19th century there was a large immigration of Roman Catholic Irish and Germans, and at the end of the century Italians, Poles, and Jews came in large numbers, accompanied by smaller groups of Ukrainians, Russians, Scandinavians, and Greeks. These newcomers settled mainly in Wilmington.

Demography. Though federal laws reduced the flow of immigrants after World War I, Delaware experienced its largest population growth in the middle of the 20th century. From 1950 to 1960 its population grew by about 40 percent, making Delaware the ninth state in density of population. The 23 percent growth during the 1960s was

a rate exceeded by only seven other states, but the growth rate slowed in the 1970s.

Many of the newcomers were highly skilled scientists or technicians. Wilmington also received a large influx of blacks, many of them unskilled. In 1950, 15 percent of Wilmington's population was black; by 1960 blacks represented 26 percent, by 1970, 44 percent, and by 1980, 51 percent. This growth rate did not match the exodus of whites to the suburbs from 1950 to 1970, when the population of Wilmington proper declined from 110,000 to 80,000. By 1980 the population had declined further to 70,000.

The suburbs of Wilmington, largely unincorporated, received not only the people fleeing Wilmington but also most of the white newcomers to Delaware after 1945. By 1980 more than half of the state's population lived outside the city of Wilmington but within 15 miles of it. This suburban band includes the second largest city, Newark, which nearly doubled in size during the 1960s to 21,000 people, partly because of the extension of its boundaries. Thus, suburbia has become the seat of Delaware's population, political power, and wealth. By 1980 suburban areas generally were populated by whites but with a few black enclaves. The descendants of the later immigrant groups have left the city as hastily as have the Anglo-Saxon Protestants.

All parts of Delaware, except Wilmington itself, have shared in the state's growth to some degree. The capital, Dover, third city in size, grew from 7,000 people in 1960 to 17,000 in 1970, aided by some extension of its boundaries and by employment offered by new industries and the Dover Air Force Base. By 1980 Dover's population had grown further to 23,000.

Interesting ethnic groups in rural Delaware include Polish potato growers in Kent, who came from Long Island; Italian mushroom growers at Hockessin; a colony of Finns that originated at Iron Hill after World War I; an Amish settlement near Dover; and the historic groups of mixed-bloods, called Moors and Nanticokes, at Cheswold, in Kent County, and beside Indian River Bay, in Sussex County.

#### THE STATE'S ECONOMY

Delaware's prosperity depends upon its favourable location: four of the 10 largest cities in the United States lie within 150 miles.

Goods produced. Though the number of farmers has continued to decline, agriculture remains important. In 1978 Delaware ranked fourth in net income per farm. More than half of the farmers' cash income comes from poultry raising, centred in Sussex County. Soybeans are of continuing importance, and other major agricultural products include corn, milk, and vegetables. The coastal and inland waters produce fish, clams, and crabs. The only mining is of gravel and sand.

The major economic enterprise in Delaware is manufacturing, especially the chemical industry. Wilmington boasts of being the chemical capital of the world because it is the centre of administration and research of several chemical companies; du Pont, Hercules, and ICI Americas (formerly Atlas) are the largest. Chief chemical products are pigments, nylon, and petrochemicals. Delaware also has automobile-assembly plants, an oil refinery, a synthetic rubber plant, packaging plants, textile mills, and various food-processing plants.

Taxation. In the public sector, because of Delaware's small size, many things are done by the state that elsewhere would be left to local government. Consequently, state taxes and indebtedness are relatively high, whereas local equivalents are low. The largest source of state income is the tax on personal and corporate incomes. There is a state inheritance tax, which frequently produces a windfall when a very wealthy citizen dies.

The second most important source of state revenue is the corporation franchise tax. Delaware has made a business of incorporating companies, many of which operate primarily in other states, since early in the 20th century. It offers them favourable laws that are kept up to date to reflect changing business conditions, a convenient location,

Process of  
suburbanization

Agriculture and  
manufacturing

very moderate taxation, stable institutions, and a judicial system with experience in corporate litigation.

There is no general sales tax in Delaware and no state property tax. Real estate taxes are, however, the chief support of county and municipal governments. Though the schools are supported chiefly by the state, school districts must raise part of the money for new buildings by property and other taxes, after approval by a referendum. They may also, again with voter approval, raise money to supplement the state appropriation for school operations, including salaries.

**Transportation.** The chief flow of highway traffic in Delaware is between Wilmington and its suburbs and the interstate traffic crossing northern Delaware between New York or Philadelphia and Baltimore or Washington. Slightly less important is the traffic up and down the state on the du Pont Highway. The state maintains all roads and bridges as well as through streets in municipalities. A joint Delaware-New Jersey agency operates both the twin bridges across the Delaware River near New Castle and a ferry between Lewes and Cape May.

Delaware lies on the railroad passenger line between Philadelphia and Baltimore. Freight service is also available to the southern state line and in northern Delaware. Local bus transportation in the Wilmington area is provided by a public authority. Wilmington has a marine terminal and an airport.

#### ADMINISTRATION AND SOCIAL CONDITIONS

**Structure of government.** The constitution of Delaware was adopted in 1897 but has been amended many times. **Amendments** require a two-thirds vote in two successive legislatures, with an election intervening. The governor, who has no veto on amendments, serves a four-year term and may be reelected only once. Traditionally, the legislature has been strong and the governor relatively weak, but adoption of the cabinet form of government in 1970 centralized and strengthened executive authority. The bicameral legislature is known as the General Assembly.

An unusual feature of Delaware's judicial system is the retention of the Court of Chancery, which handles equity cases involving civil rights and litigation concerning Delaware corporations. Most other states have merged their chancery into their law courts. The highest court is the Supreme Court, which hears appeals from the Chancery Court and the Superior Court. At the lowest level in the state judiciary are the magistrate courts, presided over by justices of the peace, who seldom are lawyers. All Delaware judges are appointed by the governor.

Weak county governments have traditionally been the rule in Delaware. Each was headed by an elected levy court that set the tax rate and appropriated funds. The levy courts of New Castle and **Sussex**, however, have been replaced by stronger elected councils, and New Castle also elects a county executive who appoints the chief administrative officers. Unique to Delaware is the county subdivision known as a hundred, an ancient English governmental unit that has survived nowhere else in the United States. It no longer has a governmental function and is retained purely as a geographical name.

**Politics.** Democrats and Republicans have been fairly evenly matched in Delaware, although the Democrats have the larger number of registered voters. Many voters decline to list party preference, and numerous swing votes may go to either side. Primaries had little significance until 1978, when they were first used for all offices.

After the Civil War, Delaware Democrats used their control of such offices as assessor and tax collector to discourage blacks from qualifying as voters, but Republicans actively sought the black vote and, with its aid, won control of the state early in the 20th century. In 1932 the Democrats abandoned their all-white tradition. At first they won black votes only for the national ticket, but gradually, during the next two decades, Delaware's blacks, like those in other Northern states, realigned themselves with the Democratic Party. Thereafter, only an exceptionally popular Republican was able to win black support. Bipartisan black support was largely responsible for passage of a fair-housing law.

**The social milieu.** Delaware maintained racial segregation by both custom and law until the 1950s, when court decisions began to strike down old laws separating the races, as well as acts of discrimination in housing and public accommodations. Integration was accomplished fairly smoothly in many schools, including the University of Delaware and Delaware State College, the latter integrating whites into a formerly all-black student body. In 1977 the 3rd Circuit Court of Appeals ordered the 11 New Castle school districts consolidated into one in order to implement desegregation plans. Federal programs to assist the poor home buyer helped blacks move into vacated housing; some of these blacks earlier had been dispossessed by urban-renewal projects. Even with such programs and the end of legal discrimination, social pressure and economic realities have served to maintain some degree of segregation in education and housing. In Wilmington school integration and fair-housing laws have had the effect of accelerating the number of whites leaving the city.

The state, meanwhile, has been called upon to provide an increasing number of services for its citizens. The demands for expenditures, especially in education and welfare, have been brought on partly by population growth and immigration of young families with children, and partly by recognition of long-ignored needs. Kindergartens, schools for the handicapped, and mental-health clinics have been established. Delaware ranked in the upper half of the states in per capita expenditures for public welfare.

The University of Delaware grew from 1,500 students in 1952 to more than 12,000 in 1971 and to more than 19,200 in 1980. Because the small population would make the establishment of a medical school a heavy expense, the state has arrangements with Jefferson Medical College of Philadelphia to save places in each class for Delaware students. Similar arrangements are made for veterinary students and in fields like law and dentistry in which no training is offered in Delaware's public institutions. In 1979 the state ranked seventh in per capita expenditures for education, partly because the state government, not smaller units, assumed the major responsibility.

#### CULTURAL LIFE AND INSTITUTIONS

**Museums and libraries.** Two major museums are located in the outskirts of Wilmington. The Henry Francis du Pont Winterthur Museum is noted for its collection of American decorative arts, which are displayed in authentic period rooms. The **Hagley** Museum portrays the development of American manufacturing through preservations of the early mills and other structures of the du Pont company, as well as by indoor exhibits. Other interesting museums include the Delaware Museum of Natural History, Greenville; the Delaware State Museum, Dover; and the Old Town Hall, Wilmington.

A number of historic houses in the state are permanently open to the public, including the John Dickinson Mansion, near Dover; the Parson Thorne Mansion, in Milford; and several houses in Odessa and New Castle. Several blocks in New Castle surrounding the colonial capitol, known as the Old Court House, remind visitors of the restorations of colonial Williamsburg in **Virginia**—except that in New Castle very few buildings had to be restored. Immanuel Episcopal Church, on the Green, was begun in 1703; its graveyard contains numerous interesting stones. The Presbyterian Church nearby dates from 1707. No buildings survive from the Dutch period. Old Swedes Church and Hendrickson House in Wilmington were built in 1698 for a Swedish Lutheran congregation, but it is now Episcopalian. The Swedes brought a tradition of log construction to the New World, but none of their work remains except, perhaps, portions of a few small log structures.

The state's foremost research library is that of the University of Delaware. The Wilmington Institute Free Library is the largest unit in the consolidated New Castle County library system. The Delaware State Library Commission serves the lower counties; and most towns also support a library of their own. Among the specialized

Social services and special schools

Historic buildings, houses, and colonial capitol

The black voter

libraries, the Eleutherian Mills Historical Library, featuring business and industrial history, and the library division of the Winterthur Museum, specializing in the decorative arts and crafts, are internationally known.

The arts and communications. Wilmington long has been the centre of a distinguished group of illustrators, many of them pupils, either directly or indirectly, of Howard Pyle, whose work is displayed at the Delaware Art Museum. N.C. Wyeth, a pupil of Pyle, made his home just across the Pennsylvania line at Chadds Ford, which members of his family have made famous as the home of the Brandywine school, a group of mainly genre and narrative painters.

Wilmington has one legitimate theatre, the Playhouse, as well as the Grand Opera House, restored as a state centre for the performing arts. The small village of Arden is remarkable for its theatrical traditions, both amateur and professional, which include annual productions of Gilbert and Sullivan operettas and, until recently, of Shakespeare by the townspeople.

The News-Journal papers of Wilmington, published mornings, evenings, and Sundays, are controlled by the Christina Securities Company, a du Pont family holding company. They became part of the Gannett chain in 1978. Dover also has a daily newspaper. There are many radio stations but only one television station, an educational outlet that has studios both in Wilmington and Philadelphia. Most Delawareans tune in Philadelphia television stations, a continuation of the historic Delaware pattern of looking toward Philadelphia.

Recreation. Delaware's ocean beaches are popular not only with Delawareans but also with people from neighbouring areas, especially Washington, D.C. Rehoboth and Indian River bays are boating, fishing, and clamming centres. State parks, such as Lum's Pond, are also used for recreation. The week-long Delaware State Fair is held annually in Harrington. Pari-mutuel betting lures crowds to racetracks in Stanton, Dover, and Brandywine Hundred.

#### PROSPECTS

The 1897 constitution of Delaware overtly discriminated against Wilmington in the allocation of representatives and senators in the General Assembly. At the time, the city had almost half of the state's population, but it received only two of the 17 senators and five of the 35 representatives. Since only the legislature could change the constitution, the shackles on Wilmington—on its wealthy manufacturers and merchants as well as on its immigrant labourers—seemed to be fastened forever. By 1964, when the U.S. Supreme Court declared against such practices, such populous upper middle-class suburbs as Brandywine Hundred, with 58,000 people, and Christiana Hundred, with 48,000, had no more representation than rural Blackbird Hundred with 1,600, or Appoquinimink Hundred with 2,500. The resultant reapportionment hardly profited Wilmington, with its falling population. The suburbs, however, came into their own. A majority of the seats in each chamber went to New Castle County outside Wilmington.

This sudden acquisition of political power by suburban Delaware, in addition to the state's steady growth in population and the changing character of Wilmington, are important factors in Delaware's future. The suburban representatives speak for new constituencies in the state, replacing in large measure the representatives of the long-established rural citizenry who tended to seek preservation of traditional ways, and for white-collar rather than blue-collar attitudes. Seats in the party nominating conventions were also reapportioned, and the first changes following this move were the election of a research chemist as governor and a corporation lawyer as a U.S. senator.

A progressive spirit prevails in the state government. The problem of budget deficits, which created a critical financial situation, was corrected in 1977 by restraints on spending rather than adoption of a sales tax. There also has been renewed interest in the environment, demonstrated by the various restrictions on waterfront industry and efforts to protect the beaches.

## Delhi

Delhi is the third largest city of India, surpassed in size only by Calcutta and Bombay. New Delhi, the capital of the Indian union, lies to the south of Delhi (popularly known as Old Delhi). The city is situated in north central India and stands on the west (right) bank of the Yamuna River, a tributary of the Ganges. It is located within the union territory of Delhi, which covers an area of 573 square miles (1,485 square kilometres). The union territory is bounded on the east by the state of Uttar Pradesh and on the north, west, and south by Haryana. In 1981 the union territory had a total population of more than 6,196,000, of which Old Delhi's population amounted to about 5,351,000 and New Delhi's population about 272,000. It is generally presumed that the city was named after Raja Dhilu, a king of the Mauryan dynasty who reigned in the 1st century BC, and that the various names by which it has been known (Delhi, Dehli, Dillī, and Dhili) are corruptions of this name. Delhi is a focal point in India's transportation network. It stands about 100 miles (160 kilometres) to the south of the Himalayan mountain ranges.

Delhi has been the capital city of a succession of mighty empires or powerful kingdoms; ruins mark the sites of the various cities, both ancient and medieval. According to popular tradition, the city has changed its locality seven times, although some authorities, who take smaller towns and strongholds into account, claim it has changed its site 15 times. All these locations are confined to a triangular area of about 70 square miles called the Delhi triangle. Two sides of this triangle are represented by the rocky hills of the Arāvalli Range in the west and south and the third by the shifting channel of the Yamuna. The present site of Delhi is bounded to the west by a northern extension of the Arāvalli Range known as the Delhi Ridge.

The Delhi triangle

#### HISTORY

The earliest reference to a settlement at Delhi is to be found in the famous epic *Mahābhārata* (a narrative about the descendants of the prince Bharata), which mentions a city called Indraprastha, built about 1400 BC somewhere between the sites where the historic Purāna Qal'ah (Old Fort) and Humāyūn's tomb were later to be located. The first reference to the place-name Delhi seems to have been made in the 1st century BC, when Raja Dhilu built a city near the Quṭb Minār (Quṭb Tower) site and named it for himself. Thereafter Delhi faced many vicissitudes and did not reemerge into prominence until the 12th century AD, when it became the capital of the Cāhamāna ruler Prṭhvīrāja. After the defeat of Prṭhvīrāja the city passed into Muslim hands. Quṭb-ud-Dīn Aybak, founder of the Mu'izzī (Slave) dynasty and builder of the famous tower Quṭb Minār (completed in the early 13th century), also chose Delhi as his capital.

'Alā'-ud-Dīn Khalji (1296–1316) built the second city of Delhi at Siri, three miles northeast of the present Delhi. The third city of Delhi was built by Ghiyās-ud-Dīn Tughluq (1320–25) at Tughlakābād but had to be abandoned in favour of the old site near the Qutb Minār because of scarcity of water. Muhammad ibn Tughluq (1325–51) extended the city farther northeast and built new fortifications around it. It then became the fourth city of Delhi, under the name Jahānpanāh. These new settlements were located between the old cities near the Qutb Minār and Siri Fort. Muhammad ibn Tughluq's successor, Firiiz Shāh Tughluq (1351–88), however, abandoned this site altogether and in 1354 moved his capital farther north near the ancient site of Indraprastha and founded the fifth city of Delhi, Firūzābād, which was situated in what is now the Kotla Firiiz Shāh area.

Invasion  
of Timur

After the invasion of Delhi by Timur (Tamerlane) in the latter half of the 14th century, the last of the sultan kings moved the capital to Agra, so that Delhi experienced a temporary diminution in its importance. Bābur, the first Mughal ruler, re-established Delhi as the seat of his empire in 1526. His son Humāyūn built a new city, Din Panāh, on the site between Kotla Firiiz ShPh and the Puriina Qal'ah. Shēr ShPh, who drove Humāyūn from the country in 1540, razed Din Panāh to the ground and built his new capital, the Shēr Shāhi (Puriina Qal'ah), as the sixth city of Delhi.

Delhi later again lost importance when the Mughal emperors Akbar (1556–1605) and Jahāngīr (1605–27) moved their headquarters to Fatehpur Sikri and Agra in the late 16th and early 17th centuries, but the city was restored to its former glory and prestige in 1638, when Shāh Jahān, Akbar's grandson, laid the foundations of the seventh city of Delhi, Shāhjahānābād, which is presently known as Old Delhi. The greater part of the city is still confined within the space of ShPh Jahān's walls, and several gates built by him—the Kashmir Gate, the Delhi Gate, the Turkmen Gate, and the Ajmer Gate—still stand.

With the fall of the Mughal Empire during the mid-18th century, Delhi again faced many vicissitudes—raids by the Marāthās (a people of peninsular India), the invasion by Nāder Shīh of Persia, and a brief spell of Marāthā rule—before the arrival of the British in 1803. Under British rule the city flourished, except during the Indian Mutiny in 1857, when the mutineers seized the city for several months, after which British power was restored, and Mughal rule ended. In 1912 the British moved the capital of British India from Calcutta to the new city of New Delhi, then adjacent to Delhi and now a part of it.

#### THE LANDSCAPE

**Elevation and area.** The union territory of Delhi lies at an altitude of between 700 and 1,000 feet above sea level. Out of its total area of 573 square miles (the union territory of Delhi), Old Delhi occupies 93 square miles, Delhi Cantonment 17 square miles, and New Delhi 16 square miles.

**Climate and environment.** The climate of Delhi is characterized by extreme dryness, with intensely hot summers and cold winters. It is associated with a general prevalence of continental air, which moves in from the west or northwest, except during the season of the monsoon (rain-bearing wind), when an easterly to southeasterly influx of oceanic air brings increased humidity. The summer season lasts from mid-March to the end of June, with average maximum and minimum temperatures of 97° F (36° C) and 77° F (25° C); it is characterized by frequent thunderstorms and squalls, which are most frequent in April and May. The monsoon season, following the hot summer, continues until the end of September, with an average rainfall of about 25 inches. The post-monsoon period of October and November constitutes a transition period from monsoon to winter conditions. The winter season extends from the last week of November to mid-February; average maximum and minimum temperatures are 70° F (21° C) and 52° F (11° C), respectively. The air in Delhi is dry for most of the year, with very low relative humidity from April to June and mark-

edly higher humidity in July and August, when weather conditions are oppressive. The mean daily temperature is highest in May, and the monthly mean temperature is highest in June, when the night temperature is also at its maximum. The mean daily temperature may rise as high as 110° F (43° C). The coldest month is January, when both the mean maximum temperature and the mean minimum temperature are at their lowest—70° F (21° C) and 45° F (7° C), respectively.

Air and water pollution do not cause serious problems, although sometimes a temperature inversion (which often occurs when a warm air mass remains over a land surface that cools during the night) forms in the winter months, which traps pollutants (coal dust and soot) and increases contamination considerably. In the past, the danger of water pollution caused by drainage water mixing with the city's water supply in summer months was a serious problem. Since 1960, steps have been taken, however, to prevent this situation.

**Vegetation and wildlife.** The natural plant cover in the Delhi area varies according to the physical features with which it is associated. The ridges and hillsides abound in thorny trees, such as acacias. During the monsoon season, herbaceous species grow in profusion. The shisham, or sissoo, tree, which yields a dark-brown and durable timber, is commonly met with in the Bangar (Plain) area of the union territory. Riverine vegetation, consisting of weeds and grass, occurs on the banks of the Yamuna. New Delhi is famous for its avenues of flowering shade trees, such as the neem (a drought-resistant tree with a pale-yellow fruit), jaman (a tree with an edible grapelike fruit), mango, pipal (a fig tree), and shisham. It is also famous for numerous flowering plants, which provide a splash of colour during the winter. These include a large number of multicoloured seasonals: chrysanthemums, phlox, violas, and verbenas. The transition from winter to spring is very gradual, and only the flowers can testify to changing conditions, with chrysanthemums in December yielding place to roses in February.

The  
avenues of  
shade trees

The animal life of the union territory, like its plant life, is quite diverse. Among carnivorous animals are leopards, hyenas, foxes, wolves, and jackals, which inhabit the jungles, low forests, and hilly ridges. In some places along the bank of the Yamuna, wild boars are found. Monkeys are not uncommon. Bird life includes partridge (gray and black), rock pigeons (black and blue), parrots, and bush quail. Peafowl are numerous on the hilly ridges. The Yamuna abounds in fish, and an occasional crocodile may be found.

**The city plan.** The city plan of Delhi is a mixture of contrasting old and new road and circulation patterns. The contrast between the convoluted form of the old city and the diagonal features of the modern traffic arteries in New Delhi is particularly striking.

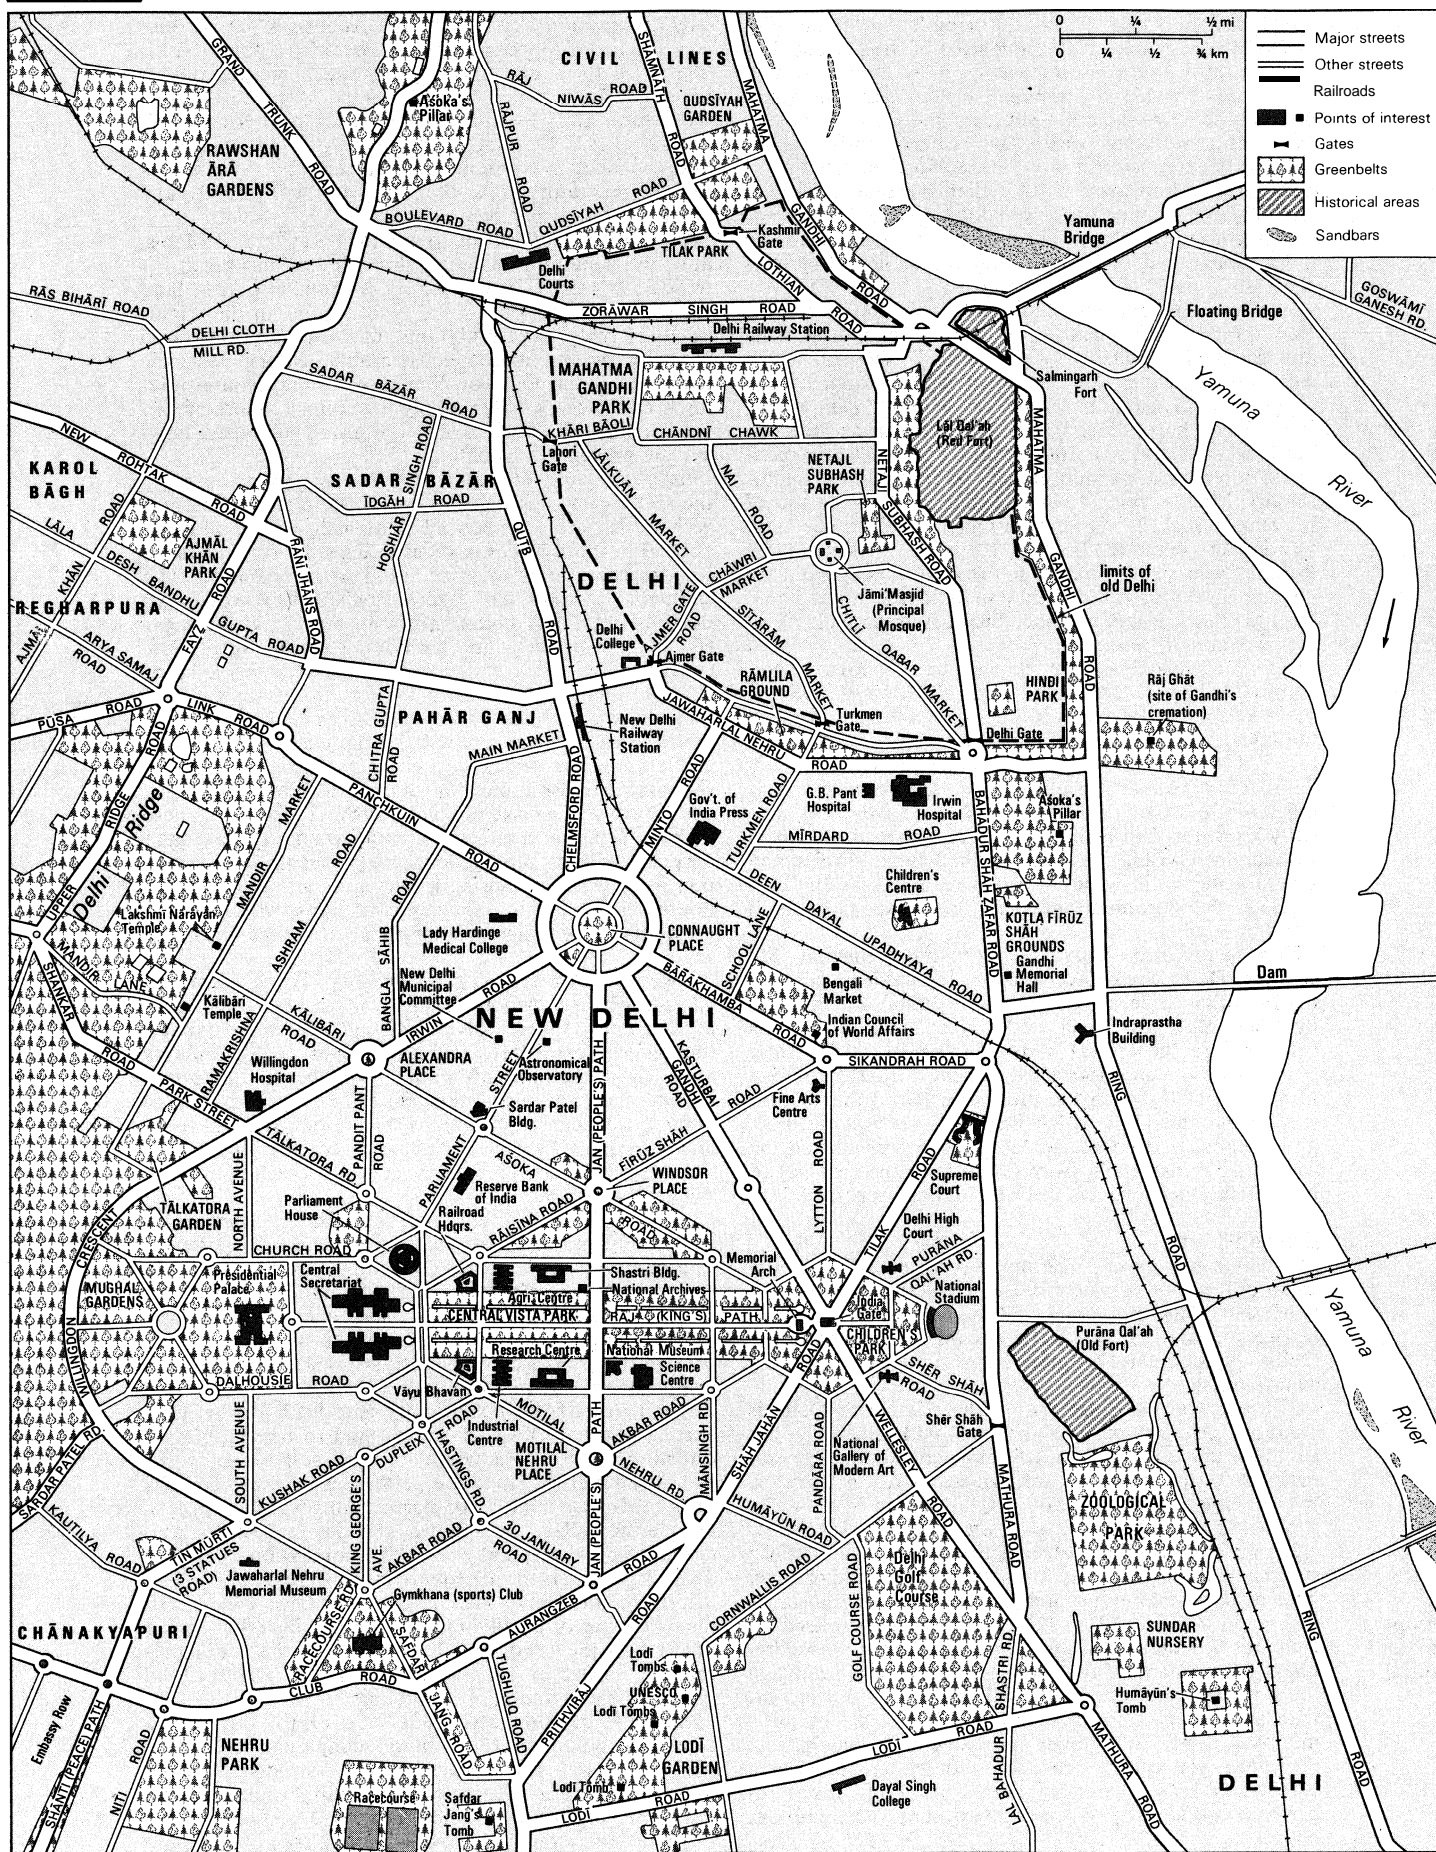

The street pattern of Old Delhi reflects some of the older requirements of defense, with a few transverse streets leading from one major gate to another. Occasionally a through street from a subsidiary gate leads to the main axes. The other Old City streets tend to be irregular in direction, length, and width and are suitable only for pedestrian traffic. Thus, the pattern as a whole consists of a confusing mixture of narrow and winding streets, culs-de-sac, alleys, and byways giving access to residences and commercial areas. The population density—about 35,000 persons per square mile—is high.

In sharp contrast to the Old City, the Civil Lines (residential areas originally built by the British for senior officers) in the north and New Delhi in the south present an aspect of relative openness, characterized by green grass and trees, order, and quiet.

When the decision was made in 1911 to transfer the capital of India from Calcutta to Delhi, and a town planning committee was formed, a site was chosen three miles south of the existing city of Delhi, around Rāisīna Hill. This was a well-drained, healthy area between the ridge and the river that provided ample room for expansion. The Rāisīna Hill, commanding a view of the entire area, stood 50 feet above the plain, but the top 20 feet

Copyright 1969

were blasted off to make a level plateau for the major government buildings and to fill in depressions. With this low acropolis as the focus, the plan was laid out.

The New Delhi plan was characterized by wide avenues with trees in double rows on either side, creating vistas and connecting various points of interest. Almost every major road has a specific focal point closing the vista so that no avenue is lost in the horizon. Besides the diagonal road pattern, the most prominent feature of the entire plan is the Central Vista Park, starting from the National Stadium in the east, continuing through the memorial arch and the Central Secretariat, and culminating in the west at Rishtrapati Bhavan (the Presidential Palace). This is the main east-west axis; it divides the New City into two parts, with the fashionable shopping centre, Connaught Place, in the north and extensive residential colonies in the south.

**Land use.** The pattern of land use in Delhi has been changing with the implementation of the Delhi Town Planning organization's master plan. Broadly, the public and semipublic land use is confined to the Central Secretariat area of New Delhi and to the Old Secretariat area in the Civil Lines, with subsidiary centres developing in the Indraprastha Estate (an office complex) in the east and in Ramakrishnapuram (an office-cum-residence district) in the south. A large number of small manufacturing establishments have entrenched themselves in almost every part of the Old City, but the main industrial areas are concentrated along the Najafgarh Road, in the west, and on Kalkaji Road, in the south, where a large planned industrial estate (Okhla) has been established. Areas for commercial land use are confined to Chāndnī Chawk (Silver Street) and Khārī Bāoli (both in the north), the Sadar Bāzār of Old Delhi, the Ajmāl Khān Road of Karol Bāgh in west Delhi, and the Connaught Place area of New Delhi. A number of district and local shopping centres have also developed in other localities. The University of Delhi is located in the north, where a number of educational institutions for college education and for higher studies are located. Another educational complex is growing in south Delhi (see below Recreation).

**Traditional city neighbourhoods and regions.** In a city such as Delhi, which bears the impress of history, there is a clear distinction between areas where indigenous influences are uppermost and areas characterized by colonial and postindependence influences. Although the social structure of Delhi has changed from coherence to a heterogeneity that is in keeping with its position as the national capital, certain residential neighbourhoods in the Old City, in the Civil Lines, in government housing areas, and in recent-growth areas have acquired a specific character of their own. In the Old City, there is a strong *mohalla* ("neighbourhood") feeling, partly induced by its peculiar housing layout. Here gates or doorways open onto private residences and courtyards or onto *katras* (one-roomed tenements facing onto a courtyard or other enclosure and having access to the street by only one opening or gate). The Civil Lines area consists of upper-income-group residences. The government housing areas also exhibit segregation by income groups. In some recent growth areas, "mixed neighbourhoods" have been created. Chiinakyapuri, with its concentration of foreign embassies, represents a microcosm of international architecture. Cultural "islands" are formed in such areas as the Bengali Market area or Karol Bāgh; Karol Bāgh, for example, is characterized partly by Bengali and partly by South Indian culture, although cultural distinctiveness is being eroded as other city residents move in. The Regharpura area, inhabited by *Camārs* (persons engaged in shoemaking and leather tanning), offers an interesting spectacle of an Indian ghetto. Similarly, the Kotla Mubārakpūr area is an example of a village enclave in the urban matrix: houses and streets retain their rural characteristics, though residents have urban employment.

#### THE CONTEMPORARY CITY

**Transportation.** The geographical position of Delhi on the great plain of India, where the Deccan tableland and the Thar Desert (*q.v.*) approach the Himalayas, pro-

ducing a narrow corridor, ensures that all land routes from northwestern India to the eastern plain must pass through it, thus making it a pivotal centre in the subcontinent's network of transportation. Five national highways—connecting with Amritsar to the north, Agra to the south, Jaipur to the southwest, Rohtak to the west, and Lucknow and Calcutta to the east—converge on Delhi. Four broad-gauge railway lines and one metre-gauge line also meet there, linking the city with all parts of the country. It is also the most important air terminal in northern India for both domestic and international air services, having two airports, at Palam and Safdar Jang. Palam airport is one of the hubs of the international airway system and is located far away from the main city. Safdar Jang was originally on the southern fringe of the city but is now in the midst of the built-up area. It is used mainly by the Delhi Flying Club.

The traffic-circulation pattern within a city that was designed for a smaller population now poses serious problems. Slow-moving bullock carts and bicycles, together with motorcars and trucks, create traffic snarls that are aggravated by peak-hour conditions. Mass-transportation facilities are inadequate. Proposals have been made for a comprehensive traffic-development program, including the construction of a ring railway.

**Demography.** Delhi's population of 240,000 in 1911 had increased nearly tenfold, to 2,350,000, by 1961. Between 1911 and 1941 its growth was comparatively slow, but between 1941 and 1951 the population doubled, due mainly to the immigration of a large number of refugees into the city at the time of independence. Between 1961 and 1971, a growth rate was maintained that was substantially higher than those of the other metropolitan cities in the country. The population of the union territory in 1971 was 4,044,000, including about 3,630,000 living in the urban area.

The average gross density of population of the city, which was 35,000 persons per square mile in 1971, does not suggest overcrowded conditions. But there were marked intra-urban differences, with the Old City Sadar-Pahār Ganj area having a gross density of well over 100,000 persons per square mile in 1971, while New Delhi and the Cantonment Area have densities of only 18,000 and 3,300 persons per square mile, respectively.

The population structure of Delhi in 1971 revealed a sex ratio of 798 females to 1,000 males. The younger age groups (less than 18 years old) constituted nearly half of the population in 1961 (49%); adult males and females constituted 29% and 18%, respectively in the same year; while the older age group constituted only 4%. Of the total population, 53% were unmarried. The literacy rate in 1971 was 59%. The working force constituted 30% of the population.

The composition of Delhi's population reflected its truly cosmopolitan character, with 56% of its inhabitants in 1961 coming from outside the territory. Of these, 36% were immigrants from other Indian states, 19% were immigrants from adjacent countries, and only 0.02% consisted of resident foreigners. The religious composition of the population was also varied. In 1961 it included Hindus (84%), Sikhs (about 8%), Muslims (almost 6%), Jains (1%), Christians (1%), and Buddhists (0.2%).

**Housing.** The housing situation in Delhi deteriorated after 1947 as a result of the influx of refugees and the city's emergence as the national capital of India. Building activity was insufficient to close the gap or to keep pace with the increasing population. This compelled nearly a third of the city's population to seek shelter in congested areas and in unauthorized dwellings or to settle as squatters in slums. The Delhi master plan estimated the housing shortage in 1961 at 150,000 units, a figure that later greatly increased, the shortage being most acute for low-income groups.

The houses in Old Delhi are unplanned, consisting of old structures of two, three, or more stories with a high proportion of single-room dwelling units. In the Civil Lines area, there are a number of old one-story bungalow-type houses. In New Delhi the government housing colonies have been laid out in a lavish manner and are

The  
Central  
Vista Park

The  
refugee  
immigra-  
tion

grouped on an income basis. The earlier constructions consisted of one-story houses, but later multistoried structures were built.

The implementation of the housing program is in the hands of various agencies, such as the union government, the Municipal Corporation of Delhi, the New Delhi Municipal Committee, and the Delhi administration, and various individuals and cooperatives.

monu-  
ments

**Building types and architectural features of note.** There is perhaps no city in India that can compare with Delhi in the number of its monuments. These edifices illustrate the types of Indian architecture from the time of the imperial Gupta dynasty 1,600 years ago to the style of such architects as Sir Edwin Lutyens and Sir Herbert Baker, which was in evidence in New Delhi during the period of British rule. Delhi is particularly rich in material for the study of Indo-Muslim architecture. The monuments of the early Pathan style (1193–1320)—represented by the Qūwat-ul-Islām mosque, the Qutb Mīnār, the tomb of Iltutmish, and the 'Alā'i Darwāzah ("gate")—reveal the adoption and adaptation of Hindu materials and style to Saracenic motifs and requirements. The later Pathan styles represented in Tughlakābād and tombs of the Sayyid Kings (1414–51) and Lodī kings (1451–1526) are characterized by finer domes and decoration and the use of finer marbles and tiles. The later Mughal architecture represented in the Red Fort and the Jāmi' Masjid (Principal Mosque) reveals an increasing use of marble, over-elaboration with florid decoration, and the construction of bulbous domes and lofty minarets.

The Red Fort (Lāl Qal'ah) is one of the most important buildings of the city. Its massive red-sandstone walls, 75 feet in height, enclose a complex of palaces, gardens, military barracks, and other buildings. The two most famous of these are the Dīuān-e 'Āmm and Dīuān-e Khāss. The Dīuān-e 'Āmm (Hall of the Public Audience) has 60 red-sandstone pillars supporting a flat roof. The Dīuān-e Khāss (Hall of the Private Audience) is smaller and has a pavilion of white marble.

The architectural styles in the British period, represented by the Central Secretariat, Parliament House, and Rāshtrapati Bhavan (formerly the British viceroy's palace, now the residence of the president of India), combine the best features of the modern English school of architecture with traditional Indian forms. In the post-independence era, public buildings in Delhi show a utilitarian bias and a search for a synthesis between Indian and Western styles; the attempt, however, is not always successful, as is evident from the Supreme Court building, Vigyān Bhavan (a conference hall), and the government *bhavans* (buildings enclosing public areas). The buildings of the BHI Bhavan (a childrens' centre) and Rabindra Bhavan (a fine-arts centre) show a trend toward a new style, using modern materials. The prevailing style, in both public and private buildings, emphasizes functionalism and humanism. Along the Yamuna River front, memorials set in flowering gardens have been built for such 20th-century national leaders as Mahatma Gandhi, Lal Bahadur Shastri, and Jawaharlal Nehru.

**Economic life.** Workers in the Delhi Union Territory comprise 50% of the males and about 5% of the females. In the economy of Delhi, the service sector comes first in importance (employing 22% of the total working population), the industrial sector is second (9%), and the agricultural sector is third (0.4%). The general structure of Delhi's occupational specialization can be seen from the fact that among the individual occupational categories "other services" holds the first place (46%), manufacturing comes second (21%), and trade and commerce third (19%). A substantial proportion of Delhi's working population is engaged in various services, including public administration, the professions, the liberal arts, and various miscellaneous personal, domestic, and unskilled-labour services. As a trading and commercial centre, Delhi has held a dominant position in northern India for many centuries. In modern times, it has also become a manufacturing centre with small- and medium-scale industries.

Traditionally, Delhi has been famous for its artistic work, such as ivory carving and painting, gold and silver embroidery, decorative ware, copperware, and brassware. More recently, it has become important for the manufacture of various sophisticated products in small-scale industry, such as electronics and engineering goods, automobile parts, precision instruments, lathes and drilling machines, and electrical appliances. Delhi has the largest number of establishments for the manufacture of electronics goods in the country. Hosiery items, ready-made garments, sports and leather goods, handloom products, and handicrafts are also produced. There are two modern industrial estates for small-scale industries—the Okhla Industrial Estate and the Badli Industrial Estate, which is a rural project.

Delhi's position as the national capital has accentuated its function as a banking, wholesale-trade, and distributive centre. It is the headquarters of the Reserve Bank of India and of the regional offices of the State Bank and other banking institutions. It is also a divisional headquarters for the insurance business and an important stock-exchange centre. In various distributive trades, such as those for cloth, dry fruits, spices and herbs, hosiery, and general merchandise, Delhi holds an important position. It also has a large share in the regional market for bicycles, fresh fruits and vegetables, furs, skins, and wool, motor parts and machinery, and iron and steel. Most of the distributive trades are carried on from within the Old Delhi area, where most of the markets are located in close proximity to each other.

Delhi's economic base is sound; this fact is reflected in its high per capita income of 872 rupees in 1960–61, as compared with the average per capita income of the country as a whole, for the same year, which was 330 rupees.

**Political and governmental institutions.** Delhi was a chief commissioner's province when India attained independence in 1947. It became a Part C (*i.e.*, centrally administered) state in 1952, but, as a result of the recommendations of the States Reorganisation Commission, its

The city's  
role as a  
manufacturing  
centre

status as a Part C state was abolished, and it became a union territory under the central government in 1956. A unified corporation for both urban and rural areas was established early in 1958. The administrative system was further modified by the Delhi Administration Act of 1966. Under the present arrangement, Delhi has a three-tier administration consisting of a lieutenant governor and his executive council, an elected metropolitan council, and the municipal corporation. The lieutenant governor is appointed by the president of India and is the chief administrator of the union territory of Delhi. He is assisted by an executive council of four members (headed by a chief executive councillor), which is also appointed by the president. The metropolitan council is a purely deliberative body. The municipal corporation is an elected local body, having under its control all statutory autonomous bodies, except the New Delhi Municipal Committee, the Delhi Cantonment Board, and the Delhi Development Authority. The New Delhi Municipal Committee is a body nominated by the central government. The Cantonment Board consists of partly nominated and partly ex officio members.

**Public utilities.** Water supply, drainage, sewerage, and conservancy and scavenging services are obligatory functions of the municipal corporation. Such functions as city transportation and the generation and distribution of electricity, though not obligatory, are performed by the corporation as activities in the public interest. Three statutory undertakings—the Delhi Water Supply and Sewerage Undertaking, the Delhi Electric Supply Undertaking, and the Delhi Transport Undertaking—perform these functions.

Water supply in Delhi is far from adequate, in spite of the fact that it has been augmented several times. The Yamuna River, the main source of supply, is practically dry during the summer months. Underground water has generally been found to be brackish in the territory; Delhi, therefore, must depend for part of its needs upon the adjoining states. The average per capita supply was 40 gallons per day in the early 1970s.

The sewerage of Delhi needs much improvement, both by way of extension to new areas and by the expansion of its capacity in older areas. Arrangements for the treatment of sewage are inadequate.

Delhi's electric-power supply depends on power generated by the local coal-burning thermal stations, augmented by a bulk supply received from the Bhākra-Nangal grid system. The supply of power has always lagged behind demand, with the result that industries have not been able to operate at full capacity.

**Health and safety.** Health facilities. In 1970 there were 50 hospitals in Delhi, with a total of 9,500 beds. Besides the hospitals, there were almost 90 allopathic dispensaries, 15 Ayurvedic and Unani (*yūnānī*) dispensaries (*i.e.*, practicing indigenous systems of medicine that use mostly herbs and minerals), and six homeopathic dispensaries. Among the larger institutions are the All India Institute of Medical Sciences, the Willingdon Hospital, and the Safdar Jang Hospital, all administered by the central government, and the Irwin Hospital and G.B. Pant Hospital, run by the Delhi administration. The central government has its own health scheme for its employees.

**Fire and police services.** The Delhi Fire Service, with 13 fire stations located in various parts of the city, is under the control of the municipal corporation. Its jurisdiction extends over both the urban and rural areas of the union territory. In the rural areas, temporary stations are opened during the summer.

The Delhi Police Service is under an inspector general of police of the Delhi administration. The city is divided into four police districts, each of which is under a superintendent of police. There are about 80 police stations or posts in the city.

**Education.** There were almost 1,940 schools (including about 730 primary schools, 380 middle schools, and 470 higher secondary schools) in urban Delhi in 1969–70, with an enrollment of nearly 800,000 children. A Board of Higher Secondary Education regulates school

educational standards. Among the institutions of higher learning is the University of Delhi (established 1922), which is an affiliating and teaching institution. In 1970 the university had an enrollment of 59,000 students, including 26,000 women. There are 39 colleges of arts, science, and commerce, including research institutions, affiliated to the university. There are also almost 30 colleges for professional and other studies. The most important among them are the Indian Agricultural Research Institute, the Indian Institute of Technology, and the All India Institute of Medical Sciences. Another university campus, the Jawaharlal Nehru University, was being developed in the early 1970s.

**Cultural life.** Delhi's cultural life has been considerably influenced by the cosmopolitan character of its population, which comes from different parts of India and the world and possesses variegated cultural backgrounds. The city's cultural life may be said to be still evolving. With the younger generation, cultural activities of earlier days, such as dancing, music, and poetry forums (*mushā'ira*), are yielding place to frequenting the cinema, the cabaret, and clubs. At the same time there are also some theatre groups and institutions that foster indigenous literature and fine arts. Among the national cultural institutions are the Sangeet Natak Akademi, which promotes such cultural activities as the dance, drama, and music; the Lalit Kala Akademi, which promotes study and research in painting, sculpture, architecture, and applied arts; and the Sahitya Akademi, which fosters and coordinates literary activities in all the Indian languages. The National Gallery of Modern Art has works by nearly 100 artists.

**The media.** Press, television, and radio establish effective contact with Delhi's citizens. More than 1,100 newspapers and periodicals were published in the city in 1968, mostly in Hindi or English; these included 27 dailies, 180 weeklies, and about 600 monthlies. There are four radio stations. Television broadcasts, available on only one channel, were inaugurated in 1959 and can be seen by viewers within a range of 19 miles.

**Recreation.** Delhi is a city of gardens and fountains, with many places for recreation. Among the major recreation areas being developed in the early 1970s were the ridge (the principal green space of the city) and the Yamuna riverfront. There are also a number of parks and gardens, notably the parks at Okhla, Hawz-e Khāṣṣ, and Quṭb; the Rawshan Ārā Garden (developed in the Japanese style), and a rock garden in Patel Nagar. Delhi also has a Zoological Park situated on a 250-acre site. The National Stadium and the Kotla Firiiz Shāh Grounds are important sports centres. An ambitious scheme for constructing swimming pools, stadia, and sports complexes is being pursued by the Delhi administration.

**BIBLIOGRAPHY.** For an authentic work on the history and places of interest of Delhi, see PRABHA CHOPRA (ed.), "Delhi: History and Places of Interest," Delhi Gazetteer (October 1970). One of the earliest historical works is G.R. HEARN, *The Seven Cities of Delhi*, 2nd ed. (1929). A. CUNNINGHAM, *Archaeological Survey of India 1862–65*, vol. 1 (1871), presents the report of the Archaeological Survey of India. V.K.R.V. RAO and P.B. DESAI, *Greater Delhi: A Study in Urbanisation, 1940–1957* (1965), is a socio-economic survey of Delhi conducted by the Delhi School of Economics. A. BOPEGAMAGE, *Delhi: A Study of Urban Sociology* (1957), deals with the sociological aspects of planning for metropolitan Delhi. THE INSTITUTE OF TOWN PLANNERS (DELHI), "Papers of the Seminar on National Capital Planning and Development," *Journal of the Institute of Town Planners (India)*, no. 58 (March 1969), is a collection of papers covering various problems in the restructuring of the Delhi region.

(V.L.S.P.R./K.V.Su.)

## Demography

The first person to use the word demography was the Frenchman Achille Guillard, who wrote in 1855 that the field of demography was "the natural and social history of the human species." In this broad sense, demography is closely linked with the disciplines of biology, genetics, psychology, sociology, history, and economics. In a narrower sense Guillard defined demography as "the mathe-

mathematical study of populations, their general movements, their physical, civil, intellectual and moral condition." Demography as a modern field of study examines the structure of human populations (their distribution by age, sex, marital status, etc.) and their dynamic aspects (births, deaths, migratory movements, etc.). This involves statistical measurement and the use of mathematical methods. Demography is first of all a quantitative science, but it obviously cannot be divorced from a knowledge of the various political, social, and biological influences that affect such statistics.

**Historical development.** The beginning of demography as a science may be found in the work of the Englishman John Graunt, who in 1662 published *Natural and Political Observations . . . Made upon the Bills of Mortality*. The "Bills of Mortality" were weekly records of deaths and baptisms going back to the end of the 16th century, which furnished Graunt with his raw material. In search of statistical regularities Graunt made an estimate of the male-female ratios at birth in London and rural communities; he also compared deaths with births, concluding that the former exceeded the latter in London, whereas the opposite situation prevailed in the countryside. But Graunt's most famous contribution was his construction of the first mortality table; by analyzing birth and death rates he was able to estimate the number of men currently of military age, the number of women of childbearing age, the total number of families, and even the population of London. Doubtless the results were imprecise; but the novelty and quality of the arguments and the originality of the enterprise sufficed to establish Graunt as the founder of demographic analysis.

Another precursor of the modern science was the German pastor Johann Süssmilch, who published the first edition of his *Die Göttliche Ordnung* in 1741. Süssmilch's researches, based on information collected in 1,056 parishes in Brandenburg and in various cities and provinces of Prussia, allowed him to describe concretely many of the dynamic aspects of populations; among other things he constructed several mortality tables, including the first one for the whole population of Prussia (1765). Working with extensive statistical series, he was probably the first to perceive the "law of large numbers."

In the 18th century an interest arose in the study of mortality statistics, resulting from the development of life insurance and from the growing attention given to public health; to this period belongs the work of Willem Kersseboom in Holland (1740), Antoine Deparcieux in France (1746), Daniel Bernoulli in Switzerland (1760), and Pehr Wargentin in Sweden (1766), all mathematicians or astronomers. In the 19th century demographic statistics developed rapidly. The establishment of a civil registry of demographic events (births, deaths, marriages) was, in effect, an extension of the old church registries. In the United States, however, the large number of religious groups and the opposition of the civil authorities in certain states greatly retarded the establishment of an adequate system of registration for the whole country; one was set up for births and deaths only in 1933.

Censuses of the population also developed during the 19th century—decennial censuses in the United States began in 1790 and in England in 1801, quinquennial censuses in France in 1801. Demographic research was still concentrated on mortality, notably in the mathematical works of Benjamin Gompertz (1825), William Makeham (1860), Wilhelm Lexis (1875), and Karl Pearson (1897). Interest in fertility developed much later, for it seemed to be a more fundamentally stable phenomenon and one which did not call for collective action. This lack of interest in the study of fertility is remarkable on the part of scientists living in the century of Thomas Malthus, whose thesis that reproduction tended to outrun the means of subsistence was enormously influential. When it became apparent that a considerable decline of fertility had taken place in the industrialized countries during the second half of the 19th century, however, demographers began to make studies of fertility and reproduction.

The phenomenon of differential fertility, with its implications about selection and more particularly about the evolution of intelligence, evoked widespread interest as shown in Charles Darwin's theories and in the works of Francis Galton. Wilhelm Lexis (1875), G.F.R. Bockh (1884), and Robert Kuczynski worked out measurements of population reproduction, while Alfred Lotka, starting in 1907, founded mathematical demography.

As fertility continued to decline, the period between the two world wars saw the development of studies on this subject. At the same time demography took on a broader, interdisciplinary character, as can be seen in the fundamental work of Frank Lorimer and Frederick Osborn, *Dynamics of Population*. After 1920 international demographic conferences multiplied, and in 1928 the International Union for the Scientific Study of Population was created.

In recent decades the field of demography has greatly expanded, reflecting the increased importance of population problems in both the underdeveloped and the developed countries. This has been marked by the creation of numerous specialized research institutes, the publishing of several dozen periodicals devoted exclusively to demographic research, and the great importance assigned to demographic questions by international organizations, particularly the United Nations.

The basis for most demographic research continues to lie in population censuses and the registration of vital statistics. A population census is a gigantic and costly operation, since it involves collecting a considerable amount of information from all the inhabitants of a country in a brief period of time. Various methods are used. One can try to reach the population on a *de facto* basis (that is, to count all persons where they happen to be at the time of the census), or one can reach the population on a *de jure* basis, according to their customary place of residence. In order to reach the population *de facto*, the census must be carried out in a very short period of time; for example, on a fixed day. Increasingly the trend appears to be toward *de jure* censuses that can be spread out over several weeks. No census is ever completely accurate, since omissions and double counts are inevitable; thus it is estimated that in the 1960 census of the population of the United States there was a 3% omission and a 1.3% double count, giving a net underestimate of 1.7%. Moreover, if the questions are too numerous it is not possible to obtain replies of a high quality except by making exceptional efforts, which add to the expense; to avoid this, some questions are asked of only a fraction of the population.

Birth and death statistics are based on certificates drawn up by local authorities and turned in to the regional or national government. In countries with a long tradition of birth and death registration, such statistics have considerable accuracy. Marriages are often recorded in the same way, but divorces—to the extent that they are determined in law courts—are not.

Demographic studies pursued in depth require extensive data from each individual, some of it of a qualitative nature (opinions, miscellaneous situations, intentions). The inquiry is concentrated on a limited number of persons (a few thousand), chosen in a representative manner by some sampling technique; they may be questioned not only about the situation at a given moment but about their history. Such observations are called *longitudinal*, as contrasted to *transverse* observations made when events occurring over a short period of time are collected from a rather large population. Recent developments in demography have given particular weight to longitudinal observations and the analyses that follow from them.

**Life tables.** All demographic research begins with a statistical treatment of quantitative data on the population; this is called demographic analysis. The demographer must calculate the rates of annual events in a population. The commonest are crude rates. For example, the crude death rate is the ratio of deaths in a given year in a population to the average total size of this population

Longitudinal analyses

The construction of mortality tables

Population censuses

during that year; in 1967 there were 1,851,000 deaths in the United States for an average population (total size of the population in the middle of the year) of 199,114,000, which yields a crude death rate of 9.4 per 1,000. The crude birth rate is defined in the same way: with 3,521,000 births in the United States in 1967, a rate of 17.8 per 1,000 is then obtained. Likewise, the marriage rate is the ratio of marriages during the year to the average population.

But demographic phenomena have variable frequencies depending on the age of the individuals; this leads to the calculation of age-specific rates. If in a given year 2,474 persons die between their 50th and 51st birthdays and the average total number of persons between 50 and 51 years of age is 282,000, the death rate at age 50 is 8.8 per 1,000. Age is not the only temporal characteristic used in analyzing demographic phenomena. Marital fertility rates, for example, become more significant if they are analyzed on the basis of the duration of the marriage.

Demographic rates are usually presented in the form of a table, the best known example of which is the mortality or life table. A mortality table describes the frequency with which deaths occur between successive birthdays in a group of persons born during the same calendar year (a birth cohort). For example, if we take a group of 10,000 women born in France in 1820 we have a mortality table that begins as in Table 1. The probability of death

Table 1: Mortality

age in years ( $x$ )	number surviving to age $x$ ( $l_x$ )	number dying between the ages $x$ and $x+1$ ( $d_x, x+1$ )	mortality rate (per 1,000 women) ( $q_x$ )
0	10,000	1,527	152.7
1	8,473	525	62.0
2	7,948	294	37.0
3	7,654	193	25.2
4	7,461		

is defined as the ratio of those dying between the ages  $x$  and  $x+1$  to the survivors of age  $x$  (or the figures in the third column divided by the figures in the second column). The probability of death is also the probability of the survivors of age  $x$  dying before they reach the age  $x+1$ . The table can be used to compute life expectancies for populations having the same general characteristics.

A similar table may be constructed for marriage rates. Taking, for example, the French female birth cohort of the year 1900, we get a table that begins as in Table 2.

Table 2: Nuptiality

age in years ( $x$ )	number remaining single to age $x$ ( $e_x$ )	number marrying between the ages $x$ and $x+1$ ( $m_x, x+1$ )	marriage rate (per 1,000 women) ( $n_x$ )
15	10,000	57	5.7
16	9,943	176	17.7
17	9,767	396	40.5
18	9,371	722	77.0

The fundamental difference between a marriage table and a mortality table consists in the fact that the second column of the former does not generally end with zero, while that is necessarily the case with the mortality table.

It is possible also to construct a table relating births to the age of a particular cohort of women. For the French female cohort born in 1900, the table begins as in Table 3. The figures in the final column are cumulative, and the total of 2,094 is the sum of all the births (divided by 1,000) for that cohort of women during their reproductive span. The total of female births is known as the gross reproduction rate; when this figure is adjusted downward

Table 3: Fertility

age in years* ( $x$ )	number of births between the ages $x$ and $x+1$ ( $n_x, x+1$ )	number of births by age $x$ †
15	4	0
16	10	4
17	23	14
18	43	37
19	66	80
48	...	2,094

\*Data for ages 20–47 omitted.

†Per 1,000 women.

in accordance with the survival rate of the mothers the result is called the net reproduction rate.

The preceding tables represent the *longitudinal* method of analyzing population characteristics, which is based on the life history of actual cohorts; such data are necessarily more than a century old. The application of current mortality rates to a population results in a current life table. This is compiled by having a fictitious cohort go through all the ages of life, assigning to each age a risk of death, which is the risk observed in the various real cohorts of that age during the current year. This permits an estimate of life expectancy at birth during the current year. Due to declining mortality rates, the life expectancy at birth computed in this way always underestimates the average length of life of a new born generation.

Some demographers have contended that the net reproduction rate gives a better indication of the rate of population increase than other measurements, such as crude birth rates and natural increase rates, because it is based on age-specific fertility rates. In applying it to a given population, however, one must make the assumption that the age-specific fertility rates and mortality rates will not change over a period of several decades.

Demography is also concerned with describing and interpreting population distributions, the simplest of which are distributions by sex and age. A graphic representation of such a distribution is known as an age pyramid. In an age pyramid, ages are plotted on the vertical axis and the total numbers of males and females in each age category on the two horizontal semi-axes; the progressive narrowing of the pyramid as ages increase is due to the effects of mortality; but the form of the pyramid is also governed by many other factors, including fertility, migration, the impact of wars, etc.

The methods of demographic analysis can be adapted to other fields such as epidemiology, sociology, human genetics, history, etc. Demography itself finds many applications in social and economic fields. Population projections are the basis of forecasts of school population, numbers of pensioners, numbers of households, the structure of the labour market, medical requirements, housing requirements, etc. In making such forecasts it must be remembered that long-range population projections cannot be regarded as predictions; rather, they are attempts to show what the consequences will be if present trends continue. This is the sense, for example, in which we must approach the current demographic projections that indicate that the earth is likely to become overpopulated in the near future.

**BIBLIOGRAPHY.** Classic textbooks on the subject include PETER R. COX, *Demography*, 4th ed. (1970), well documented with regard to the United Kingdom; and MORTIMER SPIEGELMAN, *Introduction to Demography*, rev. ed. (1968), data specifically on the United States. GEORGE W. BARCLAY, *Techniques of Population Analysis* (1958), discusses methods usable in countries with incomplete statistics; ROLAND PRESSAT, *L'Analyse démographique* (1961; expanded Eng. trans., *Demographic Analysis*, 1972), describes techniques with the use of detailed and complete statistics. PHILIP M. HAUSER and OTIS DUDLEY DUNCAN (eds.), *The Study of Population: An Inventory and Appraisal* (1959), is a symposium by a number of authors on the present state of demography.

Applications of demographic analysis

## Demosthenes

A Greek statesman who is often called the greatest orator, of all time, Demosthenes, for almost 30 years, rallied the citizens of Athens to oppose the military power of Philip of Macedon and Philip's son Alexander the Great. Demosthenes' speech "On the Crown," a defense of his career delivered in 330 BC, has been termed "the greatest speech of the greatest orator in the world."

BY courtesy of the Ny Carlsberg Glyptotek, Copenhagen

Demosthenes, marble statue, Roman copy of a Greek original, which was placed in the Athenian marketplace in 280 BC. In the Ny Carlsberg Glyptotek, Copenhagen.

Demosthenes' life falls into four periods. His first 20 years were spent preparing to regain a lost inheritance, then for another ten he wrote speeches for other speakers. The third period, when he was the virtual leader of the Athenian city-state, lasted for three decades. The last two years of his life found him twice a refugee from Athens, convicted of a grave crime, and finally sentenced to death by the people he had once led.

**Heritage and youth.** A contemporary of Plato and Aristotle, Demosthenes was born in a township of Athens in 384 BC, the son of a wealthy sword maker. His father died when he was seven, leaving a large inheritance, but the boy's unscrupulous guardians took advantage of their position, and when he came of age Demosthenes received very little of his estate. His strong desire to sue his guardian, Aphobus, in the courts, coupled with a delicate physique that prevented him from receiving the customary Greek gymnastic education, led him to train himself as an orator. He also studied legal rhetoric. In his *Lives of Noble Grecians and Romans* Plutarch, the Greek historian and biographer, relates that Demosthenes built an underground study where he exercised his voice, shaving one half of his head so that he could not go out in public. Plutarch adds that Demosthenes had a speech defect, "an inarticulate and stammering pronunciation" that he overcame by speaking with pebbles in his mouth and by reciting verses when running or out of breath. He also practiced speaking before a large mirror.

Despite this self-improvement program, his first youthful speaking efforts in the public Assembly met with disaster; he was laughed at by his audiences. His lawsuits against Aphobus and two other guardians in 363 were more successful; they produced little money, but he learned much about speaking strategy and methods of argument. Three of his speeches against Aphobus and two against the sculptor Antenor have survived.

**Demosthenes as speech writer.** At the age of 20, then, the young Demosthenes found himself without his fortune, without a trade or profession, and with seemingly little prospect for success in any field. But his rhetorical skill had been noticed. In 4th-century democratic Athens every citizen who wished to prosecute a lawsuit or to defend himself against accusation had to do the speaking

himself. Not every citizen, of course, possessed sufficient skill to write his own speeches—a fact that gave rise to the practice of employing a speech writer (logographer) to prepare a speech for such occasions. Demosthenes' skill in his speeches against Aphobus was recognized by wealthier men in need of a logographer; he soon acquired wealthy and powerful clients willing to pay well for his services. Thus began a lifelong career that he continued even during his most intense involvement in the political struggle against Philip of Macedon, much as a modern lawyer might retain a private practice while engaged in public affairs.

Demosthenes was already 30 when, in 354, he made his first major speech before the Assembly. The speech, "On the Navy Boards," was a marked success. The Assembly or Ecclesia (Ekklēsia), a legislative body composed of all adult male Athenian citizens, had convened to consider a rumoured threat against Athens by the king of Persia. Demosthenes' tightly reasoned oration helped persuade the Athenians to build up their naval strength quietly to show the Persians that, though Athens would not launch an attack, it was ready to fight. He pointed out that, while Athens would have no allies if it attacked first, every other Greek city-state would join Athens if the Persians were the first to attack. Here, for the first time, Demosthenes sounded a theme that was to run through his whole public career—the policy that Athens could best keep its democratic freedom by remaining independent of all other cities while, on the other hand, being ready to make temporary alliances whenever danger threatened. In the same speech, revealing his penchant for careful fiscal planning, he proposed an elaborate revision of the method used to tax the wealthy to raise money for ships.

**Leader of the democratic faction.** From this point on (354), Demosthenes' career is virtually the history of Athenian foreign policy. It was not very long before his oratorical skill made him, in effect, the leader of what today might be called the democratic party. Some interests, especially the wealthy, would have preferred an oligarchy instead of a democracy; many merchants would have preferred peace at almost any price. While they agreed that the Macedonians were barbarians, most Athenian citizens distrusted other Greek city-states, such as Thebes and Sparta. The Athenian Assembly was a loosely organized, often tumultuous body of up to 6,000 male citizens; it was capable of shouting down a speaker it did not like or of routing him with laughter. Any citizen could speak, but the criteria were so high that only the best orators survived for long. In this turbulent arena Demosthenes stood out. Contemporaries refer to him as "a water drinker"; that is, a severe and perhaps forbidding personality. Although name-calling was common practice in the Assembly, Demosthenes' wit was exceptionally caustic; when defending himself in his speech "On the Crown" against the attacks of his lifelong rival, Aeschines, he did not scruple to call him "sly beast," "idle babbler," "court hack," and "polluted." Demosthenes was not merely better at abuse than most; he also realized the advantage of making an audience lose respect for his opponent.

He was an assiduous student of Greek history, using detailed historical parallels in almost all his public speeches, and reportedly copied out Thucydides' *History of the Peloponnesian War* eight times in order to improve his command of language and to absorb its history. He constantly asked the Athenians to recall their own history, to remember their past belief in democracy, and to remind themselves how much they hated tyrants. His love of democracy gives his speeches a humanistic breadth that makes them interesting even today. Demosthenes was also extremely industrious. Plutarch says that it was his habit to sit down at night and go over the conversations and speeches he had heard during the day, experimenting with various replies or speeches that could have been made. He excelled whenever he could prepare his speeches carefully in advance, but the nature of Athenian political life must often have forced him to reply to an opponent on the spur of the moment. Unfortunately, because all of the surviving speeches are

and career

carefully edited texts, it cannot be established how often Demosthenes spoke extemporaneously.

His famous speech in 354 "On the Navy Boards" was addressed to the threat from the East. Meanwhile, in Macedonia, to the north, the young King Philip, almost the same age as Demosthenes, was gradually annexing Greek cities south of his borders. In 356 Philip had captured an Athenian possession in Thrace, after hoodwinking the Athenians with promises to protect the city, and in 354 he took another Athenian possession. By 353 both Sparta and Arcadia were asking Athens for military assistance against Philip. When he continued to move south, employing bribery and threat as well as military force, the Athenians sent a small force to close off the pass at Thermopylae. Although Philip turned aside to the coast of Thrace, avoiding a direct confrontation with Athens, his intentions were clear. Yet many Athenians continued to believe that Philip's threat was transitory.

**The Philippics.** Early in 351 Demosthenes delivered a speech against Philip, the so-called "First Philippic," that established him as the leader of the opposition to Macedonian imperial ambitions. For the next 29 years Demosthenes never wavered; as Plutarch says, "The object which he chose for himself in the commonwealth was noble and just, the defense of the Grecians against Philip." In the "First Philippic" he reminded the Athenians that they had once defeated the Spartans, who were as strong as Philip, and sarcastically pointed out that Philip would never have conquered their territories if he had been as timid as the Athenians seemed to be. He concluded by challenging his countrymen to take their affairs in their own hands rather than let Philip win by default.

This goading speech nonetheless failed to rouse the Athenians. Philip advanced into Chalcidice, threatening the city of Olynthus, which appealed to Athens. In 349 Demosthenes delivered three stirring speeches (the "Olynthiacs") to elicit aid for Olynthus, but the city fell the following year without significant help from Athens. Finally, Philip and the Athenians agreed in April 346 to the Peace of Philocrates; Demosthenes, partly to gain time to prepare for the long struggle he saw ahead, agreed to the peace and went as one of the ambassadors to negotiate the treaty with Philip. During the negotiations, Philip, recognizing Demosthenes' eloquence as a threat to his plans, ignored him and addressed his fellow ambassador Aeschines instead. The two men returned from the embassy bitter foes, Demosthenes denouncing Aeschines and Aeschines assuring everyone of Philip's good intentions.

In his oration "On the Peace" late in 346 Demosthenes, though condemning the terms of the treaty of Philocrates, argued that it had to be honoured. Meanwhile, Philip continued his tactic of setting the Greek city-states, such as Thebes and Sparta, against each other. Demosthenes was one of several ambassadors sent out on a futile tour of the Peloponnese to enlist support against Philip. In retaliation Philip protested to Athens about certain statements made by these ambassadors. Demosthenes' "Second Philippic," in 344, retorted that he would never have agreed to the Peace of Philocrates if he had known that Philip would not honour his word; moreover, he asserted, Aeschines and others had lulled the Athenians into a false sense of security. The issue came to a public trial in the autumn of 343, when Demosthenes, in his speech "The False Legation," accused Aeschines of rendering false reports, giving bad counsel, disobeying instructions, and being susceptible to bribery. The court, however, acquitted Aeschines.

The tangled pattern of threat and counterthreat continued into 341, until an Athenian general incurred Philip's wrath for operating too near one of his towns in the Chersonese. Philip demanded his recall, but Demosthenes replied in a speech, "On the Chersonese," that the motive behind the Macedonian's "scheming and contriving" was to weaken the Athenians' will to oppose Philip's conquests. "Philip is at war with us," he declared, "and has broken the peace." Shortly afterward, Demosthenes delivered his "Third Philippic," perhaps the

most successful single speech in his long campaign against Philip. As a result, Demosthenes became controller of the navy and could thus carry out the naval reforms he had proposed in 354. In addition, a grand alliance was formed against Philip, including Byzantium and former enemies of Athens, such as Thebes. Indecisive warfare followed, with Athens strong at sea but Philip nearly irresistible on land. The Macedonian army was well organized under a single brilliant commander who used cavalry in coordination with highly disciplined infantry, while the Greek alliance depended upon what was essentially a group of citizens' militia.

Disaster came in 338, when Philip defeated the allies in a climactic battle at Chaeronea in north central Greece. According to Plutarch, Demosthenes was in the battle but fled after dropping his arms. Whether or not he disgraced himself in this way, it was Demosthenes whom the people chose to deliver the funeral oration over the bodies of those slain in the battle. After the peace concluded by the Athenian orator and diplomat Demades, Philip acted with restraint; and, though the pro-Macedonian faction was naturally greatly strengthened by his victory, he refrained from occupying Athens. Demosthenes came under several forms of subtle legislative attack by Aeschines and others.

**Alexander's campaign.** In 336 Greece was stunned by the news that Philip had been assassinated. When his son Alexander succeeded him, many Greeks believed that freedom was about to be restored. But within a year Alexander proved that he was an even more implacable foe than his father—for, when the city of Thebes rebelled against him in 335, he destroyed it. A string of victories emboldened Alexander to demand that Athens surrender Demosthenes and seven other orators who had opposed his father and himself; only a special embassy to Alexander succeeded in having that order rescinded. Shortly thereafter, Alexander began his invasion of Asia that took him as far as India and left Athens free of direct military threat from him.

In 330, nevertheless, judging that the pro-Alexandrian faction was still strong in Athens, Aeschines pressed his charges of impropriety against Ctesiphon—first made six years earlier—for proposing that Demosthenes be awarded a gold crown for his services to the state. The real target was, of course, Demosthenes, for Aeschines accused Ctesiphon of making a false statement when he praised the orator's patriotism and public service. The resulting oratorical confrontation between Aeschines and Demosthenes aroused interest throughout Greece, because not only Demosthenes but also Athenian policy of the past 20 years was on trial. A jury of 500 citizens was the minimum required in such cases, but a large crowd of other Athenians and even foreigners flocked to the debate.

The oration "On the Crown," Demosthenes' reply to Aeschines' charges of vacillating in his policy, accepting bribes, and displaying cowardice in battle, is universally acknowledged as a masterpiece of rhetorical art. It covers the entire two decades of Greek involvement with Philip and Alexander, contrasting Demosthenes' policies in every case with what he terms the treachery of Aeschines as an agent of the Macedonians. As always, his command of historical detail is impressive. Over and over again he asks his audience what needed to be done in a crisis and who did it. Addressing Aeschines directly, he says, "Your policies supported our enemy, mine, our country's." His scathing epithets picture Aeschines as a contemptible turncoat, a hireling of Philip. The jury's verdict was resoundingly clear—Aeschines failed to receive even one-fifth of the votes and was thus obliged to go into exile. Demosthenes and his policies had received a massive vote of popular approval.

**Imprisonment and exile.** Six years later, however, he was convicted of a grave crime and forced to flee from prison and himself go into exile. He was accused of taking 20 talents deposited in Athens by Harpalus, a refugee from Alexander. Demosthenes was found guilty, fined 50 talents, and imprisoned. The circumstances of the case are still unclear. Demosthenes may well have intended to

Crown"

use the money for civic purposes, and it is perhaps significant that the court fined him only two and one-half times the amount involved instead of the ten times usually levied in such cases. His escape from prison made it impossible for him to return to Athens to raise money for the fine. The onetime leader of the Athenians was now a refugee from his own people.

Another dramatic reversal occurred the very next year, however, when Alexander died. The power of the Macedonians seemed finally broken; a new alliance was concluded against them. The Athenians recalled Demosthenes from exile and provided money to pay his fine. But at the approach of Antipater, Alexander's successor, Demosthenes and other orators again fled the city. His former friend Demades then persuaded the Athenians to sentence Demosthenes to death. While fleeing Antipater's soldiers, he killed himself by taking poison at Calauria on October 12, 322. Following his long service to the state, which nonetheless ended in abandonment by the fickle Athenian citizenry, Demosthenes' death can be viewed as a symbol of the decline of Athenian democracy.

**Influence and assessment.** After his death, according to Plutarch, the Athenians erected a brass statue to his memory. In the following century the scholars at the library in Alexandria carefully edited the manuscripts of his famous speeches. The Roman orator and politician Cicero was so impressed with his speech "On the Crown" that he translated it into Latin and wrote a prologue for it. When Cicero delivered a series of speeches in 44 BC opposing Antony, in circumstances not unlike those in which Demosthenes opposed Philip, Cicero's speeches were called Philippics too. Roman schoolboys studied Demosthenes' speeches as part of their own oratorical training. During the Middle Ages and Renaissance his name was a synonym for eloquence; Queen Elizabeth I was so impressed with Demosthenes that she studied the Greek texts of his speeches with the scholar Roger Ascham. Some 19th-century scholars regarded the Macedonian conquest of the bickering city-states of Greece as a natural political evolution and thus condemned Demosthenes as an opponent of progress. A curious revival of interest in Demosthenes occurred in Europe during World War I: French writers such as the statesman Georges Clemenceau admired him for his resistance to the Macedonian invaders of Greece; some German writers, on the other hand, praised him for his skill in mobilizing political power. Modern scholars such as Werner Jaeger present a more dispassionate view by pointing to the highly complex political issues Demosthenes handled with his oratorical skill. Whatever the interpretations of his personality and work, he has in every age been regarded as one of the world's greatest orator-statesmen.

**BIBLIOGRAPHY.** "Demosthenes," in *Plutarch, the Lives of the Noble Grecians and Romans*, trans. by JOHN DRYDEN and rev. by ARTHUR HUGH CLOUGH, pp. 1024-1040 (1955); WERNER W. JAEGER, *Demosthenes: The Origin and Growth of His Policy* (1938, reprinted 1963), a balanced view of his life and policies; JAMES J. MURPHY (ed.), *Demosthenes' on the Crown: A Critical Case Study of a Masterpiece of Ancient Oratory* (1967), includes Plutarch's biography, an analysis by GEORGE KENNEDY of Demosthenes' oratorical career, a translation of his speech "On the Crown," and analyses of his use of style, argument, and historical detail.

(J.J.M.)

## Denmark

The ancient European kingdom of Denmark comprises the northern part of the low-lying Jutland Peninsula, an archipelago at the entrance to the Baltic Sea, as well as the tiny Faeroe Islands and the immense mass of Greenland, both in the northern Atlantic Ocean. It is the smallest of the three Scandinavian kingdoms, with an area (excluding Greenland) of 16,629 square miles (43,069 square kilometres). Denmark's situation in the Northern Hemisphere, in an area containing more than one-ninth of the world's population and an even greater part of its productive capacity, and especially its location on the North Sea, have brought it the advantage of close proximity and accessibility to the densely populated industrial states

of western Europe and have made it a physical, cultural, and commercial bridge between Scandinavia and central Europe. The country was the home of almost 5,000,000 people in the early 1970s.

Division of the country into numerous islands has given it an exceptionally long coastline for its area. The configuration of much of this coast into fjords has, since ancient times, provided natural harbours that encouraged the growth of fishing, shipping, and associated industries. Denmark's economic and political life has long centred around these outlets to the sea. Periods of great political and economic power in the country's history have been based on strong naval power, as in the Viking period, the medieval expansion in the Baltic, the mercantile expansion and colonization of the 16th century, the thriving trade of the 17th century, and the shipping and associated activities of today.

Of Denmark proper the peninsula of Jutland covers 11,449 square miles. To the east, between the Skagerrak and the Baltic, lies the main archipelago of 483 islands, of which 97 are inhabited. Sjælland (Zealand), the largest island in the group, covers 2,708 square miles and is separated from southern Sweden by The Sound (Øresund). Fyn, the second largest island (1,152 square miles), is separated from Sjælland by the Great Belt (Store Bælt) and from Jutland by the Little Belt (Lille Bælt). In the Baltic, farther east of Sjælland, is the island of Bornholm. The Faeroe Islands, with an area of 540 square miles, have a special status within the kingdom as a self-governing region. Greenland (*q.v.*), a Danish colony until integrated into the kingdom in 1953, is the largest island in the world, covering 840,000 square miles, with 132,000 square miles along the coast ice-free. Denmark's 42-mile-long frontier with West Germany extends across the Jutland peninsula from Flensburg Fjord (Flensburger Förde) to a point between the islands of Rømø and Sylt.

The nation whose Viking ancestors terrorized the Atlantic Europe of 1,000 years ago was, in the early 1970s, a small but thriving community enjoying the 10th highest standard of living in the world, yet vulnerably dependent on foreign trade and looking for its future prosperity to the achievement of a state of full European economic cooperation. (For related information, see COPENHAGEN; SCANDINAVIA, HISTORY OF; and GREENLAND.)

### THE LAND

The Danish landscape derives its character from the glaciations that covered northern Europe during the Quaternary Period (within the last 2,500,000 years). Erosion and sedimentary deposits in uplands, plains, and valleys are the predominant features.

Denmark proper is a lowland area, on average not more than 100 feet above sea level; its highest point, Yding Skovhøj in central Jutland, reaches only 568 feet.

Although the whole of Denmark is relatively low-lying, a remarkable scenic boundary can be traced from Nissum Fjord on the west coast of Jutland eastward toward Viborg, thence swinging sharply south down the spine of the peninsula toward Åbenrå and the German city of Flensburg. This boundary represents the extreme limit reached by the Scandinavian and Baltic ice sheets during the last glaciation, which began about 600,000 years ago.

The ice front is clearly marked in the contrast between the flat west Jutland region, composed of sands and gravels strewn by the meltwaters that poured west from the shrinking ice sheet, and the fertile loam plains and hills of east and north Denmark, which become markedly sandier toward the ice front. In the northwest, around the Limfjorden area, there are numerous landscapes of flat, sand-and-gravel tracts created by marine deposits. Where drainage is difficult, some of these are overlaid by bogs, the peat being exploited and the land then drained for grazing.

In north Jutland and along the coast of south Jutland where there is a perceptible tidal range, salt marshes have been formed by evaporation of what was, in the Late Permian Period (around 225,000,000 years ago), an inland sea. These deposits are commercially exploited.

by glacial  
boundaries

Senonian chalk, deposited around 100,000,000 years ago, is exposed at the base of the impressive cliffs (Stevns Klint) in southeast Sjælland, at Bulbjerg, and again at Møns Klint. Younger Danian limestone (around 65,000,000 years of age) is extensively quarried in south-east Sjælland.

Georae Whiteley—Photo Researchers

Møns Klint, chalk cliffs on Møn Island, which rise sharply to a height of over 400 feet (122 metres).

On the island of Bornholm the contrasting solid rock reveals close affinities with that of southern Sweden. Exposure of Precambrian granites (among the oldest on the planet's surface, more than 570,000,000 years old) cover extensive areas of the northern half of the island, which is overlaid to the south by Cambrian sandstone and shales.

About 85 percent of Greenland lies under an ice cap, the thickness of which is as great as 8,900 feet and averages 4,971 feet. The topography of the island is mountainous, consisting largely of Precambrian gneiss and granites. Its highest point, Gunnbjørns Fjeld, reaches 12,140 feet above sea level. The Precambrian bedrock is exposed along the whole west coast and on the east coast from Kap Farvel (Cape Farewell) to Kangerdlugsuaq. The north and east coast to Scoresby Sound consists of very thick continental and marine sediments.

The high and rugged Faeroe Islands, 17 of which are inhabited, are situated between Scotland and Iceland in the North Atlantic (between 6°15' and 7°41' W longitude and 61°26' and 62°24' N latitude) and consist of sheets of weather-resistant basaltic lavas from 30 to 100 feet thick (known locally as "hammers"), which originated from volcanic eruptions during the Tertiary Period (from 65,000,000 to 2,500,000 years ago). These hammers are topped with a reddish stone (tuff) about three feet thick. The coasts are indented with deep-cut cliffs and the mountain sides stepped because of the varying resistance of the strata to the ice sheets, which once covered them. Ice action has gouged the valleys into troughshaped hollows.

In Denmark proper the largest stream, the Gudenå, rises in east central Jutland and flows 98 miles to its mouth in the Randers Fjord on the east coast. Small lakes are numerous; the largest is 15.7-square-mile Arresø, on Sjælland. Large lagoons have been formed in places in the west such as Ringkøbing and Nisum fjords.

The substratum on which the Danish soils have developed are chiefly moraines of glacially deposited debris and meltwater sand. By admixture with the subterranean limestones the moraine became calcareous, a factor of vital importance to agriculture. Through centuries of cultivation the Danish soil has been radically improved; the result is an agricultural area comprising 70 percent of the land surface, with maximum potential cropping.

Climate. Being in the Temperate Zone at the meeting point of extremely diverse air masses from the Atlantic, the Arctic, and eastern Europe, Denmark experiences very changeable weather. Although the west coast faces

the inhospitable North Sea, the climate—particularly in winter—derives great advantage from the warm North Atlantic Drift (the terminal section of the Gulf Stream). The mean temperature in the coldest month (just under 32° F [−0.1° C] in February) is 12 degrees higher than the average for its latitude. In summer, continental heat may be experienced. The mean temperature in July, the warmest month, is 61° F (16° C). The number of days when frost occurs ranges annually from 70 on the west coast to 120 in the interior.

The climate is moist; the mean annual precipitation of 25 inches (639 millimetres) ranges from about 32 inches (800 millimetres) in southwest Jutland to about 16 inches on Sprogø in the Great Belt. Rain falls all year-round but is relatively low in winter and spring. The largest monthly volumes of rain fall in August and October.

Climatic variations between north and south on Greenland, situated partly within the Arctic Circle, are considerable. At Ivigtut in the south the mean temperature in July is 50° F (9.9° C) and in February is 18° F (−7.9° C). The corresponding figures for Upernavik in northern Greenland are 41° F (4.9° C) and −9° F (−23° C). Rainfall diminishes from 40 inches per year in the south to eight inches in the north.

The climate of the Faeroes is typically oceanic, with frequent fogs and heavy rain (63 inches annually). The mean temperature in January is 38° F (3.2° C), and in July 51° F (10.8° C). Periods of frost seldom last long and harbours are rarely icebound because of the North Atlantic Drift.

Vegetation and animal life. Denmark's natural vegetation is deciduous forest; but as the country borders the coniferous belt, plantations of spruce and fir thrive. Natural deciduous forests survive in only a few places and consist of oak, elm, beech, and lime. About 10 percent of the land is forest, but almost all of it has been planted and is cultivated. Plants include dune vegetations and heathers.

Greenland's vegetation consists chiefly of tundra types—heather, birch, willow, and alder scrub, together with lichens, sedge, and cotton grass. In the south, vegetables such as lettuce and radish are raised, and hay is grown for sheep.

Because of frequent gales, strong west winds, and poor soil, forests do not thrive in the Faeroes and vegetation consists mainly of grass, moss, and mountain-bog flora, affording a basis for large-scale sheep raising.

As Denmark is a densely populated and intensively cultivated country, its original stock of large mammals has been heavily reduced. The largest wild species is the red deer, which inhabits Jutland's forests and plantations. Three hundred and thirty-three bird species have been observed in Denmark, 163 of which breed in the country. Livestock, chiefly cattle and swine, number 12,000,000. Horses number around 40,000 but are in fast decline. The fresh water fauna have been seriously affected by pollution; the least disturbed animal communities are the marine fauna, which form the basis of a large fishing industry.

The rich animal life of Greenland includes reindeer, musk-oxen, polar bears, ermines, snow hares, lemmings, and Arctic foxes, as well as many types of sea birds—eiders, guillemots, auks, wild geese, ducks, and gulls. Land birds include ravens, ptarmigan, falcons, white-tailed eagles, snowy owls, snow buntings, and longspurs. Salmon and trout are found in the rivers; and flounder, capelins, and halibut are important saltwater fish.

On the Faeroes, rats and mice have come with ships, and polar hares have been imported, but there are no indigenous land mammals. Millions of sea birds, including eider ducks, guillemots, and puffins, nest in the high cliffs, and there are abundant trout in the several lakes.

Pattern of land settlement. The original form of habitation in Denmark was the nucleated village with a common-field system. This system was abolished around 1800 and today the landscape is characterized by dispersed farms. West of the ice front is a region of scattered farms, low population density, and rapid population growth; east of the front there is village habitation,

Islands

high population density, and a declining rural population. Oats, rye, turnips, and potatoes dominate the fields of west Jutland, while barley, wheat, and sugarbeet are characteristic of east Denmark. As a result of industrialization there has been an increased migration from country to town over the past century. By 1970, 55 percent of the population were living in towns and urbanized districts.

### THE PEOPLE

There is little archaeological evidence of human habitation in Denmark earlier than 100,000 years ago. Nomadic hunters were in evidence from about 10,000 BC, living by fishing and catching birds and large animals from the forests. (The skeleton of an auroch with arrowheads embedded in it was found during peat cutting in 1900.) Agriculture was introduced around 3000 BC.

Although the present Danish population is the result of a racial mixture that occurred in the New Stone Age, along with the additional integration of various small groups that have immigrated since, the Nordic characteristics of blond hair and blue eyes do predominate.

The only non-Danish minority in Denmark consists of a German colony in south Jutland, numbering 40,000. Copenhagen (København), a principal transit port of

northern Europe, with its suburbs, contained 1,384,000 inhabitants, or just over 25 percent of the total population, in 1971. Other large cities were Århus with 238,000, Odense with 166,000, and Ålborg with 155,000. The Greenland population (47,000 in 1970) is partly Eskimo but consists chiefly of Greenlanders, a Mongoloid-Caucasian intermixture of Eskimos and Danes. Godthåb (population 8,000) is the capital and an important fishing centre. The Faeroese population (39,000 in 1970) is descended from 9th-century Norse settlers. The capital and port is Thorshavn (10,000) on the largest island, Streymoy (144 square miles).

**Language and religion.** The Danish language, too, is Nordic, forming a subdivision of the Germanic group. It is closely related to Norwegian and Swedish, though less melodic; it was first distinguishable from Swedish only around 1100 AD. Outside Denmark, Danish is spoken in southern Schleswig-Holstein in northern West Germany.

The Faeroese language resembles modern Norwegian and Icelandic; and, of course, there is a vast difference between Danish and the Eskimo languages spoken in Greenland. Both Greenlandish and Faeroese are recognized as the principal languages of their respective regions, but a thorough grounding in Danish is still compulsory in the islands' schools.

The religion to which the bulk of the population belongs is Evangelical Lutheran.

**Demography.** Population growth in Denmark is determined primarily by the annual increase in births over

than 2 percent by 1971. Average life expectancy, put at 50 years at the beginning of the century, by 1971 was just over 70 years for men and 75 years for women. The most frequent causes of death in Denmark were heart diseases (34 percent) and cancer (23 percent). About 5.25 percent of deaths were caused by accidents. The suicide rate in Denmark (2 percent) was high: it was 24 per 100,000 for men and 12 per 100,000 for women.

Until World War I the distribution of the population in terms of age groups (children, young people, adults, and old people) was very stable. Since then, considerable changes have taken place, partly because of the declining birthrate. The youngest age groups were comparatively smaller and the oldest comparatively larger. In 1969, 12 percent of the population was under seven; 11 percent was aged between seven and 13; 9 percent between 14 and 19; 59 percent between 20 and 66; and 10 percent was 67 and over. (Estimates based on present rates of increase give a total population of 6,000,000 by 2000 AD, slightly more than 800,000 of whom will be older than 67.)

In Greenland the birth rate was two and one-half times as high as in Denmark proper. A halving of the death rate during the 1950s, primarily from a marked decrease in fatalities from tuberculosis, led to a 1971 deathrate of 0.7 percent, considerably lower than in the rest of Denmark (0.98 percent in 1970). Children under 14 in Greenland made up more than 40 percent of the population, however, as compared with 20 percent for the rest of the country; and the age group above 60 years constituted only 4 percent of Greenland's population, compared with 14 percent in the rest of the country. Life expectancy in Greenland was 57 years for males and 63 for females—13 and 12 years lower, respectively, than in the rest of Denmark. The difference was partly accounted for by an infant mortality rate that, despite a marked reduction, was still two or three times as high as in the rest of the country. The most serious diseases reported in Greenland were gonorrhea, influenza, and quinsy; and the most frequent causes of death were accidents, particularly drowning.

There was a distinct tendency among the Danes to marry younger. Over the past century the average marrying age for those marrying for the first time dropped by 7 years: for men, from 32 to 25 years, and for women, from 29 to 22 years. Just over 25 percent of marriages contracted annually were solemnized by a secular authority, not in a religious ceremony.

Between 1901 and 1905 there were, on average, 500 divorces annually; thus, 4 percent of all marriages were dissolved. In 1969 there were 9,000 divorces; thus, almost 25 percent of marriages were dissolved that year, by death or divorce.

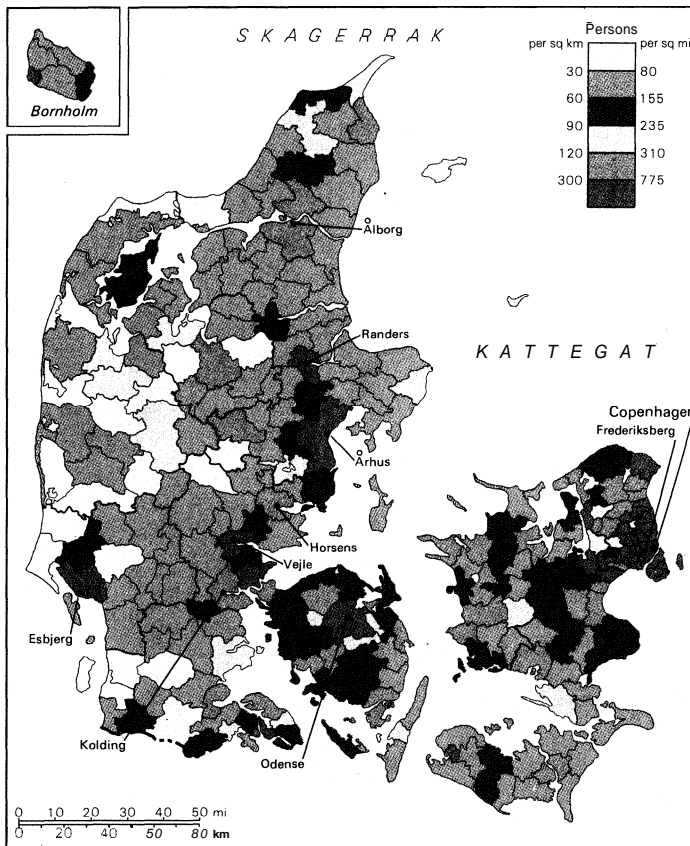

#### THE NATIONAL ECONOMY

**Resources and production.** Despite rather poor natural resources, the Danish population enjoys a standard of living equalled by few other countries in the world. The 1970 gross national product (GNP) represented the 10th highest average income per capita in the world. In proportion to its size Denmark has an extremely large volume of foreign trade (exporting 30 percent of GNP). Its chief trading partners are Great Britain, the Federal Republic of Germany, Sweden, and the United States.

Natural deposits of importance to industry as fuels or raw materials are found to a very limited extent in Denmark. There is a particular scarcity of metals, coal, and oil. Oil and gas prospecting is indeed going on in the Danish sector of the North Sea, with good expectations of early exploitation, especially of gas resources. Nevertheless, next to its labour force, the soil is still Denmark's most important raw material, for, as has been mentioned, about 70 percent of the nation's land is devoted to agriculture, and only a small percentage of this is permanently in grass. The soil is intensively exploited and extensively fertilized. More than half of the cultivated land is devoted to cereals, barley accounting for about 70 percent of the total grain harvest. Dairy farming is important, with annual production of milk around

Changing pattern of age distribution

Standard of living

Population density of Denmark.

deaths rather than by the effect of net migration, which is normally insignificant in comparison. In the mid-1960s, immigration and emigration figures cancelled each other out, with an approximate movement of 30,000 in either direction. By the early 1970s, however, immigration of short-time workers from countries of southern Europe was increasing. In 1968 the overall increase in population amounted to 27,000 annually, but the introduction of the contraceptive pill resulted in a rapid fall in the birth rate, even though the average woman giving birth was younger. The death rate among infants in Denmark over the past half century was cut from more than 10 percent to less

5,000,000 tons. About 12,000,000 pigs are killed each year. Chickens numbered about 18,000,000 in 1970, producing 90,000 tons of eggs.

Farms are generally small or medium sized, with holdings of between 25 and 150 acres shouldering the main burden of production. There is an unusually large number of freehold farms—98 percent against 2 percent rented. Cooperatives help to make small farm operations profitable, and the dominance of animal husbandry also lends itself to individual enterprise. There were 140,000 agricultural properties by 1970, although the number was decreasing by around 7,000 annually.

Of the total value of Danish animal and vegetable output, domestic animal products account for 90 percent. Total agricultural production is sufficient to meet the requirements of more than 16,000,000 people and is steadily increasing despite the fall in agricultural manpower.

The fishing industry employs approximately 13,000 fishermen in over 8,000 vessels with a total tonnage of just over 100,000 gross registered tons. Herring, cod, and plaice (or flatfish) account for about half the total catch, which is made up of about 50 species in all; other important species are salmon, mackerel, eels, and deepwater shrimp.

Denmark's small extractive industry relies on the supply of granite (for roads and house building) and kaolin (for ceramic and paper manufacture) found on Bornholm. At brickworks all over the country boulder clays are molded and baked to make bricks and tiles; moler (marine diatomaceous earth) is used in insulating materials for the building industry and white chalk in the important cement industry.

In Greenland, marble is mined at Marmorilik and coal on Disko Island. Cryolite mining at Ivigtut ceased in 1962 although stockpiles were expected to last for 20 to 30 years. There is intensive exploration for minerals such as uranium and thorium. Fairly well developed coal deposits are mined on Sudhuroy in the Faeroe Islands.

**Organization, trade, and finance.** Imports of raw materials and fuel used to be paid for largely by exports of agricultural products, supplemented by income from Danish shipping and the tourist trade. But since the early 1960s the overseas trade pattern has changed, and industrial products were accounting for 66 percent of total exports by 1970, against only 40 percent in 1959. Agriculture's share fell in this period from over 50 percent to around 30 percent. The largest employers were the iron and metal industries (28 percent of all workers); followed by the food industry (18 percent); the paper and graphic industries and transport (both 9 percent); and then footwear and clothing, wood and furniture, and extraction industries. By mutual agreement between workers' and employers' organizations, wages are automatically adjusted to the cost-of-living index every six months and wage agreements negotiated biennially.

Power plants are owned by cooperatives or municipal authorities and mainly burn imported oil or coal. Some power is imported from Swedish hydroelectric plants.

The National Bank of Denmark is the only bank of issue and has a special status as a self-governing institution under government supervision. Profits revert to the state treasury. There are three large private banks and about 110 smaller ones. Besides these commercial banks, there are approximately 370 nonprofit-making savings banks.

Denmark's trade is almost entirely within Europe. Its trade within the European Free Trade Association, of which it became a member in 1960, increased over the 1960s, although trade with the European Economic Community (EEC) was also considerable. Before EEC entry, EFTA countries accounted for 50 percent of Denmark's exports and EEC countries for 23 percent of exports.

Great Britain is the chief buyer of Danish agricultural produce, with West Germany second. Those two countries jointly absorb almost 60 percent of all agricultural exports. Sales to West Germany, however, dropped at a considerable rate as a result of the EEC's self-supplying policy. Sweden is Denmark's largest market for manufactured goods and its second largest market overall (after Great Britain).

Denmark's is a mixed welfare-state economy, with private sector expenditure accounting for 55 percent of net national income. The very high share of public expenditure in the net national income is the result of a considerable expansion in higher education, national defense, social services, and, through subsidization, agriculture. Neither state nor local government authorities own capital nor have they any significant commercial or industrial income. The greater part of public income is thus derived from taxation: on real estate, on personal income and capital, and through customs and excise duties.

Taxes on real estate amounted to about 5 percent of total receipts in 1971, by far the greatest part being received by local authorities. Personal income tax—levied by both state and municipal authorities—represents 45 percent of total tax receipts. Local taxes are always proportional to income, and there is a state surtax on incomes above a certain level. Income tax is deducted on a PAYE (pay-as-you-earn) system. Danish company tax is relatively low.

The chief of the indirect taxes, which go to the state, is the VAT (value-added-tax) of 15 percent. In addition to these and to customs duties, there are high indirect taxes on selected goods such as wines and spirits, tobaccos, petroleum, and motor vehicles.

Both employers and employees are well organized in Denmark. Workers are normally organized according to their particular skills, no matter what industry they happen to be in. The dominant national employees' organization is the National Trades Union Centre (Landsorganisationen i Danmark, De Samvirkende Fagforbund). The principal employers' organization is the Danish Employers' Confederation (Dansk Arbejdsgiverforening).

The change that Denmark underwent in the 1960s from an agricultural to an industrial country was financed by foreign borrowings and resulted in increasing inflation. That inflation and the accompanying deficit in the balance of payments, which had grown from near zero in 1960 to U.S. \$1,550,000,000 by 1970, were the chief economic problems facing contemporary Danish governments. Their solution was seen, in part, in participation in the expanded market that EEC entry (effective January 1, 1973) would bring.

**Transportation.** Communications by land, sea, and air are conditioned principally by comparatively high population density, a small and low-lying geographical area, the considerable amount of overseas trade engaged in, and the fact that Denmark is one of the most dissected landmasses in Europe.

Highways total 5,400 miles; of these 1,400 miles are arterial roads. Secondary roads maintained by local district authorities total 29,000 miles. Road networks in cities and towns account for a further 4,000 miles. The number of motor vehicles in Denmark has risen rapidly in recent years. In December 1968 there were 1,140,000 automobiles, of which 870,000 were private cars, just over 65,000 motorcycles and 140,000 certified tractors. (The number of private cars exceeded 1,000,000 by 1970.) While the number of motorcycles was declining, that of cars had virtually doubled since 1966. By 1971 there was one private car to every six persons. Bicycles were estimated to number 2,000,000.

Throughout the country in 1969 there were 1,100 bus and coach routes, the majority operated by the Danish State Railways. The routes totalled about 19,000 miles.

Denmark's comparatively large railway network, built mainly during the last half of the 19th century, totals 2,199 route miles; two-thirds of that trackage is state-operated, and the rest is run by companies the shares of which are normally owned by local government authorities and the state.

An important supplement to the railways and a characteristic feature of the Danish communications system are the ferries and many bridges. The principal ferry services are the Great Belt Ferry between Sjælland and Fyn and the ferries linking Denmark and Sweden. Two bridges connect Fyn and Jutland. Denmark's longest bridge, the Storstrøm (two miles), connects Sjælland and Falster.

Denmark's considerable overseas trade and many good harbours provide favourable conditions for shipping. In 1970 the Danish merchant fleet comprised 1,433 ships of 100 gross registered tons or more, making a total tonnage of 3,220,000 gross registered tons; 85 of them were tankers with a combined weight of 1,200,000 tons.

Copenhagen, with one of the busiest airports in Europe (at Kastrup), serves inland routes to Jutland and Bornholm and is a centre of international traffic. The Scandinavian Airlines System (SAS), a joint Danish-Norwegian-Swedish enterprise, serves European and intercontinental lines.

#### ADMINISTRATIVE AND SOCIAL CONDITIONS

**Constitution and politics.** Constitutional monarchy was introduced in Denmark on June 5, 1849. Legislative authority, based on the constitution of June 5, 1953, rests jointly with the crown and with parliament, which consists of one chamber, the Folketing, with 179 members (including two from the Faeroe Islands and two from Greenland) elected for four years. Acts passed by the Folketing must be signed by the king and countersigned by at least one minister before becoming law. Furthermore, the monarch, as chief executive, is responsible for carrying legislation into effect, seeing that laws are observed and violations prosecuted. The king exercises his executive powers through the 19-minister State Council, headed by the prime minister. No minister can remain in office if the Folketing passes a vote of no confidence in him.

Apart from the Faeroes and Greenland, where special administrative arrangements are in force, the country is divided into 14 counties and 277 municipalities. All persons over 20 are entitled to vote in both the Folketing and local council elections, and the ballot is voluntary and secret. All voters (except those found guilty of a criminal offense) are also eligible to stand for election. In an attempt to achieve the equitable representation for all prevailing political outlooks, as guaranteed in the constitution, elections in individual constituencies are combined with election by proportional representation.

At the 1971 general election the Social Democratic Party, mainly representing the workers, won 70 seats; the Conservative People's Party, representing the more prosperous urban population, gained 31 seats; the Liberal Party, representing the farmers, held 30 seats; the Radical Liberal Party, which obtained most of its support from intellectuals, the urban middle class, and independent smallholders, gained 27 seats; and the small Socialist People's Party took 17 seats.

The amendment to the Constitution passed in 1953 included the introduction of the Ombudsman (1954), whose office was, on behalf of the Folketing, to superintend the administrative services of the government and, to a certain extent, those of the municipalities. Every citizen could thus lodge a complaint in the event of arbitrary treatment from ministers, civil servants, or others employed by the public administration. Once a case has been investigated, the Ombudsman may express an opinion and, if necessary, bring the case before the courts. If a complaint concerns a minister or former minister the Ombudsman may report it to the Folketing.

**Justice and police.** The administration of justice is exercised by more than 100 lower courts, two high courts and a Supreme Court with its seat in Copenhagen. The independent judiciary is appointed by the king.

The police service is organized on a national basis under the control of the chief of state police; there are 72 police districts, each headed by a chief constable.

**Defense.** Danish national defense policy is based on membership in the North Atlantic Treaty Organization (NATO). It is the constitutional duty of all men capable of bearing arms to contribute to national defense. The normal period of compulsory national service is 12 months, but the armed forces also enlist many volunteers. Conscientious objectors to military service may serve in the Civil Defense Force, in special camps in the state forests, or in various positions in social work. Service in the Home Guard and Civil Defense Corps is voluntary.

There is a United States military base at Thule in Greenland, but no nuclear weapons are admitted on Danish soil or over Greenland's air space.

**Social welfare.** *Education.* Education in Denmark is compulsory for children between seven and 16 years of age. A growing number continue education after primary school, either in a grammar school or in various recently established nonacademic institutes. The majority of schools are publicly run and free. Private schools receive large grants from the state, as do youth schools, which offer vocational and other supplementary training. Denmark's most significant contribution to adult education is the folk high school, in which no entrance conditions are imposed; great freedom exists within the folk high school curriculum, and no examinations are held on conclusion of courses.

Further education is given at commercial and technical colleges, professional institutions, and at the universities of Copenhagen (founded in 1479), Arhus (1928), and Odense (1964). A fourth university was scheduled to open in Roskilde in 1972. All universities and higher seats of learning receive their incomes from the state.

*Social insurance.* According to the Danish constitution, "any person unable to support himself or his dependents shall, where no other person is responsible for his or their maintenance, be entitled to receive public assistance."

A national old-age pension scheme is available for all persons over 67, with basic amounts being paid, irrespective of the recipient's financial position. The scheme is administered by the municipalities and financed largely by the state through taxation. In addition, a supplementary pension is financed by contributions from wage earners themselves and employers (although employers' contributions to social-insurance schemes in general are substantially lower than in some other European countries). There is, moreover, a disability pension, and a pension for widows over 55 years of age is also in effect. Membership in the public health insurance program is compulsory, and all persons are entitled to free hospital treatment and home nursing. The cost of medicine is largely subsidized.

Unemployment insurance is voluntary but widespread: worker and employer pay the insurance but get state repayments if unemployment rises or becomes protracted. Industrial injury insurance is paid by all employers to cover employees against the consequences of accidents; and the Family Act, for the physical, mental, and occupational training of vocationally handicapped persons. Children's allowances are paid until the age of 16, irrespective of a family's total income. All children are medically examined, free of charge, at regular intervals throughout infancy and schooling.

*Housing.* At the 1965 census of population and housing there were 1,600,000 dwellings (5,500,000 rooms) in Denmark. Of these, 12 percent were in agricultural properties, 35 percent in other single-family houses, nine percent in two-family houses, and 44 percent in blocks of flats. The average size of dwellings was probably one of the highest in Europe. Under a 1966 act tenants receive rent rebates from both state and municipal authorities according to a graded scale dependent on rent level and family income. Annual housing production amounted to 50,000 dwelling units, or more than 10 dwellings per 1,000 inhabitants. In money terms, housing construction represented just over 4 percent of total national production.

*Health and leisure.* With free medicine available to all and a high standard of living (per capita consumption at three times the level of the turn of the century), health conditions are good. An increasing proportion of the Danes' income is spent on the enjoyment of leisure hours. The Danes are keen sportsmen. Football (soccer) and gymnastics are the most popular sports. There are an estimated 200,000 or more football players and 120,000 amateur gymnasts in the country. Other popular sports include sailing, rowing, skating, tennis, badminton, and swimming. All major provincial towns have their own sports hall, stadium, or ice rink.

Further education in technical schools and universities

Role of the Ombudsman

Popularity of sports

Denmark is among the richest nations in the world, and, although there are great differences in living conditions between Denmark proper and Greenland and the Faeroes, the emphasis on high public-sector expenditure at the expense of private consumption has tended to narrow the income range and prohibit extremes of wealth or poverty.

### CULTURAL LIFE

Just as Denmark is economically dependent on its more powerful neighbours, so too its culture reveals their influence. English, French, and German thought has often provided inspiration. German in particular has been a frequent channel, though not always a source, of ideas. It has been only in those periods when German intellectual life was stagnant, as, for example, under the Nazis, that cultural influences from Denmark's southern neighbour have dwindled.

**The arts.** *Literature.* There is an original Danish contribution to literature, however, and it dates back almost 1,500 years. Although the original texts produced during the great tribal migrations of the 5th century were lost, their contents are preserved in the Icelandic sagas, dating from around 1200, and in the great history *Gesta Danorum* by the Danish monk Saxo Grammaticus (died 1204). The richest source of medieval Danish literature is the folk ballad, its lyrical qualities stemming from the German influence; in the Reformation a homiletic literature flourished.

In the 18th century, Danish literature was dominated by Norwegian-born Ludvig Holberg, whose philosophic writings were inspired by John Locke and the French Encyclopaedists, his contemporary satire by Jonathan Swift and his comedy by Molière and the Italian commedia dell'arte. Another notable figure of the period was poet and hymn writer Thomas King.

Among the 19th-century writers were the religious philosopher Søren Kierkegaard; N.F.S. Grundtvig, who was the founder of the folk high school; the critic Georg Brandes; the lyrical novelist Jens Peter Jacobsen; and Hans Christian Andersen. All of these writers produced works valued by the world at large.

The Nobel Prize for Literature was awarded to the Danish novelist Henrik Pontoppidan in 1917 and, in 1944, to Johannes Vilhelm Jensen for his novel *Den lange rejse* (*The Long Journey*). Other 20th-century writers of note include story writer Karen Blixen (Isak Dinesen; 1885–1962); novelist Martin A. Hansen; and poet and novelist Klaus Rifbjerg.

From the late 1960s pornography was the one area of the Danish "literary" scene that fell under the spotlight of international notoriety. The laxity of Denmark's censorship laws, the subsequent increase in production of pornographic material, and the claimed drop in public interest and sex crimes gave the rest of the European world much matter for contemplation.

*The theatre.* The Danish theatre, like others in Europe, stemmed from medieval morality plays and court entertainments. The first Danish-speaking theatre was opened in Copenhagen in 1722 in Lille Grønnegade, followed in 1748 by the establishment of the Royal Theatre at Kongens Nytorv, which remained under court patronage for a century. In 1848 it was taken over by the state and is now administered by the Ministry for Cultural Affairs. An annex, the so-called New Stage, was built in 1931. These two theatres are subsidized by the state and produce drama, ballet, and opera.

Since World War II the number of private commercial theatres has been declining. In 1970 there were eight left in Copenhagen. The three large provincial towns of Århus, Odense, and Ålborg have theatres subsidized by the local authorities. Besides a relatively large number of classical and modern Danish plays, the theatrical repertoire includes much that is current in England, the United States, Germany, and France.

The Danish ballet goes back more than 200 years, but it is only through its youngest generation of dancers in the style of choreographer August Bournonville that it has become internationally famous as the Royal Danish

Ballet. An important contribution to its renown has been the regular annual Copenhagen Summer Festival held since 1950.

*Music.* Music in Denmark has been practiced since ancient times. Medieval sagas and chronicles tell of harp playing and horn blowing. Splendid relics of Bronze Age instruments have been found in the form of elaborate bronze lurs (trumpets of mammoth tusk shape). Denmark supports 10 symphony orchestras; two of the more important are the Danish Radio Symphony Orchestra and the Royal Orchestra. Musicians and singers are trained at the Royal Danish Conservatory in Copenhagen, at four other conservatories, and at the Opera Academy.

*Fine arts.* The Royal Danish Academy of Fine Arts was established in 1754 and has produced men of international repute, especially among its sculptors and architects. Among them are the sculptor Bertel Thorvaldsen and more recently the sculptor Robert Jacobsen and the architects Arne Jacobsen and Kaj Gottlob. Danish schools of arts and crafts have also produced talented young designers, and Danish industrial and handicraft design enjoys a high international reputation. Famous craft concerns include the Royal Copenhagen Porcelain Factory, Bing and Grøndahl, the glassworks Holmegård and Kastrup, and the furniture manufacturers Fritz Hansen Eftf.

*Communications.* The Danish press dates back to 1666. The guarantee of its freedom was secured in the 1849 constitution, and by 1914 each region had newspapers representing the four main political parties. A large number of these publications were forced into liquidation after World War II. In 1970 there were about 60 independent newspapers with a total circulation of nearly 2,000,000.

Radio Denmark, established in 1925, is an independent public institution exercising a monopoly on all radio and television broadcasting in Denmark. No private individuals own shares in the institution. There are three radio channels and one television channel covering the whole country and all owners of radios and television sets (248 per 1,000 in 1968) pay license fees to Radio Denmark.

### OUTLOOK AND PROSPECTS

The traditional dependence of Denmark's 5,000,000 people on foreign markets had, before the agreement (approved 1972) to take the nation into the EEC the following January, placed the nation in a somewhat cruel dilemma and pointedly underlined the inherent tension between its Nordic and European interests.

Though a member of NATO, Denmark has traditionally sought neutrality; and though a member of EFTA, it had for some time cast longing glances at the EEC. The change from its traditional agricultural base to an industrial one has given greater impetus to Denmark's search for new agricultural and industrial markets. Thus, its sponsorship of the ill-fated Nordic Economic Union (Nordek) and its anxiety to join the EEC were based largely on the need to diversify its outlets, to lessen the dependence of its agricultural exporters on Great Britain and that of its industrial exporters on Nordic neighbours such as Sweden.

It seemed that much of the 1970s would be devoted to working out these complex problems.

**BIBLIOGRAPHY.** *Denmark: An Official Handbook*, edited in cooperation with the Royal Danish Ministry of Foreign Affairs (1970), gives concise and accurate information about Denmark: its geography, history, institutions and occupations, science, art, and general culture. This book also contains a bibliography of 850 titles, covering all major publications and periodicals about the subjects. Other works particularly recommended are NIELS NIELSEN (ed.), *Atlas of Denmark*, 2 vol. (1949–62); V.E. KAARIS, *Do You Know Denmark?*, 12th rev. ed. (1968), Denmark in pictures with descriptive text in English and Danish; E.T. APPLETON, *Denmark* (1968), a tourist guide; JOHANNES BRONSTED, *Vikingerne* (1960; Eng. trans., *The Vikings*, 1965); PALLE LAURING, *A History of the Kingdom of Denmark*, 3rd ed. (1968); BENT FURSTNOW-SØRENSEN, *Social Conditions in Denmark*, 6 vol. (1968, revised periodically); COPENHAGEN. THE MINISTRY OF

HOUSING, *Housing in the Nordic Countries*, 2nd ed. (1968); and TOBIAS FABER, *The New Danish Architecture* (1968). *Facts About Denmark* (1969, revised periodically), provides a brief account of most aspects of Danish society. See also the *Statistisk Årbog* (annual), the statistical yearbook of Denmark, with English subtitles and summaries; the *Yearbook of Nordic Statistics*, edited by the Nordic Council; *Danish Journal* (quarterly), and the *Economic Survey of Denmark* (annual), both issued by the Royal Danish Ministry of Foreign Affairs; and *Monetary Review* (quarterly), issued by Danmarks National bank (text in English).

(A.M.SI.)

## Density Currents

Density currents are currents in liquids or gases that are kept in motion by the force of gravity acting upon relatively small differences in density. A density difference can exist between two fluids (or gases) or between different parts of the same fluid and is caused by a difference in temperature, salinity, or sediment concentration. Density currents in nature include large-scale ocean currents, currents in lakes and reservoirs that are entered by rivers, and currents in meteorological frontal systems (see WINDS AND STORMS). In each case that part of the fluid that is either colder, more saline, or contains more suspended sediment than the other will be more dense and under the effect of gravity will flow beneath the less dense fluid. A cold air mass will flow beneath a warm air mass when the two converge, and a river will sometimes plunge beneath the surface of a lake and flow along its bottom in accord with this principle. The term density current is not used, however, when the difference in densities involved is a very large one. A river, for example, contains water that is about 800 times as dense as the air above it, but the river is not termed a density current relative to the air.

Density currents in which the density difference is caused by suspended sediment are called turbidity currents. Small turbidity currents have been studied in the laboratory and have been observed directly in lakes. Indirect evidence suggests that very large-scale turbidity currents occur in ocean basins. These large currents are thought to be caused by the slumping of sediment that has piled up at the top of the continental slope, particularly at the heads of submarine canyons. Slumping of large masses of sediment creates a dense sediment-water mixture, or slurry, that then flows down the canyon to spread out over the ocean floor and deposit a layer of sand in deep water. Repeated deposition forms submarine fans, which are analogous to the alluvial fans found at the mouths of many river canyons. Sedimentary rocks that are thought to have originated from ancient turbidity currents are called turbidites and are common in the geological record.

Density currents are of considerable practical importance. Deposition of sediment from turbidity currents in lakes may lead to a rapid decrease of reservoir capacity. Industries discharging large volumes of hot or polluted water may create density currents that have many adverse effects on neighbouring human or animal communities. On the other hand, proper design and placing of sewage outlets in the deeper, cooler water below the warm surface layer of the sea may permit formation of a sewage deepwater mixture that will not rise to the surface because its density is greater than that of the surface waters.

Because of the practical importance of density currents many experimental studies of their properties have been undertaken. Wilhelm Schmidt, a Viennese meteorologist, first studied small saltwater currents in the laboratory in 1910 in an attempt to understand the movement of cold fronts. Much of the knowledge of the hydraulics of density currents, however, stems from more sophisticated experiments since 1950.

### HYDRAULICS OF DENSITY CURRENTS

If a dyed salt solution is released from a lock into a horizontal channel filled with pure water to the same depth as the lock, then the salt solution will flow beneath the

pure water because it is more dense, and the pure water will flow into the lock replacing the solution (Figure 1). A notable feature of such flows is the formation of a dis-

From B.J. Daly and W.E. Pracht, *Physics of Fluids*, vol. 11, no. 1 (1968), p. 23

Figure 1: Motion of fluid particles in a density current surge. The denser fluid is on the right and the flow begins when the partition between the denser and the lighter fluids is removed.

tinct head at the front of the density current. After the current has fully developed, the head has a depth or thickness ( $d_2$ ) about twice that of the current behind the head ( $d_1$ ). It has been shown both theoretically and experimentally that the velocity of the head,  $v$ , may be expressed in terms of the density of the overlying fluid,  $\rho$ , the density difference between the two fluids,  $\Delta\rho$ , and the acceleration due to gravity,  $g$ :

$$v = 0.7 \sqrt{\Delta\rho/\rho g d_2}.$$

Density current surges of this type may be created by the opening of river locks in estuaries or they may be brought about by catastrophic events in nature such as the slumping of an unstable mass of sediment down the continental slope.

If the density current is not a transient surge, then steady flow may be established. This type of flow has been studied by introducing a constant discharge of denser fluid at the upstream end of a tilted channel that is initially filled with lighter fluid. At first a head forms that is very similar in shape and behaviour to the head formed in density current surges. Behind the head, a thinner current is established that is steady in character, almost uniform in thickness, and has an average velocity,  $u$ . In small-scale laminar flows (nonturbulent flow, in which motion is best represented by parallel streamlines), the boundary between the denser and lighter fluids may be sharp and

Flow boundaries and mixing

planar, or waves may form and travel along the interface downstream. In large-scale turbulent flows (which are most common in nature), the boundary between the denser and lighter fluid is not sharp and distinct but is a zone of mixing between the two fluids. It has been established that in such a density current, below the velocity maximum, the velocity profile is similar to that observed in a river channel (see FLUVIAL PROCESSES). The exact nature of the profile will depend on the roughness of the bottom. In the part of the underflow above the velocity maximum, however, the velocity decreases due to mixing, in the same manner as at the boundary of a fluid jet, and the velocity profile is Gaussian in character. Above the zone of mixing, the lighter fluid is not at rest but is pulled along or entrained by the underflow (Figure 2).

Figure 2: Velocity and concentration profiles for a uniform, steady density underflow of thickness ( $d$ ). Concentration may be of salt or suspended sediment.

The degree of mixing that takes place at the interface can be related to the densimetric Froude number, a dimensionless parameter involving flow velocity and density, which may be expressed:

$$F = u / \sqrt{(\Delta\rho/\rho)gd},$$

in which  $u$  is average velocity of flow,  $d$  is depth, and  $\Delta\rho/\rho$  and  $g$  are as previously given. An alternative commonly used by meteorologists is the Richardson number,  $R_i$ , which also is dimensionless and is expressed

$$R_i = 1/F^2.$$

For a density current flowing down a slope, the Froude number depends mainly on the degree of slope. There is maximum mixing at the interface on a steep slope and very little mixing where the slope is slight (less than about half a degree). There is also some evidence that the degree of mixing depends on the scale of the flow, with mixing being smaller for large-scale flows. These results make it possible to understand how density currents can preserve their identity, with very little dissipation of the density difference by mixing, even for flows that travel very long distances.

The average velocity,  $u$ , of a uniform density current is given by an equation similar to that for rivers (see FLUVIAL PROCESSES):

$$u = C \sqrt{RS},$$

in which  $S$  is the slope,  $R$  is the hydraulic radius (approximately equal to the depth,  $d$ , for a wide current), and  $C$  is a coefficient that depends on the density contrast and a friction factor. The friction factor, in turn, depends not only on the roughness of the bottom but also on the degree of mixing at the upper interface, and therefore on the Froude number, or slope.

It has been postulated that there must be a condition for which the turbulence induced by the flow is just sufficient to maintain in suspension all of the sediment in a turbidity current, so that no sediment is deposited on or eroded from the bottom. This condition has been called auto-suspension, but the criteria for auto-suspension are not yet fully understood. Indirect evidence suggests, however,

that large turbidity currents can transport clay, silt, and fine sand on slight slopes for very long distances, so that the conditions of auto-suspension must be approached very closely in these flows.

By courtesy of R.G. Walker

Figure 3: Motion within the head of an experimental density current, showing characteristic shape of head, upward diverging flow, breaking away of eddies from the back of the head. Depth of water is about 30 centimetres.

Observation of tracer particles in experimental flows indicates that the pattern of flow in the head of a turbidity current is similar to that shown in Figure 3. The head of the current is a region of diverging flow, where upward components tend to sweep material off the bottom and circulate it around inside the head. It might be expected, therefore, that the head of the current is not a region of deposition of particles but, rather, a region in which there may be some erosion of the bottom, even in flows in which there is deposition of particles taking place behind the head. Based on experimental observations, this conclusion is consistent with structures observed in beds of sediment thought to have been deposited by natural turbidity currents.

The sediment in turbidity currents cannot be held in suspension indefinitely. It is deposited, even in fast, eroding currents, from the tail of the current, where the thickness and velocity of the current begin to diminish as the supply of suspended sediment from upstream is reduced. Moreover, the current itself must begin to decelerate as the bottom slope becomes reduced. The first sediment to be deposited on the sea bottom is the coarsest; and the grain size decreases upward, producing what is termed a graded bed. This grading is caused by the gradual decay of turbulent eddying, a decrease of velocity from the head to the tail of a given flow, and the transfer of the coarsest material to the head of the current during the early stages of a flow.

#### DENSITY CURRENTS IN LAKES AND RESERVOIRS

It was a Swiss engineer who first observed that where the glacial meltwaters of the Rhône River enter Lake Geneva, they are denser than the lake water because they are both cold and highly charged with fine-grained sediment (glacial flour). As a result, the river water does not mix with the lake water but plunges below the surface and flows to a depth of over 300 metres (about 1,000 feet) down a subaqueous channel that extends for ten kilometres (about six miles) down the front of the Rhône Delta. The channel has a depth below its rim of almost 60 metres and the rim has subaqueous natural levees, which rise over five metres above the surrounding part of the lake floor. Two hypotheses for the origin of the channel were first considered: that it was produced by building up of the sides by deposition or that it was produced by subaqueous erosion of the delta slope. A similar phenomenon was also described for the Rhine Delta in Lake Constance.

In 1935 the Hoover Dam was completed on the Colorado River in Nevada and Arizona, and Lake Mead began to form as the canyon was inundated upstream from the dam. In the first year of operation, when the reservoir was 110 to 145 kilometres (70 to 90 miles) long, it was observed that at three different periods turbid density currents formed at the head of the lake and flowed in the old river channel along the bottom of the lake all the way to the dam, where they were discharged through tunnels near the base of the dam. Analyses of the sediment and dissolved salts in the underflow at the dam indicated that

Findings  
at Lake  
Mead

very little mixing with the lake water had taken place, even over this great distance of travel. Records of turbidity levels above and below the dam showed that the density currents flowed through the reservoir in about one week.

Subsequently, the tunnels near the base of the dam were closed, but further investigations were carried out in the lake, including the measurement of temperature, suspended sediment, and velocity profiles near the bottom. From these surveys it was established that underflows were formed whenever the density of the inflow was greater than the density of the lower lake levels: density differences of as little as one part per thousand were sufficient. Underflow was almost continuous during the fall and winter, and was intermittent at other times. The downward plunge of the underflow could clearly be seen at the head of the lake, where it was marked by an accumulation of floating logs and debris at the convergence of the underflow and the reverse circulation, which was induced in the upper parts of the lake water. Most underflows did not travel the full length of the lake, presumably because of the loss of density due to the deposition of the coarser silt in suspension. Underflows that did travel through the lake carried only very fine sediment in suspension (over 90 percent of the sediment being finer than 20 microns or 0.02 millimetre, as determined after dispersion). Velocities of the underflow ranged from less than 9 centimetres per second (cm/sec) to more than 30 centimeters per second. Thickness of the underflows was generally only a few metres, so that the flows were restricted to the old submerged channel of the Colorado River. Density of the underflows was generally less than 1.05 grams per cubic centimetre (g/cc), and the contact with the clear water above was quite sharp. The slope of the bottom was about one to two per thousand.

Density currents in Le Sautet Reservoir on the Drac River, in France, arise from concentrations of about 0.01 to 0.05 grams per cubic centimetre suspended sediment. The currents are two to ten metres thick and flow at velocities of about 5 to 15 centimetres per second down slopes of about .01 or half a degree.

Tempera-  
ture con-  
trast

Density currents have been recorded and studied in many other reservoirs. Density currents caused by temperature differences have proved to be of economic importance in some reservoirs. Flow into reservoirs on the Cumberland and Clinch rivers in Tennessee is controlled from storage dams located upstream, which release cold water during the summer. This cold water forms density currents when it enters the reservoirs because of a temperature contrast of 15° C (59° F) or more. Structures have been designed which permit the diversion of the density underflow and preferential withdrawal of the denser water for use as a coolant in power plants.

Turbidity currents in lakes and reservoirs are of relatively small size and low density, travel at low velocities, and carry only fine-grained sediment in suspension. They are generated by inflow of muddy river water, and continue to flow over long periods of time, whereas most oceanic turbidity currents are probably transient phenomena generated by relatively short-lived episodes of submarine slumping.

#### DENSITY CURRENTS IN THE SEA

**Salinity and temperature currents.** The composition of seawater is remarkably constant, at least with respect to the relative proportions of the major dissolved salts. Locally, the concentration of salts may be changed by the discharge of large rivers, by melting of ice, or, more importantly, by evaporation of water from the sea surface. There are also large variations in temperature, particularly in the surface layer of the oceans.

These salinity and temperature variations produce stratification in the oceans (see OCEANS AND SEAS). Below the surface layer, which is disturbed by waves and is lighter than the deeper waters because it is warmer or less saline, the oceans are composed of layers of water that have distinctive chemical and physical characteristics, which move more or less independently of each other and which

do not lose their individuality by mixing even after they have flowed for hundreds of miles from their point of origin.

An example of this type of density current, or stratified flow, is provided by the water of the Mediterranean Sea as it flows through the Strait of Gibraltar out into the North Atlantic. Because the Mediterranean Sea is enclosed in a basin that is relatively small compared with the ocean basins and because it is located in a relatively arid climate, evaporation exceeds the supply of fresh water from rivers. The result is that the Mediterranean contains water that is both warmer and more saline than normal deep-sea water, the temperature ranging from 12.7 to 14.5° C (55 to 58° F) and the salinity from 38.4 to 39.0‰ (parts per thousand). Because of these characteristics, the Mediterranean water is considerably denser than the water in the upper parts of the North Atlantic, which has a salinity of about 36‰ and a temperature of about 13° C (55° F). The density contrast causes the lighter Atlantic water to flow into the Mediterranean in the upper part of the Strait of Gibraltar (down to a depth of about 200 metres) and the denser Mediterranean water to flow out into the Atlantic in the lower part of the strait (from about 200 metres to the top of the sill separating the Mediterranean from the Atlantic, at a depth of 320 metres). Because the strait is only 20 kilometres wide, both inflow and outflow achieve relatively high speeds. Near the surface the inflow may have speeds as high as two metres per second and the outflow reaches speeds of over one metre per second at a depth of about 275 metres. One result of the high current speeds in the strait is to cause a considerable amount of mixing, which reduces the salinity of the outflowing Mediterranean water to about 37‰. The outflowing water sinks to a depth of over 1,000 metres, where it encounters colder, denser Atlantic water. It then spreads out as a layer of more saline water between two Atlantic water masses and extends as far as the Azores before the salinity is reduced to about 35‰ by mixing. During World War II, submarines commonly used the salinity currents to traverse the Strait of Gibraltar with engines silent.

**Turbidity currents.** Density currents caused by suspended sediment concentrations in the oceans are relatively short-lived, transient phenomena. They occur at great depths and consequently are much more difficult to observe than turbidity currents in reservoirs. In fact, large scale turbidity underflows have never been directly observed in the oceans, and their very existence is somewhat hypothetical. There exists, nevertheless, much evidence that indicates that very large turbidity currents are formed in the present oceans and that, although their occurrence may be infrequent, they produce important physiographic effects.

The evidence for the present and past existence of turbidity currents in the oceans may be briefly summarized: (1) Telegraph cables have been broken in the deep sea in a sequence that indicates some disturbance at the bottom moving from shallow to deep water at speeds of the order of 10 to 40 knots (11 to 46 miles per hour). The trigger for this phenomenon is commonly, though not exclusively, an earthquake near the edge of the continental slope. The only disturbance that seems capable of being transmitted downslope at the required speed is a large turbidity current. The best known example of such a series of cable breaks took place in the North Atlantic following the 1929 earthquake under the Grand Banks of Newfoundland (Figure 4), but other examples have been described from the Magdalena River Delta (Colombia), the Congo Delta, the Mediterranean Sea north of Orléansville and south of the Straits of Messina, and Kandavu Passage, Fiji. (2) Cores taken from the sea bottom in the area downslope from cable breaks reveal layers of sand interbedded with normal deep-sea pelagic or hemipelagic oozes (sediments formed in the deep sea by quiet settling of fine particles). In the case of the cable breaks south of the Grand Banks, a large diameter core taken from the axis of a submarine canyon in the continental slope contained one centimetre (about ¼ inch) of gray

Strait of  
Gibraltar

Evidence  
for  
currents

Ocean floor  
sediments

clay underlain by at least 20 centimetres of gray pebble and cobble gravel. Cores farther south showed a graded layer, about one metre thick, of coarse silt and fine sand. The presence of these gravel and sand layers is consistent with the hypothesis that they were deposited by the turbidity current that broke the cables. (3) Coring has revealed layers of fine-grained sand or coarse silt at many other localities in the abyssal plains of the oceans. These layers are generally moderately well sorted and contain microfossils characteristic of shallow water that are also size sorted. In some cases the layers are laminated and arranged in a definite sequence (Figure 5). It is clear that the sand forming these layers has been moved down from shallow water, and in many cases the only plausible mechanism appears to be a turbidity current. (4) At the base of many submarine canyons there are very large submarine fans, large sea channels on the surfaces of many tens of kilometres and have depths of over a hundred metres and widths of a kilometre or more. Submarine levees are a prominent feature, and these project above the surrounding fan surface to elevations of 50 metres or more. The gross characteristics of such channels suggest that they were formed by a combination of erosion and deposition by turbidity currents.

Turbidites

(5) Thick deposits of interbedded graded sandstones and fine-grained shales are common in the geological record. In some cases there is good fossil evidence that the shales were deposited in relatively deep water, perhaps as much as several thousand metres deep. Relatively deepwater deposition is also suggested by the absence of sedimentary structures characteristic of shallow water. The interbedded sandstones, however, contain shallow-water fossils that are sorted by size, have a sharp basal contact with the shale below and a transitional contact with the shale above, and display a characteristic sequence of sedimentary structures (Figure 5). The structures include erosional marks made originally on the mud surface but now preserved as casts on the base of the sandstone bed (sole marks) and internal structures including some or all of the following: massive graded unit, parallel lamination, ripple cross-lamination or convolute lamination, and an upper unit of parallel lamination.

This combination of textural and structural features can be explained by deposition from a current that slightly erodes the bottom and then deposits sand that becomes finer grained as the velocity gradually wanes. The properties inferred from these ancient sandstone deposits are consistent with the properties of turbidity currents inferred from laboratory experiments.

In spite of the convincing nature of the evidence, there

Figure 5: Turbidity currents.

(Top) Ideal sequence of sedimentary structures deposited in a bed by a turbidity current. (Bottom) Radiograph of a turbidite off southern California showing sequence of sedimentary structures. are still some objections to the turbidity current hypothesis. Most geologists and oceanographers accept that such currents exist and that they are important agents of erosion and deposition, both in modern and ancient seas, but some believe that the turbidity current hypothesis has been overworked. Many geologists have suggested, for example, that large submarine canyons (*q.v.*) have been eroded by turbidity currents. Direct proof is lacking, however, and attempts to trigger turbidity flows by underwater detonation have thus far been unsuccessful.

Moreover, a growing body of evidence suggests that currents flowing parallel to submarine contours exist in many ocean basins. These bottom currents have been observed in a few cases, and velocities from 20 to 50 centimetres per second have been recorded. These currents can produce some of the features that previously had been attributed to turbidity current action.

Finally, nearly all features of sands that are produced by turbidity currents can be formed by shallow water action, such as fluvial processes (*q.v.*). Hence the problem of discriminating between deposits of turbidity currents and deposits of other current types is quite complex and requires a careful assessment of all lines of evidence in each case. Some ancient sandstones have been interpreted as "fluxoturbidites" because the sedimentary structures and other properties suggest a transporting agent intermediate between turbidity currents and large-scale slumping and sliding of sediment. Future studies will no doubt resolve many of the problems connected with turbidity current deposits and will provide further insight to the hydrodynamics of density flows and their possible economic utilization.

## Dentistry

Dentistry is that profession concerned with the prevention and treatment of oral disease, particularly disease of the teeth and supporting tissues. In addition to general practice, dentistry includes such specialties as oral surgery, prosthodontics, periodontics, orthodontics, pedodontics and public health. These specialties are defined and considered later in this article.

The article includes sections on the history of dentistry, dental education, the practice of dentistry, dental specialties, and dental auxiliaries.

International organizations

Present status of dentistry. Associations of dentists, dental journals, and dental schools now exist in almost every country of the world. The *Fédération Dentaire Internationale* (International Dental Federation) was founded in 1900 and has met annually except in times of war. It has sponsored international dental congresses that are planned to meet every five years. Other international organizations include the International Association for Dental Research (Association Internationale pour la Recherche Dentaire) and the Association pour les Recherches sur les Pasadentopathies (Association for Research into Periodontal Diseases), which was organized in 1932. *The International Dental Journal*, published by the *Fédération Dentaire Internationale*, was founded in 1950.

Within the general framework of the World Health Organization, which has now existed for about 25 years, the dental health program has progressed steadily from the beginning. A proposal for a joint review of stomatology (study of the structures, functions, and diseases of the mouth) and dental hygiene in collaboration with the International Dental Federation was made at the first World Health Assembly in 1948.

Between 1956 and 1961 the World Health Organization provided a number of short-term dental consultants to developing countries. The regional offices' dental health activities in the developing countries expanded, but the dental profession was not represented on their staff except in the regional office for the Americas, where a post of dental health officer was established in 1954. Between 1963 and 1967 a technical unit in the Division of Health Protection and Promotion was developed, a long-term program was set up, and new posts of dental epidemiologist and technical officer were established.

In 1963 dentistry was being practiced in 72 countries with a total population of 2,422,623,000. There were 371 dental schools, including 7 in Africa, 136 in the Americas, 59 in Asia, 129 in Europe, 33 in the Union of Soviet Socialist Republics and 7 in Oceania. These schools served a population of 6,530,000 per school and graduated 15,290 dentists. There were 432,237 practicing dentists with an average of 5,600 population per dentist. The disparity between the areas was as follows: in Africa, one dentist per 81,000 population; in the Americas, one dentist per 2,620; in Asia, one dentist per 17,000; in Europe, one dentist per 3,080; in the Union of Soviet Socialist Republics, one dentist per 3,900; in Oceania, one dentist per 3,160.

The prevalence of dental disease throughout much of the underdeveloped areas of the world, its interrelationship with general health, the paucity of dental manpower at the professional level, and the competing demands of other needs render the acceptance, training, and use of dental auxiliaries an urgent necessity.

Statistically valid dental health surveys of many countries do not exist, but scattered evidence from Thailand,

Jamaica, Guatemala, Indonesia, Kenya, and many other countries, indicates that dental caries, periodontal disease, and malocclusions are widespread, and cancers of the soft and supporting tissues of the mouth fairly frequent.

Certain organizations, including the World Health Organization and *Fédération Dentaire Internationale*, and countries including New Zealand and the United States offer direct and financial assistance to many developing countries in the development of health educational and dental care services. For example, New Zealand has been active over the past 14 years in providing developing countries with the benefit of its experience in the use of dental auxiliaries or what is commonly known as school dental nurses. Direct assistance is being provided in the development of other public-health dental services to Ceylon, Malaysia, Singapore, Brunei, Thailand, Indonesia, Hong Kong, and Papua New Guinea. A number of dentists from the aforementioned countries have had the opportunity of studying the New Zealand system; a sizeable number of school dental nurses (63 in 1966) have received their training, others have received advanced training, enabling them to assist the developing countries in the establishment of their own training facilities.

Dentistry in Latin America is developing at a steady pace. Certain countries have quite adequate systems of dental education, and some dental schools have excellent training facilities. Government still has a great deal to say in the control of dental education, including admission of students, but this situation is changing. The dental profession is beginning to become an autonomous health profession, as in Canada and the United States.

The history of dentistry. The foundations of scientific medicine were laid in the 16th and 17th centuries, the same centuries that saw the beginnings of a separate dental literature and a recognized specialization in the practice of dentistry.

In France during the early 1500s barbers treated teeth and performed almost all surgical procedures, although there was a Faculty of Medicine at the University of Paris at the time. During the century, surgeons were first licensed, and surgery began to pass out of the hands of the barbers, although they still continued to perform dental services. In England in 1544, Henry VIII granted a charter to the Barber-Surgeons' Company of England, to which women were admitted. During the same period some consideration was being given to the improvement of dental service. The first textbook in dentistry was published in Leipzig in 1530, and 50 years later students of dentistry were admitted to the University of France. By 1622 a number of men had been granted the title of surgeon-dentist, although the title was not fully established for a number of years after that. During the reign of Louis XIV, the surgeon-dentists formed a separate subdivision of the surgeons' guild and, the year after the subdivision was formed, it became law that those who wished to practice in the field of mouth surgery and artificial restoration had to pass prescribed examinations. At this time some women were permitted to practice dentistry in France, although the privilege was revoked during the mid-1700s.

In the 17th century in England dentistry was referred to as an independent specialty. The first English text on the subject of dentistry was published in 1685.

Publication of three highly significant textbooks occurred during the 18th century. The French dentist Pierre Fauchard's *Le Chirurgien Dentiste* ("The Surgeon Dentist") in 1728 put dental treatment on a more scientific plane than ever before and advocated a broader education for dentists. In 1756 a German dentist Philipp Pfaff's *Abhandlung von den Zahnen* ("Treatise on the Teeth") appeared, and in 1771 an anatomist and surgeon of England, John Hunter, who was giving lectures on dentistry, published *The Natural History of the Human Teeth*. Joseph Fox was appointed dental surgeon at Guy's Hospital in 1799, and at the same time lectures on dentistry were set up in Guy's and in a number of other areas.

No formal dental schools were established in England

Barbers as dentists

Early  
dental  
schools

until 1858, although dental hospitals had been established earlier. These dental hospitals were created as service centres for the poor. They were founded and supported by dentists. For the most part they were independent of medical schools and general hospitals. They did accept some students, however, who partly provided cheap labour to operate the hospital and whose fees were used to support the charitable work undertaken. The honorary dental surgeons were responsible for any teaching that was done. In 1858 the first dental school in the United Kingdom was established by the Odontological Society of London and the second school the following year by the College of Dentists of England. Both were private schools.

At about the same time the Royal College of Surgeons arranged to hold examinations for licensure for dental surgery. It remained the examining body for dentistry in Great Britain for about 20 years. In 1878 the first Dentists' Act in the United Kingdom was passed and the General Medical Council established a register of those qualified to hold the title of dental surgeon. The act did not, however, prohibit individuals without these qualifications from practicing. The General Medical Council also prescribed a curriculum for the training of dentists. It required two years of preceptorship to learn dental mechanics and three years in a medical school and dental hospital. An inspector of the examination procedures at the colleges in 1897 recommended that the one examination be replaced by three—in preliminary science and dental mechanics and a final examination. These recommendations were put into effect and remained without much alteration until 1922.

While schools were being established and standards for licensure created in England, rapid development had also been going on in North America. Dentistry was being practiced in the United States by the late 1790s, and the first textbooks appeared in the early 1800s. By 1834 dental services were being provided by three distinct classes of people. First, there were those who had qualified by a course of study in the principles of medicine and surgery. Second, there were individuals who had obtained a preparatory course of medical study and then commenced practicing dentistry without having studied the mechanics of dental operations. These people were held in comparative respect since in due course they did obtain some degree of skill in their operations, although they were criticized for not having obtained this skill before actually inflicting their services on the public. The third group included a great number of charlatans—anyone who decided he would like to practice dentistry. It is this group that brought dentistry into disrepute.

The first meeting of a dental society in the United States was held in 1834. Shortly thereafter two unsuccessful attempts to establish dental schools were made, the first in Kentucky and the second in New York City. The latter failed to get under way because of staff problems. No money was available at that time for salaries, and local dentists evidently felt that they could not spare time from their practice for teaching.

The first dental school in North America was established in Baltimore in 1840. Subsequently many other schools were started, many of which were operated privately or commercially. All of the early schools were separate from universities. The first, and for many years the only, school of dentistry in the United States associated with a university was opened at Harvard in 1867.

This was the era during which dentistry became organized in Canada. British schools had just started, and in the United States requirements for qualification and examination had only recently been drawn up; some standards for practice were being established and a number of schools begun.

The first dental act in Canada was passed by the legislature of the Province of Ontario in 1868. This act incorporated the Royal College of Dental Surgeons of Ontario and gave it the dual function of teaching and licensing. License requirements stipulated five years of practice in a dental office for registration. Except for a simple act that was passed in Alabama in 1841, the Ontario Act was

the first law respecting dental practice on this continent. The regulations for registration were fairly simple by today's standards, but with the large number of itinerant dentists, who had no formal training whatever, moving back and forth across the Canadian-American border at that time, even this five-year requirement proved useful.

**Dental education.** *Predental programs.* There are 72 countries in the world in which undergraduate training in dentistry is available. Of these, 34 require predental training prior to acceptance into a school of dentistry. The predental training is in addition to primary and secondary education, which usually takes from 10 to 12 years. The required number of years in predental education varies from one to seven (such countries as Portugal, Italy, Spain, and Austria require from five to seven years of medical education before entering dentistry). In the two-year predental course training usually includes such studies as biology, chemistry, physics, and mathematics. Certain faculties of dentistry in Canada and the United States require a bachelor's degree in arts or science as a prerequisite for admission into a dental faculty.

*Dental school and training.* After the two-year predental course, training consists of four years in a faculty of dentistry to qualify as a doctor of dental surgery (D.D.S.) or doctor of dental medicine (D.M.D.). The program of studies during the four-year course includes the following biological sciences: human anatomy, biochemistry, bacteriology, histology, pathology, pharmacology, microbiology, and physiology, upon which the succeeding studies of the theory and techniques of dental practice are based. Studies required with respect to dental practice include restorative dentistry, prosthetics, orthodontics, surgery, preventive dentistry, medicine, dental public health, pedodontics, periodontics, radiology, clinical practice, and anesthesia.

#### THE PRACTICE OF DENTISTRY

**Licensure requirements.** The practice of dentistry is now well controlled, and in all countries of the world in which dentistry is practiced there is a licensing requirement. Licensing authority may be government, national dental organizations, state boards, or provincial boards. Some examples follow.

*Canada.* In Canada each province has its own licensing authority. This can be a college such as the Royal College of Dental Surgeons of Ontario, or an association, such as the Manitoba Dental Association. There is also a national authority, the Dental Examining Board.

The university degree (doctor of dental surgery or doctor of dental medicine) does not in itself entitle the holder to practice but is an academic qualification for presentation to the licensing board under whose jurisdiction the holder desires to obtain a license to practice. The regulations of the provincial licensing boards vary but usually require an examination for licensing.

In some provinces the provincial board accepts the university examination results of the final year for licensing graduates of a dental school in that province. The national Dental Examining Board conducts an examination for persons who have been graduated prior to 1971 from approved dental schools, and who are Canadian citizens but does not require an examination for graduates of such schools in 1971 or later. The certificate granted by the board is valid for licensing in all provinces except one, where a clinical examination is required.

The national board still requires examinations of graduates of schools outside the United States and Canada.

*United States.* Licensing authority in the United States is vested in state boards of dental examiners. Thirty-three states require United States citizenship as a prerequisite; 12 states and the District of Columbia require the declaration of intent to become a citizen or the first papers as a requirement for admission to the dental licensure examination; six states and Puerto Rico do not require citizenship for such admission.

Nationals with foreign diplomas may be admitted to practice if their diplomas were issued by a school approved by the American Dental Association and if they pass the state licensure examination.

Early  
dentistry  
in the  
United  
States

Require-  
ments in  
Canada

Require-  
ments in  
the United  
States and  
Britain

*The United Kingdom.* Permission to practice is granted by the General Dental Council to those holding (1) a degree or diploma in dentistry or dental surgery conferred in Great Britain or Ireland, (2) a degree or diploma in dentistry or dental surgery granted elsewhere that has been recognized by the General Dental Council, or (3) a degree or diploma approved by the General Dental Council provided that these graduates have passed the statutory examination written under arrangements made by the General Dental Council.

*Union of Soviet Socialist Republics.* The status of the dentist of the type called stomatologist is on a par with that of the physician in the Union of Soviet Socialist Republics. He receives training equal to that of the physician and, in addition, is trained in operative dentistry, crown and bridge dentistry, prosthetics, exodontia, and anesthesia, both general and local. The stomatologist attends professional school for five years. His degree entitles him to operate on the hard as well as all soft tissues in the mouth and throat.

The stomatologist receives his education free of charge and is, in fact, paid to go to school. His income is sufficient to maintain himself and his family during his entire school year.

At present there are three classifications of dentists in the Soviet Union, known as the two-, three- and five-year dentists. The two-year dentist is a dental technician who studies for two years beyond high school, after which he is eligible to work in a dental laboratory. He cannot treat patients. The three-year dentist can treat patients, but his work is limited to restorative, prosthetics, and prophylactic dentistry. The five-year dentist is the stomatologist.

*Federal Republic of Germany.* Dentists must hold a dental surgeon's diploma, which authorizes private practice without further examination. They must be registered by the local dental boards and by the health authorities. Persons holding foreign qualifications may obtain registration without taking a further examination by presentation and approval of their credentials.

*Italy.* The diploma in dentistry, which allows the use of the title of Specialist in Diseases of the Mouth, Teeth, and Jaws, constitutes license to practice. Holders of the diploma of Doctor of Medicine have passed examinations in dentistry and for this reason may also practice dentistry but do not have the specialist title.

Citizens of foreign countries, both those who have qualified in Italy and those who hold foreign degrees or diplomas, are authorized to practice if the relevant reciprocity exists between Italy and their country of origin.

*Japan.* Persons wishing to practice dentistry or dental surgery must be recognized by the Ministry of Health and Welfare (Dental Health Section, Medical Affairs Bureau, Ministry of Health and Welfare, Japanese Government). Applicants for registration must pass the national examination for dentists and obtain license to practice from the Ministry of Health and Welfare. These requirements must also be fulfilled by registered medical practitioners wishing to practice dentistry, by Japanese citizens, and by foreigners who have qualified in Japan.

Western medicine was first introduced into Japan from The Netherlands about the middle of the 17th century. In the 18th century German medicine was introduced, and from then on Japan made rapid and significant progress in the field of medicine. The introduction of modern American dentistry into Japan is thought to have occurred about 1903. Since then Japanese dentistry has been mainly patterned after that of the United States.

The first dental schools were established in the 1890s, and Japanese dentistry progressed thereafter independently, in co-operation with Japanese general medicine, though dentistry has never been considered a branch of medicine. Japanese dentistry has achieved success through its own basic research in clinical science techniques.

**Types of practice.** *Private practice.* In such countries as Canada, the United States, the United Kingdom, France, the Federal Republic of Germany, and Australia, dentists in private practice constitute the vast majority of

all licensed dentists. It is expected that this type of practice will continue to be the prevalent type in most countries of the world, although dentists may shift even further to group practice or make more extensive use of auxiliaries.

In such countries as the Union of Soviet Socialist Republics dentists are employed by the government, and there is little private practice.

Dental practice has changed markedly since 1920. It has changed significantly in the last quarter century, without a concurrent change in the basic dental curriculum as developed in 1935. Dental procedures shifted from the repair of a few teeth and extraction of teeth for the relief of pain in 1920 to an era of disease prevention in 1967. Dental practice has changed in the larger centres from the isolated private practice common in 1920 to a complex grouping of professional persons in a central location.

In Canada, for example, especially in the western provinces, group practices are developing whereby patients are examined on their first visit by one dentist who then allocates the patient to a suitable dentist within the group.

Extensive use is being made of dental hygienists, who receive the patient from the examining dentist. This type of practice is conducted like any other business with a business manager and competent clerical staff. There are sufficient dental hygienists to provide services such as preventive procedures, prophylaxis, scaling, X-rays, and dental-health education, and there is a supporting group of dental assistants, enabling the practice to run as a competent, smooth-working operation.

Another development that has occurred in dental-health-care services and could completely change the present concept of dental practice is the extension of the duties currently carried out by dental auxiliaries. New Zealand pioneered in the field with the creation of the dental nurse, an auxiliary trained to provide dental care for children and works without dental supervision. The United Kingdom has also developed the "dental auxiliary," who performs somewhat similar duties but under closer supervision.

In Canada and the United States pilot projects are being conducted to test the feasibility of using dental auxiliaries for certain operative procedures to increase productivity, quality, and general service to the public.

France may be taken as an example of the development of the practice of dentistry in continental Europe. The practice of dentistry in France as a *chirurgien dentiste* has, since 1892, been restricted to persons (1) of French nationality, (2) who hold a state diploma, and (3) who are registered with the Order of Dentists. The Order of Dentists is responsible for registration and discipline but is not concerned with dental education, which is controlled by the state through the common state diploma.

There are two types of dentists practicing in France, the *chirurgien dentiste* and the stomatologist. Stomatologists are practitioners who possess a diploma in medicine together with either the diploma in dental surgery or a certificate of special studies (two years) in stomatology. Specialization within the field of dentistry is not encouraged. There are no rules laid down for it nor are there any special courses or diplomas or titles.

*Hospital dental practice.* Three types of dental care are normally carried out in the hospital environment: (1) clinical procedures normally provided in a dental office, for ambulatory inpatients and outpatients; (2) bedside care for persons admitted for medical reasons; and (3) inpatient care for patients admitted to the hospital for purely dental conditions.

Dentists may treat patients in hospitals either privately, on a fee-for-service basis, or under some form of government program, such as the National Health Service in the United Kingdom or the Provincial Medicare Plan (surgery only) in Canada. Hospital dental services have for years been an integral part of dental-health care and dental education in the United Kingdom, and such services by hospital dental departments are expanding steadily in the United States and Canada.

Shift from individual to group practice

Requirements in West Germany, Italy, and Japan

Hospital dental departments are normally established in the same manner as any other hospital department and are headed by a chief of service, who has the same status as other chiefs of service within the hospital. In some instances, the chief of the dental department may be responsible to the chief of surgery. There are two types of hospital dental departments—one that is established in a teaching hospital, and the other in a general hospital with no teaching component. In the teaching hospital the dental department is associated with a faculty of dentistry and forms an integral part of the undergraduate curriculum and, if they exist, of the graduate and postgraduate programs. One of the chief purposes of hospital dental departments is to make available the service of consultants to other hospital departments and general practitioners. This service is most highly developed in teaching hospitals. Usually certain general dental treatment is provided for inpatients and outpatients.

Under the present regulations of the National Medicare Bill in Canada necessary surgical services must be performed in a hospital in order to qualify for payment, to the dentist, under the plan. Surgical services which are performed in a private office must be paid for personally by the patient. It follows that many more surgical services are now being performed in a hospital facility than ever before. This regulation can bring about the development of an ever-increasing number of hospital dental departments. In Canada in order for a hospital dental department to be recognized, it must be accredited by the Canadian Dental Association. A similar situation is in effect in the United States, where the 176 oral-surgery training programs are assessed and, if up to standard, approved by the American Dental Association's Council on Education.

Hospital dental services or departments are most prevalent in western Europe and the Union of Soviet Socialist Republics.

**Public health practice.** This section is concerned with governmentally supported health education and disease prevention, as in Canada and the United States. The provision of dental care for all, as in the Soviet Union, is discussed in the section *Governmental practice*.

Generally typical of dental public-health practice in Canada and in many areas of the United States is the program carried on in the Province of Ontario. In the early 1970s about 20 dentists trained in public health, about 70 hygienists, and numerous dental assistants carried out a preventive and educational program basically concerned with examination of children, recording basic dental conditions, and providing dental-health education. Cards sent home to parents advise them of the dental conditions of their child and stress any need for dental care. The care itself, except for families receiving social assistance, is provided by the family dentist. In addition, a detailed examination of a random sample of the children is carried out in conjunction with the screening to provide the data to develop statistical reports, required for a yearly evaluation of the program. The program also includes the application of fluorides to the teeth and, in certain areas, special efforts to encourage brushing. Dental-health education is carried out directly in the schools. The cooperation and active aid of the school principal and teachers is solicited in an attempt to have dental health stressed throughout the school year. A dental-health manual is made available to the teachers; pamphlets and posters are used extensively. Outside the school system hygienists regularly attend dental child-health conferences or well baby clinics, organized by the local health unit, where the importance of dental health is discussed with the mothers of young children. Lectures are also given to teachers' colleges and to any organization or group interested in the health of children.

**Military practice.** Most countries of the world provide dental-care service for their armed forces. The organization of such a service varies extensively. In Canada the Royal Canadian Dental Corps has the same status as the Royal Canadian Medical Corps, with a brigadier-general as the director. Military service for dentists in the United States is under the United States Public Health Service,

the chief of service being an assistant surgeon general. In the United Kingdom dental care is provided by three separate dental branches—Navy, Army, and Air Force.

**Governmental practice.** In certain countries, such as the Union of Soviet Socialist Republics, all dentists are employed by the government. In certain other countries dentists are required to work a stated number of years for the government before being considered private practitioners of the type known in Canada and the United States. This requirement may be based on the fulfillment of an obligation for government financial support during undergraduate training, or there may be a government regulation that all dental graduates must work for the state a prescribed number of years. Another example of government practice is in the United Kingdom, where dentists are employed by local authorities to provide dental care under the Maternal and Child Welfare Services and the School Dental Service.

The employment of dentists on a salary basis for the general practice of dentistry is not extensive in the United States or Canada. At the national level it may be the provision of dental care for eligible Indians and Eskimos, care provided for war veterans, or inmates of penitentiaries. At a municipal level, dentists may be employed in a school dental service. Dentists in both Canada and the United States commonly agree to provide service for families who qualify for social assistance. They are paid on a fee-for-service basis; the fee schedule is usually set, normally after consultation with the profession, by the agency responsible for the social-service plan.

Government medical care was introduced in Japan in the late 1930s. This system was expanded until by 1962 almost the entire population was covered. There are limitations to the services offered by government medical care, as in orthodontics or in preventive dentistry.

**Dental specialties and subspecialties.** A specialist may be defined as a person who, because of graduate or postgraduate training, possesses special knowledge and skills of an expert nature, by reason of which he is capable of rendering a service above the average. The term therefore implies not only the qualities developed through limiting of practice but in addition the academic qualifications linking this special field with all related studies.

In most countries that recognize specialties in dentistry, the specialist is limited to practice in the specialty and must not carry out the practice of general dentistry. Where the specialty is thus limited the general dentist may refer patients, and a specialist's practice is mainly on a referral basis. In certain provinces in Canada specialists may now conduct a general practice.

**Orthodontics.** Orthodontics has for its objective the prevention and correction of malocclusion of the teeth and associated dentofacial incongruities. The orthodontist is commonly thought of as a dentist who specializes in straightening crooked teeth.

Orthodontics has been in existence since the days of the early Egyptians, but the more elaborate methods of treatment involving the use of bands and removable appliances have become prominent only since the beginning of the 20th century. The United States gave great impetus to this development and orthodontics was recognized as a specialty with the formation of the American Society of Orthodontists in 1900.

In practice the orthodontist may deal directly or indirectly with the alleviation or elimination of any one or more of the following: impairment of ability to chew; susceptibility to dental caries; periodontal disease (disease in the structures around the teeth) and other disturbances of the oral tissues; an unaesthetic facial appearance; dentofacial abnormalities of genetic, congenital, and environmental origin, including those resulting from surgery; shifted teeth and abnormal jaw relationship (these the orthodontist may correct prior to the construction of partial dentures or any other dental restorations); abnormal respiratory habits; and abnormal mental attitudes in relation to dentofacial aesthetics.

Currently the demand for this service has extended from the child patient to the mature adult, although human bone responds to tooth movement best in the person

The status of the specialist

Ontario program

under 18, and it is logical that the child will benefit from treatment more than the adult. In general, oral health and physical appearance are the two most important reasons for undertaking a course of orthodontic care. There is a great need for enlarged training facilities in this field at the postgraduate level.

Training in orthodontics is provided by a two-year postgraduate course open only to dentists who have had two years of general practice. A diploma is awarded upon completion of the course.

*Pedodontics.* Pedodontics, analogous to pediatrics in medicine, is concerned with the dental care of children and adolescents.

Much of the routine of practice is centred about caries (tooth decay) control and involves the use of fluoride and dietary and hygienic instruction. The need to influence tooth positions presents the next most frequently encountered problem. The correction of incipient abnormalities in tooth alignment may obviate the necessity for lengthy treatment. Many pedodontists use growth-influencing techniques to correct jaw alignments. A working knowledge of children's behaviour patterns, patience, a knowledge of childhood physical and mental diseases and their oral ramifications, and a facility in the hospital environment round out the qualifications of the pedodontist. The postgraduate course in pedodontics is of two years' duration, leading to a diploma in pedodontics.

*Periodontics.* Periodontics is concerned with the prevention, diagnosis, and treatment of diseases of the periodontal tissues—the tissues that surround and support the teeth. These tissues consist mainly of the gums and the jaw bones and their related contiguous structures.

The most prevalent periodontal disease is periodontitis, commonly called pyorrhea, an inflammatory condition usually produced by local irritants. Periodontitis, if untreated, destroys the periodontal tissues and is a major cause for the loss of teeth in adults.

The advances of periodontics in the past quarter century have been mostly in techniques of treatment. It is believed that bacterial plaque, a hard layer of substances rich in bacteria that adheres to the teeth, is the factor responsible for most destruction of the gums and the tissues surrounding the teeth. Periodontists advocate removal of such plaque in a treated or healthy mouth by a specific regimen of controlled hygiene.

*Prosthodontics.* Prosthodontics is concerned with the restoration and maintenance of oral function, comfort, appearance, and health by the replacement of missing teeth and contiguous tissues with artificial substitutes, or prostheses.

There are three main branches of the specialty, concerned, respectively, with removable prostheses, fixed prostheses, and maxillofacial prostheses. Maxillofacial prostheses are supplied to persons who have suffered congenital, traumatic, or surgical defects of the mouth, jaws, or associated facial structures.

A prosthodontist must be competent to make necessary judgments concerning, among other matters, social and psychological complications, nutritional imbalances, appropriate medications, the diagnosis and early detection of oral cancer, the diagnosis and treatment of many varieties of oral lesions, and the restoration of a normal appearance and of a normal ability to chew one's food and to speak. The substitutes for missing teeth should function in harmony with the remaining teeth to prevent their premature loss.

The proper fitting of oral prostheses requires a detailed knowledge of the anatomy of the head and neck, of the physiology of the neuromuscular system, and of the science of occlusion and jaw movements. It also requires skill in planning, mouth preparation, impression making, registration of jaw relations, try-in procedures, placement of the prostheses, and follow-up care.

The usual course in prosthodontics is of two years' duration, leads to a master's degree in prosthodontics, and is restricted to candidates holding a D.D.S. or equivalent with good standing from an approved institution.

*Oral pathology.* Oral pathology is the study of the causes, processes, and effects of oral disease, together

with the resultant alterations of oral structure and functions. The oral pathologist need not treat a disease directly but through knowledge of the disease guides his associates to more effective therapy.

*Oral surgery.* Oral surgery deals with the diagnosis and with the surgery required by the diseases, injuries, and defects of the human jaws and associated structures.

Both dentists and physicians refer a wide variety of special dental problems to the oral surgeon. These may include the removal of impacted and infected teeth, the treatment of cysts, tumours, lesions, and infections of the mouth and jaws. In addition there are the more complex problems such as jaw and facial injuries, cleft palate, and cleft lip.

The program leading to the diploma in oral surgery is of three years' duration after the candidate has qualified as a dentist at an accredited faculty of dentistry.

*Public health dentistry.* Dental public health is recognized as a specialty in three Canadian provinces and is expected to be recognized by the Canadian Dental Association in the near future. In the United States and in Canada postgraduate courses in dental public health of one-year's duration lead to a master's degree in public health, in the United States, and a diploma in dental public health in Canada. The American Dental Association recognizes dental public health as a specialty if the holder of the master's degree proceeds to a further year of study in training and passes the examination of the American Board of Dental Public Health. Training in dental public health is available in the United Kingdom, but the specialty is not emphasized to the same degree in the rest of the world.

#### ANCILLARY DENTAL FIELDS

*Dental hygienists.* The hygienist is becoming an important figure in the campaign to reduce tooth decay and to improve physical well-being by promoting better care of the mouth.

The prevention of oral disease through education and treatment is the chief function of hygienists. The specific duties and services that they are allowed to perform depend on the bylaws of the provincial licensing bodies, the requirements of the dental offices in which they are employed, and the aims and objectives of the public-health programs in which they are engaged. At all times hygienists work under the effective supervision of a qualified dentist, and they are not permitted to establish their own practice.

Hygienists employed in dental offices remove deposits and stains from the patient's teeth and apply fluorides. In addition, they observe and record conditions of decay and disease for the dentist's information. Further duties may include the taking of X-ray photographs of parts of the mouth, which the hygienist develops and mounts. Another function of the hygienist is to promote dental health by advising on diet and nutrition and encouraging oral hygiene.

Hygienists employed by educational authorities assist school dentists by examining children's teeth and performing other duties as required. They may also visit classrooms to explain the importance of oral hygiene and to give instruction in the proper care of the teeth and gums.

In hospitals they perform mainly the same duties as for private practitioners.

In Canada five universities offer a two-year diploma course in dental hygiene. Plans are also proceeding to establish a four-year course in dental hygiene leading to a bachelor of science degree. In the United States diploma courses in dental hygiene are available at the university or junior college level. Programs are also available whereby a holder of a certificate in dental hygiene may proceed to a bachelor's or master's degree. In the United Kingdom and certain other European countries schools of dental hygiene have been established; these have a two-year course with entrance requirements below university level.

*Dental nurses and dental auxiliaries.* In New Zealand an auxiliary known as the dental nurse has been carrying

Dental  
care for  
children

Branches  
of prosthodontics

Chief  
function of  
hygienists

out a dental-care program for children for a number of years. The dental nurse receives minimal supervision but has proven to be equipped to provide a quite adequate dental-care program for children up to 13 years of age. The dental nurse is trained for two years in a special course for dental nurses with entrance requirements below the university level. There is a similar auxiliary in the United Kingdom who, after two years of training, provides, under more direct supervision than the New Zealand dental nurse, a dental-care program for children. The training is again a two-year course with entrance requirements below university level.

**Dental assistants.** The majority of dentists in private practice employ one or more dental assistants to provide such services as reception of patients, the keeping of records and accounts, chairside assistance for the dentist while he is treating patients, general upkeep of the office, developing of dental X-rays, and sterilization of instruments. The general trend is toward a greater utilization of auxiliary services.

**Dental technicians and dental mechanics.** The dental technicians, also called dental mechanics, make artificial crowns, bridges, dentures, and other dental appliances according to dentists' specifications. Work orders, accompanied by models or impressions of patients' mouths, state the exact requirements for each particular job. In large laboratories the various stages of manufacture are often divided and the technicians employed may specialize. Sometimes partially skilled persons are hired to work in limited aspects of production on an assembly line basis. (R.A.Co.)

**BIBLIOGRAPHY.** Dental literature is extensive and international. Of some 1,958 dental periodicals that have existed since 1839, when the first dental periodical appeared, 770, of all sizes and kinds in at least 29 languages, were extant in the early 1970s. The United States accounts for 511 of these. The *Index to Dental Literature* (quarterly and cumulative) offers the most comprehensive coverage of the world dental literature. *Oral Research Abstracts* (monthly), and the *Advances* series in caries, oral surgery, orthodontics, pedodontics, periodontics, and prosthodontics derived from it, are comprehensive compilations of abstracts of current articles related to all phases of dentistry published in hundreds of journals throughout the world. *Dental Abstracts* (monthly) is a more selective compilation intended for general distribution but based on the same body of literature. *The Year Book of Dentistry* is an annual review of selected articles in the literature published since 1936. To select a bibliography from the tremendous number of works published on this subject is difficult. The bibliography that follows attempts to be representative only and to show the various facets of dentistry. PIERRE FAUCHARD, *Le Chirurgien Dentiste*, 2nd ed. (1746; Eng. trans., *The Surgeon Dentist*, 1946), is the all-time dental classic. H.M. GOLDMAN et al. (eds.), *Current Therapy in Dentistry*, 4 vol. (1964-70), correlates the latest research information with a reasonable immediacy in the practice of dentistry. LESTER W. BURKET, *Oral Medicine: Diagnosis and Treatment*, 6th ed. (1971); and DAVID F. MITCHELL, S. MILES STANDISH, and THOMAS B. FAST, *Oral Diagnosis/Oral Medicine*, 2nd ed. (1971), expose the foundation upon which the dental curriculum and dental practice rest. G.V. BLACK, *Operative Dentistry*, 9th ed., 2 vol. (1955), is a long-time classic; while B.H. BELL and D.A. GRAINGER, *Basic Operative Dentistry Procedures*, 2nd ed. (1971), provides a fine example of a general recent work. H.M. GOLDMAN and D.W. COHEN, *Periodontal Therapy*, 4th ed. (1968); and IRVING GLICKMAN, *Clinical Periodontology*, 4th ed. (1972), are the standard works on the subject. A.J. LAZARE (ed.), *Periodontal Therapy: A Review* (1967), reprints a number of classics that have appeared in the periodical literature. KURT H. THOMA, *Oral Surgery*, 5th ed., 2 vol. (1969), is probably the most comprehensive book on this subject; other outstanding works are W. HARRY ARCHER, *Oral Surgery*, 4th ed. (1966); and GUSTAVE O. KRUGER (ed.), *Textbook of Oral Surgery*, 2nd ed. (1968). NORMAN L. ROWE and H.C. KILLEY, *Fractures of the Facial Skeleton*, 2nd ed. (1968), is a classic text on the specific area of facial trauma. ROY G. ELLIS and KEITH W. DAVEY, *The Classification and Treatment of Injuries to the Teeth of Children*, 5th ed. (1970); DAVID B. LAW, THOMPSON M. LEWIS, and JOHN M. DAVIS, *An Atlas of Pedodontics* (1969); and RALPH E. MACDONALD, *Dentistry for the Child and Adolescent* (1969), are fine representatives of the numerous works in this area. S.N. BHASKAR, *Synopsis of Oral Pathology*, 3rd ed. (1969); W.G. SHAFER, M.K. HINE, and B.M. LEVY, *A Textbook of Oral*

*Pathology*, 2nd ed. (1963); KURT H. THOMA, *Thoma's Oral Pathology*, 6th ed. (1970); and R.W. TIECKE, *Oral Pathology* (1965), give excellent coverage of the field of oral pathology. On preventive dentistry, see J.L. BERNIER and J.C. MUHLER, *Improving Dental Practice Through Preventive Measures*, 2nd ed. (1970); and A.E. NIZEL, *Nutrition in Preventive Dentistry: Science and Practice* (1972). T.M. GRABER (ed.), *Current Orthodontic Concepts and Techniques* (1969); P.R. BEGG and P.C. KESLING, *Begg Orthodontic Theory and Technique*, 2nd ed. (1971); and C.P. ADAMS, *The Design and Construction of Removable Orthodontic Appliances*, 4th ed. (1970), are recent texts in the extensive orthodontic literature. L.I. GROSSMAN, *Endodontic Practice*, 7th ed. (1970); SAMUEL SELTZER, *Endodontology: Biologic considerations in Endodontic Procedures* (1971); and R.F. SOMMER, F.D. OSTRANDER, and M.C. CROWLEY, *Clinical Endodontics*, 3rd ed. (1966), are excellent standard texts in this field. F.M. MCCARTHY, *Emergencies in Dental Practice*, 2nd ed. (1972), outlines ways of preventing, recognizing, and treating emergency problems that occur in every dental practice. Excellent standard texts in prosthodontics are R.W. DYKEMA, D.M. CUNNINGHAM, and J.F. JOHNSTON, *Modern Practice in Removable Partial Prosthodontics* (1969); C.O. BOUCHER (ed.), *Swenson's Complete Dentures*, 6th ed. (1970); S.D. TYLMAN, *Theory and Practice of Crown and Fixed Partial Prosthodontics*, 6th ed. (1970); and J.M. BUCHMAN, *An Atlas of Complete Denture Prosthesis* (1970). E.W. SKINNER and R.W. PHILLIPS, *The Science of Dental Materials*, 6th ed. (1967), is now a classic work with a noteworthy companion, F.A. PEYTON and ROBERT G. CRAIG, *Restorative Dental Materials* (1971). H. SICHER and E.L. DUBRUL, *Oral Anatomy*, 5th ed. (1970); I. SCHOUR, *Noyes' Oral Histology and Embryology*, 8th ed. (1960); and H. SICHER and S.N. BHASKAR (eds.), *Orban's Oral Histology and Embryology*, rev. 7th ed. (1972), are excellent representatives of their fields. VINCENZO GUERINI, *A History of Dentistry* (1909), has not been superseded in English although closely followed by B.W. WEINBERGER, *An Introduction to the History of Dentistry* (1948). M.D.K. BRENNER, *The Story of Dentistry*, 3rd ed. (1954), is written in a more popular vein. B.W. WEINBERGER, *Orthodontics* (1926); and JOHN ENNIS, *The Story of the Federation Dentaire Internationale, 1900-1962* (1967), are two examples of more specialized histories in dentistry; while C. PROSKAUER and F.H. WITT, *Bildgeschichte der Zahnheilkunde* (1962), is an excellent pictorial history with descriptive material in five languages. J.M. DUNNING, *Principles of Dental Public Health*, 2nd ed. (1970); W.O. YOUNG and D.K. STRIFFLER, *The Dentist, His Practice, and His Community*, 2nd ed. (1969); R.K. STINAFF, *Dental Practice Administration* (1968); and S.H. WILLIG, *Legal Considerations in Dentistry* (1971), provide examples of the relationship between the dentist and society. G. GUSTAFSON, *Forensic Odontology* (1966); and T. FURUHATA and K. YAMAMOTO, *Forensic Odontology* (1967), illustrate the developing field of dental identification. C.O. BOUCHER (ed.), *Current Clinical Dental Terminology* (1963), is the present standard dictionary, though it should be supplemented by more recent glossaries for various areas in dentistry, such as oral surgery and periodontics.

## Descartes, René

René Descartes, French mathematician and philosopher, was the first to liberate philosophical thought from the confines of tradition-bound Scholasticism. Hegel and many others have called him the father of modern philosophy. He is the proponent of a thoroughgoing dualistic philosophy. Descartes radically divides the mind between the mind, perceived as indubitable in his famous statement, "I think, therefore I am," and the body (or matter in general), for which he was the first to provide a comprehensive explanation on the basis of purely mechanistic principles.

**Early life.** Descartes was born on March 31, 1596, in the village of La Haye (now called La Haye-Descartes) in the province of Touraine. His father was a counsellor in another province, Brittany, at the local parliament of Rennes; in modern terms he was a lawyer as well as a judge. Both he and his wife belonged to the same social class, the *noblesse de robe*, below the nobility itself, yet above the bourgeoisie, able to maintain its independence and privileges because the functions of lawyers were largely hereditary.

René was the fourth child of the marriage. His mother was to die a year later in childbirth. Little is known about his childhood. He was probably brought up by his grandmother and only saw his father, who remarried, during

Descartes, oil painting by Frans Hals, 1649. In the Louvre, Paris.

Cliché Musées Nationaux, Paris

the six months of the year when the courts at Rennes were on vacation. A delicate child, he also had a nurse to whom he was devoted and to whom he paid a pension up to the day of his death. His apparent want of robustness later allowed him indulgent exceptions to the rules in his collegiate days, but from his 20th year, Descartes enjoyed fairly good health. Based chiefly on the character and actions of the mature man, biographers have drawn the picture of a solitary and exceptionally intelligent boy. Undoubtedly, introspective detachment dominated his relations with his closest family. He did not, for instance, attend the marriage of either his brother or sister, nor was he present at his father's death.

All other evidence indicates a normal and happy upbringing. It is known that his father was amused by the precocious curiosity of his small son who plied him with questions about "the reasons of things and their causes" and that he called him "his little philosopher." Some 30 years later, Joachim Descartes was to declare that, of all his children, René was the only one who had given him cause for discontent and spoke scornfully of him as "only fit to be bound in calf-skin." It was the contemporary comment of a father, disappointed that his son had relinquished the quasi noble profession of law and taken up the socially doubtful status of a writer.

In 1604 Joachim Descartes made a decision about the education of René, then eight years old, that had a crucial effect on his development. The Jesuits had opened that very year a college, the Royal College, endowed by Henry IV, in the small town of La Flèche, north of Touraine. In the charge of these very competent educators, La Flèche was to become, in Descartes's own words, "one of the most celebrated schools of Europe." René was sent there and confided to the special care of Father Charlet, a distant relative. Charlet was a distinguished scholar, who soon became rector of the college; Descartes was to call him "his second father." The effect of the approximately ten years that Descartes spent at La Flèche can be estimated from his reactions in his works, in which he relates some of his debts as well as doubts, his gratitude as well as dissatisfaction.

The syllabus of studies followed the pattern laid down for all Jesuit schools. The first five years were devoted to the humanities (that is, the study of Latin and Greek and the classical authors), the French language with prose and verse composition, music, acting, and the accepted accomplishments of a gentleman—riding and fencing. Descartes certainly acquired a remarkable ability to write a fluent and clear prose, both in Latin and French. He later composed a short work on the art of fencing (he fought a duel) and also a small treatise on music. He read the classics and poetry with pleasure during his school days, but this was a passing interest that he dropped and later

condemned as wasteful. His character and natural bent were essentially opposed to those of the learned scholar, in the sense of one who merely acquires handed-down knowledge.

Philosophy was the generic name given to the three final years of the curriculum. The first year consisted of logic, based on the syllogistic system derived from Aristotle, and moral philosophy, which consisted of a detailed analysis of another Aristotelian work, the *Nicomachean Ethics*. The study of physics, mathematics, and astronomy filled the second year, but the science then taught was little more than the theories of Aristotle, elaborated and developed by medieval commentators. Only in mathematics and astronomy did his teachers impart some of the more recent advances. The third year consisted of metaphysics, chiefly the philosophy of Thomas Aquinas, and the glosses of Jesuit commentators.

On these vital formative years, one can compose, from the sources available, two school reports. The first, from his professors, would note him as intelligent, hard working and well behaved, introspective and disinclined to be competitive, with a marked inclination and ability for mathematics. Because of his delicate health, he was allowed to stay long in bed in the mornings and even to miss some lectures, but this did not affect his progress, as he was capable of working alone and inclined to "meditate." The second report, according to Descartes's own account in later years, was quite different. By his graduation ("admitted into the ranks of the learned"), he was bewildered and utterly disappointed by what he had been taught. The subtle dialectical arguments and inconclusive and contradictory theories of his textbooks had left him with nothing but doubts and uncertainties. Only in his mathematical studies had he found some consolation "because of the self-evidence of its reasonings." The inquisitive child, the "little philosopher," was not only dissatisfied with his own baggage of knowledge, but he equally rejected the erudite lumber of his textbooks. Instead of considering himself a learned man, he thought of himself as ignorant, because he had acquired no certainty about anything. All he had was his deep religious faith as a Catholic, which he retained to his dying day, and a resolute, passionate desire to discover the truth or some truths—if this was possible.

Less explicitly perhaps than his own actual account, the young Descartes made two major decisions that were to dictate the subsequent pattern of his life, a strange pattern of nomadic restlessness contrasted with periods of almost hermitic solitude. The first decision was "to abandon the study of letters": he rejected a life of erudition and scholarship. Instead he would "gain experience" in the study of "the book of the world": he would travel and observe. The second was "to make studies within myself" and thus attempt to fulfill "his extreme desire to distinguish truth from falsity": these words formulate the vocation of Descartes, the adult philosopher.

In 1616, after two years of study, Descartes took his degree in law at the University of Poitiers, as his elder brother had done before him. But henceforth he no longer followed the path traditional in his family. Without entirely breaking all familial ties, his visits became infrequent and short during the rest of his life. One visit, in 1623, was important, for it was then that he sold the properties in Poitou inherited from his mother, including a small estate at Perron. Descartes, in fact, was known in his family as M. du Perron, but he detested the title. He invested the monies from the sale in a form of bonds. With this moderate wealth he was thus able to live the comfortable life of a gentleman of leisure whose tastes and needs were simple.

Travel and study were the plan of the dissatisfied and restless student. Both of these objectives were to be fulfilled in an unusual and intricate way. It is possible to simplify the complicated story, because his travels between 1618 and 1628 are sparsely documented and little is known of his studies and thoughts, except for a few evocative incidents. The period of intensive study, or rather of writing and publishing, would then be allotted

Rejection  
of  
textbooks

Jesuit  
education

to the period 1628–1649, when Descartes lived in Holland, although even there he was to change his abode 18 times. In making such a simplification, it should be noted that during his travels he was also studying "the book of the world" and even making notes and beginning drafts of his future works. During his stay in Holland, but to a much lesser extent, he also travelled, returning to France and paying visits to his friends.

Military service. In 1618 Descartes went to Holland and joined, as an unpaid officer, the army of Maurice of Nassau, prince of Orange, who at that moment was deploying his troops against the Spanish forces, which were trying to recover Spain's richest European province. It was a quite conventional move on Descartes's part, since military service and the practical study of warfare were complementary to a gentleman's education. That Descartes, a Catholic, should volunteer to serve in the army of a Protestant prince was in no way exceptional: there were many young Frenchmen in William's army. Eighteen months later, by contrast, Descartes was, in the early stages of the Thirty Years' War, in the army of the Catholic Duke of Bavaria, Maximilian, who was taking the field against Frederick V, the Elector Palatine and Protestant king of Bohemia. Frederick was to lose his throne in 1620, after the decisive battle of the White Mountain, near Prague. His daughter, Princess Elizabeth, became in 1643 one of the philosopher's closest friends and correspondents. It is improbable that Descartes ever participated in any real fighting. The camp life bored him: there was, in his own words, "too much idleness and dissipation." He continued to observe and to make notes, and above all, his fascination for the mathematical sciences was given impetus by a close friendship with the Dutch philosopher, doctor, and physicist Isaac Beeckman, who was then a professor at a nearby town. Beeckman was struck by the mathematical bent and ability of the young French officer who alone, so we are told, was able to solve in a short time an elaborate mathematical puzzle. The friendship was to continue for 20 years, with some upsets. Beeckman, at least, brought his young friend up-to-date with many recent developments in mathematics, including the work of the French mathematician Franciscus Vieta, who by using letters as symbols for constant quantities and for unknowns in an equation was one of the pioneers of modern algebra. An important part of the fame of Descartes was that in a treatise he applied algebraic formulation to geometrical problems, the basic concept of modern analytic geometry. This treatise, part of his first published work (*The Discourse on Method*, 1637), attempts to deal with abstract general qualities, in their relations and orders, instead of groups of geometric figures and separate theorems: it is essentially a method of simplification and unification.

Formulation of a rational scheme of knowledge. The meeting with Beeckman renewed Descartes's enthusiasm to pursue his chosen path. He noted, in March 1619, the possibility, which he hardly yet believed himself, "of a completely new science which would be capable of solving in a general manner all problems which could be proposed in all the quantitative fields, whether continuous or numerical." He had begun to envisage the possibility of a universal method to solve problems of a mathematical nature. Toward the end of the same year this possibility was to become even more far-reaching in its application.

Leaving the army of the Prince of Orange, Descartes travelled to Denmark, Danzig, Poland, and Germany and then joined the Bavarian Army in its winter quarters, near Ulm. According to his own account, he lived in a well-heated room, slept ten hours nightly, "occupying myself with my own thoughts." According to his first biographer, Adrien Baillet, who had Descartes's own detailed account before him, it was there on November 10, 1619, that Descartes "was filled with enthusiasm, he discovered the foundations of the Admirable Science, and at the same time his vocation was revealed to him in a dream." The notes in fact spoke of three separate parts of a dream. The symbolism, interpretation, and import

of this dream episode have been the controversial subject of many articles and even books, as its cause has been variously attributed to overwork, indigestion, fever, or a mystical crisis. Whatever the meaning or cause, Descartes definitely had the idea, or even vision, of some kind of unitary universal science that would link all possible human knowledge together into an all-embracing wisdom. The mystical element, completely out of context with the almost ruthless reasonableness of Descartes's character, had certainly the psychological effect of confirming his intent to pursue his search for truth and of convincing him of his ultimate success. This conviction may even account for the arrogance with which he defended impatiently his published works against his critics.

The ardent belief about his real vocation in life, the conviction that he had discovered the key to final success in his search for certainty and true knowledge, did not outwardly alter the vagabond pattern of his life in the next seven years. In 1621, he was—for the last time—experimenting with the military life as an officer in the Imperial Army in Hungary. More travels in Germany and Holland followed and then, in 1622, a stay in France, in Brittany, and Paris. From the autumn of 1623 to the spring of 1625, he wandered around Italy, returning thence to France, where he lived mainly in Paris. There he made new friends among the savants and renewed old acquaintances, especially with Father Marin Mersenne, a great polymath, who was to act as his trusted correspondent and adviser in future years. Mersenne was in touch with all of the famous intellectuals in Europe and was thus in a unique position to introduce the work of Descartes to them and report back their comments and criticisms. Discussions with friends, private study, and reflection were the pattern of Descartes's life in Paris. One noteworthy incident is reported. At the house of the Papal Nuncio, after someone expounded "a new philosophy," Descartes in a succinct argumentation, based on reasoning akin to the mathematical methods of proof, confounded and refuted his opponent. All present were deeply impressed: the name of the young philosopher began to be repeated. Cardinal de Bérulle, the leader of the Catholic reaction against Calvinism, who was present, sent for him and insisted that Descartes had the duty to utilize his talents to the full and complete the design that he had outlined to his audience.

Philosophical works. This advice corresponded exactly with Descartes's innermost feelings. But to carry out this work, he needed peace and quiet, and Paris was too distracting. In the autumn of 1628 he went for a few months to the north of France and then to Holland, where he was to live, except for short absences, until 1649. The travels as such were over: it was time to put in writing the results of his experience of "the book of the world" and of his own meditations. If in Holland he was to change his place of residence almost yearly, except for the last five years at Egmond-Binnen, this apparent restlessness enabled him to enjoy periods of solitary work and yet, but only at his own choice, to keep contact with congenial friends by visits and correspondence. Descartes was not, despite appearances, antisocial but merely, for the sake of his comfort and work, opposed to an indiscriminate social life. As his fame in Europe grew, this frequent moving around was to prove a prudent precaution. From 1628 onward, Descartes composed the works that made his name famous in his own lifetime, but he also kept in touch with old and new friends in a voluminous correspondence, of which a great deal is extant. All these show abundantly that the years of travel had also been years of intensive study and reflection and that Descartes had accumulated a wealth of ideas, which he was ready to put in writing.

In 1701 a posthumous collection of Descartes's works was published, which contained a treatise on methodology called "Rules for the Direction of the Mind" (abbreviated generally as *Regulae*). This treatise, incomplete and roughly drafted with repetitions and inconsistencies, was composed by Descartes during the winter months of 1629 and the following year. Possibly never intended

Posthumous publication of *Regulae*

Mathematics: coordinate geometry

Vision of a unitary universal science

for publication, it may have been used by Descartes as a kind of intellectual balance sheet for future reference. The new method itself was expounded in simple terms, with less mathematical emphasis, in Descartes's first published work on philosophy, the *Discourse on Method*, in 1637. But the fundamental novelty of his approach was already sketched in the first rules of the *Regulae*. There he asserts that all knowledge is of one kind only, since its acquisition is entirely dependent on the use of the human mind. He rejects the Scholastic view that there is a distinction between various kinds of knowledge based on the diversity of knowable objects. To him the mind, the "power of knowing," is always the same, whatever the objects to which it is applied. Well applied, it can attain truth and certainty; misapplied it will fall into error or doubt. All sane men have this natural ability of discerning the true from the false, a "natural light of reason." Only by discovering the nature and limits of this power can one determine the correct way of using this ability. This implies in the first instance the elimination of any factors that may constitute a hindrance, such as preconceived opinions of any kind, and secondly the strict practice of an orderly method, such as is found, for instance, in the mathematical sciences. Thus one must start from self-evident data, which is known to be clearly and distinctly true, and make doubly sure that every step in the deductive progress from the data is itself self-evident. The syllogistic reasoning, on which Scholastic philosophy was based, must be rejected as useless for the discovery of truth. The unity of all the sciences and the analytic method of reasoning were the germinal ideas that had been fermenting in Descartes's mind during his years of travel: they are the basis of the Cartesian revolution in science and philosophy.

The *Regulae* did not suppose naively that anybody and everybody can discover new truths merely by following a set of rules. Apart from inborn mental ability, which is obviously unequal among persons, a long apprenticeship of self-training was indispensable to acquire what Descartes called sagacity and perspicacity. This stage, Descartes considered, with justification, he had reached. For four years, from 1630 onward, he spent his time mainly in the study of different sciences, which, unified by his new method, would lead to a universal scheme of knowledge. This study, which nowadays would be regarded as research into the mathematical and physical sciences, was carried out, occasionally with a friend, often in letters to other savants, especially Father Mersenne, but mainly alone in different houses in Holland. The research covered many fields: optics, the nature of light, the laws of refraction; meteorology, the nature and structure of material bodies, air, water, earth; mathematics, especially geometry; and the physiological and anatomical sciences, in which he engaged in dissection of different organs, obtaining his specimens from local slaughterhouses, inventing the term of embryogeny for what is now called embryology.

It was Descartes's ambition to publish a comprehensive work, which he had entitled *Le Monde* (*The World*). By 1633, he had almost completed his draft. Then, in a letter from Mersenne, he learned that the astronomer Galileo had been condemned in Rome by the Catholic Church for his advocacy of the Copernican system. From Beeckman he borrowed Galileo's book, in which he recognized many of his own conclusions, particularly his endorsement of the Copernican theory of the earth's movement around the sun. Although he risked no physical danger in Holland, he was sufficiently prudent not to publish his work: he did not even send the manuscript to Mersenne.

This decision left him unshaken in his own self-certainty about the truth of his conclusions, and later criticism was never to affect his convictions. But Descartes realized that his scientific work was a set of interconnected propositions based on a unitary strand of premises and argumentation and therefore stood or fell as a whole. He therefore undertook, in the next three years, to demonstrate that his new method, and some instances of its applica-

tion, was essentially based on a firm philosophical foundation, on a metaphysical doctrine that he believed was also acceptable to the Catholic theologians, including his former teachers, the Jesuits.

At Leyden, in 1637, Descartes published anonymously a volume entitled: *Discours de la méthode* (1637; *Discourse on Method*). It was, quite exceptionally, written in French, when Latin was the common language of all learned works. He had salvaged three sections of his ill-fated *World* and composed, in fact very hastily, as an introduction, a semi-autobiographical account of his method and philosophical doctrine: the efficacy of his methodological principles was demonstrated by successful examples of the application of these principles to three scientific problems. These essays as such are of interest mainly to historians of science, who point out that the first essay, on optics, formulated the law of refraction; the second, attempting a scientific explanation of the weather, included an explanation of the rainbow; the third, in Descartes's view, and correctly so, the clearest vindication of his method, introduced the famous Cartesian coordinates (so named by the philosopher G.W. Leibniz) and, using algebraic notation to deal with geometrical problems, laid the foundations of modern analytic geometry.

"**Discourse on Method.**" The introduction, merely a seventh of the original volume in number of pages, is the famous *Discourse on Method*, the most widely read of his works. Simply and elegantly written, the polished brevity of its text tends to conceal the difficulties of Descartes's doctrine, which philosophers, from its publication to the present day, have more often criticized—or even rejected—than praised. Yet, in praise or blame, it is generally agreed that the *Discourse* has radically influenced the trend of modern philosophical thought. It is a philosophical classic: it introduced a new mentality and, of course, new problems.

The opening phrases of the *Discourse* have become a commonplace:

Good sense is, of all things in the world, the most equally shared: for everyone thinks himself so well provided with it that even those who are most difficult to satisfy in every other way, do not usually desire more of it than they already have.

The courteous irony hides the fundamental assertion that the human mind is basically sound and the only means of attaining truth. The first three sections of the *Discourse* tell how the author was deceived by the knowledge he acquired from education and books. His answer was twofold: to pull down the house before rebuilding it and, as expressed in the first four rules of method, here condensed from the *Regulae*, "never to accept anything as true which I did not clearly and distinctly see to be so." Descartes thus implies the rejection of all accepted ideas and opinions, the determination to doubt until convinced of the contrary by self-evident facts. In the *Discourse*, written in French for the general public, conventional moral principles are provisionally excepted since life must go on during this radical revision. The second rule is an instruction to analyze the problem to be solved. Once cleared of its prejudices, the mind, using the example set by mathematicians, "must divide each of the difficulties under examination into as many parts as possible"; that is, discover what is relevant to the problem and reduce it as far as possible to its simplest data. The third rule is "to conduct my thoughts in order, beginning with objects that are the simplest and easiest to know and so proceed, gradually, to knowledge of the more complex." The fourth rule is a warning to recapitulate the "chains of reasoning" to be certain that there are no omissions. These simple rules are not to be considered a mere automatic formula; they are to be regarded as a mental discipline, based on the example of mathematical practice.

To find the self-evident datum on which to build his science, Descartes, in the fourth section of the *Discourse*, outlined what he called the metaphysical foundations of his doctrine, since the science of the physical world must, in his view, be based on the absolute certainty of the

Publica-  
tion of the

on *Method*

"I think,  
therefore  
I am"

real world. The method of doubt is universally applied; the arguments of the Sceptics pushed to their limits, the uncertain evidence of the senses rejected, even the existence of my own body doubted as a possible illusion, a dream. But I who doubt, I who am deceived, at least while I doubt, I must exist, and, as doubting is thinking, it is indubitable that while I think, I am. (The Latin formulation is *Cogito, ergo sum*, "I think, therefore I am.") From this cornerstone of self-evident certainty, Descartes derived all philosophical propositions. The idea of God, he argued, implies the real existence of God. No finite or imperfect being like man could have produced the idea of an infinite or perfect being—hence only God could have revealed it to man. Inasmuch as the body can be so easily doubted, whereas the existence of the mind cannot be doubted, it is clear that the two are radically distinct. The body, as such, is subject to mechanistic explanation. Animals, being without rational minds, are strictly to be considered as machines, automata subject to instinctive reflexes. The universe consists of two different substances: minds, or thinking substance, and matter, the latter being basically quantitative, theoretically explicable in scientific laws and mathematical formulas. Only in man are the two joined in a substantial union.

Despite the anonymity of the *Discourse*, the author's name and theories were soon known in the learned circles of Europe. It was the scientific essays that attracted attention and provoked much controversy, among others with the French mathematician Pierre de Fermat. But there were also enthusiastic disciples who spread the Cartesian doctrine in the Dutch universities, provoking again bitter opposition. As far as was possible, except for a few visits and letters, from 1638 to 1640, Descartes was busy writing in the small town of Santpoort. He was not entirely alone. With him was a Dutch servant girl, Helen, who had borne him a daughter in 1635. The child, to his bitter grief, died in 1640.

"**Meditations.**" The work he was writing was in Latin, a more elaborate development of the fourth part of the *Discourse*, his metaphysical doctrine. The final manuscript was sent to Mersenne, who was entrusted with the task of getting the formal approval of the Sorbonne and also "the opinions of the learned." Mersenne collected these critical opinions, including those of the English philosopher Thomas Hobbes and the French mathematician and philosopher Pierre Gassendi, and forwarded them to Descartes, who drafted replies, somewhat irritably and reluctantly. Ultimately, in 1640, the text, with the objections and replies, was published in Paris. The work is known as the *Meditations*: it was translated into French in 1647. Despite differences of detail and some omissions, the doctrines expounded in the *Discourse* and in the *Meditations* are essentially similar. The most striking difference is that the methodological doubt is pushed even further, to include the hypothesis of an omnipotent and malignant demon who could make everything that one thinks to exist into nothing more than one great cosmic deception. The answer is the same: at least I, who am deceived, exist. The *Meditations*, constructed as a single argument, each link dependent on the previous in an elaborate "order of reasons," is the major exposition of Descartes's philosophical doctrine.

If the publication of the *Meditations* brought Descartes renown as one of the most famous philosophers, it also involved him, directly or indirectly, in bitter controversies carrying theological overtones. In Holland, the president of the University of Utrecht accused him of atheism, and Descartes was, in fact, condemned by the local authorities in 1642 and again in 1643. The intervention of the French ambassador prevented worse consequences, and in 1645 a decree of the University of Utrecht created an armistice by forbidding the publication of any works for or against the Cartesian doctrine. At Leiden, in 1647, another attack, including an accusation of Pelagianism—the belief that the will is equally free to choose to do good and to do evil—produced a similar decree of neutral censorship. In France, the Jesuits, with a few exceptions

among the younger fathers, had given a cool reception to the work of their former pupil. In the midst of these disputes, Descartes began work on a more formalized account of his whole thought, philosophical and scientific, which he thought might receive support in Catholic circles, especially among the Jesuits. But his hope was vain: eventually the Jesuits officially rejected Cartesianism, and his works were placed on the *Index*, the Catholic Church's list of forbidden books.

**Other works.** *Principles of Philosophy* appeared in Amsterdam in 1644, while Descartes was on a short visit to France: it was translated from Latin into French in 1647. His philosophical doctrines are formally repeated in the first part. The other three parts are a comprehensive attempt to give a logical account of all natural phenomena in one single system of mechanical principles, through the whole field of physics, chemistry, and physiology. Historically, the importance of these three parts lies in the total rejection of all "spiritual" or qualitative notions in scientific explanation, as well as the refusal to include teleological or purposive causes. On the positive side, the expressed determination to explain all physical phenomena in mechanical terms and to relate these terms to geometrical ideas and the use of hypotheses to aid generalizations led the way to the modern approach to scientific theory. On the other hand, Descartes's own views were often wrong or quickly made obsolete.

Descartes visited Paris again in 1647 and 1648, always for a few months at a time. He met the French mathematician and theologian Blaise Pascal on the first visit and suggested to him the famous experiment proving that air exerts pressure on all objects. The later visit enabled him to meet some of his famous contemporaries, and critics, Gassendi and Hobbes and, of course, Mersenne, who was to die soon. The political situation was unsettled, and Descartes detested the noise and bustle of the city as well as its social life: he longed for "the innocence of the desert." He seemed to feel an urgency to continue his studies: he had already begun to rewrite another part of the *World*, a treatise on physiology, *On Man (de Homine)*. He returned to Holland at the end of the summer.

The *Principles* were dedicated to Princess Elizabeth of Bohemia. They had met in 1643, and an affectionate friendship had developed between Descartes and the intelligent young woman. Visits were rare, but there was a voluminous correspondence, with a documentary value scarcely less than that of the correspondence with Mersenne and the French theologian Antoine Arnauld. It ranged over a varied field, from geometry to political science, from medicine to metaphysics, but concerned itself especially with the problems of the interaction of body and soul. In dealing with this last problem, both in a practical and theoretical manner, Descartes unsystematically sketched the outlines of his views on ethics. He summarized these views in a small book, printed in 1649, the *Treatise on the Passions*. Descartes described his approach to the subject not as that of a moral philosopher but of a physician. The mind, in many of its activities, is dependent on the body: a passion (*i.e.*, that which is felt) is often an action in the body. Physiologically, Descartes placed the centre of interaction in the pineal gland, a small body centrally located at the base of the brain. The body itself, the most perfect of machines, works by what is now called conditioned reflexes, but the effects of these automatic instincts and desires can be controlled or modified by the mind, by rational willpower. Bodily hygiene is important, but there is equally a need of a mental hygiene, which is based on true knowledge of the psychophysiological factors that condition behaviour. But it is also based on the training of the "good sense" and the acquiring of "wisdom," which depends upon the knowledge of the truths of metaphysics, which in turn include knowledge of God; that is to say, the supreme Good. Descartes thus concludes that moral activity is based on a true knowledge of the relative value of things.

A manuscript copy of the *Passions* had gone to Queen Christina of Sweden, who since 1647, through the French

*Principles  
of Philosophy*

*Treatise  
on the  
Passions*

Impact of  
*Meditations*

ambassador, had obtained the works of Descartes and begun to write to him. An ambitious patron of the arts and collector of learned men for her court, she was anxious to meet "the celebrated M. Descartes." Despite pressing invitations, even the sending of a naval vessel, Descartes was extremely loath to leave Egmond and offered excuses of all kinds, suggesting that it was sufficient to read his books. Finally he accepted and, as he wrote, "born in the gardens of Touraine," he went to the "land of bears between rock and ice," arriving in Stockholm in October 1649. He was welcomed with great ceremony and was impressed by the eagerness and energy of the 23-year-old queen; he was less impressed by her devotion to classical studies and her ignorance in philosophy. Excused from most court ceremonial, except from writing French verses for a ballet, his chief obligation was to instruct the queen in philosophy. Tutorial time was at five in the morning. In the rigorous climate, where, in Descartes's words, "men's thoughts freeze during the winter months," his health deteriorated. On February 1, 1650, he caught a chill that developed into pneumonia. Ten days later, after receiving the last sacraments, he died in the confession "of the faith of his nurse."

Death in  
Sweden

In Protestant Sweden he was, as a Catholic, buried in the cemetery reserved for unbaptized children. In 1667, his remains were conveyed to Paris and buried in the church of St. Genevieve-du-Mont. Disinterred during the French Revolution for burial among the illustrious French thinkers in the Panthéon, his tomb is now in the church of St. Germain-des-Près.

#### MAJOR WORKS

*Compendium musicae*, 1618; *Regulae ad Directionem Ingenii*, written 1628, published posthumously 1701; *Traité du monde ou de la lumière*, written 1633; *Discours de la méthode . . .*, 1637; *Meditationes de prima philosophia*, . . . 1st ed. 1641; *Meditationes de prima philosophia*, . . . 2nd ed. 1642; *Principia philosophiae*, 1644; *Les passions de l'âme*, 1649.

For translations into English of the above works and others, see below *Bibliography*.

**BIBLIOGRAPHY.** GREGOR SEBBA, *Bibliographia Cartesiana: A Critical Guide to the Descartes Literature, 1800–1960* (1964), is a readable bibliography covering biographical and doctrinal books and articles. On Descartes's life, the basic sources are his own works and letters. The classical edition is *Oeuvres de Descartes* (1897–1913) in 12 volumes, the last of which is a biography by CHARLES ADAM, still the most comprehensive modern work. The letters were republished, to include many from Constantyn Huygens, in *Descartes: Correspondence*, 8 vol. by CHARLES ADAM and GÉRARD MILHAUD (1936–63). The other major source is ADRIEN BAILLET, *La Vie de Monsieur Descartes*, 2 vol. (1691). Despite apologetic bias, Baillet is still a unique source of contemporary information. An abridged version of 1692 (reprinted in 1950) is more readable.

In the English language, E.S. HALDANE, *Descartes: His Life and Times* (1905) and J.R. VROOMAN, *René Descartes: A Biography* (1970) are the only full biographies. As to the works, many English translations of the *Discourse* exist: E.S. HALDANE and G.R.T. ROSS, *The Philosophical Works of Descartes* (1931–34), still in print, includes the *Regulae*, the *Discourse*, the *Meditations*, with the *Objections* and *Replies* and the *Principles*. Another edition, published by Great Books of the Western World (1952), excludes the *Principles*, but includes the *Geometry*. Another translation by N. KEMP SMITH (1952) includes the three works, *Regulae*, *Discourse*, and *Meditations*, as well as sections of the *Dioptric*, and the *Passions*. There are also English translations in R.M. EATON, *Descartes: Selections* (1927); LOWELL BARR, *Essential Works of Descartes* (1961); and A. KENNY (ed.), *Descartes: Philosophical Letters* (1970). More modern in style is the translation by E. ANSCOMBE and P.T. GEACH, *Descartes: Philosophical Writings* (1954). Most readers would find the Haldane-Ross edition (now in paperback) quite adequate.

Recent particular studies of Descartes include: L.J. BECK, *The Metaphysics of Descartes: A Study of the Meditations* (1965); F. BROADIE, *An Approach to Descartes' Meditations* (1970); and HG. FRANKFURT, *Demons, Dreamers, and Madmen* (1970), all of which cover the philosophical doctrine. Collected essays on Descartes are contained in A. SESONSKE and B.N. FLEMING (eds.), *Meta-meditations* (1965); WILLIS DONEY (ed.), *Descartes* (1967); and *Cartesian Essays*, ed. by MAGNUS and WILBUR (1969). The best introduction to Descartes is to read the *Discourse on Method*.

## Deserts

Deserts are arid areas of sparse to absent vegetation and very low population density that comprise more than one-third of the Earth's land surface, if semi-arid regions are included. Approximately 5 percent of the Earth's land area can be categorized as extremely arid; the regions involved are the central Sahara and the Namib Desert areas of Africa, the coastal areas of Ethiopia and Yemen (Ṣan'ā') near the southern end of the Red Sea, the Rub' al-Khali in Saudi Arabia, the Takla Makan in Central Asia, the Atacama Desert of Peru and Chile, and parts of the southwestern United States and northern Mexico. Despite the fact that the desert environment exists on parts of each of the continents, the nature and diversity of deserts are not widely understood.

The term desert is commonly associated with extremes of heat, the near absence of life, and the adventures of a few of the better known explorers and travellers of the past, such as H. St. John Philby, who traversed the Arabian Desert in a remarkable effort in the 1930s. These generalizations are not too wide of the mark, but the popular view of deserts as predominantly sandy areas that have existed in their present locations throughout geological time is an unfortunate misconception. Sands, for example, may cover about 10 percent of the surface area in the Sahara and, where dunes or sand sheets occur, are certainly prominent features of the Namib, Arabian, and some other deserts. In general, however, desert sands must be regarded as a minor portion of the deserts as a whole and are essentially absent over vast reaches of arid terrain. And with regard to the permanence of deserts, it is fair to say that the land areas subjected to arid conditions have varied widely throughout Earth history. This is a consequence both of continental drift—the shifting about of landmasses on the Earth's surface, thus bringing different regions into conjunction with arid climatic zones—and climatic changes per se. Moreover, it should be made clear at the outset that several decidedly different desert types occupy the arid environmental niche, and certain of these are not necessarily associated with elevated temperatures.

One desert type, for example, persists in the polar regions of the Earth. These areas are mantled by snow and ice or consist of barren tundra; in either case, extremes of heat clearly are alien. Nevertheless, they are true desert areas because lack of vegetation and low values of atmospheric water vapour are common characteristics. Although definitions of aridity are both numerous and subjective, a value of mean annual precipitation equal to 250 millimetres (10 inches) or less is one of the criteria commonly used to delimit desert areas. Variability of precipitation is another hallmark of arid climates, but it has been shown that variability is closely related to mean annual values, increasing as the total rainfall decreases. On this basis it need only be noted that the annual precipitation in the interior of Antarctica and over most of the Arctic region is about 125 to 200 millimetres (five to eight inches).

On similar grounds, such extra-terrestrial neighbours as the Moon and Mars represent a second desert type. The Moon has essentially lost its atmosphere through time, thus precluding the possibility of occurrence of precipitation or life-forms, and the entire atmosphere of Mars contains the equivalent of only three cubic miles of water. This water content is intimately related to the seasonal fluctuation of the polar caps of frost or ice on Mars. Some have argued that the melting of these caps, approximately once every 10,000 years, may involve the discharge of surface water. This is highly speculative, however, and it is fair to conclude at present that by any reasonable standard the prevailing environments on both the Moon and Mars are extremely arid.

In a third category are regions in various parts of the world that receive more than the requisite 250 millimetres of annual precipitation but that are nonetheless dry, barren, and relatively devoid of vegetation. Such regions are termed edaphic deserts, which signifies that the physical cause of aridity resides in the nature of the surface materials. The latter usually consist of very porous vol-

Polar,  
extra-  
terrestrial,  
and  
edaphic  
deserts

canic debris; as a consequence, moisture penetration to the subsurface is too rapid to permit plant sustenance regardless of the amount of rain that may fall. Some parts of Iceland, the Canarys and other volcanic islands, and the so-called cinder lakes on the Colorado Plateau of the western United States are examples of edaphic deserts.

Hot, arid regions and their variation with time

Finally, there are the relatively hot arid regions of the world that are more commonly intended when reference to the desert environment is made. These owe their existence largely to meteorological causes, being located along the Earth's two great subtropical belts of minimal precipitation, or otherwise removed from sources of rainfall; but, aside from some commonality of climate, considerable diversity exists and generalizations are poorly advised. Both physiographic and geological variations abound, and even the ages of these deserts are non-uniform; some have existed in their present state for millions of years, whereas others have changed drastically since the end of Pleistocene time—*i.e.*, during the last 10,000 years approximately.

Parts of the Sahara and Australian deserts, for example, were glaciated during the Paleozoic Era (570,000,000 to 225,000,000 years ago), and the ancient rocks that underlie all desert areas reflect many kinds of former nonarid environments or conditions of formation. These range from marine limestones and sandstones, many of which contain petroleum and natural-gas reserves in the Middle East and elsewhere, to coal deposits that indicate the existence of former swamps and lush vegetation, and crystalline rocks of many varieties that were formed by the cooling of molten silicate material (magma) above or beneath the Earth's surface. As shown in Figure 1 below, there is evidence that great trees once grew in currently arid Algeria.

Figure 1: Silicified tree trunks in the Sahara between Aoulef and In Saiah, Algeria.

In the more recent past, during the Quaternary Period (the last 2,500,000 years), some rather profound climatic changes of uncertain synchronicity with the ice ages affected some desert areas. Artifacts such as those shown in Figure 2 indicate that early man hunted large mammals in areas that could not possibly sustain such life today; forests of oak and cedar grew in such highland areas as Tibesti, in the central Sahara; lakes and lake systems were at one time extensive in such regions as the Kalahari, the Iranian desert, and the western United States, where there is evidence of a former body of water 180–210 metres (600–700 feet) deep in Death Valley, for example. Indeed, relict surface features of many kinds, as well as some relict animals (specialized fishes and some crocodiles in oases), point toward the existence of former moist conditions in many of the world's desert areas in the relatively recent past. The same may be said of habitation in Roman times in North Africa. The theatre at Leptis Magna, Libya, was designed to seat many thousands (Figure 3), but the site today is reminiscent of a ghost town.

The arid lands were clearly of great importance to man during the beginnings of his historic record. The history

Figure 2: Acheulean artifacts from Ijâfen, found in the region of the Algerian Sahara.

of land use in the vicinity of Mt. Carmel, Israel, and Mt. Hermon on the Syria–Lebanon border and in the Jordan Valley dates back to 6000 BC, when cereals were cultivated, and the irrigation systems of this region and the use of the annual Nile floods for agricultural purposes in Egypt are well documented. Similarly, civilizations are known to have flourished in the fertile Crescent formed by the Tigris and Euphrates rivers and in the Indus Valley region of Baluchistan more than 5,000 years ago. Early settlement and land use also occurred in some of the Asian desert areas, and in Iran, where *qanats* (galleries of tunnels in alluvial material that are dug to provide irrigation waters) still form part of the water supply system. In North and South America the advent of man came later; absolute age dating by radioactive-carbon techniques has failed to provide evidence of man's presence prior to 12,000 to 15,000 years ago in the Western Hemisphere, although work in progress may ultimately yield a greater age for sites of early man near Mexico City. In any case, one of the most curious facets of the history of man's development in both the Old World and the New is his apparent attraction to harsh arid regions despite the availability of better watered neighbouring terrain.

The importance of the arid regions today resides largely in their great mineral wealth. The oil and gas resources of Algeria, Libya, and Egypt in the Sahara and those of Saudi Arabia, Kuwait, and Iran clearly provide a prominent fraction of the world's total proved reserves. Gold and diamonds in southern Africa, phosphates in Spanish Sahara, nitrates in Chile, and vast iron-ore de-

Figure 3: The theatre at Leptis Magna, Libya

Rotalfoto

posits in Australia comprise but a few examples of other kinds of mineral resources. Given sufficient water for irrigation and the necessary fertilizers, the arid regions certainly can be rendered fertile, and the promise of augmentation of the world's food supply and relief of population pressures is implicit in the cliché of turning the deserts green. Although desalinization techniques to produce fresh water from seawater may prove a boon to desert coastal areas, the cost of constructing distributive systems to desert interiors is so prohibitive that it has never been seriously discussed. The widely quoted cost of water per 1,000 litres by means of desalinization is always the cost *in situ*—tomatoes can be grown along the Persian Gulf at a price within reason, but they would be precious as pearls if cultivated in the interior of the Arabian Desert. Hence, it is presently unrealistic to conceive of the world's desert areas as loci for vast population centres of the future.

This article treats the general climate, hydrology, and physical features of deserts and includes a section on the permanence of deserts through time. It concludes with coverage of desert flora and fauna. For detailed information on the characteristics of specific desert areas, see articles on those deserts—*e.g.*, THAR DESERT; GOBI (DESERT); NORTH AMERICAN DESERT. Some aspects of desert hydrology and climatology are covered in the more general articles CLIMATE: CLIMATIC CHANGE; and HYDROLOGIC CYCLE. The interested reader should see also appropriate sections of RIVERS AND RIVER SYSTEMS and SOILS, and those articles specifically covering desert features and processes—*i.e.*, ALLUVIAL FANS; PEDIMENTS; SAND SHEETS AND SAND DUNES; PLAYAS, PANS, AND SALINE FLATS; and WIND ACTION. An overview of the development of landforms is provided in LANDFORM EVOLUTION; and mineral formation in arid environments is covered in EVAPORITES.

#### THE ARIDITY OF DESERTS

General cause of the arid zones. The general cause of the arid zones of the Earth and, hence, of the present

location of the world's deserts resides largely in the dynamics of the atmospheric circulation. In the simplest sense, the engine that drives the planetary atmosphere is incoming solar radiation combined with the effects of the Earth's rotation. Much more incident heat is received in the equatorial region than at the poles, and this tends to lead to a poleward transfer of heat and to a meridional atmospheric circulation pattern. The rotation of the Earth produces latitudinal wind zonation at the Earth's surface—*e.g.*, the trade winds, or easterly winds, in equatorial regions and the westerlies in middle latitudes. Although the physical causes of these two circulatory patterns are complex (see WINDS AND STORMS), the reason that they lead to the existence of arid zones is easily understood.

Basically, air that is heated at the Equator by incident solar radiation rises, cools, condenses, and releases its moisture content in the tropical zone; it then subsides toward the Earth's surface near latitudes 30° N and 30° S, thus producing two great belts of subtropical high pressure. This descending air is also the source of the easterly trade winds that blow toward the Equator. Some of the world's greatest deserts are located beneath or near these high-pressure belts—the hot, dry trade winds blow across the Sahara (Figure 4), the deserts of the Middle East and South Asia (Figure 5), and part of the North American Desert (Figure 6) in the Northern Hemisphere, and this effect of the general planetary circulation is also responsible for the occurrence of the Atacama-Peruvian desert of South America (Figure 7), the Namib and Kalahari in southern Africa, and the Australian Desert (Figure 8) in the Southern Hemisphere. It should be noted, however, that where the trade winds blow onshore, as along the east coasts of Africa, South America, and Australia, the moisture they bear precludes the existence of deserts.

These generalizations concerning the locations of the world's deserts and wind systems are borne out by several of the maps shown in Figures 4 to 8. Aside from the disruption in continuity of the arid zone along the east coasts of the continents mentioned above, it also may be noted that several of the world's deserts can be characterized as high-latitude types—*i.e.*, they lie north or south of the principal arid belts. Included in this group is much of the North American Desert and the Patagonian Desert of Argentina. These arid areas result principally from physiographic causes: a rain-shadow effect is involved. The latter term is applied when warm, moisture-laden winds must cross a mountain system or similar topographic barrier. When this occurs, as on the west sides of the Andes and the Sierra Nevada, the air masses cool as they rise, and condensation and precipitation occur over the mountains proper. When the air descends on the leeward sides of such barriers, it is thus devoid of moisture and deserts result. The deserts of Central Asia, principally the Takla Makan and Gobi, are also related to physiographic causes in the sense that their locations in the continental interior are quite remote from any sources of moisture. The distribution of land and sea can therefore be cited as a second general cause of aridity on the Earth's surface.

The definition of aridity. To any who have traversed one of the proverbial "burning wastelands" beneath a summer sun, the question "What is a desert?" would appear to be the ultimate inanity. But the definition is elusive and has from time to time been couched in terms of scarcity of inhabitants, lack of cultivated crops, and certain soil and vegetation characteristics. The common thread that binds all desert areas, however, is aridity; deserts are clearly drier than other environments, and thus the question "What is a desert?" really turns upon the question "What is an arid climate, or aridity in general?"

There are several possible approaches to this question, one of which is to attempt climatic classification based upon some set of attributes that is presumably suitable to delineate the arid areas. The word climate is derived from the Greek *klimatos*, meaning "inclination," which reflects the ancients' realization that climate varies with

Relation to atmospheric circulation

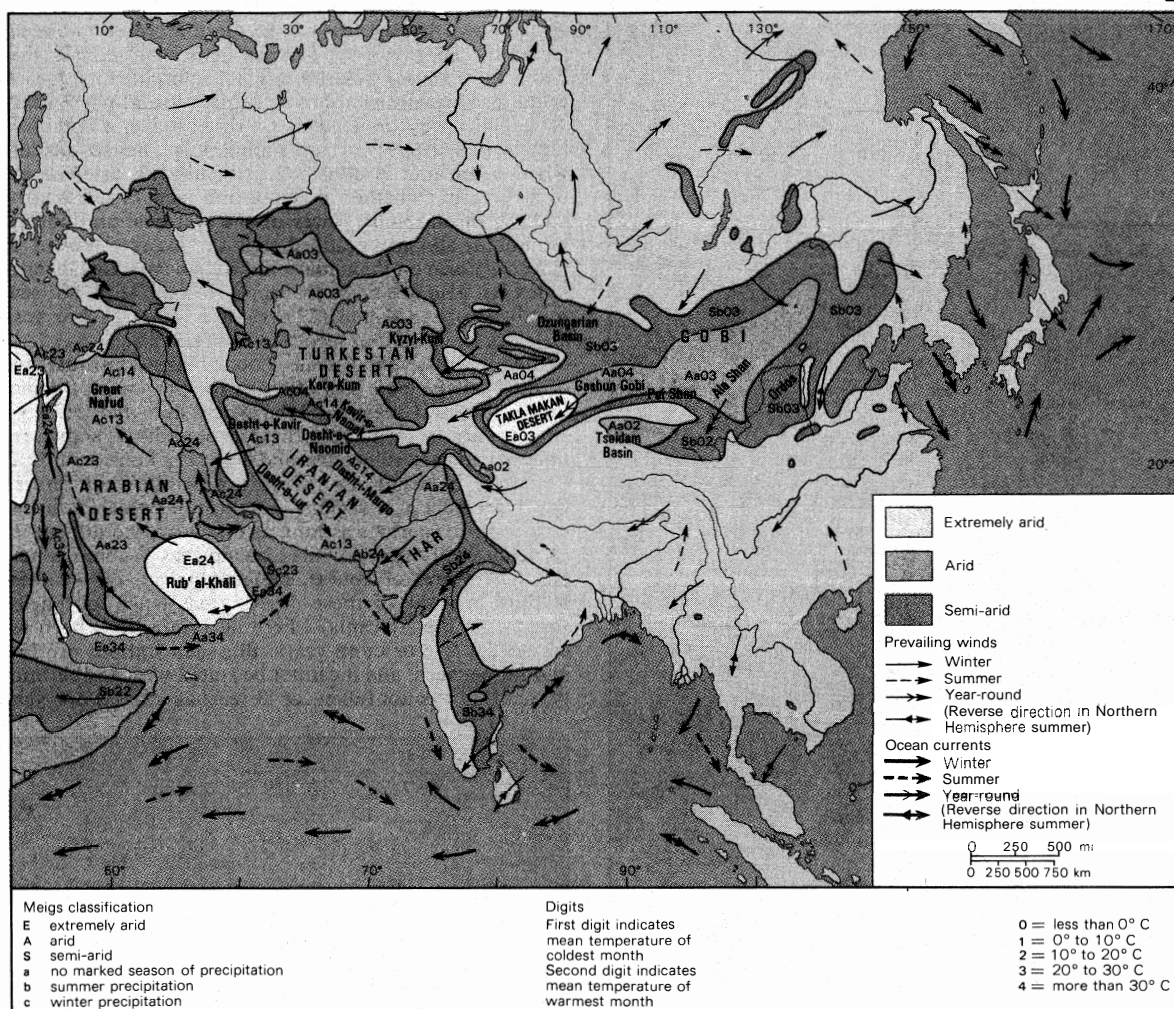

Figure 5: Deserts of Asia.

Adapted from UNESCO, Reviews of Research on Arid Zone Hydrology, "World Distribution of Arid and Semi-arid Homoclimates" (1953)

latitude because of differential inclination of the Earth's surface to the Sun's rays. One of the first climatic classifications, in fact, was provided by Ptolemy, and its basis was geographic latitude and length of day. The most widely used classification of climates today is the Köppen system (see CLIMATE), or some modification thereof, which was based upon the world distribution of vegetation. Vegetation is sensitive, of course, to temperature and precipitation and tends to reflect these variables in a general way.

To delineate the boundaries of the arid zones more precisely, however, a large number of indices of aridity have been provided by various scientists, including Köppen. He believed that boundaries could be established in terms of the mean annual temperature ( $T$ ) and mean annual precipitation ( $P$ ). The limit between subtropical and semi-arid climatic types was expressed by the relation

$$P = 2(T + 7),$$

in which  $P$  is in centimetres and  $T$  is in degrees Celsius. Köppen's arid index was defined by setting  $P = T + 7$ , which for a typical temperature of 18° C (34° F) would yield an arid-semi-arid boundary at a mean annual precipitation value of 500 millimetres (20 inches). The index was later modified to reflect the differences that exist between areas with summer and winter rainfall.

A more widely used index of aridity was provided by the French scientist Emmanuel de Martonne, who related monthly precipitation and monthly temperature to the degree of aridity; ultimately he refined his formulation to the expression

$$I = \frac{n\bar{p}}{t + 10}$$

in which the index of aridity,  $I$ , equals the mean daily precipitation,  $\bar{p}$ , for any particular period times the number of days,  $n$ , in that period, divided by temperature,  $t$ , in degrees Celsius plus 10.

Many other indices of aridity have been set forth over the years, but, like those of Köppen and Martonne, they suffer from several failings. It is questionable, for example, whether mean annual values of precipitation indicate similarities between two regions sufficient to permit their placement in the same climatic category. Clearly, it is not inconceivable that two areas might receive 300 millimetres (12 inches) of precipitation a year, for example, which falls in one area at the rate of 25 millimetres per month but in the second in the form of two 150-millimetre storms. In such an instance the climate, vegetation, soils, drainage characteristics, and other physical factors might well be disparate, despite the equivalence of mean annual precipitation. And with regard to values of temperature, these are really used in lieu of evaporation data, which are more meaningful but more difficult to obtain over widespread desert areas. Moreover, it should be noted that nearly all such indices of aridity involve relationships between millimetres or centimetres of rainfall, on the one hand, and degrees Celsius, on the other. Such unitary chaos always indicates that the underlying physical relationships are not clear.

Indeed, because aridity is a measure of dryness, the most superior index would be one based on the water balance of an area. This is, basically, the relationship between the moisture received by an area and the moisture that is lost. The former consists chiefly of precipitation, whereas the losses are produced by all forms of evaporation, surface runoff that transports water out of the area,

Definition

and seepage to the subsurface—i.e., to the groundwater reservoir present. There are several difficulties involved in any water-balance determination (see HYDROLOGIC CYCLE), but this is particularly true in the arid regions because of their vast area and the paucity of necessary data in most instances.

The merits of considering aridity in terms of water input versus water output were so great, however, that the American scientist Charles Warren Thornthwaite devised several indices that are more closely reflective of water-balance considerations. His widely cited precipitation effectiveness ratio, for example, is of this nature. It relates precipitation, evaporation, and temperature in a relatively realistic way. Thornthwaite's aridity index is rather complex; it relates potential evapotranspiration—the total evaporation that would occur from a surface completely covered with vegetation when moisture is continually available—to the length of day and temperature at a particular location.

This aridity index can also be criticized on a number of meteorological grounds; among other things, it has been argued that the index lacks universal applicability and is biased toward the climatic conditions prevailing at the particular stations (locations) employed by Thornthwaite in its derivation. The index is practical, however, and also is simple to apply because nomograms (graphs that permit immediate determination of the index for any set of climatic values) are available. In fact, the Thornthwaite index of aridity was used in the preparation of the

maps shown in Figures 4 to 8. Certain values were selected to define varying degrees of aridity, and further distinctions among desert areas were obtained by considering seasonal distributions of temperature and rainfall. As explained by the legends on these maps, a combination of two letters and two numbers is used to indicate whether an area is classified as semi-arid, arid, or extremely arid, whether precipitation occurs seasonally, and the mean temperatures of the warmest and coldest months. It should be added that the areas classified as extremely arid on these maps not only have a high aridity index but also are areas in which (1) rainfall is not seasonally distributed and (2) periods as long as one year have occurred without recorded rainfall.

Although these small-scale global maps constitute one of the best available sets of maps for purposes of depiction of the arid regions of the world and their subdivision, it must be recognized that the boundaries shown remain somewhat subjective and may err considerably if examined in detail. Considering only the requirement that extremely arid regions are those in which rain has not fallen for periods as long as one year, the difficulties of delineating extremely arid boundaries become apparent. There are, of course, meteorological, or weather, stations in some of these desert areas (such as that at Iquique, in the Atacama) where no rainfall has been recorded for five or more years. But such stations are few and far between, and it cannot be stated with any certainty that rain has not fallen for at least as long as one year

throughout the entire coastal Atacama, the Rub'al-Khali, the Takla Makan, or any other desert area that is indicated as extremely arid on Figures 4 to 8. It can be said, however, that these areas do generally tend to be hotter and drier than those designated as arid and that rainfall

tends to be more spasmodic with respect to both frequency of occurrence and areal distribution. Some climatic data for selected stations in the deserts of the world are given in the Table.

#### HYDROLOGIC ASPECTS

**Principal hydrologic factors.** The factors that govern the hydrology of arid regions are climatic, topographic, and geologic. Considering climatic factors first, precipitation and evaporation are perhaps most important because, as mentioned in connection with aridity indices, these two variables tend to control the water balance of an area. Precipitation is highly variable in arid areas, and as a general rule the variability is inversely related to the mean annual precipitation—i.e., as annual precipitation decreases, the variability increases. This variability, in turn, is directly related to the nature of surface runoff in desert regions; it is very spasmodic, and streamflow on a large scale will occur only after intense rainfall.

Another moisture source in deserts is dew, which is worthy of mention because its contribution to the water input and, hence, to the general hydrology of an area has been overemphasized upon occasion. Dew can be derived from the condensation of atmospheric water vapour or from water vapour that is emitted from moisture that is present in the soil. In the latter instance, there clearly can be no net water gain, so the dew derived from soil moisture can be disregarded. The maximum total dewfalls reported do not exceed 0.2 millimetres per day in any case, whereas total daily evaporation of about five to six millimetres is not uncommon. On these grounds it can be argued that the contribution of dew to the overall water balance in arid regions is of negligible import. Its greatest significance is (1) in west-coast deserts such as the Namib in South West Africa, where the influx of humid air from adjacent oceans permits optimal dewfall that benefits vegetation and (2) as a necessary moisture source for the chemical weathering of rocks.

Evaporation in all desert regions is a factor of great significance. It is here designated a climatic factor, be-

\*Six-year record. †Fifty-four year record.

Evaporation in desert regions

cause it is related to incident solar radiation and air temperature and to atmospheric humidity. The total annual evaporation everywhere exceeds total precipitation greatly, and, indeed, this relationship can be considered one of the climatic hallmarks of the arid regions. Wherever evaporation exceeds precipitation, the presence of free-standing natural water bodies such as lakes is generally precluded, unless some permanent source of water is involved. The Nile, for example, can cross the eastern part of the Sahara despite very high evaporation rates (approximately 120 inches per year at 'Aṭbarah, The Sudan) because its source is in the equatorial highlands and because groundwater contributes to its flow over part of its course. This is flowing water, however; an equal volume of standing water whose only input was derived from precipitation would eventually dry up.

Evaporation is greater over water surfaces than over bare soil surfaces, but it occurs over the latter as well and has much to do with depleting soil moisture and inhibiting plant growth. The occurrence of hot dry winds will tend to increase evaporation rates, and for these and other reasons—including difficulty of accurate measurement—existing evaporation data are in some instances debatable. Some representative values are listed in the Table, however.

With regard to topographic and geologic factors that influence desert hydrology, these can best be considered together. Topography may on occasion promote increased aridity by the rain-shadow effect previously mentioned, but it also may promote rainfall where highlands occur within arid regions. The Tibesti massif (Figure 4), within the central Sahara, for example, attains a maximum elevation of 3,415 metres (11,204 feet); this is sufficient to render it a semi-arid "island" in an extremely arid area by reason of the increase of precipitation with increasing elevation.

Geologic factors such as rock type and structure, the character of the soil, and the porosity and permeability of surface materials in general also can affect the hydrology in two ways. If water will readily seep to the subsurface because of the presence of rock fissures and fractures or of highly permeable materials, then the runoff from a given amount of precipitation will be less than normal because of water losses. On the other hand, this same set of conditions may promote recharge (the addition of water) of the groundwater reservoir in the area. Where geological factors inhibit the downward percolation of water, runoff following a storm may be enhanced, but, ultimately, greater evaporation may result.

Streamflow and drainage characteristics

**Surface water.** Although hydraulic and hydrologic principles are unvarying in all environments, some substantial differences exist between the characteristics of streamflow in arid regions and in more humid areas. The drainage networks that exist in the latter, for example, generally reflect the nature of runoff conditions today, whereas in desert areas there are many drainage systems that reflect establishment during Pleistocene time (2,500,000 to 10,000 years ago), when moister conditions prevailed and streamflow was more abundant.

Streamflow in humid and semihumid areas has been studied in detail, and it has been established that the channels of all rivers are in adjustment to a number of hydraulic parameters—*i.e.*, the width, depth, and velocity of flow and the sediment discharge are related to the bankfull water discharge, and this water discharge governs the nature of the channel. The frequency of occurrence of the bankfull discharge is generally about once every 1.5 to 2.5 years, and overbank floods of great magnitude tend to occur every 50 to 100 years. Rivers in these regions exhibit far more days of low flow than of high flow per year; they usually transport the bulk of their suspended sediment load during high-flow stages, but the many low flows during a year serve to transport much of the total load (the suspended load, dissolved load, and bed load). Finally, flow is perennial, with rivers linking up to ultimately reach the sea.

In desert areas, by way of contrast, streamflow is extremely sporadic. An effective precipitation sufficient to overcome both evaporation and seepage losses into the

channel bed and the surrounding dry terrain of the drainage basin involved is required for streamflow to occur. This usually involves a storm yielding relatively intense precipitation (*e.g.*, 36 millimetres [1.4 inches] of rain were recorded in 40 minutes during a storm at Tamanrasset, in the central Sahara). Low flows tend to be few by reason of the seepage and evaporation losses, and, when flow does occur in arid areas, it will likely be of high stage, violent, and highly charged with sediment that is derived from the abundance of loose sand and gravel that blankets most areas. Discharge of any magnitude, however, and particularly bankfull discharge, may have a frequency of occurrence that is as small as once in 100 or more years, and the recurrence interval of major overbank floods may be measured in thousands of years in extremely arid areas. Streamflow is thus characterized as ephemeral rather than perennial, and because drainage generally fails to reach the sea, save for rivers of the first rank such as the Nile or those with relatively short distances to traverse such as the Kuiseb in the Namib Desert, it is termed interior drainage. The Kuiseb is of some interest because it flows to the sea with sufficient frequency to prevent the migration of dunes from the southern Namib Desert despite northern prevailing winds. Its channel thus serves as a boundary between the dunes and the gravel plains to the north (Figure 9).

L.K. Lustig—EB Inc

Figure 9: Red sand dunes of the southern Namib Desert separated from the northern gravel plain (foreground) by the Kuiseb River. The channel is marked by a row of vegetation, visible at the base of the dune area.

Where surface flows are ponded or terminate in low depressions, marshy areas or lakes may result. If there is sufficient precipitation over the site of termination or if there is sustenance by groundwater flow, then a relatively freshwater lake may result. Most desert lakes are without outlet, however, and thus become highly saline, because each increment of inflow transports additional salts in solution and the constant evaporation of water from the lake causes salt concentrations. Salinity values as high as 200 to 300 parts per thousand are not uncommon (see further EVAPORITES).

Desert lakes

One of the larger areas of interior drainage in a desert area is the Lake Eyre Basin, in Australia (Figure 8). It embraces a total of 1,300,000 square kilometres (500,000 square miles), and the mean annual rainfall is less than 250 millimetres over most of the headwater region. In 1967, however, an overnight rainfall of more than 150 millimetres occurred, causing ephemeral streams to flow far beyond any previously known distances; water depths as great as five metres were observed, and widths of flow were as great as several kilometres. Some of the streams linked up to provide a surface-water input to Lake Eyre proper, an exceedingly rare occurrence, but the point to be drawn here concerns the origin and significance of the many dry lakes in arid regions. The latter are variously termed playas, pans, and saline flats, all of which are depressional features that sometimes hold standing water but that are more often dry.

Where such features occur in isolation, as in the basin and range areas of the North American or Iranian des-

erts, this discussion is not applicable, but, in several areas of vast desert plains, a veritable legion of these dry lakes dot the landscape in relatively close association. Noteworthy examples are to be found in Western Australia and in western Botswana, in the Kalahari (Figure 10). These dry lakes show evidence of linkage by ephemeral streams, and, rather than relicts of Pleistocene time, they may well be parts of overall drainage systems that, like the central Australian case, flow today infrequently in response to precipitation events of great magnitude and intensity.

**Subsurface water.** Subsurface water is present in each of the desert areas, but lack of exploratory drilling precludes definitive statements on the total amount of water involved in most instances. Suffice to say that groundwater is easily the principal water resource of the arid regions. Water seeps into the ground and flows downward under the influence of gravity—always assuming, of course, that the materials through which it migrates possess the requisite porosity and permeability. Some of this water migration occurs in the deserts proper; surface-water losses caused by downward percolation into the sands and gravels of stream beds have been previously mentioned. Indeed, there is always some close relation between groundwater and surface water wherever stream channels occur, but much of the groundwater also is related to the vast areas over which rain may fall and ultimately reach the saturated zone in the subsurface.

In the near-surface zone, the water present, principally derived from rainfall, is termed soil moisture. Some of the moisture is lost because capillary action brings it back to the surface, where it may form dew, as previously noted, and is in general subject to evaporation. There is a second zone extending to perhaps 100 metres beneath the zone of soil moisture in many areas. This is a relatively dry zone, but it may contain lenses of water-bearing sediments surrounded by more impermeable beds or layers. Such groundwater is termed perched in reference to its mode of occurrence. Beneath this zone the groundwater proper occurs; the surface of this saturated zone is called the water table (see further GROUNDWATER).

In many instances the general subsurface structure, or configuration of strata, in desert areas is that of a basin. When the principal water-bearing strata, or aquifers, are upturned and are exposed at the surface in regions of high rainfall, much of the water input to the groundwater system will be so derived—rather than from seepage due to rainfall over the entire basin region. In the Great Artesian Basin, in Australia, for example, the total area is about 1,760,000 square kilometres (680,000 square miles), but the principal water intake is on the eastern edge of the basin, over an area of about 100,000 square kilometres, in which precipitation is 625 millimetres (25 inches) per year. The water flows downward through upturned sandstone aquifers and thence into the centre of the basin, which attains depths of as much as

2,100 metres (6,900 feet). This circumstance of distant intake for groundwater, wherever it occurs, is responsible for the age of the water that has been determined in North America, in the Libyan Desert of the eastern Sahara, and elsewhere. All absolute age measurements on groundwaters in desert areas indicate a range in age of between 20,000 and 35,000 years. This means that waters tapped by wells in Egypt, Libya, and adjacent regions of the Sahara entered the groundwater system from Pleistocene rainfall in highland areas to the south. The groundwater is often called fossil water for this reason.

If the principal water intake is at the upturned edge of a basin structure and if the water-bearing strata crop out at the surface (or occur near the ground surface) farther out in the basin, then there will be a pressure difference caused by the difference in elevation of the water within the aquifer. When this condition exists, the flow of water is termed artesian, and artesian water is the source for most springs, oases, and near-surface water wells in desert regions. The other principal mode of occurrence of these lifesaving caravan stops is also related to groundwater flow. Instead of artesian conditions, the termination of a subsurface aquifer within permeable sediments or the existence of fractures that penetrate the aquifer may be responsible.

#### DESERT LANDFORMS

**Geomorphic processes.** Geomorphic processes are those natural physical, chemical, and biological processes that affect landscape in general and the configurations of individual landforms in particular. Considering the arid regions, there are essentially four processes of importance in this regard: weathering, gravitational, fluvial, and eolian.

Weathering refers to the breakdown of solid rocks into smaller fragments or into their component parts by mechanical or chemical means. It is the first essential step in the molding of landforms and their ultimate reduction, because the weathered debris or loose sediment produced is then available for subsequent transportation by wind or water. The decay and reduction of bedrock is an extremely slow process under arid conditions. Many monuments that are thousands of years old remain relatively well preserved today and bear witness to this fact (Figure 11). The abundance of unconsolidated sediment that blankets desert areas, however, is mute testimony to the effects of time; given sufficient time even the slowest processes will be effective.

Two pronounced effects of weathering processes in desert regions are desert varnish, a dark patina of iron and manganese oxides that coats individual particles and large rock surfaces alike, and duricrusts, indurated (hardened) soil layers that may consist principally of calcium carbonate or iron-, silica-, or alumina-rich compounds. Desert varnish is thought to require at least 2,000 years to form, largely because of its occurrence on datable

monuments, artifacts, and similar objects that are known to be of this age or older. There is one reported instance of possible varnish formation within 50 years (in the Mojave Desert), but, in the absence of additional evidence, the 2,000-year or greater range is accepted by most authorities. The iron and manganese involved in varnish formation are thought to be derived from the solid rock beneath the patina, with dew playing an important role as a moisture source in this chemical process.

Duricrusts result from soil-forming processes involving, in arid regions as in other environments, the leaching of chemical constituents from some soil layers and their concentration in others, where they cement and replace existing rock particles. The most common type of crust is perhaps the one rich in calcium carbonate, which is variously termed caliche and hardpan, among other names. No form of crust is rare, however, and in some areas, such as the Sudan, the ubiquitous reddish-brown colour of crusts and surface sediments (Figure 12) suggests the abundance of iron that exists. The crusts in this instance form a protective caprock and tend to preserve the djebeles by their resistance to erosion. Duricrusts and

L.K. Lustig—EB Inc.

Figure 12: Crest of an isolated djebele near Omdurman, the Sudan, capped by an iron-rich duricrust. Djebeles visible in the distance are similarly capped.

varnish both result from chemical processes in arid regions, but the formation of crusts reflects a time requirement that is far in excess of that associated with varnish. The crusts are most abundant in areas that have been stable for the last few millions of years, such as the Australian Desert, where duricrusts were first described (see further DURICRUSTS).

Mechanical weathering in deserts is thought to be reflected by the angularity of most of the weathered debris and by the spalling off of great rock sheets concentric about boulders and rock domes that are usually of granitic composition. For many years it was believed that these phenomena resulted from alternate heating and cooling due to large diurnal temperature changes in deserts, but this concept has been demonstrated to be wrong by laboratory experiments. It now seems clear that chemical processes are involved, with dew again serving as the principal moisture source. Although dew in the desert is small in quantity, the abundance of time for repeated increments of hydration and solution in arid areas makes possible these large-scale weathering results.

Gravitational processes refer principally to the downslope movement of weathered materials under the influence of gravity. This will occur when instability develops on a hillslope or when a mass of material is sufficiently lubricated by water or a water-sediment mixture to overcome frictional resistance. The range of movements possible extends from the fall of a single particle or fragment from a cliff to great rockslides and landslides. The latter do occur in arid regions as elsewhere but are not of great quantitative importance save locally. (For information on the role of gravitational processes in hillslope development and the nature of these processes, see EARTH MOVEMENTS ON SLOPES; and HILLSLOPES.)

L.K. Lustig—EB Inc.

Figure 13: Meander in the Helmand River, Dasht-e Mārgow, southern Afghanistan, showing vertical bluff cut in valley alluvium. Rounded hill (centre) may be a relict feature.

Fluvial processes are those associated with flowing water. As mentioned above in the section **Surface** water, there is no difference between the laws governing fluid flow and channel characteristics in arid regions or other environments. The characteristics of desert streamflow derive from the lack of vegetation and abundance of weathered sediments and from the infrequent distribution of precipitation both in space and time. An intense storm in a given area leads very rapidly to the merger of runoff from slopes in small confined channels or in sheets. This water then pours into the larger arroyos, wadis, or desert washes present, and large quantities of sediment are transported. Some of this sediment is picked up on the initial slopes involved, but much sand and gravel that may have accumulated within the channels since the previous runoff event also is transported. Sediment is also scoured from channel banks, which cave in when wetted. This commonly occurs on the outside banks of meander bends, as in the case of the Helmand River, Afghanistan (Figure 13).

In mountainous regions the concentration of rainfall within a particular drainage basin often leads to the assimilation of so much sediment by surface runoff that mudflows—dense, viscous, water-sediment mixtures—

Gravitational and fluvial processes

are produced. These flows can do much erosional work, particularly with respect to their capacity to transport very large blocks and boulders. Without continued rainfall in the drainage area or with a diminution of slope, mudflows will come to rest and dry out. The resulting sedimentary deposit will be virtually indistinguishable from other channel deposits.

Another fluvial process that is characteristic of arid regions is piping—a subsurface sapping of unconsolidated sediments that may effectively produce natural pipes, or tunnels, beneath large areas. Some parts of southern Arizona, for example, are honeycombed by pipes, and continual enlargement of them leads to the formation of natural bridges in these deposits (Figure 14). Piping is intimately related to the formation of desert washes, and in many cases the head of an arroyo receives water from a pipe network during storms, thus causing upstream migration and enlargement of the wash. It is a fluvial process that is underrated because the extensive development of pipes eventually obliterates evidence of their existence.

Effects of  
wind  
action

Eolian processes result from the work of the wind, and because wind action has always been more visible in deserts than surface runoff, early workers thought that desert features were largely attributable to the wind. Although this view is held to be in error today, much evidence of wind action is indeed present. Prolonged wind erosion can lead to lag-gravel deposits, in which the wind winnows finer particles, thus leaving coarse fragments behind; to blowouts, or deflation basins, which are circular to oval areas of depression thought to have been scoured out by the wind; and to ridges, flutes, and other scouring effects in bedrock surfaces when an abundance of fine particles suspended by the wind produce a sandblasting effect. The latter is also responsible for the production of ventifacts in desert regions; these are gravel particles the sides of which have been worn smooth by sandblasting, leading to a distinctively shaped stone formed by intersecting facets.

Desert winds also produce deposition of sediment whenever their velocities are checked by opposing winds, a mountain mass, or some other cause of wind shadows. The finest material in transport is usually called dust, and windblown dust can travel great distances. Dust storms in the western Sahara, for example, have led to deposition as far away as the eastern United States and Europe. Sedimentary deposits that consist largely of windblown dust are called loess; such deposits are exemplified by bluffs as thick as 100 metres in Mongolia and by widespread blankets of loess in eastern Europe and elsewhere (see further LOESS).

The deposition of sand by the wind is perhaps more widely known. The many desert sand sheets and the variety of existing sand dunes all result from eolian processes. Where dune migration is involved, the cause is wind transport of sands up and over the windward face of a dune; deposition of these same sand grains occurs on the lee face, and in this way an entire dune or group of dunes will migrate downwind. Wind directions are frequently variable rather than unidirectional in the course of a year, and dunes may well migrate in different directions in response to such shifts in stress. Nevertheless, there must always be some net wind component over a long period of time, and this will be the determining factor in considerations of net dune movement or migration. In many instances the net component is zero, in which case dunes may migrate to and fro but will tend to remain in a fixed average location through time.

Finally, the phenomenon of frosted sand grains is worthy of mention here. Because the sandblasting effect of windblown sand on rocks and other objects has long been known, the presence of quartz grains with milky surface coatings was assumed to be caused by the striking of one grain upon another during wind transport. Surface frosting can indeed develop in this way, and the mere presence of frosted grains was accepted by many as absolute proof of arid conditions. Philip Kuenen, the Dutch geologist, made a remarkably simple but astute observation of such frosted grains, however. Microscopic examination revealed that many grains possessed pits of small

Figure 14: Natural bridges of alluvium in southern Arizona. The bridges result from a process of subsurface erosion and channel development called piping. When the bridges ultimately collapse, the channel beneath them will be indistinguishable from any other desert wash, or arroyo. L.K. Lustig—EB Inc.

dimension that resembled miniature tunnels extending from the grain surfaces toward their centres. These pits were obviously far too small for sand grains to gain entrance, but frosting was nonetheless present. The only possible conclusion to be drawn is that frosting of sand grains can be produced by means other than grain to grain impact and, therefore, that the presence of frosting cannot be cited as unequivocal evidence of an arid environment.

**Surficial features.** A considerable number of landforms occur in desert areas, and though some are considered characteristic of arid regions, nearly all have counterparts in the more humid environments. Mountain ranges and plateaus, volcanic peaks and isolated bedrock knobs, peripheral landforms that are termed alluvial fans if composed of sediment and termed pediments if consisting of a sloping rock surface, sand sheets and sand dunes, playas and other dry lakes, and desert plains and depressions—these are the principal elements of the desert landscape, which is often described as stark, harsh, and angular in profile. This is to some extent more closely related to the relative absence of vegetation and soil cover in arid regions than to some fundamental physiographic distinction that is climatically based (see further LANDFORM EVOLUTION).

Mountains are present in some deserts, such as the Atlas and Anti-Atlas ranges of the northern Sahara or the many mountain ranges of the North American and Iranian deserts, but they are basically absent in others—e.g., the Australian Desert. Wherever they do occur, these highlands tend to be deeply embayed by canyons and are blocky or steeply sloping in general aspect. The specific appearance of any particular mountain range or isolated mountain mass, however, is always governed by the rock type and structure involved and the response of these two elements to the fluvial, eolian, and weathering processes that are operative upon the landform. Hence, it is possible to encounter such disparate forms as the rounded rock mass that occurs in the Dasht-e Mārgow, Afghanistan (Figure 13), the mesa-like features of the Sudanese djebels that result from resistant iron-rich cappings (Figure 12), or the granitic inselberg (derived from German: "island mountain") in the Namib Desert (Figure 15). The last named is of some interest because it indicates the effects of fluvial erosion, albeit accompanied by some cavernous weathering, even in so arid an area as the central Namib, where the mean annual rainfall is approximately 50 millimetres (two inches) today.

An inselberg is one kind of isolated highland landform that rises abruptly from desert plains; pinnacles of several types also occur. Erosional remnants near western Tibesti, in the Sahara, exist as spectacular rock towers that seem to thrust upward from the desert floor. These

Inselbergs,  
fans, and  
pediments

L.K. Lustig—EB Inc.

pinnacles represent the remains of a formerly continuous sandstone layer, most of which has been long since eroded away. Other desert pinnacles, by way of contrast, may be the remains of algal deposits in a now-dry lake basin (Figure 16).

Many of the desert highlands, but not necessarily the smaller inselbergs and pinnacles, are surrounded by deposits of sediment that have been transported by floods from the highlands outward, toward desert plains. These deposits are commonly fan-shaped, with their apices located at the mouths of mountain canyons; they are called alluvial fans (*q.v.*), and they occur in most desert regions. If a relatively large open area exists beyond the mountain front, then the fan-shaped form may be nearly perfect, the size being governed only by the distance to which successive floods will debouch before fluvial transport of coarser sediment ceases. The alluvial fan at the mouth of Copper Canyon, in Death Valley, California, is a fine example of this circumstance (Figure 17, left). If, on the other hand, the sediment transported to the mountain front is intersected by a through-flowing transverse channel, then fan development may be nearly or entirely inhibited. This is the case along part of the mountain front in western Saudi Arabia (Figure 17, right). The similarity of colour and hue in this pair of photographs despite their very different geographic locales is noteworthy; the darker tones reflect the occurrence of desert varnish.

L.K. Lustig—EB Inc.

Figure 16: Pinnacles of calcareous tufa in the southern end of Searles Lake Basin, California. The tufa was deposited by algae in a former lake; the depth of water was at least as great as the height of the tallest pinnacle.

The same desert highlands that are fringed by alluvial fans, again excepting the smaller inselbergs and pinnacles, may also be bordered by sloping bedrock surfaces called pediments. These slope abruptly from the mountain front to the surrounding desert plain and may or may not be veneered with alluvium of varying thickness. The principal distinction between alluvial fans and pediments, aside from the fact that fans consist of unconsolidated

sediments and pediments are solid rock surfaces, is that fans are depositional forms, whereas pediments represent the result of erosional processes. (For a thorough discussion of the several theories of pediment origin, see PEDIMENTS.)

The lower boundaries of fans and pediments merge with desert plains, which by any estimate must be designated the predominant desert landform. In some desert regions the plains may be partially covered by shifting sands; elsewhere, the winds have winnowed the finer sediments, leaving a gravel surface in their wake (Figure 9); and in still other cases, the surface consists principally of exposed bedrock. Desert plains are generally characterized by their vast dimensions and extreme smoothness; there is much dispute among authorities with regard to their origin, however. Although it is generally held that the plains were formed by fluvial erosion in the distant past, the gradients involved are so small that it is difficult to conceive of streams traversing their entire length and breadth.

A number of rather large depressions in desert plains have been ascribed chiefly to deflation; that is, to erosion by wind action. Several basins in the Gobi and in the Atacama, together with the better known Qattārah Depression near al-'Alamayn, are in this category. Desert basins in general, however, are essentially structural features. In the basin and range terrain of the western United States, Iran, Pakistan, and elsewhere, the basins that exist were formed principally by the downward movement of large blocks of the Earth's crust between bordering, uplifted blocks that are now mountain ranges. Thus, desert basins alternate with mountain masses in these regions.

Smaller depressions in desert surfaces that are subject to periodic flooding and subsequent evaporation are termed dry lakes, playas, pans, and saline or alkali flats, among other names. They commonly occur at the lowest elevation within the larger basins discussed above; indeed, dry lakes are characteristic of basin and range regions. The playas in such areas may contain several thousands of feet of sedimentary fill beneath their saline crusts. The vertical sequence commonly includes silts, clays, and numerous salt beds, reflecting the occurrence of substantial hydrologic change during the alternating warm and cold episodes of the Pleistocene Epoch. Elsewhere, as in southern Africa and Western Australia, however, the climatic pulses were less pronounced, and only a few feet or tens of feet of sedimentary fill overlies bedrock in many instances. The pans of the Kalahari Desert (Figure 10) are of this type. Common to all dry lakes is the flatness of their upper surface; they are the flattest of all varieties of landforms, save for instances of disruption by pressure ridges which occasionally form along the margins of salt polygons. (For a detailed description of such surface features as well as of other characteristics of dry lakes in desert regions, see PLAYAS, PANS, AND SALINE FLATS; and for information on the nature of the associated salt deposits in arid regions, see EVAPO-RITES.)

## Desert sands

Desert sands and their configurations constitute the last category of landforms to be discussed here. In many ways they are the most interesting of desert landforms because of the complexities associated with the origin of the sands proper and the interpretation of the sheets and dunes that they comprise. It should be reiterated, however, that desert sands occupy only a minor fraction of the deserts as a whole. Even in the Sahara, which contains some of the largest sand seas in the world (*e.g.*, the Grand Erg Oriental in Algeria), the area occupied by sand has been estimated to be no more than about 10 percent. This figure would be somewhat greater for the Arabian Desert, in which the Rub' al-Khali and an-Nafūd are principally sandy areas, and for the Namib Desert of South West Africa which can be roughly divided between a southern sand-covered area and a northern area of gravel plains.

The sands involved in all instances are probably ancient, derived by the erosion of rocks in these areas millions of years ago. Many authorities believe that the great sand volumes of the Sahara and the Arabian Desert reflect accumulation in shallow seas during Tertiary time (65,000,000 to 2,500,000 years ago), followed by uplift of the land areas to their present elevations. In the Saharan case, some have argued that sand accumulation also may have occurred in ancient lakes, but the point to be made is that, contrary to popular belief, wind action is not responsible for the initial assemblage of these vast quantities of sand. The work of the wind has been to move, modify, add to, and subtract from these desert sands after their gathering by marine, fluvial, or lacustrine processes.

Many different kinds of sand dunes have been observed in desert areas, and a nearly equal number of classification systems have been set forth. Basically, dunes may be

either fixed or mobile, the former designation being applied to those dunes sufficiently covered by vegetation to prevent their migration under prevailing winds. Some of the more common types of dunes are the following: longitudinal and transverse, referring to the orientation of linear dunes with respect to wind direction; sigmoidal, or S-shaped, dunes; pyramidal, domed, and star-shaped dunes; and the common crescent-shaped dunes termed barchans. Some longitudinal dunes in the western Kala-

By courtesy of Arabian American Oil Company

Figure 19: Giant sand mountains in the Rub' al-Khali, southern Saudi Arabia. These dunes attain heights of 300 metres; smaller dunes of several types may form on their surfaces.

hari are shown in Figure 18; they are fixed by vegetation on the dune crests. This type of dune also is widespread in the Australian Desert, where, again, the dunes are well spaced, symmetrical, with ridges ranging to about 30 metres in height. Sand dunes in general, however, may range in size from a small pile of sand about one metre in height to the so-called giant sand mountains that attain heights of 300 metres, as in the Rub' al-Khali, in the Arabian Desert as shown in Figure 19. These sand mountains commonly sustain other, smaller dune features on their surfaces.

Although a great amount of work has been done on the dynamics of windblown sand, it remains difficult to relate specific dune types to specific wind velocities, frequencies, and directions. This is partially because of a lack of satisfactory data on desert winds and partially because a time lag is always present—*i.e.*, a particular dune type or dune system may exist under the present prevailing wind regime but may still reflect the effects of an earlier and somewhat different wind regime (see further SAND SHEETS AND SAND DUNES).

Figure 18: Longitudinal sand dunes in the western Kalahari, Botswana.

## THE PERMANENCE OF DESERTS

It was once believed that the present desert areas of the world had always been arid and that the phrase "once a desert always a desert" aptly summarized the subject of permanence. This view is patently indefensible, however, because there is abundant evidence that climatic changes have occurred throughout geological time and will doubtless continue to occur in the future. Changes of two kinds will be considered here, namely, those of the distant geological past and those of more recent vintage—within the past 3,000,000 years, approximately.

**Climatic change.** Meteorologists have argued on theoretical grounds that, because the Earth's rate of rotation and its heating by incident solar radiation have been essentially everpresent and invariant, some form of latitudinal climatic zonation like that existing today must have persisted throughout geological time. As indicated above in the section *General cause of the arid zones*, the existing climatic zonation and general atmospheric circulation are directly responsible for the Earth's two great belts of aridity at latitudes 30° N and 30° S, approximately. This being true, it is not surprising that the idea of the permanence of deserts once held sway.

Considering but a few examples of relatively remote vintage, however, there are many ancient evaporite deposits in the Arctic areas today and sandstone beds with marked eolian characteristics in the mid-latitudes (including western Europe) that are as old as 200,000,000 years. Both evaporites and sandstones of this nature form today only under arid conditions. In today's deserts, on the other hand, many of the ancient rocks were formed under marine conditions, and even coals, reflecting a paludal (swampy) environment, are known. Moreover, in recent years an international group of respected geologists visited a number of locations in Algeria and concluded that widespread striations and other grooves in bedrock, heterogeneous sedimentary deposits, and other features definitely reflected a glacial origin. In fact, the group generally agreed that the present Saharan area was subjected to widespread glaciation during Ordovician time, around 450,000,000 years ago.

These examples indicate that some high- and middle-latitude areas have undergone arid conditions in the distant past, whereas the world's largest desert area today was at one time host to ice sheets. These data seemingly conflict with the meteorological view that the Earth's climatic zones have not changed through time. Reconciliation is possible, however, by recourse to the theories of continental drift and plate tectonics. The former, in its simplest aspect, holds that the present continents have "drifted" about on the Earth's surface since the breakup of a parent landmass about 200,000,000 years ago. Plate tectonics is essentially a refinement of this view, based on abundant evidence that ocean basins have been created along midoceanic ridges through time and that many of the Earth's major mountain systems and earthquake zones can be interpreted in terms of the intersection and abutment of six major "plates" (and a number of lesser ones) that comprise the Earth's crust and upper mantle. These plates—or plates of an earlier system—are thought to have been in motion since the beginning of geological time. The main point involved here is that the present climatic zones of aridity may well be relatively permanent global features but different land areas may have resided in these arid zones during different intervals of geological time. This then is one form of climatic change that has occurred, considering long-term changes.

Evidence of climatic change in arid areas during the more recent past is rather abundant. Physical features that indicate the former existence of more humid conditions include (1) vast drainage systems that are today desiccated and partly filled by sand dunes, (2) the presence of large numbers of dry lakes in many parts of the world, some of which (e.g., Great Salt Lake and Lake Chad) covered areas 10 times as great during intervals of Pleistocene time, (3) the presence of travertine and other spring deposits in currently arid areas, (4) the red soils and other soil varieties thought to form under tropical conditions that occur in the Sahara, Australia, and else-

where, (5) rock weathering of many kinds that seems to require the presence of standing pools of water, (6) vast dune areas that are today fossilized because they have become fixed by vegetation, and (7) a variety of alluvial deposits and terrace sequences that have been interpreted in terms of climatic change; the persistent occurrence of gravel beds within a sequence of lake clays may reflect a change in hydrologic regime, for example (Figure 20).

L.K. Lustig—EB

Figure 20: Part of an irrigation system near Quetta, Pakistan, exposing alluvium in a basin floor. The gravel layer within the fine-grained sediments has been interpreted in terms of climatic change.

In addition, there are relict floras and faunas in arid areas that reflect more humid times; cave paintings, artifacts, and fossils that indicate the former presence of large mammalian faunas that were hunted by prehistoric man; and fluctuating widths of tree rings, as well as historic records of lake level and of streamflow, that suggest measurable climatic changes within the last few thousand years.

It is not claimed that arid areas were everywhere tropical during the several pluvial, or humid, episodes of the Pleistocene Epoch, when the ice ages descended on the middle- and high-latitude regions. Synchronicity of the ice ages and humid episodes in deserts is similarly doubtful, save in a few areas of basin and range topography. It is clear, however, that deserts are sensitive to the changes of precipitation and temperature that have occurred periodically throughout geological time and that these changes have had pronounced effects on the range, abundance, and kinds of plants and animals present and on the principal physical processes operative in the arid regions of the world. If this were not so, then the evidence cited would not exist.

**Desert boundaries.** Knowledge of the shifts in desert boundaries in response to climatic change, such as the estimated 200–300-kilometre shift toward the centre of the Sahara during the last (and mildest) moist episode of the Pleistocene, has occasionally led to cries of alarm that the deserts have been expanding in modern times. Such fears have been expressed with respect to the southern boundary of the Sahara and some parts of the Iranian and Thar deserts. In the latter case, evidence was assembled from all national scientific agencies responsible for the collection of relevant data, and a symposium on the question was organized and held. The conclusion in this case, as indeed in every instance of determined investigation, was that no evidence existed of natural expansion of desert boundaries. Overgrazing by livestock and the de-

Geological evidence

Humid conditions during Pleistocene time

nudation of hillslopes for firewood or fuel appear to be principally responsible for any changes from semi-arid to arid conditions in the vicinity of any desert boundary. It can be argued, however, that the precise location of any desert boundary is actually indeterminate except on small-scale maps and that constant pulsations, or expansions and contractions, about some mean position are the rule rather than the exception. This would accord with the climatic definition of these boundaries, the elements of which are known to change in value through time.

(L.K.L.)

#### LIFE IN THE DESERT

The desert as a biological environment. *Climatic patterns and the biota.* Biological activity is inevitably limited in the absence of water. Above all, it is the green plant that is so limited. Few plants can continue photosynthesis for long in the absence of water; and in the absence of plant growth other living forms have no opportunity to develop. Animals and micro-organisms can exist only if energy sources from green plants are available. They are further limited, though, in the absence of water, for most animals and all micro-organisms can be active only while moisture is adequate.

In the cold deserts in the interior of continental masses, drought is severe for at least a part of the year, and the daily and annual range of temperature may be great. Moreover, very low winter temperatures have a more severe impact on the biota than they might in a region with greater precipitation, because the protection by snow cover is less.

In the tropical deserts cold is no problem, but the clear skies result in a high radiation load on organisms and in high daytime temperatures, often with very large fluctuations from night to day. These factors, too, create more intense stresses on organisms than occur in most environments.

Other effects on the biota of the desert environment arise from the abrasive effects of windblown sand and from the high surface salinity in areas where temporary waters accumulate and evaporate or where evaporation leads to upward movement of salts through the soil profile.

Limited leaching and the small accumulation of organic matter in deserts result in desert soils remaining much closer to the types found in pioneer habitats than do soils in more moist environments. Desert soils seem particularly subject to the formation of impervious surface layers—either by physical processes or through the surface development of algae and lichens—so that the effective drought is accentuated by excessive runoff.

The pioneering conditions that organisms encounter in the desert are permanent, unlike those of other bare and inhospitable habitats, such as coastal sand dunes, rocks, and denuded areas left by human activity. In these climatically more favoured situations, the pioneering organisms initiate changes in the parent soil material that render it more hospitable to newcomers; and a succession of different living communities, each more complex than the last, can take place, leading to a climax community. In the deserts, harsh conditions are not ameliorated by biological activity, and the pioneers themselves constitute the climax.

There are limited desert areas—notably along the coast of South America but also in Baja California, Mauritania, and South West Africa—where the extremely low rainfall is supplemented by dew and the aridity is ameliorated by frequent mist and cloud. The relatively low evaporation rates make conditions in such areas much more moist than their precipitation records would suggest.

*Spatial dispersion of biota.* All of the organisms in a desert do not live under the same environmental conditions. Although the variety of habitats is less than in many wetter environments, it is still great enough to provide effective living conditions for a wide diversity of organisms. Moreover, many organisms show structural and behavioral responses to the environment that tend to neutralize at least some of its extreme features.

It is well known, for instance, that perennial plants in the desert tend to be widely spaced. But, although there are large unoccupied areas between the aerial parts of the plants, excavation may reveal that the root systems are in contact and they exploit the soil so effectively that establishment of new individuals becomes difficult. When rain penetrates the soil, it is rapidly absorbed by the continuous net of roots, and little penetrates to the subsoil. If situations differing in rainfall but otherwise similar are compared, it is found that the plants are more widely spaced as the rainfall decreases. This implies that the amount of plant material remains roughly proportional to the rainfall and that the individual plant is receiving about the same amount of rainfall, thanks to its inhibitory effects on the establishment of competitors.

A similar response leads to the establishment of denser vegetation around the watercourses, even when they run very infrequently, for there the longer periods of availability of subsoil water permit more plants to have similar productivity without more water per individual.

Different plant species in the desert under the same climatic conditions may differ markedly in their local environment, thanks to differences in soil conditions and topography. Even in the tropics there may be a marked difference in growth conditions between the steeper slopes that face north and those that face south. Desert soils, though with little organic matter and less well developed profiles than are usual in more humid conditions, differ sufficiently in their mechanical and chemical properties from place to place to support different types of vegetation. And where stones and boulders are scattered over the soil surface, the microclimates they generate—and the local increase in rainfall penetrating the soil around their edges—permit even some moisture-loving plants such as mosses to develop. Oases similarly are places where a locally dense vegetation corresponds with a locally available water supply.

For animals, the variety of habitats is still greater, for they are generated by the vegetation itself, and since animals are not rooted and dependent on light as green plants are—facts that oblige plants to be more or less exposed to the prevailing atmospheric conditions, however harsh they may be—animals are free to move to more comfortable locations if they desire, even underground. Each species of plant modifies the conditions for the animals around it and may generate living conditions that permit particular animal species to exist, whether providing food, shelter (shade or protection from predators), or layers of litter in which they can live. Movement between different habitats further varies the living range of animals, as when bats roost in caves during the day and emerge in the evening to feed or when the subterranean larvae of darkling beetles, feeding on living and dead roots, emerge as adults into the harsh world of the desert soil surfaces to begin their reproductive activities.

Like plants, some animals may show a wider dispersion in deserts than elsewhere, thus giving each individual a broader area of ground as "his own." Kangaroo rats, for instance, are reported to manifest more aggressive behaviour in the deserts than in other habitats, resulting in larger and more effectively defended territories for each individual.

Types of desert ecosystems. *Cold deserts and shrub steppes.* These occur mainly in the interior of Asia and in the intermountain zone of North America. Winter temperatures are well below freezing, and the ground may be snow covered for considerable periods. Summer temperatures are moderately high (up to 40° C), though the temperature extremes of regions further south near the tropics are avoided since the sun is not so high in the sky. Precipitation often is between 200 and 300 millimetres (8 and 12 inches), and a good part of it commonly falls as snow.

The dominant vegetation is of shrubs, with a discontinuous canopy, but not as widely spaced as in the drier deserts nearer the Equator. In the spring, as the snow melts, there is a flush of growth, and many short-lived annual plants occupy the soil surface. Among the shrubs, species of the genus *Artemisia* are prominent, as are a number

Plants as the basis of living communities

The effects of soil types and local elevation differences on desert environment

of species of the family Chenopodiaceae, particularly in lower lying areas, where there is some accumulation of salt.

**Shrub deserts and thorn scrub.** These ecosystem types occupy a large part of the area of the tropical deserts. The peripheral zone of the Sahara (the Sahel) is dominated by species of *Acacia*, many of them thorny. The Mojave and Chihuahuan deserts in North America are dominated by a range of shrubs, of which the creosote bush (*Larrea tridentata*) is probably the commonest. The same is true in similar deserts of South America. Much of the Australian dry country is dominated by sparse small trees of the very variable genus *Acacia*, while other species of this genus, *Eremophila*, *Cassia*, and members of the family Chenopodiaceae form a denser understory. In other peripheral parts of the Australian arid zone, the low-growing mallees (*Eucalyptus* species) take the place of the treelike *Acacia* species.

Under the shrubs there is often a partial ground cover of tufted perennial grasses, while the interspaces are filled with short-lived, small flowering plants following rain.

Larger plant-eating animals are not uncommon in this type of country, entering from the surrounding areas of somewhat higher rainfall and more grass during periods when forage is more abundant and retreating when times are harder. Some, such as the desert white-tailed deer and collar peccary in America and the kangaroo in Australia, make their permanent home in such conditions.

**Stem-succulent deserts.** These striking formations are of rather limited extent and consist of only the Sonoran Desert (Gran Desierto) of Arizona and northwestern Mexico, the area between Peru and Argentina, and the Namib Desert in South West Africa. Their special appearance rests on the geographical availability of certain plant groups absent from many of the deserts—the cactus family (Cactaceae) of the Americas and the arborescent members of the family Euphorbiaceae mainly found in Africa. These plants have adopted a special growth habit that provides one alternative solution to the problem of survival in drought. Elsewhere, their role is taken over by shrubs.

**Herbaceous deserts.** There are desert areas where shrubs or stem succulents are few or absent and where the bulk of vegetative matter is in the form of perennial herbs. These are nonwoody plants whose tops die back each year but whose roots survive to produce new tops year after year. The Nullarbor Plain in southern Australia is of this type; the soil is thin over a continuous limestone substrate, permitting water to penetrate freely, and these harsh conditions are doubtless responsible for the lack of shrubs. Even the perennial species of the family Chenopodiaceae form only a sparse ground cover. In southern Africa, there are areas where the dominant vegetation is formed of low-growing succulents.

**Salt deserts.** Within the deserts, there are many areas where the soil contains a high concentration of salts; most commonly sodium chloride is predominant, but in some places sulfates or carbonates may be more important, and other substances may also, in part, take the place of sodium. These areas are usually in basins of internal drainage, and they may surround highly saline lakes, such as the Dead Sea in Jordan and Israel and the Great Salt Lake in the western United States, or large salt pans flooded only after exceptional rains, such as Lake Eyre in South Australia. Very few organisms can grow in a concentrated salt solution, and in consequence the area of a salt pan has a very simple community and may appear quite bare. As the salinity decreases, either around margins of such an area or through seasons of high rainfall, a limited range of higher plants can establish themselves—mainly shrubs or sub-shrubs of the family Chenopodiaceae. It is noteworthy that these are closely related to—sometimes, indeed, the same as—the species found in the coastal salt marshes. There, too, a high and variable salinity obtains, and near the spring high-tide mark, in some seasons, high salinity and low moisture content persist for a week or more. In the salt deserts, on the other hand, these conditions may persist for months.

Whereas in salt marshes the increase in soil level with buildup of organic matter may eventually take the area above tide level, so that leaching can take place and succession proceed, the vegetation in salt deserts is a soil-dependent climax and will not develop further.

**Sand dunes.** Where sand dunes occur in deserts, their consolidation or stabilization by vegetation is much more difficult than along seacoasts. In both situations consolidation depends on plant species with wide-spreading root or rhizome (underground rootlike stems) systems. At the coast, this normally permits invasion and establishment of other species, and thus begins a succession. In the desert, the pioneers are the climax, and the barely consolidated dunes are likely to become mobile again if any disturbance breaks the fragile cover and permits wind blowouts. The free drainage of the sands implies that moisture conditions, as well as substrate mobility, are particularly harmful to plant life; and sand dunes in an arid landscape are likely to be among the most persistently bare areas on the Earth's surface.

**Wadis and watercourses.** Along the ephemeral wadis and watercourses of the desert, the occasional violence of the waters discourages perennial plants; but along the sides, where flow is less frequent and less violent, a special vegetation of deep-rooted moisture-requiring shrubs and trees develops. These benefit not only from water that actually flows down the channel but also from its much deeper penetration into the soil—often quite permeable in these situations—and consequent longer availability. Some of these plants, called phreatophytes, may be able to tap water many metres below the surface and thus survive a drought during which most of the vegetation around dies. A special population of birds and other animals is associated with the vegetation around the watercourses.

**Aquatic ecosystems in the deserts.** A torrent that flows for two or three days and is then dry clearly does not permit the development of an aquatic ecosystem. But some waters in the deserts are longer lived, and they have their own special biota. Even in the temporary watercourses, there may be pools that remain filled for weeks, and in these an ecosystem with algae, insect larvae, and amphibians will develop. The same applies to the temporary lakes known as playa lakes lying in hollows and filled for a month or so following rain. If these temporary lakes are saline, the ecosystem may be much simpler, for the salt concentration may considerably exceed that of seawater and the species that can endure it are few.

Virtually the only permanent waters of low salinity originating in the deserts are springs, renewed by flow from underground. These may develop complete ecosystems of similar structure to aqueous systems elsewhere, though generally simpler—due, doubtless, to isolation. These include rooted aquatic and riparian higher plants, algae, crustaceans, insects, amphibians, and fish.

The desert biota and their adaptations. **Protists.** Soil micro-organisms occur in desert soils in about the same degree of diversity as in other soils and can survive frequent desiccation and remoistening. In some deserts, there is a noteworthy development on the soil surface of blue-green algae, which are thought to be active in nitrogen fixation (converting atmospheric nitrogen to forms that plants can utilize) and may also modify the infiltration properties of the soil.

**Plants.** A great deal has been written of desert plants and their adaptations to the rigours of desert life. Apart from the blue-green algae mentioned above, other algae are practically confined to the limited water areas of the desert. Parasitic fungi are as abundant as in other environments, though mainly confined to the higher groups not requiring free water for swimming reproductive cells. **Saprophytic fungi** (*i.e.*, fungi obtaining food from dead organic matter) are not abundant, the limited organic matter in and on the soil providing little in the way of nourishment, and active growth being possible only during the short periods when the soil is moist.

Lichens are numerous and often prominent—particularly the crustose types. They often form an almost continu-

Vegetation on dunes and along ephemeral streams

The deserts of cactus and cactus-like plants

Algae, fungi, lichens, and mosses

ous covering to the soil surface and are then able to take advantage of any wetting of the soil for short-lived periods of photosynthesis.

Mosses and liverworts are few and are often confined to special habitats more moist than the deserts as a whole. Ferns are not infrequently found in rock crevices and similar habitats. Club mosses also occur, some showing the remarkable adaptation of being able to dry out and withstand desiccation and lack of active growth in the form of a ball, which may be blown about freely.

Some gymnosperms (nonflowering seed plants) are noteworthy inhabitants of the deserts. Conifers and cycads are few in desert areas, but several species of *Ephedra* are important desert shrubs—a role to which their near-leaflessness suits them; on the other hand, the remarkable *Welwitschia*, with its large, split leaves, is also a desert plant, confined to the Namib in South West Africa.

Among the angiosperms (flowering seed plants), there are some families that are especially characteristic of the deserts. The family Chenopodiaceae is such a characteristic inhabitant of salt deserts (and other saline habitats) throughout the world. Some members of the family Zygophyllaceae are also normally desert plants. In the Americas, species of the family Cactaceae are characteristic of the deserts, and the small family of Fouquieriaceae are found there only. Another group playing an important part in many of the world's deserts, though not confined to them, is the family Mimosaceae, and particularly the genus *Acacia*. Species of this genus characterize the peripheral zones of the Sahara, are dominant in many parts of the Australian desert, and are far from negligible in the American and Asian deserts.

Plants in the deserts have to surmount a difficulty that the photosynthetic mode of nutrition imposes on them. In order to produce food by means of photosynthesis, carbon dioxide from the atmosphere must be taken into the plant. This unavoidably leads to the loss of water from the plant at the same time, since the same small openings in the plant surface (called stomates) serve for both purposes. Various solutions to this problem are to be seen in desert plants.

One way to avoid the adverse effects of limited water availability is to live through dry periods in a completely inactive form—as a seed. This is the solution to the problem adopted by the ephemerals, or short-lived annual plants. These plants shorten the duration of their life cycle so that seed germination follows very promptly after an adequate storm and seed formation is already in progress by the time soil moisture is reduced to the wilting point. This means, of course, that the total period of photosynthesis is limited to a few weeks every year—perhaps in some years to none at all. Nevertheless, this group of plants is a very successful element in desert vegetation, as is evident in the flowery display often seen over the desert floor a month or so after rain.

Another solution, rather similar, is for the plant to restrict itself during the dry season to inactive tissues that have very limited gas exchange and to form tissues capable of free gaseous diffusion only during periods when soil moisture is available. This mode of growth is called the deciduous habit, and it is expressed by plants everywhere that drop their leaves during winter or, in the case of deserts, during dry periods. A good many species of desert plants have short-lived leaves and are bare for much of the year. The spectacular ocotillo (*Fouquieria splendens*) of the Sonoran Desert of southwestern North America is one example.

Another solution is to separate temporally (*i.e.*, in time) the gaseous-diffusion process from that of energy utilization. Normally, the photosynthetic surfaces must be open to carbon dioxide diffusion during daylight periods, in order that radiant energy may be converted to chemical energy in the photosynthetic process, and this incurs the penalty of water-vapour loss at a time when the diffusion gradient for it is particularly high because of high daytime temperatures and dry air and that for carbon dioxide is no more favourable than at any other time. If carbon dioxide can be taken up at night instead, the concomitant loss of water can be much reduced. Many des-

ert plants have this ability, carbon dioxide being stored in the form of carboxylic acids at night, which are converted to carbohydrates when radiant energy becomes available in the day. The stomates in these plants open by night to allow entry of carbon dioxide into the intercellular spaces and close by day to restrict loss of water vapour while photosynthetic reduction of the "stored" carbon dioxide proceeds. This so-called crassulacean metabolism is not confined to the family Crassulaceae but is found in a good many other plants of the deserts.

Another mechanism, like the deciduous habit, restricts gas exchange when drought conditions prevail not by loss of leaves (a wasteful process) but by direct restriction of gaseous diffusion. The stomates, through which most gas exchange occurs, can generally open or close according to prevailing environmental conditions; adaptations may increase their responsiveness to water stress and at the same time reduce the amount of gaseous diffusion in other ways. The means used include increased thickness of the cuticle (outer layer of stem and leaves), development of wax layers, rolling of leaves in drought, and so forth—a series of adaptations often described under the heads of xeromorphy or xerophily.

Another mechanism, often combined with restriction of gaseous diffusion by stomates during periods of drought and with crassulacean metabolism, is water storage in succulent tissues. This has developed in rather few taxonomic groups—the families Aizoaceae, Crassulaceae, Cactaceae, some Asclepiadaceae (especially the subfamily Stapelieae), some Chenopodiaceae, some Liliaceae, the arborescent Euphorbiaceae, and a few others.

In some cases, plants can grow in deserts without suffering water shortage through having an extremely deep root system penetrating to subsoil water. A high ratio of root to shoot tissue is indeed a common feature of desert plants, whether the root system is deep or spreads widely.

A hazard of the deserts, when water loss from aerial parts is restricted, is the high temperature in these organs that may result from intense sunlight when cooling by evaporation is limited. Resistance to high tissue temperatures may be part of the adaptational equipment of these plants.

Temperatures on the soil surface in deserts may be very high (70° C, or 158° F), and plants growing there must be prepared to endure them. Lichens and blue-green algae, which compose the bulk of the soil-surface flora, are usually dry at times when the soil-surface temperature is highest, in which state they are highly resistant to extreme heat. Perennial plants usually provide shade to the soil immediately around their bases, so that very high temperatures are eliminated there. For small annuals, on the other hand, high soil temperatures around their stem bases when soil moisture has been depleted may cause some death of tissues and accelerate flower and seed maturation.

Another factor to which adaptation is required in some desert situations is the high salinity of the soil solution. Usually plants growing in such situations have difficulty taking water into their roots from such solutions. Many plants have adapted to these conditions with a highly concentrated sap, enabling the root to take up water even from saline solutions.

Invertebrate animals. Many groups of invertebrates require a marine environment and are consequently absent from the deserts; other groups occur in desert waters but not on land. The flatworms (phylum Platyhelminthes) occur as parasites inside the bodies of animals, as elsewhere. The various groups of nematodes (phylum Aschelminthes)—animal parasites, plant parasites, and those living free in the soil—are found in the deserts as in other habitats, though activity in the soil is restricted by their need for free water. The segmented worms (phylum Annelida) are represented by a few earthworms, occurring only in favoured situations. There are a fair number of snails found in deserts, some species of which are remarkably resistant to arid conditions.

It is, however, of the insects and spiders and their relatives (phylum Arthropoda) that one thinks when desert invertebrates are mentioned. The crustaceans of that phy-

Adaptations of plants to high temperatures

The problem of water loss during photosynthesis

lum are represented by the brine shrimps that live in concentrated salt solutions and by the terrestrial isopods (wood lice, or sow bugs) that occur fairly widely. Myriopods are reasonably numerous in the desert, both the vegetarian millipedes and the carnivorous centipedes. All the groups of arachnids (spiders, scorpions, etc.) except the primitive marine *Limulus* occur in the deserts, and some are more at home than in many other environments. Scorpions are numerous, as are ground-dwelling spiders (web-building spiders are not particularly common), and there are plenty of mites, including those inhabiting the soil.

Insects are abundant, though forms with aquatic larvae such as the dragonflies and mayflies are found only around the waters; termites, beetles, butterflies, moths, flies, ants, bees, and wasps are all universally present in deserts, as are the grasshoppers and true bugs.

Adaptations to desert conditions by insects and their relatives

For many insects and arachnids, the problems of life in the deserts are easier than for most vertebrates. Like many desert plants, they have a waterproof cuticle, or skin, to retain water; and the frequently short life cycle, often combined with metamorphosis (changes during the life cycle from egg to larva, etc.), enables vulnerable stages to be timed for the less adverse seasons. By persisting through unfavourable periods in an inactive stage (egg or pupa), the animal can avoid many of the difficulties of desert life, much as does the ephemeral plant that persists as a seed or the deciduous plant when reduced to inactive woody tissue during dry periods. Another means of avoiding environmental difficulties is to burrow beneath the soil. Many arthropods burrow for at least a part of their life cycle; and there is an abundant fauna that spends its whole life beneath the soil. This is true of nematodes and the few desert earthworms, of course, as well as large numbers of mites and almost all insects of the order Collembola (springtails). These soil arthropods form part of a trophic cycle (food chain) within the soil mass, in which material originally derived from plant roots is eaten by herbivores and they, in turn, by several carnivore levels. This material eventually returns to detritus, or the decaying organic state, to be acted upon by micro-organisms, which are again taken into the animal sequence.

Some of the subterranean arthropods are larval stages of adults that spend their life on the soil surface. There are important groups, however, whose adult life is divided between the upper and lower worlds. The most important are the ants and the termites. Not all ants have subterranean nests, but, in deserts, by far the majority do so; and all termites avoid the light, building covered runways when they come above ground level or developing channels through woody stems. Thus the ants, and even more the termites, avoid the risk of exposing the more vulnerable immature forms to the high radiation, temperature, and evaporation rate of the open desert; and they limit the time of exposure of the more resistant adults to what is required for food gathering (in the case of ants) and defense.

**Vertebrate animals.** The desert waters, when permanent and not too saline, contain fish, and in some cases the species are endemic (peculiar to the locality), because of the isolation of some of these ecosystems. They are generally closely related to species in nearby non-desert areas. Little is known of their special adaptations, though they must often tolerate a higher and more variable salinity than do their relatives elsewhere.

Frogs and toads are far from uncommon in the deserts, despite their need of an aqueous environment for reproduction. Consequently, desert amphibians need to be opportunistic, responding very quickly to rain that leaves standing water and then passing through the stages of egg laying and larval life before this water dries up. The selection pressure for rapid larval development must be very intense, for those larvae still dependent on gill breathing when the pools dry will die. The adults, with a moist and unprotected skin, are also very vulnerable to high evaporation rate and spend most of the time between rains inactive in a protected spot, often burrowing deep into the soil.

Reptiles are perhaps the most characteristic group of the desert animals. Lizards and snakes are numerous, tortoises and even turtles occur, and crocodiles are common in some tropical desert waters. The majority of the lizards are insectivorous, though some are herbivores. The snakes mostly feed on other vertebrates, in the main small mammals and birds' eggs and nestlings. Some of them have refuges in holes in the soil—perhaps more from predators than from the climate. But the majority spend most of their life exposed to high temperatures and evaporation on the surface of the soil. Their scaly skin is indeed resistant to water loss, but the radiation load they suffer is often considerable. They have no means of temperature regulation except seeking shade, and their tissues must be resistant to temperatures well above the normal limits for warm-blooded animals. Though some show bright warning coloration, many are camouflaged in the colours of the soil surfaces on which they live.

Birds are as numerous in deserts as food availability permits but often spend only part of their lives in this environment. Apart from seasonal migration, they may move between roosting or nesting sites and feeding areas. The lack of trees or tall shrubs to provide nesting positions excludes many species (apart from foraging excursions), and many desert birds nest on the ground. The eggs are in some cases covered with mounds of vegetable material, which give partial protection and provide a more uniform temperature for incubation. Running birds are numerous in the deserts and include some of the largest—the ostrich in South West Africa (and previously in North Africa and the eastern Mediterranean countries); and the emu in Australia, both of which are herbivores. Some birds are present that are prominent predators and carrion eaters, such as the roadrunner and magpie of the North American deserts. **Raptors** (hawks, eagles, etc.) are important and have in the deserts excellent visibility for attacking prey from the air. They may nest in rocky parts of the deserts themselves, but their range of movement is such that they can often operate from areas in adjacent but different vegetation.

Desert birds

Some bird species show notable adaptation to the desert environment in their reproductive habits. Gambel quail, for instance, do not reproduce in years with below-normal rainfall, when food for the young would be scanty; ducks in central Australia have lost the annual reproductive rhythm and will breed at any time when rain falls.

There are many mammals in the deserts, though the modifications required in behaviour or physiology (or in both of these) are considerably greater than for the reptiles. This is largely because they are warm-blooded and because they excrete urea rather than uric acid, which imposes extra demands on body water.

Most mammalian orders, other than those that are purely aquatic, are found in the deserts. Primates (apes, monkeys, etc.), mainly tree dwellers, are naturally not prominent, although several species of baboon are found in the African and Arabian deserts. Edentates (anteaters) and insectivores are few, but bats are often numerous, roosting in the caves and rock crevices that are commonly found in desert regions. The rodents (rats, mice, etc.) and lagomorphs (rabbits, hares, etc.) form the largest group of desert-inhabiting mammals. Some of them are remarkably successful there—the European rabbit, for instance, which, following its introduction from Europe into Australia in the 19th century, not only spread through the temperate parts of the continent but also colonized a large part of the southern desert region. The native rodents of the deserts often show marked physiological adaptation to the desert, water requirements being reduced to a minimum. Some, in fact, can subsist on the metabolic water produced by respiration of their food-stuffs. Many desert mammals avoid high radiation loads and decrease their water losses by spending the midday hours in the shade of bushes and feeding in the early morning, late evening, or at night. Many seek the shelter of burrows in the earth, with their much more moist and consistent conditions, at least during the daytime hours, and their life above ground may be limited to nocturnal foraging.

Herbivores in the desert can benefit from the ability to move rapidly, from one feeding place to another or between feeding and drinking places, so it is not surprising that a fair number of ungulates (hoofed animals) make the desert their home. Many are nomadic and range over large areas, thus being able to benefit from vegetation growth following local storms, without the risk of starvation imposed by eating out the forage within a limited territory. There are numerous antelopes, goats, and sheep in the deserts of all continents but Australia. Some of the wild asses are at home in the deserts of western Asia and North Africa, and escaped domestic equines (burros in North America, brumbies in Australia) have taken successfully to the deserts and desert margins. Outstandingly successful among ungulates in the deserts, however, are the camels, whose adaptation to life there is well-known. Their broad feet suit them to movement over sandy areas (though such areas are extensive only in limited parts of the desert regions); they have large reserves of fat, to enable them to live through long periods of scanty forage; and they can live for many days without drinking, making up their water deficit by enormous drafts when opportunity presents itself.

Among the carnivores, lions inhabit the desert margins of Africa and Asia, and some smaller cats also hunt in the deserts, both in the Old World and the New. Several of the hyenas are desert animals, and some of the dogs are also prominent desert carnivores, notably the coyote and kit fox in North America and the dingo in Australia.

The marsupials (pouched animals) include a number of species well adapted to life in the Australian desert—many of the kangaroos and wallabies and a variety of smaller herbivorous and omnivorous species.

**Man.** A wide variety of human races have adapted successfully to life in the deserts. Caucasoid peoples inhabit the deserts of North Africa and western Asia, and the Australian Aborigines, thought to be more closely related to them than to other major racial groups, live in the deserts of Australia. Negroid peoples live on the southern margins of the North African desert and in South West Africa. Mongoloid peoples occupy the Central Asian deserts and those of North and South America.

As would be expected in an animal of such behavioral diversity as man, his adaptations have been behavioral and cultural rather than physiological. Irrigation civilizations have been developed in many arid regions of the world—in fact, the Nile Valley and the valley of the Tigris and Euphrates, which were two of the cradles of civilization, run through deserts. Where irrigation was not possible, low vegetative productivity imposed a nomadic culture on desert-dwelling societies.

Apart from nomadism and irrigation works, man's behavioral adaptations include his use of thick-walled dwellings with few windows; water storage in deep, covered cisterns; clothing, often white, protecting against excessive radiation; and domestication of desert animals, notably the camel.

Productivity of deserts. The natural productivity of the deserts is low compared with that of most other ecosystems. The dependence of all plants on water and of other organisms on plants means that the arid conditions limit productivity where radiation, temperature, and other growth factors would otherwise permit the highest levels of productivity on the Earth. The proportion of solar energy incorporated in organic matter, rarely exceeding 2 percent in natural communities, is in the deserts a small fraction of 1 percent. The bulk, or biomass, of vegetation in the Syrian Desert has been reported as ranging from 470 to 4,800 kilograms per hectare (kg/ha; or 420 to 4,300 pounds per acre) and, in the cold deserts of Central Asia, from 55 to 7,000 kg/ha.

In cold deserts in North America dominated by sagebrush, figures between 1,000 and 3,000 kg/ha of dry matter per year have been recorded, as compared with 50,000 to 100,000 kg/ha for mountain forests in the same latitude. For the Sonoran Desert a figure of 1,400 kg/ha per year has been quoted.

While the standing plant biomass may be well over 1,000 kg/ha, the animal biomass is far less. Figures on

which to base even a rough estimate are very scanty, but 100 kg/ha would probably be exceptionally high, and 10 kg/ha the more usual order of magnitude.

The deserts have been used by food-gathering human societies for many millennia. Provided the population is sparse and nomadic, a reasonably reliable living may be wrung even from these unpromising habitats. Good examples are the Australian Aborigines, who made use of a wide range of fruits and roots and insects, reptiles, and mammals. Other peoples use the deserts by grazing on them flocks of domesticated livestock and constantly moving the flocks to fresh pastures as the limited growth is grazed off. (D.W.G.)

**BIBLIOGRAPHY.** The literature on arid regions is both vast and specialized and there are few general works that embrace it in its entirety. The interested reader should consult WILLIAM G. MCGINNIES, BRAM J. GOLDMAN, and PATRICIA PAYLORE (eds.), *Deserts of the World: An Appraisal of Research into Their Physical and Biological Environments* (1968), for reviews of work on weather and climate, geomorphology and surface hydrology, surface materials, and plants and animals in the arid regions. Each of these reviews is accompanied by an extensive bibliography. Another excellent source of information has been provided by the UNESCO series of publications categorized as reviews of research or proceedings of symposia. Important volumes in the series include: *Reviews of Research on Arid Zone Hydrology* (1953); *Proceedings of the Ankara Symposium on Arid Zone Hydrology* (1953); *A History of Land Use in Arid Regions* (1961); *The Problems of the Arid Zone* (1962); *Changes of Climate* (1963); and *Geography of Coastal Deserts* (1966). The latter provides a complete descriptive summary of every coastal desert region in the world and contains much information that was touched on only briefly in this article.

Some useful articles on specific characteristics of deserts and on the potentialities of the arid regions are presented in WILLIAM G. MCGINNIES and BRAM J. GOLDMAN (eds.), *Arid Lands in Perspective* (1969). Other books and monographs covering the physical characteristics of the several world deserts are listed in the bibliographies accompanying articles on particular deserts. A few papers from the more specialized journals might be mentioned here, however, to serve as a guide to some of the topics not normally mentioned in popular accounts. Two summary papers by R.F. PEEL provide excellent insight to knowledge of the arid regions and the limitations thereof. These are: "Some Aspects of Desert Geomorphology," *Geography*, 45:241-262 (1960); and "The Landscape in Aridity," *Trans. Inst. Br. Geogr.*, no. 38 (1966). Interpretations of alluvial sequences, dune patterns, and lake expansion are set forth in three papers treating Saharan regions, namely: C. VITA-FINZI, "Late Quaternary Alluvial Chronology of Northern Algeria," *Man*, 2:205-215 (1967); A.T. GROVE, "The Ancient Erg of Hausaland, and Similar Formations on the South Side of the Sahara," *Geogr. J.*, 124: 528-533 (1958); and R.A. PULLAN, "The Recent Geomorphological Evolution of the South Central Part of the Chad Basin," *J. W. Afr. Sci. Ass.*, 9:115-139 (1964). In this vein, the recent work of KARL W. BUTZER and CARL L. HANSEN, *Desert and River in Nubia* (1968), is an outstanding example of such interpretations of alluvial chronology and history in the Nile Basin.

The phenomenon of piping in arid regions is also seldom mentioned in general works and the interested reader should consult the basic paper by G.G. PARKER, "Piping: A Geomorphic Agent in Landform Development of the Drylands," *International Association of Scientific Hydrology*, no. 65, pp. 103-113 (1963). Finally, the subject of possible glaciation in Africa and Australia is well covered in two modern papers, namely those by L.A. FRANKS and J.C. CROWELL, "Late Paleozoic Glaciation. II, Africa Exclusive of the Karroo Basin," *Bull. Geol. Soc. Am.*, 81:2261-86 (1970); and R.W. GALLOWAY, "Late Quaternary Climates in Australia," *J. Geol.*, 73: 603-618 (1965).

None of the works cited here should be considered as the best or only papers available; they are merely examples of the thousands of specialized articles to be found in the literature on physical aspects of the arid regions. The biological aspects of deserts are also treated in such articles, but the following books and symposium volumes provide good summary coverage: GEORGE W. BROWN (ed.), *Desert Biology* (1968), a symposium volume in which numerous specialist authors discuss their own fields of desert biology in varying depth—attention is concentrated on the deserts of North America; J.L. CLOUDSLEY-THOMPSON (ed.), *Biology of Deserts: The Proceedings of a Symposium on the Biology of Hot and Cold Deserts Organized by the Institute of Biology*

(1954), includes 28 papers on a wide range of biological topics relevant to desert life, some in French, and mainly relating to the deserts of Africa and the Near East; *Desert Life* (1965), a general semipopular account; and with M.J. CHADWICK, *Life in Deserts* (1964), a general account intended for use in colleges; and KNUT SCHMIDT-NIELSEN, *Desert Animals: Physiological Problems of Heat and Water* (1964), a discussion of how vertebrates (particularly mammals) adapt themselves to the shortage of water and often its salinity, and to the high temperatures in the deserts.

(L.K.L./D.W.G.)

## Detroit

Its name an international byword for the American automotive industry, Detroit and its metropolitan area in southeastern Michigan comprise one of the major industrial-commercial complexes in the United States. In spite of an increasingly diversified manufacturing and shipping base, its economy remains unusually sensitive to national or international events that affect the prosperity of its major industry, automobile production, and economic booms and depressions tend to be felt more keenly in Detroit than in most areas of the country.

Fronting the Detroit River, which connects Lake Erie with Lake St. Clair, the impressive skyline of downtown Detroit looks across the international boundary to Windsor, Ontario. By the early 1970s, however, this facade disguised a city in which the characteristic urban problems of the U.S. city existed to an extreme degree. Of its 1970 population of more than 1,500,000 (metropolitan area nearly 4,200,000), some 44 percent were black, and racial tensions that had exploded in 1967 threatened to do so again at any time. The city was losing industry and much of the more affluent white community to the suburbs, and its ability to meet the constantly spiralling costs of welfare and other social services was diminishing. Crumbling ghettos covered much of its landscape, and problems of air and water pollution added to the civic malaise. Other observers saw, on the other hand, more than a few signs of a city making a dynamic comeback: especially in the many areas of physical rebuilding and in the many persons, particularly from the black community, moving into positions of leadership and providing a new sense of buoyancy. (For information on related topics, see the articles MICHIGAN; GREAT LAKES.)

### THE GROWTH OF THE METROPOLIS

Detroit was founded in 1701 by a French trader, Antoine de la Mothe Cadillac, who was seeking a strategic location for a new post to protect and encourage the French fur trade and to advance his own economic interests. On July 24 he came ashore near the present site of the Veterans Memorial Building with 50 soldiers, an equal number of voyageurs and settlers, and about 100 friendly Indians. A palisaded enclosure, about 200 feet square, was erected and named Fort-Pontchartrain du Détroit (of the strait) in honour of Cadillac's patron, comte de Pontchartrain, Louis XIV's minister of state. Later, the British called it simply Detroit. Despite his success, Cadillac was plagued by enemies in Quebec and Paris. To placate them, the King removed Cadillac from Detroit in 1710 and appointed him governor of Louisiana.

In the century after Cadillac's departure, Detroit slowly laid the foundation for its future growth despite the effects of three changes in control.

First, on November 29, 1760, as part of the treaty ending the French and Indian War, Detroit was surrendered without resistance to a British force under the command of a famous ranger, Maj. Robert Rogers. But a threat to British control developed shortly after, when some of France's Indian allies, notably the Ottawas under Chief Pontiac, organized a plot that was to culminate in the seizure of Detroit through a ruse. In May 1763 Chief Pontiac made his move, but Maj. Henry Gladwin, commandant, learned of the plan and foiled the conspiracy. A bitter siege followed, and, in the subsequent treaty of peace, France ceded its claims to the territory east of the Mississippi River. The British then came into undisputed possession of the area.

At the close of the American Revolution, Great Britain ceded the lands west of the Alleghenies to the United States but, in violation of the treaty, refused to withdraw troops from Detroit and various other posts. Since the British then had the friendship of the Indians, they kept stirring them up against Americans migrating to the West. After a series of campaigns against the Indians culminating in the Battle of Fallen Timbers, the Jay Treaty provided for the evacuation of the British posts. On July 11, 1796, Capt. Moses Porter arrived at Detroit with 65 soldiers to occupy the fort.

There was to be one more transfer of control, one that distinguishes Detroit as the only major American city ever occupied for an extended period of time by a foreign foe. Soon after the outbreak of the War of 1812, Gen. William Hull surrendered the town to the British forces without a defense. The British held Detroit until late September, 1813, when Lieut. (later Commodore) Oliver H. Perry's victory in the Battle of Lake Erie (September 10) had made further occupation of the city impossible. Thus, the way was cleared to the continued development of the settlement that had been incorporated as a town in January 1802, with a board of trustees as the governing body.

In 1805 Michigan Territory (later to be Michigan, Wisconsin, and a part of Minnesota) was created by Congress and placed under a governor and judges. Detroit was designated the capital, and it remained the capital for ten years after Michigan became a state in 1837.

On June 11, 1805, the whole town was swept by a devastating fire. Every building except one was burned to the ground, but, miraculously, no lives were lost, and only two persons were injured. Each citizen whose home was burned was given a larger piece of land than he had previously held, and the city became less compact but, nevertheless, carefully planned. The governor, Augustus B. Woodward, produced a layout based on the design of a regular hexagon, with a round park in the centre and broad streets radiating from it. To accommodate later growth, other hexagons could be laid out adjoining the original one. As the city spread beyond its original boundaries, however, the plan was not extended, and years later only in the downtown area could one see vestiges of Woodward's dream.

In the meantime, thought also was given to government. Michigan Territory officials revoked Detroit's 1802 charter for a new one in 1806, providing for a mayor appointed by the governor and an elected council of two houses with three members each.

By 1810, Detroit had a population of 1,650 and in 1815 was reincorporated as a city. A board of trustees, who chose their own president, became the governing body, and in 1824 a new charter provided for a mayor and a council of aldermen elected by wards. With slight variations, this pattern was to persist until a new charter in 1918 provided for a nonpartisan mayor and council of nine, the latter elected at large. This nonpartisan "strong mayor" form remained intact despite many challenges in the mid-1900s.

Those early years also helped set the pattern for economic and social development. In 1818 the "Walk-in-the-Water," the first steamboat on the upper Great Lakes, began regular runs between Buffalo and Detroit—and thus was dramatized the strategic location of the city. Soon thereafter other lines appeared, and shipbuilding and chandlery became profitable enterprises. Forwarding and commission houses flourished. By mid-century, although not the queen of the Great Lakes, Detroit was at least a prominent member of the queen's court. But, more importantly, Detroit became a centre for capital, provided by fortunes amassed in the lumber industry, and a centre for skilled workmen, due to the shipbuilding and manufacturing of machinery that developed there in the mid-19th century. This combination of money and trained manpower was the base on which Detroit depended when it assumed the leadership of the automobile industry.

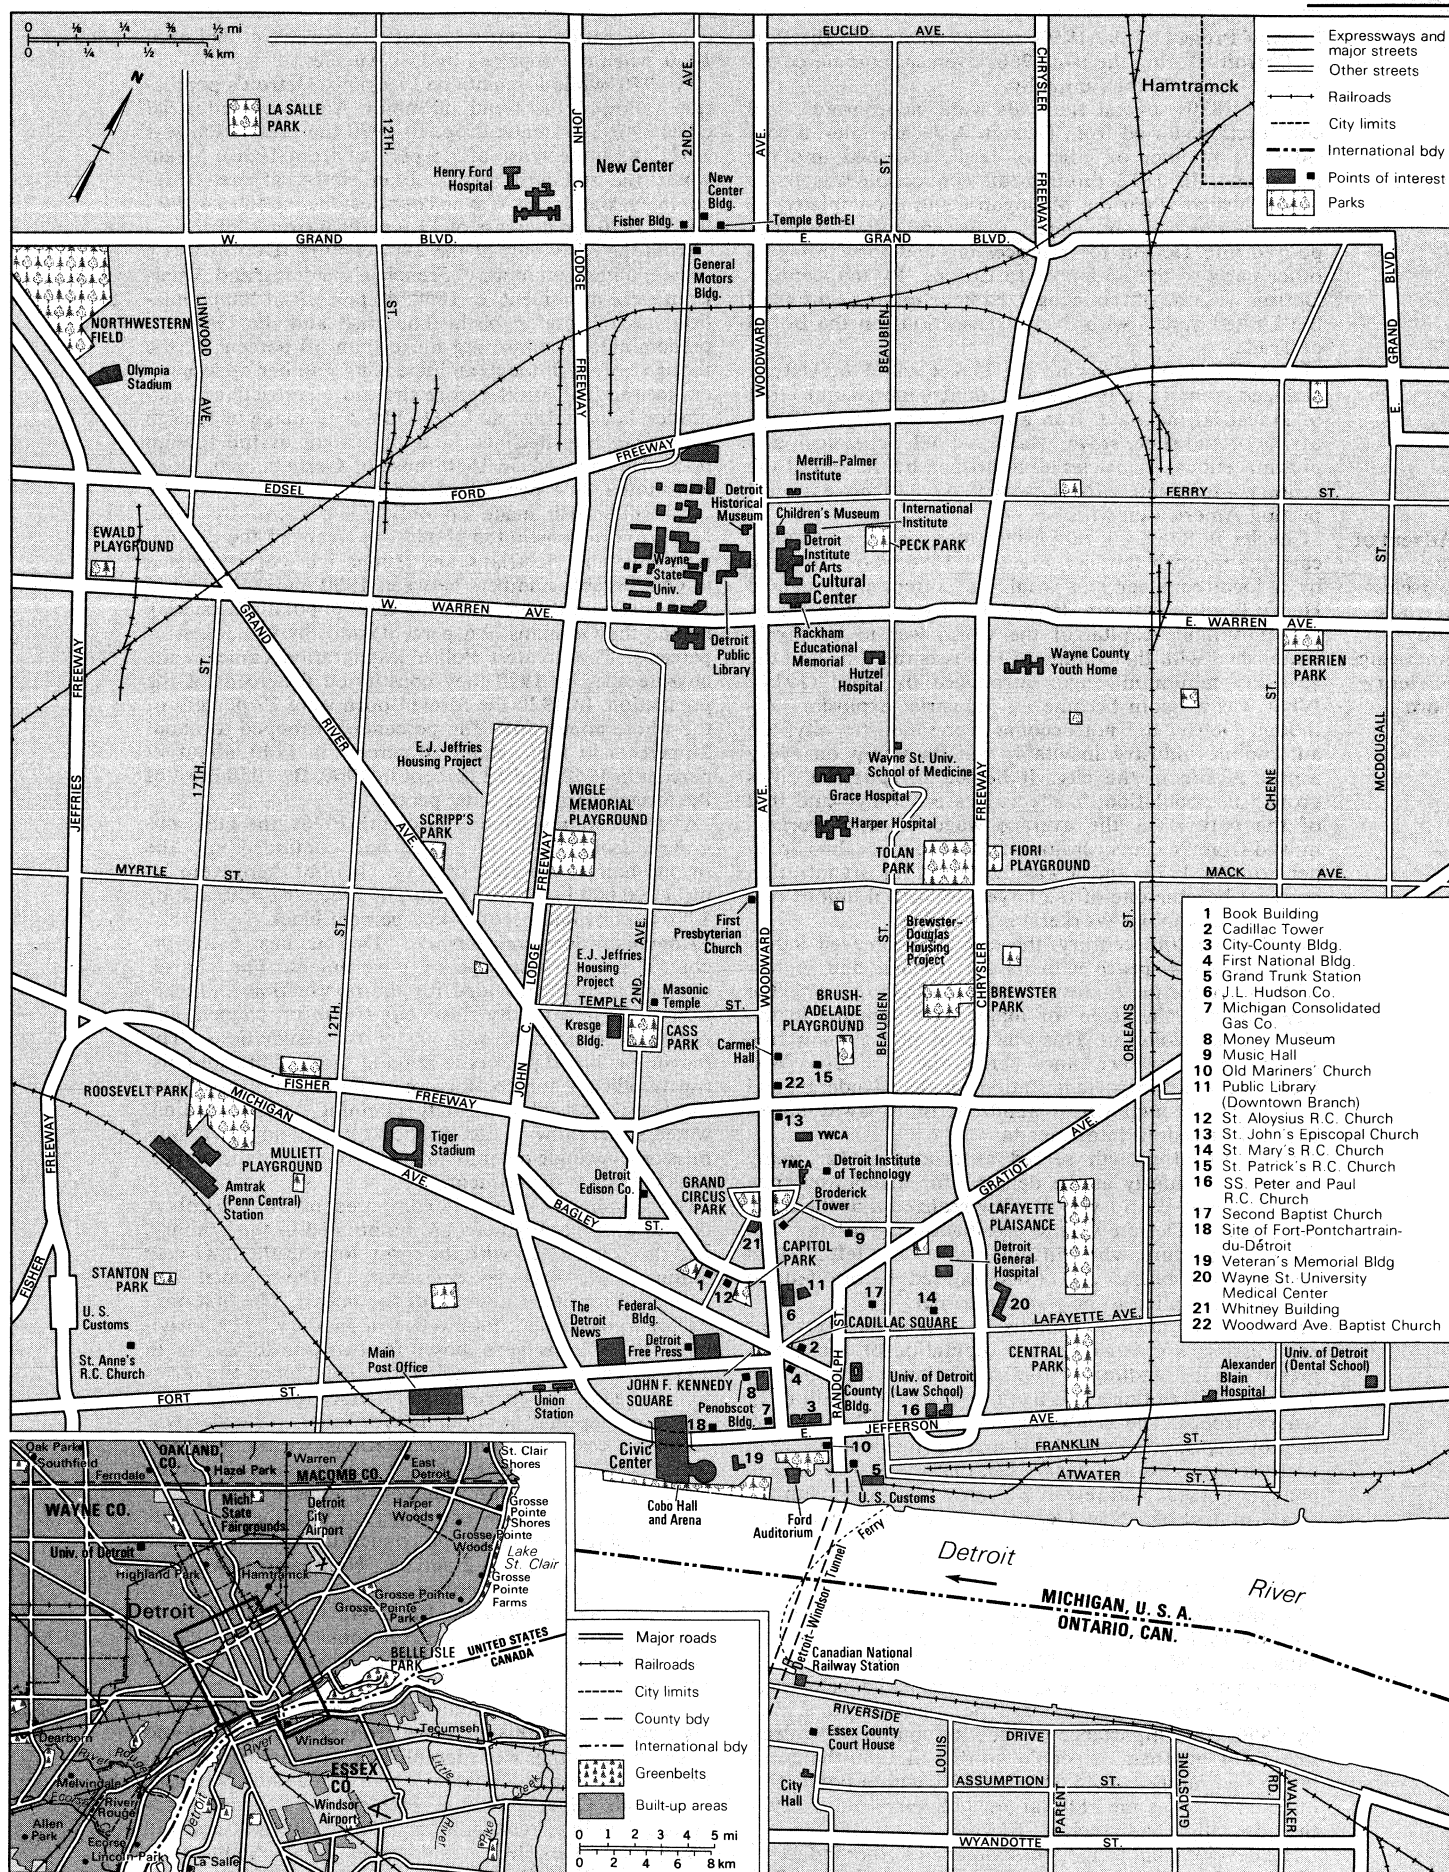

The peak of water transportation was reached in the 1880s. Then, gradual decline set in until the St. Lawrence

of the city

Central Detroit and (Inset) its metropolitan area.

Seaway Project of the 1950s revived interest in the Port of Detroit. During the late 1960s overseas commerce exceeded 1,000,000 tons annually.

In the 1830s several railroads were incorporated, and construction started from Detroit. A decade later, a considerable number of miles of track stretched into the hinterland. In 1852 through-rail connection was made with Chicago when the Michigan Central completed its line. By railroad and water, grain and other produce poured into Detroit for reprocessing and forwarding to other parts of the nation or to Europe. By mid-century Detroit was one of the recognized flour-milling centres of the United States, with lively transactions on the Board of Trade.

In the 35 years following the U.S. Civil War, Detroit changed from its early role as a country merchant to that of industrial magnate. Iron and steel, foundry, railroad car, boot and shoe, stove, wheel and axle, chemical, and pharmaceutical industries all flourished by the end of the century — fortunately for those who were to move toward putting America on wheels.

Charles B. King, a local businessman, drove a horseless carriage through the city streets in 1896, soon followed by a local engineer and would-be entrepreneur named Henry Ford; a new era dawned for Detroit. Its place as the automobile capital of the world was to be firmly established with the coming of the assembly line and the \$5-a-day minimum wage, introduced by Ford (1914). What was a hoem became an industrial explosion. Although Detroit did not become a one-industry city, the automobile industry inevitably put its stamp on every aspect of life in the city. It helped to spur the city's growth in population; it affected its economy — and that of the nation — as the average wage of auto workers moved from 76 cents per hour in 1936 to more than \$5.23 per hour by 1972; and it was the target for organization by what became one of the largest industrial unions (the United Automobile Workers) in America.

In the mid-20th century, the city that achieved industrial renown in peace with its automobiles and in war with its production of armaments was also to become the city that was the stage for major developments in the civil rights revolution. This was not an entirely new role for the city, however, since before the U.S. Civil War Detroit was an important station on the "Underground Railroad," through which hundreds of runaway slaves passed to freedom into Canada.

Its industrial growth served as a magnet for many blacks, particularly as the demand for manpower grew at the time of World War II. Few realized it at the time, but events in Detroit were to foreshadow the urban problems of the future, when, in June 1943, a riot left 35 dead (29 of them black) and 1,000 injured before federal troops were called to help restore order.

Detroit was quick to establish a community relations commission, and it earned the reputation of being progressive in its handling of human relations problems. But in July 1967 rioting once again required the calling of federal troops. The death toll was 43, with \$200,000,000 in property damage and 3,304 arrests. Incalculable were costs in bitterness and heartbreak that were to be long in being eradicated and repaired. A start was made with the establishment of a New Detroit Committee (New Detroit Inc.) on community relations.

#### THE CONTEMPORARY CITY

**Population.** In 1810 the population of Detroit was 1,650. By 1820 it had declined slightly to 1,442, partly because of the War of 1812. The opening of the Erie Canal, growing commerce on the Great Lakes, and development of the railroads helped increase the population to 21,019 by 1850. The importance of the city continued to draw increasing numbers of people, so that in 1860 the population had jumped to 45,516. In 1870, with a population of 79,577, it was the 18th largest U.S. city, and by 1900 the population had reached 285,704.

The development of the automobile and other industries after 1900 greatly stimulated Detroit's growth. By 1920, with a population of 993,678, it passed St. Louis to be-

come the nation's fourth largest city, a rank it held until 1950, when it was passed by Los Angeles.

By 1970, while it maintained its rank, Detroit's population followed the trend of major American industrial cities with a dramatic drop. In 1970 the population was 1,511,482 (a decrease of 9.5 percent from 1960). Meanwhile, the standard metropolitan statistical area (Macomb, Oakland, and Wayne counties) increased to 4,199,931 in 1970 (an increase of 11.6 percent over 1960).

From the early part of the 19th century, Detroit was a cosmopolitan community. French, Canadians, and Americans were prominent. In 1850, 47 percent of the population was of foreign birth. The Irish and the Germans predominated, comprising more than 50 percent of the foreign born. Although an increasing number of foreigners moved to Detroit before the more restrictive immigration laws of 1921 and 1924, the percentage of foreign born gradually declined, and the origin of the foreign born also changed. In 1880 those of German birth alone constituted 20.4 percent of the total population in the city, while Irish made up only 5.8 percent. By 1900, foreign born constituted about 34 percent of the population. Russians, Austrians, and Hungarians began arriving in considerable numbers between 1900 and 1910 and in 1910 made up 8 percent of the total population, ranking behind the Germans (9.6 percent) and the Canadians (9 percent). The greatest Polish immigration came in the next decade; by 1920 they constituted 6 percent of the population. In 1920 the foreign born were 29 percent of the whole population. The percentage dropped to about 26 percent in 1930, about 20 percent in 1940, about 17 percent in 1950, and 12 percent in 1960. By 1950 most of the foreign born were older people.

After the immigration laws of the 1920s, the great migration from the South set in and continued into the second half of the 20th century. In 1940 there were almost 200,000 blacks in Detroit, in 1960, 482,000, and by 1970 the city had become 43.7 percent black.

**Administration and finance.** Detroit has a mayor-council nonpartisan type of government. The charter adopted in 1918 provided for the nomination and election of the mayor, city clerk, city treasurer, council, and board of education, without party designations. The mayor has broad powers to appoint most of the administrative officials and commissions: the board of assessors, the board of health, the city planning, public lighting, water, street railway, fire, public welfare, and other commissions. A single commissioner appointed by the mayor, runs the police department.

The Common Council is composed of nine members elected at large. Eighteen are nominated in the primary, and the councilman with the most votes in the final vote automatically becomes president of the council and acting mayor in the absence of the mayor. The first non-partisan government took office in January 1919. Originally, the officials were chosen for two-year terms, but in 1953 an amendment to the charter lengthened the terms to four years. The charter also provides for recall, and in 1930, at a special election, Mayor Charles Bowles was recalled because of alleged relations with the underworld and the Ku Klux Klan; it was the first time such action was taken against a mayor of a major U.S. city.

The chief source of revenue for Detroit is the real estate tax. To increase revenue, the council imposed an income tax, which in 1970 was 2 percent. Nonresidents working in the city pay ½ of 1 percent.

**Housing and planning.** In 1934, when the federal housing program began, Detroit sponsored slum clearance and low-cost housing projects, which continued into the second half of the 20th century.

After World War II, municipal planning included a new civic centre on a 58.3-acre riverfront site. Many old and unsightly buildings were demolished, and in 1950 the first of the new civic buildings was completed — the Veterans Memorial. Other buildings include a combined city-county building, replacing the former city hall and old courthouse; the Henry and Edsel Ford Auditorium, where the Detroit Symphony Orchestra plays; Cobo Hall, a convention and exhibit building; and Cobo Con-

Major  
buildings

vention Arena, which can seat up to 12,000 persons for concerts and sports events.

Most of the city's largest office buildings, hotels, department stores, and banks are in the downtown area. The tallest is the 47-story Penobscot Building, and the largest office building outside downtown is the General Motors Building in the New Center area at Grand Boulevard and Second Avenue. Another large office building in the same neighbourhood is the Fisher Building. The General Motors, Fisher, and New Center buildings (a third but smaller office building) are connected by underground pedestrian tunnels. To accommodate the growing metropolitan area, many large, out-city shopping centres were built by private capital.

**Transportation.** By the early 1970s, the city had virtually completed an impressive network of expressways that provided relatively easy access to any area.

Dissatisfied with privately owned streetcar lines as early as the 1890s, Detroit in 1913 voted for a change in the city charter to allow for municipal ownership, but it was not until 1921 that the first such line was operated. A bitter feud between the city and the private lines ended when the city purchased the lines in 1922. In the late 1920s the city began operation of a few motor buses but again met with private competition, the Detroit Motor Bus Company, which it took over in 1932.

After World War II, patronage on the transit system began to fall, streetcars gradually were eliminated, and by 1956 the Detroit Street Railway had turned entirely to buses. The system operated as if it were privately owned, but by the late 1960s patronage had fallen sharply and deficits soared. In 1969 the citizens voted to allow a subsidy of the system from tax income.

Seven major railroad systems serve the city. Three airports—City, Metropolitan, and Willow Run—serve more than a dozen private, passenger and freight-carrying airlines.

**The economy.** Detroit is more than an automobile city, for about 1920 it became a steel centre, and the chemical business also prospered after the discovery of a layer of rock salt 34 feet thick, 1,000 feet below the surface. The Detroit Rock Salt Mine has approximately 60 miles of tunnels with fully mechanized equipment and transportation. In the second half of the 20th century Detroit ranked at or near the top in United States production of pharmaceuticals, adding machines and calculators, foundry products, and electrical household appliances. The Chrysler Corporation is the city's largest single employer.

Because of Detroit's location on the Great Lakes, the Michigan Customs District ranked third of U.S. ports in foreign trade at mid-20th century. Exports totalled about

\$700,000,000 a year. Imports included about 300 items used in automobile production. Detroit is a port of call for cargo boats and oceangoing freighters operating on the Great Lakes.

**Education and culture.** The public school system, formally organized in 1842, had more than 290,000 students in the second half of 20th century. Its facilities include trade schools as well as elementary, junior high, and high schools. Parochial and private schools had more than 60,000 students. Higher education is provided by Wayne State University and numerous sectarian, professional, technical, and junior colleges. The University of Michigan has a branch campus at Fairlane, the old Ford estate in Dearborn. Wayne State University, Eastern Michigan University, and the University of Michigan cooperate in an adult, noncredit educational program; and Wayne State and the University of Michigan operate the Institute of Labor and Industrial Relations, located on the Wayne campus.

Detroit always has had a rich cultural life. Numerous cultural societies, such as the Lyceum, Mechanics' Society, Young Men's Society, Athenaeum, fraternal groups, musical, charitable, and religious societies, reading clubs, and scientific organizations, have contributed to the intellectual life of the citizens. There are two daily newspapers: the *Detroit Free Press* and *The Detroit News*. With the great influx of immigrants in the 70 years after 1850, many cultural and social societies of the various nationality groups were started, some of which still existed in the second half of the 20th century.

Particularly notable among Detroit's cultural institutions is the Cranbrook Academy of Art, established in 1927 by two wealthy philanthropists, George and Ellen Booth. Situated on the Cranbrook estate in the suburb of Bloomfield Hills, it houses an extensive collection of paintings and sculptures. Also on the Cranbrook estate is the Cranbrook Institute of Science, founded in 1930.

Bordering Wayne State University, the Detroit Cultural Center includes the main public library, the Detroit Institute of Arts, the Detroit Historical Museum, the Horace H. Rackham Educational Memorial, and the Detroit Public Schools Children's Museum. The municipally owned Institute of Arts houses paintings, sculptures, and decorative arts from prehistoric to modern times. The Detroit Historical Museum preserves the city's history in physical survivals. In cooperation with the Detroit Historical Society, it also sponsors a large number of historical projects. The Children's Museum contains mobile and permanent exhibits to supplement the curriculum of the public schools. The Rackham Educational Memorial is the Detroit headquarters for the University of Michigan's extension services and is also the headquarters of the Engineering Society of Detroit. In suburban Dearborn, the Henry Ford Museum exhibits all forms of transportation equipment, while Greenfield Village contains reconstructions of many famous early American buildings and exhibits of early crafts.

Since 1914, Detroiters have maintained a symphony orchestra, which offers winter and summer seasons of concerts each year, in addition to a series of children's concerts. Evening band concerts are presented outdoors at Belle Isle Park during the summer. In 1928 the Detroit Civic Theatre was begun as a community venture. Its playhouse was later taken over by Wayne State University for drama projects. Because of the large number of foreign born, an International Institute has been organized; in addition to other activities, it maintains a program of folk music and dancing.

Detroit is also a city of churches, there being more than 1,000 of all denominations. St. Anne's Catholic Church is the oldest, dating from the settlement in 1701. The first Protestant society, interdenominational, was organized in 1816 and in 1825 became the First Presbyterian Church. All other main Protestant faiths are represented in Detroit. Temple Beth-El, the first Jewish society, was organized in 1850.

**Parks and recreation.** Detroit and the metropolitan area are well supplied with parks and recreational facilities. Among the larger ones that offer a variety of enter-

Cultural  
societies

Detroit's  
churches

tainment are Belle Isle and Palmer parks. Belle Isle, a wooded, 1,000-acre island in the Detroit River, was acquired by the city in 1879. It has riding stables and bridle paths, a bathing beach, a children's zoo, a botanical conservatory, an aquarium, a museum devoted to the Great Lakes, facilities for boating, and picnic areas. Palmer Park, on the north side of the city, has no waterfront but offers ice-skating in season, golf, riding, tennis, archery, and picnic grounds. The Detroit Zoological Park, in Royal Oak, is among the nation's leading zoos, with cageless exhibits on a site of over 120 acres.

Spectator sports are popular, and Detroit is the home of several professional teams: the Tigers (baseball), Lions (football), Red Wings (ice hockey), and Pistons (basketball). Throughout the city and metropolitan area there are a large number of public and private golf courses. Bois Blanc (Bob-Lo) Island, on the Canadian side of the Detroit River, offers typical amusement park entertainment. Great Lakes cruises and various excursion trips are available during the summer months.

**BIBLIOGRAPHY.** Historical accounts of the city of Detroit include SILAS FARMER, *The History of Detroit and Michigan* (1884); CLARENCE M. BURTON, *The City of Detroit, Michigan, 1701-1922*, 5 vol. (1928); GEORGE W. STARK, *City of Destiny* (1943); ARTHUR POUND, *Detroit, Dynamic City* (1940); JOHN C. LODGE, *I Remember Detroit* (1949); GEORGE B. CATLIN, *The Story of Detroit* (1923); F. CLEVER BALD, *Detroit's First American Decade, 1796-1805* (1948); and FRANK B. and ARTHUR M. WOODFORD, *All Our Yesterdays: A Brief History of Detroit* (1969). Two studies of the race question in Detroit are JOHN C. LEGGETT, *Class, Race, and Labor: Working-Class Consciousness in Detroit* (1968); and LEONARD GORDON (comp.), *A City in Racial Crisis: The Case of Detroit Pre- and Post- the 1967 Riot* (1971). Also of interest are SIDNEY GLAZER, *Detroit: A Study in Urban Development* (1965); ALMON E. PARKINS, *The Historical Geography of Detroit* (1970); and J. DAVID GREENSTONE, *A Report on the Politics of Detroit* (1961).

## De Valera, Eamon

A leader in Ireland's fight for independence from England, Eamon De Valera headed his country's government with little interruption between 1932 and 1959, when he became president of Ireland, a post he held until 1973.

De Valera's command of public confidence owed little to popular appeal but rested upon his long record of austere integrity and patriotism and his sagacity as a political leader. His academic attainments and status inspired wide respect; he became chancellor of the Na-

mother's family in a labourer's cottage in County Limerick, Ireland. He was educated at the local national school and at Blackrock College, Dublin; he graduated from the Royal University and became a teacher of mathematics and an ardent supporter of the Irish-language revival. In 1913 he joined the Irish Volunteers, which had been organized to resist opposition to Home Rule for Ireland. In the Dublin anti-English uprising of Easter 1916, he commanded an occupied building and was the last commander to surrender. Because of his U.S. birth, he escaped execution but was sentenced to penal servitude.

Released in 1917 but arrested again and deported to England in May 1918, De Valera was acclaimed as the chief survivor of the uprising and elected president of the revolutionist Sinn Féin party, which won three-quarters of all the Irish constituencies in December 1918. After a dramatic escape from Lincoln Jail in February 1919, he went in disguise to the United States, where he collected funds. He returned to Ireland before military repression ended with the truce of 1921 and appointed plenipotentiaries to negotiate in London. He repudiated the treaty that they signed to form the Irish Free State, however, because it accepted the exclusion of Northern Ireland and imposed an oath of allegiance to the British crown.

When Dáil Éireann (the assembly of Ireland) ratified the treaty by a small majority, De Valera supported the republican resistance in the ensuing civil war. William Thomas Cosgrave's Irish Free State ministry imprisoned him; but he was released in 1924 and then organized a Republican opposition party that would not sit in the Dáil. In 1927, however, he persuaded his followers to sign the oath of allegiance as "an empty political formula," and his new Fianna Fáil party then entered the Dáil, demanding abolition of the oath of allegiance, of the governor general, and of the Seanad as then constituted and of land-purchase annuities payable to Great Britain. The Cosgrave ministry was defeated by Fianna Fáil in 1932, and De Valera, as head of the new ministry, embarked quickly on severing connections with Great Britain. He withheld payment of the land annuities, and an economic war resulted. Increasing retaliation by both sides enabled De Valera to develop his program of austere national self-sufficiency in an Irish-speaking Ireland, while building up industries behind protective tariffs. In 1937 the Free State declared itself a sovereign state, as Ireland or Eire, conceding voluntary allegiance to the British crown.

De Valera's prestige was enhanced by his success as president of the Council of the League of Nations in 1932 and of its assembly in 1938. The menace of war in Europe induced Neville Chamberlain, in 1938, to conclude the "economic war" with mutual concessions. Great Britain relinquished the naval bases of Cobh, Berehaven, and Lough Swilly. In September 1939 De Valera proclaimed at once that Ireland would remain neutral and resist attack from any quarter. Besides avoiding the burdens and destruction of war, he had brought temporary prosperity, and he retained office after repeated elections.

In 1948 a reaction against the long monopoly of power and patronage held by De Valera's party enabled the opposition, with the help of smaller parties, to form an interparty government under John A. Costello. But this precarious coalition collapsed within three years, ironically, after declaring Ireland a republic by formal law, an act De Valera had avoided. De Valera resumed office until 1954, when he appealed unsuccessfully for a fresh mandate, and Costello formed his second interparty ministry. No clearly defined difference now existed between the opposing parties in face of rising prices, continued emigration, and a backward agriculture. But De Valera claimed that a strong single-party government was indispensable and that all coalitions must be weak and insecure. On this plea he obtained, in March 1957, the overall majority that he demanded. In 1959 De Valera agreed to stand as a candidate for the presidency. He resigned his position as *taoiseach* (head of government) and leader of the Fianna Fáil party. In June he

De Valera, c. 1965.

tional University of Ireland in 1921 and was founder of the Dublin Institute for Advanced Studies.

De Valera was born in the United States, in New York City, on October 14, 1882. His father, a Spanish artist, having died, De Valera was sent as an infant to his

Early life

President of the republic of Ireland

was elected president and was re-elected in 1966. He retired to a nursing home near Dublin in 1973 and died there August 29, 1975.

De Valera's career spanned the dramatic period of Ireland's modern cultural and national resurgence. It was marred, however, by the deep political divisions spawned by the civil war of the 1920s, the persistence of the partition of the island that excluded six British-ruled counties from the republic, and the relative weakness of Ireland's economic position. As an anti-colonial leader, a skillful constitutionalist, and a symbol of national liberation, De Valera dominated Ireland in the half century following the country's independence. (D.R.G.)

**BIBLIOGRAPHY.** The biography by DENIS GWYNN, *De Valera* (1933), is concise, comprehensive, and impartial; the EARL OF LONGFORD and THOMAS P. O'NEILL, *Eamon De Valera* (1970), has direct interview material from De Valera; F.S.L. LYONS, *Ireland Since the Famine* (1971), puts the career of De Valera into context and includes the views of his critics; CONSTANTINE FITZGIBBON and GEORGE MORRISON, *The Life and Times of Eamon De Valera* (1974), has a brief and impartial text combining biography with a history of Ireland and is extensively and superbly illustrated. (Ed.)

## Development, Animal

Development, in the context of this article, includes the processes that lead eventually to the formation of a new animal starting from cells derived from one or more parent individuals. Development thus occurs following the process by which a new generation of organisms is produced by the parent generation. This article is divided into the following major sections:

- I. General features
  - Reproduction and development
  - Preparatory events
- II. Early development
  - Embryo formation
  - Cleavage
  - Gastrulation
  - Embryonic adaptations
    - Adaptations in animals other than mammals
    - Adaptations in mammals
- III. Organ formation
  - Primary organ rudiments
  - Organogenesis and histogenesis
- IV. Ectodermal derivatives
  - The nervous system
  - The brain and spinal cord
  - Major sense organs
  - The epidermis and its outgrowths
- V. Mesodermal derivatives
  - The body muscles and axial skeleton
  - The appendages: tail and limbs
  - Excretory organs
  - Circulatory organs
  - Reproductive organs
- VI. Endodermal derivatives
  - The alimentary canal
  - The pharynx and its outgrowths
  - The liver, pancreas, and lungs
- VII. Postembryonic development
  - The larval phase and metamorphosis
  - Direct development
- VIII. Maturity and death

### I. General features

#### REPRODUCTION AND DEVELOPMENT

In multicellular animals (Metazoa), reproduction takes one of two essentially different forms: sexual and asexual. In asexual reproduction the new individual is derived from a blastema, a group of cells from the parent body, sometimes, as in *Hydra* and other coelenterates, in the form of a "bud" on the body surface. In sponges and bryozoans, the cell groups from which new individuals develop are formed internally and may be surrounded by protective shells; these bodies, which may serve as resistant forms capable of withstanding unfavourable environmental conditions, are released after the death of the parent. In certain animals the parent may split in half, as in some worms, in which an individual worm breaks into two fairly equal parts (except that the anterior half receives the mouth, "brain," and sense organs if they are present).

Obviously, in such a case it is impossible to say which of the two resulting individuals is the parent and which the offspring. Some brittle stars (starfish relatives) may reproduce by breaking across the middle of the body disk, with each of the halves subsequently growing its missing half and the corresponding arms.

A common feature of all forms of asexual reproduction is that the cells—always a substantial number of cells, never only one cell—taking part in the formation of the new individual are not essentially different from other body, or somatic, cells. The number of chromosomes (bodies carrying the hereditary material) in the cells participating in the formation of a blastema is the same as in the other somatic cells of the parent, constituting a normal, double, or diploid ( $2n$ ), set.

In sexual reproduction, a new individual is produced not by somatic cells of the parent but by sex cells, or gametes, which differ essentially from somatic cells in having undergone meiosis, a process in which the number of chromosomes is reduced to one-half of the diploid ( $2n$ ) number found in somatic cells; cells containing one set of chromosomes are said to be haploid ( $n$ ). The resulting sex cells thus receive only half the number of chromosomes present in the somatic cell. Furthermore, the sex cells are generally capable of developing into a new individual only after two have united in a process called fertilization (*q.v.*).

Each type of reproduction—aseexual and sexual—has advantages for the species. Asexual reproduction is, at least in some cases, the faster process, leading most rapidly to the development of large numbers of individuals. Males and females are independently capable of producing offspring. The large size of the original mass of living matter and its high degree of organization—the new individual inherits parts of the body of the parent: a part of the alimentary canal, for instance—make subsequent development more simple, and the attainment of a stage capable of self-support easier. New individuals produced by asexual reproduction have the same genetic constitution (genotype) as their parent and constitute what is called a clone. Though asexual reproduction is advantageous in that, if the parent animal is well adapted to its environment and the latter is stable, then all offspring will benefit, it is disadvantageous in that the fixed genotype not only makes any change in offspring impossible, should the environment change, but also prevents the acquisition of new characteristics, as part of an evolutionary process. Sexual reproduction, on the other hand, provides possibilities for variation among offspring and thus assists evolution by allowing new pairs of genes to combine in offspring. Since all body cells are derived from the fertilized egg cell, a mutation, or change, occurring in the sex cells of the parents immediately provides a new genotype in each cell of the offspring. In the course of evolution, sexual reproduction has been selected for, and established in, all main lines of organisms; asexual reproduction is found only in special cases and restricted groups of organisms.

#### PREPARATORY EVENTS

In the case of multicellular animals we find there are two kinds of sex cells: the female sex cell (ovum, or egg), derived from an oocyte (immature egg), and the male sex cell (spermatozoon or sperm), derived from a spermatoocyte. Eggs are produced in ovaries; sperm, in testes. Both the egg and the sperm contribute to the development of the new individual; each providing one set of genes, thereby restoring the diploid number of chromosomes in the fertilized egg. The sperm possesses a whiplike tail (flagellum) that enables it to swim to the egg to fertilize it. In most cases the egg, a stationary, spherical cell, provides the potential offspring with a store of food materials, or yolk, for its early development (Figure 1). The term yolk does not refer to any particular substance but in fact includes proteins, phosphoproteins, lipids, cholesterol, and fats, all of which substances occur in various proportions in the eggs of different animals. In addition to yolk, eggs accumulate other components and acquire the structure necessary for the development of the new

**Advantages of sexual and asexual reproduction**

Figure 1: Amphibian egg, vertical section, showing distribution of yolk and pigment in interior.

individual. In particular the egg acquires polarity—that is, the two ends, or poles, of the egg become distinctive from each other. At one pole, known as the animal pole, the cytoplasm appears to be more active and contains the nucleus (meiotic divisions occur in this region); at the other, called the vegetal pole, the cytoplasm is less active and contains most of the yolk. The general organization of the future animal is closely related to the polarity of the egg.

When the amount of food reserve is comparatively small, as it is in many marine invertebrates and mammals (in the latter the embryo is nourished by materials in the mother's blood), the egg may be barely visible to the unaided eye. The egg of the sea urchin is about 75 microns (0.003 inch) in diameter; that of a human being is slightly more than 0.1 millimetre. Eggs are classified according to the amount of yolk present. An egg with a small quantity of evenly distributed yolk is called an oligolecithal egg. One with more yolk that is unevenly distributed (*i.e.*, concentrated towards the vegetal pole) is telolecithal; and one with still greater amounts of yolk in granules or in a compact mass is megalecithal.

Protective membranes

The egg is surrounded by protective membranes, which may be soft and jellylike or hard and calcified, like shells. Egg membranes are produced while the egg is either in the ovary or being carried away from the ovary in a tube called an oviduct. The eggs of many animals have both kinds of membranes. In Insects, a hard shell (chorion) forms around the eggs in the ovaries. In frogs, a very thin vitelline membrane forms around the eggs in the ovary; subsequently a layer of jelly is deposited around the eggs while they pass through the oviducts. In birds, a very thin vitelline membrane is produced around the egg in the ovary; then several layers of secondary membranes are formed in the oviduct before the egg is laid. The outermost of these secondary membranes is the calcareous shell. In mammals the egg is surrounded by the so-called pellucid zone, which is equivalent to the vitelline membrane of other animals; follicle cells form an area called the corona radiata around this zone.

After fertilization the egg, now called a zygote, is endowed with genes from two parents and has begun actual development. (Activation of the egg may be brought about by an agent other than sperm in certain animals, but such cases of parthenogenesis are exceptional. See the articles on FERTILIZATION; and REPRODUCTION.)

After fertilization, the zygote undergoes a series of transformations that bring it closer to the essential organization of the parents. These transformations, initiated at a physiological, perhaps even at a molecular, level, eventually result in the appearance of certain structures. The whole process is called morphogenesis (Greek *morphē*, "shape" or "form"; genesis, "origin" or "production"). The process of development is more easily understood if, at every step, the changes necessary to bring the system nearer the goal are considered. Depending on the achievements necessary at any step, development can be subdivided into a number of discrete phases, the first of which, cleavage, immediately follows fertilization.

## 11. Early development

### EMBRYO FORMATION

**Cleavage.** Since the goal of development is the production of a multicellular organism, many cells must be produced from the single-celled zygote. This task is accomplished by cleavage, a series of consecutive cell divisions. Cells produced during cleavage are called blastomeres. The divisions are mitotic—*i.e.*, each chromosome in the nucleus splits into two daughter chromosomes, so that the two daughter blastomeres retain the diploid number of chromosomes. During cleavage, almost no growth occurs between consecutive divisions, and the total volume of living matter does not change substantially; as a consequence, the size of the cells is reduced by almost half at each division. At the beginning of cleavage, cell divisions tend to occur at the same time in all blastomeres, and the number of cells is doubled at each division. As cleavage progresses, the cells no longer divide at the same time.

Cleavage in most animals follows an orderly pattern, with the first division being in the plane of the main axis of the egg (Figure 2). This cleavage plane is arbitrarily called vertical, on the assumption that the main axis of the egg is vertical. The second cleavage plane is again vertical but at right angles to the first, giving rise to four equal cells arranged around the main axis of the egg (Figure 2). The third cleavage plane is at right angles to both the first and second cleavage planes and is horizontal, or equatorial. Subsequent divisions may alternate between vertical and horizontal cleavage planes, but later cleavage divisions become randomly oriented. This pattern is typical of many animal groups; however, more complicated patterns of cleavage are found in such animals as annelids, mollusks, and nematodes.

Figure 2: Cleavage of an oligolecithal egg (sea cucumber) in progressive stages 1 through 6 (see text).

As the amount of yolk in the egg increases, it influences cleavage by hindering the cytoplasmic movements involved in mitosis. If there is only little yolk (oligolecithal eggs), the yolk granules follow the movements of the cytoplasm and are distributed in the resulting blastomeres. But if the amount of yolk is larger (megalecithal eggs), cleavages occur nearer the animal pole, where there is less yolk; as a result, the blastomeres nearer the animal pole are smaller than those nearer the vegetal pole. The presence of yolk masses may retard the onset of cleavage in a part of the egg or even suppress it altogether; in this case cleavage is partial: or meroblastic. Only a part of the egg material then is subdivided into cells, the rest remaining as a mass that serves as nourishment for the developing embryo.

Influence of yolk on cleavage

Cleavage is complete, or holoblastic, in many invertebrates including coelenterates, annelids, echinoderms, tunicates, and cephalochordates. The blastomeres may be either about equal or only slightly different in size. Cleavage in amphibians is holoblastic, but the size of the blastomeres is very uneven. Blastomeres are smallest at the animal pole and largest (and yolky) at the vegetal pole. Somewhat similar conditions prevail in many mollusks. In most fishes, birds, reptiles, and egg-laying mammals (monotremes), cleavage is discoidal—*i.e.*, restricted

to a disk of cytoplasm at the animal pole of the egg, most of the yolk material remaining uncleaved (Figure 3). Cleavage in insects and many other arthro-

Figure 3: Discoidal cleavage of an egg of a bony fish.

pods is superficial—*i.e.*, the entire surface layer of egg cytoplasm subdivides into cells, and the egg contains a central mass of uncleaved yolk. The conditions of cleavage in placental mammals, including man, are peculiar.

During cleavage, development involves only an increase of cell numbers; the shape of the embryo does not change, and chemical transformations within the embryo are restricted to those necessary for cell division. Chemical and structural transformations are concerned with accumulating chromosomal material in the nuclei of the blastomeres. Before each division the chromosomes carrying the genes double in number; this means that the chromosomal material, deoxyribonucleic acid (DNA), has to be synthesized. This synthesis proceeds possibly at the expense of cytoplasmic ribonucleic acid (RNA) but certainly also from simpler organic compounds. A certain amount of protein synthesis is also necessary for cleavage to proceed: if developing eggs are treated with puromycin, a substance which is known to suppress protein synthesis, cleavage stops immediately. The proteins concerned have not yet been identified. No proteins are synthesized, however, that would foreshadow the future differentiation of parts of the embryo. It is believed that the genes in the chromosomes remain largely inactive during cleavage. The rhythm (speed) of cleavage is wholly dependent on the cytoplasm of the egg.

Although the shape and volume of the embryo do not change during cleavage, one important change in gross organization does take place. As the blastomeres are produced, they move outward, leaving a centrally located fluid-filled cavity. In cases of holoblastic cleavage, the blastomeres become arranged in a layer from one to several cells thick surrounding the cavity. The embryo at this stage may be likened to a hollow ball and is known as a blastula (Figure 4:1). The outer layer of cells is called the blastoderm, and the fluid-filled cavity the blastocoel. In discoidal cleavage the cells, which do not surround the whole embryo, lie only on the animal pole; nevertheless, a blastocoel may be formed by a crevice appearing between the blastomeres and the mass of yolk (Figure 3). The blastomeres then may be arranged as a saucer-shaped blastodisk covering the blastocoel.

The formation of the blastula signifies the end of the period of cleavage. The next stage of development is concerned not with an increase in cell number, though cell divisions continue at a slower pace, but with rearrangement of the available cell masses to conform with the gross features of the future animal.

**Gastrulation.** The embryo in the blastula stage must go through profound transformations before it can approach adult organization. An adult multicellular animal typically possesses a concentric arrangement of tis-

ues of the body; this feature is common to all animal groups above the level of the sponges. Adult tissues are derived from three embryonic cell layers called germinal layers: the outer layer is the ectoderm, the middle layer is the mesoderm, and the innermost layer is the endoderm (entoderm). The ectoderm gives rise to the skin covering, to the nervous system, and to the sense organs. The mesoderm produces the muscles, excretory organs, circulatory organs, sex organs (gonads), and internal skeleton. The endoderm lines the alimentary canal and gives rise to the organs associated with digestion and, in chordates, with breathing.

The blastula, which consists of only one cell layer, undergoes a dramatic reshuffling of blastomeres preparatory to the development of the various organ systems of the animal's body. This is achieved by the process of gastrulation, which is essentially a shifting or moving of the cell material of the embryo so that the three germinal layers are aligned in their correct positions.

The rearrangement of the blastula to form the germinal layers is seen clearly in certain marine animals with oligolecithal eggs. The hollow blastula consists of a simple epithelial layer (the blastoderm), the transformation of which can be likened to the pushing in of one side of a rubber ball (Figure 4). As a result of such in-pushing (or invagination), the spherical embryo is converted into a double-walled cup, the opening of which represents the position of the former vegetal pole. The involuted part of the blastoderm, lining the inside of the double-walled cup, gives rise to the endoderm and mesoderm, and the blastomeres remaining on the exterior become the ectoderm. As a consequence of the in-folding at the vegetal pole, the blastocoel is reduced or obliterated, and a new cavity is created, the primitive gut cavity, or archenteron, which eventually gives rise to the hollow core (lumen) of the alimentary canal. At this stage the embryo has a primitive gut with an opening to the exterior and is known as a gastrula. The opening of the gastrula is the blastopore, or primitive mouth; both terms are somewhat misleading. It would seem that the term blastopore should be applied more appropriately to an opening in a blastula, in which, of course, no opening exists. As to the term primitive mouth, it must be pointed out that the blastopore does not always give rise to the adult mouth. In certain animal groups it becomes the anus, and a mouth forms as a completely new opening.

In some coelenterates, cells at the vegetal pole do not form an invaginating pocket, but individual cells slide inward, losing connection with other cells of the blastoderm. Eventually these cells fill the blastocoel and form a compact mass of endoderm. The cavity (archenteron) within this mass and the opening (blastopore) to the exterior are then produced secondarily by the separation of these cells.

Figure 4: Gastrulation and mesoderm formation in the embryo of a starfish.

**Germinal layers**

**Amphioxus, echinoderms, and amphibians.** Gastrulation does not always proceed exactly as described above. In the course of evolution, certain animal groups have modified this critical stage of embryonic development, and these modifications have undoubtedly contributed to the successful continuation of species. In the primitive fishlike chordate amphioxus, for example, the invaginating blastoderm eventually comes into close contact with the inner surface of the ectoderm, thus practically squeezing the blastocoel out of existence or at least reducing it to a narrow crevice between the ectoderm and the endomesoderm. In echinoderms, on the other hand, a smaller portion of the blastoderm invaginates, and the blastocoel remains as a spacious internal cavity between the ectoderm and the endomesoderm. It persists as the primary body cavity and is the only body cavity (apart from the cavity of the alimentary canal) in such invertebrates as nematodes and rotifers.

In the double-walled-cup stage, the two internal germinal layers—endoderm and mesoderm—may not yet be distinct. Their separation may occur later, in the second phase of gastrulation, by one of two methods. One is the development of outpocketings from the wall of the archenteron. In starfishes and other echinoderms, the deep part of the endomesodermal invagination forms two thin-walled sacs, one on each side of the gastrula (Figure 4). These are the rudiments of the mesoderm; the remaining part of the archenteron becomes the endoderm and produces the lining of the gut. The cavities within the mesodermal sacs expand to become the coelom, the secondary body cavity of the animal. A somewhat similar process of mesoderm and coelom development occurs in amphioxus among the chordates, except that a series of mesodermal sacs forms on either side of the embryo, foreshadowing the segmented (metameric) structure common to chordates. Only the most anterior pairs of the mesodermal sacs actually contain a cavity at the time of their formation; the more posterior ones are solid masses of cells separating from the archenteric wall and from one another and developing coelomic cavities later.

A second method of mesoderm formation is by the splitting off of mesodermal cells from the original common mass of endomesoderm. This may take the form of single cells detaching themselves from the archenteron or of whole sheets of cells splitting off from the endoderm. An example of the latter type is seen in the gastrulation of amphibians. The development of specific regions of the early amphibian embryo—by the use of natural pigmentation or artificially introduced dyes—can be followed and their location in the adult recorded in diagrams called fate maps. The fate map of a frog blastula, just prior to gastrulation demonstrates that the materials for the various organs of the embryo are not yet in the position corresponding to that in which the organs will lie in a fully developed animal. The endodermal material for the foregut, for example, lies not far from the vegetal pole; the ectodermal component of the mouth region (stomodeum) is situated close to the animal pole. Extensive rearrangement of the embryo is necessary to bring all the parts into their correct relationships.

Because of the large amount of yolk and resulting uneven cleavage, gastrulation in amphibians cannot proceed by a simple infolding of the vegetal hemisphere. A certain amount of invagination does take place, assisted by an active spreading of the animal hemisphere of the embryo; as a result, the ectoderm covers the endodermal and mesodermal areas. The spreading is sometimes described as an "overgrowth"—an inappropriate term, since no growth or increase of mass is involved. The future ectoderm simply thins out, expands, and covers a greater surface of the embryo in a movement known as epiboly.

Gastrulation in amphibians, in lungfishes, and in the cyclostomes (hagfishes and lampreys) begins with the formation of a pit on what will become the back (dorsal) side of the embryo (Figure 5). The pit represents the active shifting inward of the cells of the blastoderm. As these cells undergo a change in shape, there occurs also a contraction at the external surface, with adjacent cells

being drawn toward the centre of the contraction even before an actual depression is formed. The cells most concerned in this process will become part of the future foregut. Further movement of the cells inward results in the formation of a distinct pit, which rapidly develops into a pocket-like archenteron with its opening, the blastopore. Once the archenteron is formed, more and more of the exterior cells roll over the edge of the blastopore and disappear into the interior. In the course of gastrulation the shape of the blastopore changes from a simple pit to a transverse slit and finally into a groove encircling the yolky material at the vegetal pole. As a result of epiboly of the animal hemisphere, the upper edge of the groove is gradually pushed down until the yolky cells of the vegetal pole are covered completely. The edges of the blastopore then converge toward the vegetal pole, the slit between them being eventually reduced to a narrow canal, which lies at the posterior end of the embryo and, in some species, becomes the anal opening. (In other cases the canal closes, and a new anal opening breaks through nearby, slightly more ventrally.)

Formation of archenteron in amphibians

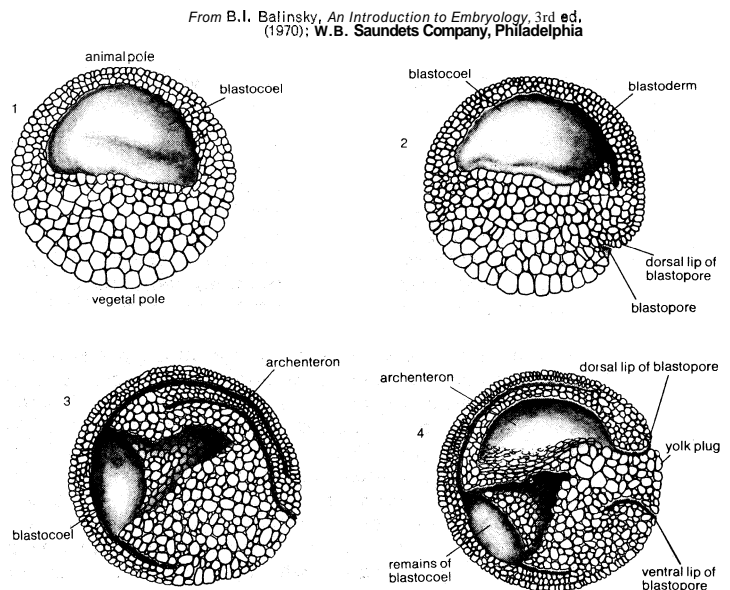

Figure 5: Gastrulation in the frog embryo. Embryos, in four progressive stages, are represented as cut in the median plane.

The cavity of the archenteron increases as more material from the outside is transferred inward, and the blastocoel becomes almost completely obliterated. Both mesoderm and endoderm are shifted into the interior, and only the ectoderm remains on the embryo surface. The mesoderm splits from the endoderm: the endoderm lines the archenteric cavity (and eventually becomes the lining of the alimentary canal), as the mesoderm surrounds the endoderm to form the chordamesodermal mantle. By the time the blastopore closes, the three germ layers are in their correct spatial relationship to each other.

**Reptiles, birds, and mammals.** Although amphibian gastrulation is considerably modified in comparison with that in animals with oligolecithal eggs (e.g., amphioxus and starfishes), an archenteron forms by a process of invagination. Such is not the case, however, in the higher vertebrates that possess eggs with enormous amounts of yolk, as do the reptiles, birds, and egg-laying mammals. Cleavage in these animals is partial (meroblastic), and, at its conclusion, the embryo consists of a disk-shaped group of cells lying on top of a mass of yolk. This cell group often splits into an upper layer, the epiblast, and a lower layer, the hypoblast. These layers do not represent ectoderm and endoderm, respectively, since almost all the cells that form the embryo are contained in the epiblast. Future mesodermal and endodermal cells sink down into the interior, leaving only the ectodermal ma-

Gastrulation in starfishes

terial at the surface. In reptiles, egg-laying mammals, and some birds, a pocket-like depression occurs in the epiblast but encompasses only chordamesoderm or even only the notochord. Individual cells of the remainder of the mesoderm and endoderm migrate into the interior and there arrange themselves into a sheet of chordamesoderm and of endoderm, the latter of which mingles with cells of the hypoblast if such a layer is present. The migration of the cells destined to form mesoderm and endoderm does not take place over the whole surface of the disk-shaped embryo but is restricted to a specific area along the midline. This area is more or less oval in reptiles and lower mammals; distinctly elongated in higher mammals and birds, it is called the primitive streak (Figure 6), a thickened and slightly depressed part of the epiblast that is thickest at the anterior end, called the Hensen's node.

In animals having discoidal cleavage, the three germinal layers at the end of gastrulation are stacked flat; ectoderm on top, mesoderm in the middle, and endoderm at the bottom. The embryo is produced from the flattened layers by a process of folding to form a system of concentric tubes (Figure 7). The edges of the germ layers, which are not involved in the folding process, remain attached to the yolk and become the extra-embryonic parts; they are not directly involved in supplying cells for the embryo but break down yolk and transport it to the developing embryo.

Higher mammals—apart from the egg-laying mammals—do not have yolk in their eggs but, having passed through an evolutionary stage of animals with yolk eggs, retain, particularly in gastrulation, features common to reptiles (and birds, which also had reptilian ancestors). As a result, at the end of cleavage the formative cells of the embryo—the cells that will actually build the body of the animal—are arranged in the form of a disk over a cavity that takes the place of the yolk of the reptilian ancestors of mammals. Within the disk of cells a primitive streak develops, and the three germinal layers are formed much as in many reptiles and birds.

Gastrulation and the formation of the three germinal layers is the beginning of the subdivision of the mass of embryonic cells produced by cleavage. The cells then begin to change and diversify under the direction of the genes. The genes brought in by the sperm exert control for the first time; during cleavage all processes seem to be under control of the maternal genes. In cases of hybridization, in which individuals from different species produce offspring, the influence of the sperm is first apparent at gastrulation: paternal characteristics may appear at this stage; or the embryo may stop developing and die if the paternal genes are incompatible with the egg (as is the case in hybridization between species distantly related).

The diversification of cells in the embryo progresses rapidly during and after gastrulation. The visible effect is that the germinal layers become further subdivided into aggregations of cells that assume the rudimentary form of various organs and organ systems of the embryo. Thus the period of gastrulation is followed by the period of organ formation, or organogenesis.

Figure 6: Anterior half of blastoderm of a bird embryo cut transversely to show migration of mesodermal and endodermal cells from the primitive streak.

Figure 7: Vertebrate body formation from three germinal layers showing separation from yolk sac after discoidal cleavage.

#### EMBRYONIC ADAPTATIONS

Throughout its development the embryo requires a steady supply of nourishment and oxygen and a means for disposal of wastes. These needs are met in various ways, depending in particular on (1) whether the eggs develop externally (oviparity), are retained in the maternal body until ready to hatch (ovoviviparity), or are carried in the maternal body to a later stage (viviparity); and (2) the length of embryonic development.

**Adaptations in animals other than mammals.** Eggs of many marine invertebrates are discharged directly into water, and the period of development before the larva emerges is relatively brief. Oxygen diffuses easily into the small eggs, and nourishment is provided by a moderate amount of yolk. During cleavage the yolk is distributed to all the blastomeres. Much of the nourishment in the egg is stored as animal starch, or glycogen, which is almost completely used by the time the larva emerges from the egg. A small amount of water and inorganic salts are taken in by the embryo from surrounding seawater. Eggs developing in freshwater carry their own supply of necessary amounts of certain salts that are not present in sufficient quantities in the environment. Products of metabolism—especially carbon dioxide and nitrogenous wastes in the form of ammonia—diffuse out from small embryos developing in water.

The eggs of terrestrial animals must overcome the hazard of drying. In certain species this danger is avoided because the animal returns to water to breed, as frogs and salamanders. Some groups of insects (e.g., dragonflies, mayflies, and mosquitoes) also lay eggs in water, and the larvae are aquatic. Eggs of other animals (e.g., snails, earthworms) are laid in moist earth and thus are protected from drying up. In terms of evolution, however, a decisive solution to the problem of development on land was arrived at by most insects and by reptiles and birds, which developed eggs with a shell impermeable to water or, at least, resistant to rapid evaporation. The shells of bird and insect eggs, while restricting evaporation of water, allow oxygen to diffuse into the egg and carbon dioxide to diffuse out. Apart from gas exchange, the eggs constitute closed systems, which give nothing to the outside and require nothing from it. Such

Mechanisms to overcome drying

Gastrulation in higher mammals

eggs are called cleidoic. Because the products of nitrogen metabolism in cleidoic eggs cannot pass through the eggshell, animals (birds and insects) have had to evolve a method of storing wastes in the form of uric acid, which, since it is insoluble, is nontoxic to the embryo.

After a short period of development in the egg, the emerging young animal has to fend for itself, unless there is some form of parental care. Exposure to the external environment at a tender age results frequently in loss of life, a hazard met by many animals through an increase in the supply of nourishment within the egg, thus allowing the young to attain a greater size and development. This tendency to produce large yolky eggs has been achieved independently in different evolutionary lines: in octopuses and squids among the mollusks, in sharks among the fishes, and in reptiles and birds among the terrestrial vertebrates.

As has been indicated, cleavage is incomplete in eggs with large amounts of yolk. Although some yolk platelets may be enclosed in the formative cells of the embryo, the bulk of the yolk remains an uncleaved mass, overgrown and surrounded by the cellular part of the embryo. In such cases a membranous bag, or yolk sac, is formed (Figure 8) and remains connected to the embryo by a narrow stalk (the evolutionary precursor of the umbilical cord of mammals). The cellular layers surrounding the yolk sac and forming its walls may consist of all three germinal layers (in reptiles and birds), so that the yolk virtually comes to lie inside an extension of the gut of the embryo; or (in bony fishes) the yolk sac may be enclosed in layers of ectoderm and mesoderm. In either case a network of blood vessels develops in the walls of the yolk sac and transports the yolk products to the embryo. As the yolk is broken down and utilized, the yolk sac shrinks and is eventually drawn into the body of the embryo. In addition to the yolk sac, extra-embryonic parts are also encountered in the form of embryonic membranes, which are found in higher vertebrates and in insects. Vertebrates have three embryonic membranes: the amnion, the chorion, and the allantois.

Figure 8: Position of a bird embryo in the egg and the relation of the allantois to the amniotic cavity and the yolk sac.

In reptiles, birds, and mammals, folds develop on the surface of the yolk sac just outside and around the body of the embryo proper. These folds, consisting of extra-embryonic ectoderm and extra-embryonic mesoderm, rise up and fuse dorsally, enclosing the embryo in a double-lined, fluid-filled chamber known as the amniotic cavity. The inner lining of the fold becomes the amnion, and the outer becomes the chorion, which ultimately surrounds the entire embryo. The amniotic fluid protects the embryo from drying, prevents the adhesion of the embryo to the inner surface of the shell, and provides the embryo with efficient shock absorption against possible damaging jolts. (The amnion and chorion develop in the same way in insect embryos.) The third membrane, or allantois, is originally nothing more than the urinary bladder of the embryo. It is a saclike growth of the

floor of the gut, into which nitrogenous wastes of the embryo are voided. It enlarges greatly during the course of development, eventually expanding between the amnion and chorion and also between the chorion and the yolk sac, to become the third embryonic membrane. In addition to providing storage space for the nitrogenous wastes of the embryo, the allantois takes up oxygen, which penetrates into the egg from the exterior, and delivers it, by way of a network of blood vessels, to the embryo.

**Adaptations in mammals.** At some early stage during the evolution of viviparous mammals, eggs came to be retained in the oviducts of the mother. The embryo then was provided with nourishment from fluids in the oviduct; the yolk, which became redundant, gradually ceased to be provided, and the eggs became oligolecithal. The eggshell, present in reptiles, was no longer needed and eventually disappeared, as did the white of the egg. The chorion, however, remained as the most external coat of the developing embryo through which nourishment reaches the embryo. It acquired the ability to adhere closely to the walls of the uterus (which was what that part of the oviduct holding the embryo had become) and became the so-called trophoblast. The blood-vessel network of the underlying allantois conveys nutrients that diffuse through the trophoblast to the body of the embryo proper. These modifications gave rise to a new organ, the placenta, formed from tissues of both the mother and the embryo: the uterine wall with its blood vessels provided by the mother; the trophoblast and allantois—and in some mammals also the yolk sac—with their blood vessels provided by the embryo.

The overall development of placental mammals as a result of these changes is profoundly different from that of their ancestors, the reptiles, and proceeds in the following way: the tiny yolkless egg is fertilized in the upper portion of the oviduct by sperm received from the male in the process of coupling (coitus); cleavage starts as the egg is propelled slowly down the oviduct by action of cilia in the oviduct lining. At the end of cleavage a solid ball of cells called a morula is produced. The surface cells of the morula become the trophoblast and the inner cell mass gives rise to the embryo (the formative cells) and also its yolk sac, amnion, and allantois. A cavity appears within the morula, converting it into a hollow embryo, called the blastocyst. This cavity resembles the blastocoel but, in fact, is analogous to the yolk sac of meroblastic eggs, except that there is no yolk and the cavity is filled with fluid. At the blastocyst stage, the embryo enters the uterus and attaches itself to the uterine wall. This attachment, or implantation, a crucial step in the development of a mammal, is attained through the action of the trophoblast, which forms extensions, known as villi, that penetrate the uterine wall (Figure 9). In higher placental mammals, the lining of the uterine wall and, in varying degrees, the underlying tissues as well are partially destroyed, resulting in a closer relationship between the blood supplies of the mother and the embryo. Indeed, in man and in some rodents, the blastocyst sinks completely into the uterine wall and becomes surrounded by uterine tissue.

While implantation takes place, the formative cells arrange themselves in the form of a disk under the trophoblast. In the disk, the germinal layers develop much as in birds, with the formation of a primitive streak and migration of the chordamesoderm into a deeper layer. A layer of endoderm is formed adjoining the cavity of the blastocyst, and an amniotic cavity develops, enclosing the embryo; in lower placental mammals, the allantois also develops. The embryo proper, lying in the amniotic cavity, is connected to the extra-embryonic parts by the umbilical cord. The umbilical cord lengthens greatly during later development. In higher mammals, the cavity of the allantois is reduced, but the allantoic blood vessels become well developed and extend through the umbilical cord, connecting the embryo to the placenta. The blood that circulates in the placenta brings oxygen and nutrients from the maternal blood to the embryo and carries away carbon dioxide and other waste products from the em-

Implanta-  
tion

Figure 9: Embryo of placental mammal surrounded by embryonic membranes.

bryo to the maternal blood for disposal by the maternal body.

Although tissues of maternal and embryonic origin are closely apposed in the placenta, there is little actual mingling of the tissues. Despite an occasional penetration of an embryo cell into the mother and vice versa, there is a placental barrier between the two tissues. The blood circulation of the mother is at all times completely separated from that of the embryo and its extra-embryonic parts. The placental barrier, however, does allow molecules of various substances to pass through; such differential permeability is indeed necessary if the embryo is to obtain nourishment. The permeability of the placental barrier differs in different animals; thus antibodies, which are protein molecules, may penetrate the placental barrier in man but not in cattle.

The maintenance of the fetus—as the more advanced embryo of a mammal is called—in the uterus is under hormonal control. In the initial stages of pregnancy, the continued existence of the embryo in the uterus depends on the hormone progesterone, which is secreted by the corpora lutea, "yellow bodies," that develop in the ovary after an egg has been released.

At birth the fetal parts of the placenta separate from the maternal parts. Contraction of the uterine wall first releases the fetus from the uterus; the fetal parts of the placenta (the afterbirth) follow. In certain cases of intimate connection between fetal and maternal tissues, the maternal tissues are torn, and birth is accompanied by profuse bleeding.

### III. Organ formation

#### PRIMARY ORGAN RUDIMENTS

Immediately after gastrulation—and sometimes even while gastrulation is underway—the germinal layers begin subdividing into regions that will give rise to various parts of the body. Subdivision proceeds in stages: initially a mass of cells is set aside for an organ system (for the alimentary canal, for instance) and subsequently further subdivided into the rudiments of various parts of the organ system, such as the liver, stomach, and intestines. The initially formed larger units are referred to as primary organ rudiments; those they later give rise to, as secondary organ rudiments.

The type of organ rudiment produced depends on the organization of the body in any particular group in the animal kingdom. In the vertebrates the earliest subdivision within a germinal layer is the segregation within the chordamesodermal mantle of the rudiment of the notochord from the rest of the mesoderm (Figure 7). During gastrulation the material of the notochord comes to lie middorsally in the roof of the archenteron. It separates by longitudinal crevices from the chordamesodermal

mantle lying to the left and right. The material of the notochord then rounds off and becomes a rod-shaped strand of cells immediately under the dorsal ectoderm, stretching from the blastopore toward the anterior end of the embryo, to the midbrain level. In front of the tip of the notochord, there remains a thin sheet of pre-chordal mesoderm.

The mesodermal layer adjoining the notochord becomes thickened and, by transverse crevices, subdivided into sections called somites (Figure 10). The somites, which later give rise to the segmented body muscles and the vertebral column, are the basis of the segmented organization typical of vertebrates (seen especially in the lower fishlike forms but also in the embryos of higher vertebrates). The lateral and ventral mesoderm, which remains unsegmented, is called the lateral plate. The somites remain connected to the lateral plate by stalks of somites that play a particular role in the development of the excretory (nephric) system in vertebrates: for this reason they are called nephrotomes. Rather early the mesodermal mantle splits into two layers, the outer parietal (somatic) layer and the inner visceral (splanchnic) layer, separated by a narrow cavity (Figure 11) that will expand later to form the coelomic, or secondary, body cavity. The coelomic cavity extends initially through the nephrotomes into the somites; in the somites it is eventually obliterated. Endoderm completely surrounds the lumen of the archenteron (when present) and produces the cavity of the alimentary canal. If no arch-

enteric cavity is formed during gastrulation, the cavity of the alimentary canal is formed by the separation of cells in the middle of the mass of endoderm (as in bony fishes) or by folding of the sheet of endoderm (Figure 7).

activating cells (the inducer). The inducing substance of the mesoderm is a large molecule, probably a protein or a nucleoprotein, which presumably penetrates reacting cells, though direct and unequivocal proof of such **pene-**

Figure 11: (Left to right) Subdivision of the mesoderm in a vertebrate embryo.

The endodermal gut sooner or later acquires an extended anterior part called the foregut and a narrower and more elongated posterior part, the hindgut. Characteristic of chordates is the development of the nervous system from a part of ectoderm lying originally on the dorsal side of the embryo, above the notochord and the somites. This part of the ectodermal layer thickens and becomes the neural plate (Figure 7:1), whose edges rise as neural folds that converge toward the midline, fuse together, and form the neural tube. In vertebrates the neural tube lies immediately above the notochord and extends beyond its anterior tip. The neural tube is the rudiment of the brain and spinal cord; its lumen gives rise to the cavities, or ventricles, of the brain and to the central canal of the spinal cord. The remainder of the ectoderm closes over the neural tube and becomes, in the main, the covering layer (epithelium) of the animal's skin (epidermis). As the neural tube detaches itself from the overlying ectoderm, groups of cells pinch off and form the neural crest, which plays an important role in the development of, among other things, the segmental nerves of the brain and spinal cord.

In developing the primary organ rudiments mentioned above, the embryo acquires a definite organization clearly recognizable as that of a chordate animal. Similar processes, which occur in the development of other animals, establish the basic organization of an annelid, a mollusk, or an arthropod.

The organization of the embryo as a whole appears to be determined to a large extent during gastrulation, by which process different regions of the blastoderm are displaced and brought into new spatial relationships to each other. Groups of cells that were distant from each other in the blastula come into close contact, which increases possibilities for interaction between materials of different origin. In the development of vertebrates in particular, the sliding of cells (presumptive mesoderm) into the interior and their placement on the dorsal side of the archenteron (in the archenteric "roof"), in immediate contact with the overlying ectoderm, is of major importance in development. Experiments have shown that, at the start of gastrulation, ectoderm is incapable of progressive development of any kind; that only after invagination, with chordamesoderm lying directly underneath it, does ectoderm acquire the ability for progressive development. The dorsal mesoderm, which later differentiates into notochord, prechordal mesoderm, and somites, causes the overlying ectoderm to differentiate as neural plate. Lateral mesoderm causes overlying ectoderm to differentiate as skin. The influence exercised by parts of the embryo, which causes groups of cells to proceed along a particular path of development, is called embryonic induction. Though induction requires that the interacting parts come into close proximity, actual contact is not necessary. The inducing influence—whatever it might be—is a diffusible substance emitted by the

tration is still unavailable. Inducing substances are active on vertebrates belonging to many different classes; e.g., inductions of primary organs have been obtained by transplanting mammalian tissues into frog embryos or by transplanting tissues of a chick embryo into the embryo of a rabbit.

Induction is responsible not only for the subdivision of ectoderm into neural plate and epidermis but also for the development of a large number of organ rudiments in vertebrates. The notochord is a source of induction for the development of the adjoining somites and nephrotomes; the latter appear jointly to induce development of limb rudiments from the lateral plate mesoderm. Further examples are mentioned below in connection with development of the various organs.

Since the results of induction are different for different organ rudiments, it must be presumed that there exist inducing substances with specific action, at least to a certain extent; thus, the lateral mesoderm induces differentiation of the skin but not neural plate from the very same kind of ectoderm. The number of inducing substances need not, however, be the same as the number of different kinds of tissues and organs, since certain differentiations could possibly be induced by a combination of two or more inducing substances, or the same inducing substance might have different effects on different tissues. It has been suggested that the regional organization of the entire vertebrate body could be controlled by the graded distribution of only two inducing substances—provisionally named the neuralizing substance and the mesodermalizing substance—along the length of the embryo. The neuralizing substance, concentrated at the anterior end, gradually decreases toward the posterior end; the mesodermalizing substance, on the other hand, is concentrated at the posterior end and decreases toward the anterior end. The differentiation of induced structures depends on the relative amounts of the two inducing substances at any given point in the embryo. Acting alone, the neuralizing substance induces only nervous tissue, which takes the form of the forebrain, and the mesodermalizing substance induces only mesodermal structures (e.g., somites, notochord).

In the amphibian embryo, induction appears to have its primary source in the dorsal lip of the blastopore, which eventually gives rise to the notochord and adjoining somites. Induction by the notochord and somites is responsible for the development of the neural plate in the ectoderm, of lateral and ventral parts of the mesodermal mantle, and of the lumen of the alimentary canal in the endoderm. The dorsal lip of the blastopore for this reason has been called the primary organizer. In higher vertebrates, in which gastrulation occurs through the medium of a primitive streak, the anterior end of the streak and the Hensen's node have properties similar to those of a primary organizer. Organization centres have been found, or suspected, in embryos of animals belong-

of organi-  
zation  
centre

ing to a few other groups, in particular the insects and sea urchins, but the interpretation of the experimental results in these animals is less satisfactory than in the case of vertebrates.

The concept of an organization centre suggests that a part of the embryo differs from the rest of the embryonic tissues in being more active. The more active parts of the embryo (and also of animals in later stages of development) are particularly sensitive to certain noxious influences in their environment. If an embryo is deprived of oxygen or subjected to weak concentrations of poisons, the first parts to suffer are the most morphogenetically active ones. In vertebrate embryos the anterior end of the head is most sensitive. Early sea-urchin embryos have two centres of maximal sensitivity: one at the animal pole and the other at the vegetal pole. The damage done by noxious influences may result in actual breakdown of cells in a region of maximal sensitivity and may also lead to a depression of the developmental potential of the cells. Thus, the graded distribution of certain physiological properties appears to play a part in morphogenetic processes: physiological gradients are in fact also morphogenetic gradients.

Gradients in the embryo can be used to control development to a certain extent, by exposing the embryo to influences that, while reaching all parts, have a local effect as the result of differences in sensitivity. Disturbances of normal development often are the result of disruptions of gradients (see also MALFORMATION, BIOLOGICAL).

#### ORGANOGENESIS AND HISTOGENESIS

The primary organ rudiments continue to give rise to the rudiments of the various organs of the fully developed animal in a process called organogenesis. The formation of organs, even those of diverse function, shares some common features, which are considered in this section. As the organs form, so do their component tissues, in a process termed histogenesis.

A germinal layer, as the name implies, is a sheet of cells. An organ rudiment may be formed and separated from such a sheet in several ways. A groove, or fold, may appear within the layer, become closed into a tube, and then separated from the original layer. A tube once formed may be subdivided into sections by constrictions and dilations of the tube at certain points. This is the way the nervous system rudiment is formed in vertebrates as already described.

Alternatively, the germinal layer may produce a round depression, or pocket. The pocket may then separate from the layer as a vesicle, or it may elongate and branch at the tip while still connected with the layer. The latter method is common in the development of various glands and also the lungs in vertebrates.

Still another method of rudiment formation in a germinal layer is by the development of local thickenings, elongated or round, and detachment from the epithelial sheet. If a lumen appears later within such a body, the result may be the same as that achieved by folding—that is, a tube or vesicle may be formed. Indeed, the same sort of organ may develop even in related animals in either of these ways. The epithelial layer may further be cut up into segments, with the layer losing continuity, as in the formation of somites in vertebrates or similar mesodermal blocks in segmented invertebrates (e.g., annelids and arthropods).

Lastly, the cells of a germinal layer may give up their connection to each other and become a mass of loose, freely moving cells called embryonic mesenchyme. This mass gives rise to various forms of connective tissue but may also condense into more solid structures, including parts of the skeleton and the muscles.

Many organs are comprised of all three germinal layers. It is very common for glands, for instance, to derive their lining from an ectodermal or endodermal epithelium and their connective tissue (sometimes in the form of a capsule) from mesenchyme of mesodermal origin. Parts of ectoderm and endoderm cooperate also in the development of the lining of the alimentary canal,

and mesoderm provides the connective tissue and muscular sheath of the canal.

In this section the development of organs of the body are dealt with according to the germinal layer that contributes the most important part, and only the development of vertebrate organs is considered.

## IV. Ectodermal derivatives

### THE NERVOUS SYSTEM

The vertebrate nervous system develops from the neural plate—a thickened dorsal portion of the ectoderm—which forms a tube, as described earlier. From the very start the tube is wider anteriorly, the end that gives rise to the brain. The posterior part of the neural tube, which gives rise to the spinal cord, is narrower and stretches as the embryo lengthens. Stretching involves the head to only a very minor degree.

**The brain and spinal cord.** Constrictions soon appear in the brain region of the neural tube, subdividing it into three parts, or brain vesicles, which undergo further transformations in the course of development. The most anterior of the primary brain vesicles, called the prosencephalon, gives rise to parts of the brain and the eye rudiments. The latter appear in a very early stage of development as lateral protrusions from the wall of the neural tube (Figure 10), which are constricted off from the remainder of the brain rudiment as the optic vesicles. The rest of the prosencephalon constricts further into two portions, an anterior one, or telencephalon, and a posterior one, or diencephalon. The telencephalon gives rise, in lower vertebrates, to the smell, or olfactory, centre; in higher vertebrates and man, it becomes the centre of mental activities. The diencephalon, with which the eye vesicles are connected, was presumably originally an optic centre, but it has acquired, in the course of evolution, a function of hormonal regulation. The floor of the diencephalon forms a funnel-shaped depression, the infundibulum, which becomes connected with the pituitary, or hypophysis, the most important gland of internal secretion (*i.e.*, endocrine gland) in vertebrates. Indeed, the posterior lobe of the hypophysis is actually derived from the floor of the diencephalon. Tissues of the infundibulum and the posterior lobe of the hypophysis produce certain hormones (oxytocin and vasopressin) and stimulate the production and release of other hormones from the anterior lobe of the hypophysis.

The second primary brain vesicle, the mesencephalon, gives rise to the midbrain, which, in higher vertebrates, takes part in coordinating visual and auditory stimuli.

The third primary brain vesicle, the rhombencephalon, is more elongated than the first two; it produces the metencephalon, which gives rise to the cerebellum with its hemispheres, and the myelencephalon, which becomes the medulla oblongata. The cerebellum acts as a balance and coordinating centre, and the medulla controls functions such as respiratory movements.

The cells constituting the wall of the neural tube and, later, of the brain and spinal cord become arranged in such a way that they point into the central cavity of the tube. The differentiation of nervous tissue involves many cells abandoning their connection to the inner surface of the neural tube and migrating outward, where they accumulate as a mantle. The first cells to migrate become the neurons, or nerve cells. They produce outgrowths called axons and dendrites, by which the cells of the nervous system establish communication with one another to form a functional network. Some of the outgrowths extend beyond the confines of the brain and spinal cord as components of nerves; they establish contact with peripheral organs, which thus fall under the control of the nervous system. Cells migrating from the inner surface of the neural tube later in development become astrocytes, which are the supporting elements of nerve tissue.

The fate of nerve cells is dependent largely on whether they succeed, directly or indirectly (through other neurons), in connecting with peripheral organs. Nerve cells that fail to establish connections die. Thus, if in early stages of embryonic development, some organ, a limb

Differentiation of nervous tissue

Embryonic  
mesen-  
chyme

rudiment for instance, is surgically removed, the nerve cells in the centres supplying nerves to such an organ are reduced in number, and the corresponding nerves also diminish or disappear. On the other hand, if an organ is introduced by transplantation into a developing embryo, the organ will be supplied by nerves from a nerve centre in which the number of cells apparently increases; no additional cells are provided, but cells that would otherwise have degenerated remain active and differentiate into functional neurons, thus satisfying the demand created by the additional organ.

Nerves do not consist entirely of outgrowths of neurons located in the brain and spinal cord. Many components of nerves are outgrowths of neurons, the cell bodies of which are located in masses called ganglia; there are three main types of ganglia: spinal ganglia, cranial ganglia, and ganglia of the autonomous nervous system. The spinal ganglia are derived from cells of the neural crest—the loose mesenchyme-like tissue that remains between the neural tube and skin after separation of the two. Part of the cells of the neural crest in the region of the trunk and tail accumulate in segmental groups (corresponding to the mesodermal somites) and provide fibres to peripheral organs and to the spinal cord. These fibres constitute the sensory pathways in the spinal nerves. The motor components of the spinal nerves—fibres that activate muscles—are outgrowths of neurons lying in the spinal cord. The ganglia of the cranial nerves are produced only in part from cells of the neural crest; an additional component comes from the epidermis on the side of the head. Cells of the epidermal thickenings called placodes detach themselves and contribute to the formation of the cranial ganglia and thus of the cranial nerves.

The ganglia of the autonomous (sympathetic) nervous system are derived, as are the spinal ganglia, from neural-crest cells, but, in this case, the cells migrate downward to form groups near the dorsal aorta, near the intestine, and even in the intestinal wall itself. The outgrowths of cells in these ganglia are the nerve fibres of the sympathetic nerves (see also NERVES AND NERVOUS SYSTEMS).

**Major sense organs. The eye.** As has been pointed out, the rudiments of the eyes develop from optic vesicles, each of which remains connected to the brain by an eye stalk, which later serves as the pathway for the optic nerve. The optic vesicles extend laterally until they reach the skin, whereupon the outer surface caves in so that the vesicle becomes a double-walled optic cup. The thick inner layer of the optic cup gives rise to the sensory retina of the eye; the thinner outer layer becomes the pigment coat of the retina. The opening of the optic cup, wide at first, gradually becomes constricted to form the pupil, and the edges of the cup surrounding the pupil differentiate as the iris. The refractive system of the eye and, in particular, the lens of the eye are derived not from the cup but from the epidermis overlying the eye rudiment. When the optic vesicle touches the epidermis and caves in to produce the optic cup, the epidermis opposite the opening thickens and produces a spherical lens rudiment. The lens develops by an induction by the optic vesicle on the epidermis with which it comes in contact. A further influence emanating from the eye changes the epidermis remaining in place over the lens into a transparent area, the cornea. Influence of the optic cup on the surrounding mesenchyme causes the latter to produce a vascular layer around the retina and, outside of that, a tough fibrous or (in some animals) even a partly bony capsule called the sclera. Thus a complex interdependence of different materials produces the fully developed and functional vertebrate eye (see also PHOTORECEPTION).

**The ear.** The main part of the ear rudiment is derived from thickened epidermis adjoining the medulla. This area of the epidermis invaginates to produce the ear vesicle, which separates from the epidermis but remains closely apposed to the medulla. The ear vesicle becomes complexly folded to produce the labyrinth of the ear. Subsequently, a group of cells of the ear vesicle becomes detached and gives rise to the acoustic ganglion. Neurons

of this ganglion become connected by their nerve fibres to the sensory cells in the labyrinth, on the one hand, and with the brain (the medulla), on the other. The ear vesicle, acting on the surrounding mesenchyme, induces the latter to aggregate around the labyrinth and form the ear capsule. Further parts with various origins are added to the ear: the middle ear, from a pharyngeal pouch and the associated skeleton, and the external ear (where present), from epidermis and dermis.

**The olfactory organ.** The olfactory organ develops from a thickening of the epidermis adjacent to the neural fold at the anterior end of the neural plate. This thickening is converted into a pocket or sac but does not lose connection with the exterior. The openings of the sac become the external nares, and the cavity of the sac becomes the nasal cavity. Some cells of the olfactory sac differentiate as sensory epithelium and produce nerve fibres entering the forebrain. In most fishes the olfactory sac does not communicate with the oral cavity; in lungfishes and in terrestrial vertebrates, however, canals develop from the olfactory sacs to the oral cavity, where they open by internal nares. A cartilaginous capsule forms around the olfactory organ from cells believed to have been derived from the walls of the sac itself, and thus it is ectodermal in origin.

**Gustatory and other organs.** Gustatory organs in the form of taste buds develop as local differentiations of the lining of the oral cavity but also, in fishes, in the skin epidermis. They are supplied with nerve endings, as are several other sensory bodies scattered among the tissues and organs of the developing body.

#### THE EPIDERMIS AND ITS OUTGROWTHS

The major part of the ectodermal epithelium covering the body gives rise to the epidermis of the skin. In fishes and aquatic larvae of amphibians, the many-layered epidermis is provided with unicellular mucous glands. In terrestrial vertebrates, however, the epidermis becomes keratinized; *i.e.*, the outer layers of cells produce keratin, a protein that is hardened and is impermeable to water. During the process of keratinization, many cell components degenerate and the cells die; the layer of keratinized cells is therefore shed from time to time. In reptiles the shedding may take the form of a molt in which the animal literally crawls out of its own skin. It is less well known that frogs and toads also moult, shedding the surface keratinized layer of their skin (which is usually eaten by the animal). In birds and mammals, keratinized cells are shed in pieces that are sloughed off, rather than in extensive layers. In many vertebrates local thickenings of the keratinized layer appear in the form of claws, hooves, nails, and horns.

The epidermis is only the superficial layer of the skin, which is reinforced by the dermis, a connective tissue layer of a much greater thickness. The cells of the dermis are derived from mesoderm and neural-crest cells. In particular the pigment cells found in the dermis of fishes, amphibians, and reptiles are of neural-crest origin. The pigment in the skin of birds and mammals (and also in hairs and feathers) is also produced by neural-crest cells, but in these animals the pigment cells penetrate into the epidermis or deposit their pigment granules there.

The structure of the skin is further complicated by the development of hairs and feathers, on the one hand, and of skin glands, on the other. Hairs and feathers develop from a somewhat similar kind of rudiment. The development starts with a local thickening of the epidermal layer, beneath which a group of mesenchyme cells accumulate. In the case of hairs, the epidermal thickening proliferates downward and forms the root of the hair, from which the shaft then grows outward, emerging on the surface of the skin. In the case of feathers, the epidermal thickening bulges outward to form a hollow fingerlike protrusion with a connective tissue core. Secondly, the shaft of the feather branches characteristically to produce barbs and barbules. In both cases, however, the final structure—shaft of the hair and shaft barbs and barbules of the feather—consists of keratinized and, thus, dead cells.

Keratinization

Formation of the optic cup

The skin of amphibians and mammals (but not of birds and reptiles) is provided with numerous skin glands, which develop as ingrowths from the epidermis. A peculiar type of skin gland is the mammary gland of placental mammals. In the first stage of development, mammary-gland rudiments resemble hair rudiments; they are thickenings of the epidermis, with condensed mesenchyme on their inner surfaces. In some mammals (rabbit, man) two continuous epidermal thickenings called mammary lines stretch along either side of the belly of the embryo. Parts of the line corresponding in number and position to the future glands enlarge while the rest of the thickening disappears. The initial thickenings proliferate inward and produce a system of ramified cords, solid at first but hollowed out later, which become the lactiferous, or milk-bearing, ducts of the gland. Further branching at the tips of the ducts gives rise to smaller ducts and to the secretory end sacs, or alveoli, of the gland.

## V. Mesodermal derivatives

### THE BODY MUSCLES AND AXIAL SKELETON

The somites, formed in the early stages of development from the upper edges of the mesodermal mantle adjoining the notochord, are complex rudiments that subdivide and give rise to very diverse body structures. The coelomic cavity, present initially, becomes obliterated by the side-to-side flattening of the somites, so that the thinner, outer parietal layer of the somite comes in close contact with its thicker visceral layer. The visceral layer of the somite very early subdivides into two parts. The upper, dorsolateral part called the myotome (Figure 11) remains compact, giving rise to the body muscles. The lower, medioventral part of the somite, called the sclerotome, breaks up into mesenchyme, which contributes to the axial skeleton of the embryo—that is, the vertebral column, ribs, and much of the skull. The parietal layer of the somite, at a later stage, is converted into mesenchyme that, together with components of the neural crest, gives rise to the dermis of the skin and, for this reason, is called the dermatome.

The cells of the myotome are elongated in a longitudinal direction and become differentiated as muscle fibres. The myotomes, originally situated dorsally, expand on either side, penetrating between the skin on the outside and the lateral plates of the mesoderm on the inside, until they meet midventrally; the whole body is thus enclosed in a layer of developing muscle. As the somites and myotomes are segmented, so are the muscles derived from them. Metamerism, or segmentation, a feature in the embryos of all vertebrates, remains preserved only in the adults of fishes and of terrestrial vertebrates that have elongated bodies (salamanders, snakes); it becomes largely erased in four-footed animals that depend on their limbs for locomotion.

The mesenchyme derived from the sclerotomes condenses as cartilage around the notochord and the spinal cord. It forms the cartilaginous vertebral column and ribs. In the head region it produces a part of the cartilaginous skull, mainly its posterior and ventral parts; anteriorly the somitic mesenchyme is supplemented by mesenchyme from the neural crest. Cartilaginous capsules of the olfactory organ and the ear fuse with the cartilaginous capsule surrounding the brain; to this complex are also added cartilages associated with the jaws and gill skeleton. Cartilage in the vertebral column and in the skull is replaced later in the bony fishes and in the terrestrial vertebrates by bone. At a still later stage, dermal bones are added, which, while they have no precursors in the cartilaginous skeleton, develop in the adjoining mesenchyme.

### THE APPENDAGES: TAIL AND LIMBS

The tail in vertebrates is a prolongation of the body beyond the anus. It develops in early stages from the tail bud, immediately dorsal to the blastopore. Material for the tip of the tail is situated slightly forward from the edge of the blastopore. The elongation of the back of the body is greater than that of the belly; as a result the tip of the tail bud is carried beyond the blastopore and thus

beyond the anus, which, in the developed embryo, marks the position of the blastopore. The consequence is that a section of the dorsal surface of the embryo comes to lie on the ventral surface of the tail; *i.e.*, becomes inflected. The tail bud is formed from parts that have already been differentiated to a certain extent; prolongations of the neural tube and of the notochord are involved, and endoderm extends into the tail rudiment as the postanal gut, which, however, soon degenerates. The bud is also encased in ectodermal epidermis. In amphibians the somites of the tail are not derived from the chordamesodermal mantle but from the inflected posterior portion of the neural plate, which loses its nervous nature and becomes subdivided into segments corresponding to the somites of the trunk. In higher vertebrates the cells in the interior of the tail bud have an undifferentiated appearance and form a growth zone, at the expense of which parts of the tail (neural tube, notochord, somites) are extended backward as the tail elongates.

The paired limbs of vertebrates derive their first rudiments from the upper edge of the lateral plate mesoderm. The parietal layer becomes thickened, and cells escape from the epithelial arrangement and form a mesenchymal mass adjoining the ectodermal epithelium at the surface of the body. The ectodermal epithelium over the mass of mesenchyme likewise becomes thickened. In higher vertebrates, the accumulation of mesodermal cells and the thickening of the epidermis occur along the entire length of the trunk, from neck to anus, but in the middle of the trunk they soon disappear, and only the most anterior and the most posterior sections develop further into the rudiments of the forelimbs and hindlimbs, respectively. In fishes, the rudiments of the pectoral and pelvic fins are more extended anteroposteriorly in earlier than in final stages.

The mesodermal masses of the limb rudiments proliferate, and, covered with thickened epidermis, form on the surface of the body conical protrusions called the limb buds, which, once formed, possess all the materials necessary for limb development. Limb buds may be transplanted into various positions on the body or on the head and there develop into clearly recognizable limbs, conforming to their origin, whether a forelimb or hindlimb, a wing or a leg in birds. This specificity of the limb is carried by the mesodermal part of the rudiment, but a complex interaction between the mesodermal mesenchyme and the ectodermal epidermis is necessary for the normal development of the limb. In four-limbed vertebrates (tetrapods), the tips of the limb buds become flattened and broadened into hand or foot plates. The edge of the plate is indented, forming the rudiments of the digits. Meanwhile, local areas of the mesodermal mesenchyme in the interior of the limb rudiment condense; these are the rudiments of the various components of the limb skeleton. In fishes, small outgrowths from the myotomes enter the limb rudiment to form the muscles of the fins. In tetrapods, however, the limb muscles develop from the same mass of mesenchyme that gives rise to the skeleton. Thus the muscles of the body and the muscles of the limbs have different origins—the first develop from the myotomes (thus from the somites), and the second develop from the lateral plate mesoderm via the limb buds.

The nerves supplying the limbs grow into the limb rudiments from the spinal cord and the spinal ganglia. The nerves are guided in some way by the limb rudiments, for, if limb rudiments are displaced by transplantation to an abnormal position, the nerves still find their way and establish normal relationships to the limb muscles. Limb rudiments transplanted to sites very far from their normal positions induce local nerves to enter the limb, thereby making it motile.

### EXCRETORY ORGANS

The kidneys of vertebrates consist of a mass of tubules that develop from the stalks of somites called nephrotomes. In some primitive vertebrates such as cyclostomes, the nephrotome in each segment gives rise to only one tubule (Figure 11), but, in the great majority of verte-

Formation of the tail bud

Limb buds

Derivatives of somites

brates, mesenchyme from adjacent nephrotomes fuses into a common mass that differentiates into a number of nephric tubules irrespective of the original segmentation of the mesoderm. Under primitive conditions each tubule opens by a funnel (the nephrostome) into the coelomic cavity; the opposite ends of the tubules fuse to form the collecting ducts of the kidney. A collection of capillaries (the glomerulus) becomes associated with the nephric tubule, forming its filtration apparatus. The glomerulus may be situated in the coelomic cavity opposite the nephrostome or, in all the more advanced animals, intercalated into the nephric tubule, forming with the latter a renal corpuscle of the kidney. In adults of all vertebrates above the amphibians, the nephrostomes disappear (or are never formed), so that the tubule begins with the renal corpuscle. Parts of the kidney in vertebrates can be distinguished as the pronephros (most anteriorly, at the forelimb level), the mesonephros (in the midtrunk region), and the metanephros (in the pelvic region). The three sections of the kidney develop at different stages, starting with the pronephros and ending with the metanephros. In their morphology and mode of development, the anterior parts show more primitive conditions than the posterior ones. The pronephros, developing early in embryo formation, is the functional kidney of fish and amphibian larvae. Its collecting duct opens into the hindmost part of the intestine, called the cloaca, and later also serves as the collecting duct of the mesonephros. In reptiles, birds, and mammals, the pronephros is nonfunctional, although even in these animals its duct persists as the mesonephric duct. The mesonephros develops later and replaces the pronephros as the functional kidney of adult fishes and of the embryos of reptiles, birds, and mammals. The tubules of the mesonephros link up with the duct derived from the pronephros. The pronephric duct in fact stimulates the development of mesonephric tubules, and, in its absence, the mesonephros does not develop at all.

The metanephros is found only in reptiles, birds, and mammals. It replaces the mesonephros of the early embryonic stages and continues as the functional kidney in the postembryonic and adult life of these animals. The metanephros develops from mesenchyme derived from the nephrotomes of the posterior part of the trunk and lying dorsal to the mesonephric duct. The actual differentiation is initiated by a dorsal outgrowth of the mesonephric duct, called the ureteric bud. The ureteric bud grows in the direction of the mesenchyme and becomes the ureter. Having penetrated the mass of mesenchyme, it starts to branch, producing the collecting tubules of the kidney; the mesenchyme, meanwhile, in response to the influence of the duct and its branches, aggregates to form the excretory tubules of the kidney. The influence of the ureter is indispensable for the development of the metanephric excretory tubules, for, if the ureter fails to develop or, in its outgrowth, stops short of reaching the kidney-producing mesenchyme, no kidney develops.

#### CIRCULATORY ORGANS

The rudiment of the heart in vertebrates develops from the ventral edges of the mesodermal mantle in the anterior part of the body, immediately adjoining the pharyngeal region. A group of mesodermal cells breaks away from the ventral edge of the lateral plate, takes a position just underneath the pharyngeal endoderm, and becomes arranged in the form of a thin-walled tube, which will become the endocardium, or lining of the heart (Figure 12). In vertebrates with complete cleavage, the endocardial tube is single and medial from its start. In higher vertebrates with meroblastic cleavage—reptiles, birds, and mammals—the embryo in early stages of development is flattened out on the surface of the yolk sac; therefore, what are morphologically the ventral edges of the mesodermal mantle lie far apart on the perimeter of the blastodisc. As a result of this arrangement, two endocardial tubes are formed, one on either side of the embryo. Subsequently, when the embryo becomes separated from the yolk sac, the two endocardial tubes meet in the midline ventral to the pharynx and fuse, pro-

Figure 12: Development of the heart in amphibian embryos. From O. Hertwig, *Handbuch der Vergleichenden und Experimentellen Entwicklungslehre der Wirbeltiere* (1906); Gustav Fischer Verlag

ducing a single heart rudiment. After the formation of the endocardium, the coelomic cavity in the lateral plate mesoderm adjoining the heart rudiment expands slightly and envelops the endocardial tube or tubes (Figure 20). The heart muscle layer, or myocardium, develops from the visceral (splanchnic) layer of the lateral plate in contact with the endocardial tube; the parietal (somatic) layer of the lateral plate forms the pericardium, or covering of the heart. The portion of the coelom surrounding the heart is separated from the rest of the body cavity and becomes the pericardial cavity.

The endocardial tube branches anteriorly into two tubes, the ventral aortas; a similar branching of the endocardial tube posteriorly forms the two vitelline veins, which carry blood from the midgut endoderm or from the yolk sac (when present) to the heart.

In its earliest development, the heart rudiment shows a degree of dependence on the adjoining endoderm. The whole of the endoderm can be removed in newt embryos in the neural-tube stage. In such endodermless embryos, the heart fails to develop, even though the mesoderm destined to form the heart rudiment is left intact.

The heart is initially a straight tube stretching in an anteroposterior direction. Rather early in development, however, it becomes twisted in a characteristic way and subdivided into four main parts: the most posterior, the sinus venosus; the atrium, which comes to lie at the an-

ment of  
the  
meta-  
nephros

teriorly directed bend of the tube; the ventricle, occupying the apex of the posteroventrally directed inflexion; and, most anteriorly, the conus arteriosus. In the course of development in the more advanced vertebrates, the atrium and ventricle become partially or completely subdivided into right and left halves. In amphibians, only the atrium is separated into two halves, by a partition starting from the posterior end. In reptiles, a partition separates the atria and part of the ventricle. In birds and mammals, the subdivision of the heart is complete, with two atria and two ventricles.

The complete subdivision of the heart is important for separating the pulmonary, or lung, blood supply from the general body circulation. But, if this separation developed early in the embryo, it would create difficulties, since the lungs of the embryo are not functional; the enrichment of the blood with oxygen occurs instead in the placenta. The partition between the atria in mammalian embryos remains incomplete, so that blood returning from the body and from the placenta enters into the right half of the heart but is shunted (through the interatrial foramen) into the left half of the heart and thence again into general circulation. At birth, however, the interatrial foramen is closed by a membranous flap, and oxygen-depleted blood from the body enters the right atrium, is channelled into the right ventricle, and thence to the lungs for oxygenating.

In an adult vertebrate, blood vessels extend to all parts of the body. It would seem that channels for the supply of blood are provided in proportion to the local demand of the tissues; progressively developing organs or parts with particularly intensified function always receive an increased blood supply. The rudiments of blood vessels are always aggregations of mesenchyme cells. In any blood vessel the endothelial tube is formed first, and the muscular and elastic layers are added later.

The main blood channels in vertebrates develop in certain favoured situations; namely (1) between the endoderm and lateral plate mesoderm; (2) around the kidneys, especially the pronephros and mesonephros; and (3) in connection with the heart, which is a special case of the first category.

From the paired forward extensions from the heart, the ventral aortas, loops develop between the pharyngeal clefts. These are the aortic arches (Figure 13), which served originally to supply blood to the gills in aquatic vertebrates. The arches are laid down in all vertebrates, six or more being found in cyclostomes and fishes; six are present in the embryos of tetrapods, but the first two are degenerate. The arches of the third pair develop as the carotid arteries, supplying blood to the head. Those of the fourth pair (and, exceptionally, in urodeles also the fifth) join dorsally to form the dorsal aorta, providing blood to most of the body. These are the systemic arches. The arches of the sixth pair are the pulmonary arches; in embryos they carry blood to the dorsal aorta, as well as to the lungs, but in fully developed amniotes (reptiles, birds, and mammals), they carry blood only to the lungs.

The paired posterior extensions of the heart of the early embryo are the vitelline veins, whose branches spread out between the lateral plate mesoderm and the endoderm, especially the endoderm of the yolk sac, when present. On their way to the heart, the vitelline veins pass through the liver and break up into a system of small channels—the hepatic sinusoids. Parts of the vitelline veins lying posterior to the liver become the hepatic portal veins, which carry blood from the intestine to the liver; the parts of the vitelline veins anterior to the liver become the hepatic veins, which carry blood from the liver to the sinus venosus in lower vertebrates (anamniotes), but become the anterior section of the postcaval vein in amniotes.

Whereas the vitelline veins and, later, the hepatic portal vein carry blood from the endodermal parts of the embryo and from the yolk sac to the heart, the blood from the mesodermal and ectodermal parts is returned to the heart through a system of cardinal veins (Figure 14). These latter veins start their development in the form

Figure 13: Relation of the aortic arches and the branchial clefts in a dogfish embryo.

From B.I. Balinsky, *An introduction to Embryology*, 3rd ed. (1970); W.B. Saunders Company. Philadelphia

of an irregular sinus around the pronephros, connected by the common cardinal veins (ducts of Cuvier), on either side, to the sinus venosus. Extensions anteriorly and posteriorly give rise to the precardinal and postcardinal veins, respectively. The postcaval vein, present in terrestrial vertebrates, is a late acquisition, both in evolution and in embryogenesis; it is a result of the intercommunication of several venous channels, including the anterior portion of the vitelline veins.

Develop-  
ment of  
the  
cardinal  
veins

Figure 14: General arrangement of blood vessels in (A) an early amniote embryo and (B) the further development of the circulatory system. The arteries are shown in white, the veins in black.

The first blood cells in vertebrate embryos form in association with the intestinal endoderm on the yolk sac. Groups of mesoderm cells derived from the splanchnic layer of the lateral plate (extra-embryonically in cases in which a yolk sac is present) become so-called blood islands, which are particularly conspicuous on the yolk sac of bird embryos (in the area vasculosa). In bird's eggs, the internal cells of the blood island start producing hemoglobin (gas-carrying component of blood) and become the first red blood cells (erythrocytes) as early as the second day of incubation. The outer cells of the blood islands develop into an endothelial layer and form a network of blood vessels covering part of the surface of the yolk sac. The network acquires a connection to the vitelline veins and vitelline arteries (the latter being branches of the dorsal aorta); thus the blood corpuscles formed in the blood islands can enter the general blood circulation.

At later stages of embryogenesis, blood-cell formation

shifts from the blood islands to the liver and, still later, to the bone marrow.

The lymphatic system, in a manner similar to the blood vessels, develops by the local aggregation of connective tissue to form lymphatic vessels.

#### REPRODUCTIVE ORGANS

In considering the development of reproductive organs, distinctions must be made between: (1) the origin of sex cells (gametes), (2) the origin and differentiation of the sex glands, or gonads (ovaries and testes), and (3) the origin and development of the supporting parts of the reproductive system (*e.g.*, genital ducts, copulatory organs).

Origin of  
germ cells

The germ (germinal) cells, which eventually give rise to the gametes, are often segregated from the somatic, or body, cells at a very early stage—during cleavage and before the subdivision of the embryo into ectoderm, mesoderm, and endoderm. In the invertebrate nematodes, the very first of these primordial germ cells is identifiable after as few as five divisions of the egg cell. The germ cell retains the large chromosomes present in the fertilized egg; in the somatic cells the chromosomes become fragmented. Subsequently, the single germ cell gives rise, by mitotic divisions, to all the gametes in the gonad.

In vertebrates, primordial germ cells arise outside the gonads, but they cannot be distinguished in early cleavage stages. In amphibians, cytoplasm at the vegetal pole, rich in ribonucleic acids, becomes incorporated into a number of cells, which, during cleavage and gastrulation, lie among the yolk endoderm cells. Later they migrate into the mesodermal layer and become incorporated into the rudiments of the gonads. In higher vertebrates, primordial germ cells can be recognized in the extra-embryonic endoderm of the yolk sac. In mammals, these cells subsequently migrate into the mesoderm and are located in the gonad rudiments. The mouse embryo, for example, originally has fewer than 100 primary germ cells; during their migration, however, their numbers increase as a result of repeated divisions, to 5,000 or more in the gonads.

Although the primordial germ cells either may appear before the separation of germinal layers or be found originally in the endoderm, the gonads are invariably of mesodermal origin. In vertebrates, the first trace of gonad development is a thickening of the coelomic lining on either side of the dorsal mesentery and medial to the kidney rudiments. The thickening, elongated anteroposteriorly, is known as the germinal ridge (Figure 15). The ridge protrudes into the coelomic cavity, and the fold of thickened epithelium becomes filled with mesenchyme. At this stage the primordial germ cells invade the rudiments of the gonads and become associated with the somatic cells of the germinal ridge. In the functionally differentiated gonads, only the actual gametes and their predecessors (spermatogonia and oogonia) are derived from the primary germ cells; the supporting cells are somatic cells of local mesodermal origin. In the ovaries, the follicle cells surrounding and nourishing the young egg cells (oocytes) are of somatic origin, as are also the connective tissue and blood vessels of the gonad. In the testes, supporting elements called Sertoli cells are somatic cells, as are the interstitial cells, which are scattered between the sperm-carrying tubules of the testes and believed to be the source of male hormones.

In the early stages of their development—even while the gonad rudiment is being invaded by primordial germ cells—the female and male gonads are in an indifferent stage. Only later does tissue differentiation of the gonads begin and male or female gonadal development proceed.

Develop-  
ment of  
genital  
ducts

The genital ducts, by which the eggs and sperm are carried away from the gonads, are, in vertebrates, linked with the excretory system. In the male, the seminiferous tubules connect with the nephric tubules of the mesonephros, and the sperm are carried to the exterior by way of the mesonephric duct. In males of lower vertebrates, the mesonephric duct thus serves as a channel both for urine and for sex cells. In amniotes the development of

Figure 15: Transverse section of a mouse embryo showing the position of the germinal ridges and their relation to the mesonephric rudiment and the dorsal mesentery.

the metanephros as the urine excreting organ has freed the mesonephric duct to carry products associated only with reproduction. In the female, a separate duct, the paramesonephric duct (Müllerian duct), develops beside the mesonephric duct. At its anterior end it utilizes the funnels of the pronephric tubules as its entrance (ostium). It is remarkable that the paramesonephric duct develops initially in both female and male embryos. The ducts remain in an indifferent stage longer than the gonads. Eventually the sex hormones produced by the differentiating gonads cause a corresponding differentiation of the ducts. The mesonephric ducts, which become reduced in female embryos, remain in male embryos as ducts for conveying sperm (ductus deferens). The paramesonephric ducts, on the other hand, degenerate in male embryos but become the oviducts in female embryos (Figure 16). In mammals, the terminal portions of the paired oviducts differentiate as two uteri, which, in primates and man, fuse to form a single uterus.

In all terrestrial vertebrates except the placental mammals, the genital ducts, as well as the ducts of excretory organs, open into the cloaca. In mammals, however, the

Figure 16: Transformations of the genital ducts in mammalian embryos in transition from an (A) indifferent stage to (B) the male and (C) female condition.

cloaca becomes subdivided into a dorsal part, which conveys the feces, and a ventral part, which receives excretory and genital products. In **male** mammals the excretory and genital ducts remain connected, having the urethra as their common outlet; in females the urethra serves only for the passage of urine and the uterus opens separately by means of the vagina.

Copulatory organs have developed independently in several groups of vertebrates having internal fertilization. The penis in mammals develops from an outgrowth called the genital tubercle, located at the anterior edge of the urinogenital orifice. The tubercle is laid down in a similar way in embryos of both sexes, and the region of the urinogenital orifice remains in an indifferent state even longer than do the genital ducts. In a comparatively late stage of embryonic life the genital tubercle of male embryos encloses the urethral canal and becomes the penis; in female embryos it remains small and becomes the clitoris.

## VI. Endodermal derivatives

### THE ALIMENTARY CANAL

The alimentary canal is the chief organ developing from endoderm. The way it forms depends on the type of egg cleavage. In eggs with holoblastic (complete) cleavage, after gastrulation the invaginated mass of endoderm lines the archenteron, the cavity of which becomes the alimentary canal, or gut. In eggs with meroblastic (partial) cleavage—and also in mammals (despite their complete cleavage)—the endoderm is produced in the form of a sheet lying flat over the yolk-sac cavity. Subsequently, folds of endoderm and splanchnic mesoderm appear—first anteriorly, then laterally, and lastly posteriorly—and sink, converging ventrally under the embryo and cutting off the future gut cavity from the cavity of the yolk sac. The most anterior and posterior portions of the gut separate, but the middle part remains in open communication with the yolk sac throughout embryonic life, eventually becoming reduced to the yolk stalk, which passes through the umbilical cord.

The alimentary canal of vertebrates becomes differentiated eventually into the oral cavity, pharynx, esophagus, stomach, and intestine. Whether derived from an archenteron or formed by folding of the endodermal sheet, the canal initially does not possess an opening at its anterior end. This is also the case in some invertebrates (lower chordates and echinoderms), which are grouped together with vertebrates as the Deuterostomia, or animals with secondary mouths.

In vertebrates, a mouth forms by a rupture at the anterior end, where the endoderm is in contact with ectoderm. The ectoderm of the future mouth region becomes depressed, forming a mouth invagination, or stomodaeum. The ectodermal and endodermal layers separating the cavity of the stomodaeum from the gut fuse to form the oropharyngeal membrane, which thins and ruptures, providing free passage from the exterior to the gut. Because of its mode of origin, the oral cavity is in part lined by ectoderm and in part by endoderm, the two parts becoming indistinguishable. Before the oropharyngeal membrane ruptures, however, a small pocket forms on the dorsal side of the stomodaeal invagination. This, the rudiment of the anterior lobe of the hypophysis, becomes apposed to the ventral surface of the diencephalon and loses its connection with the mouth cavity.

The anal opening in some exceptional cases (urodele amphibians) is derived directly from the blastopore, which persists as a narrow canal after completion of gastrulation. In other vertebrates, however, the anus develops either near the location of the former blastopore or in a corresponding region at the posterior end of the embryo, where the last remnants of mesoderm migrated to the interior. It is thus claimed that the anus in vertebrates is derived, directly or indirectly, from the blastopore. The mode of formation of the opening is somewhat similar to that of the mouth. A slight invagination of the ectoderm occurs, and a cloacal membrane forms, separating the ectodermal invagination from the gut cavity. The membrane ruptures later to provide the anus.

### THE PHARYNX AND ITS OUTGROWTHS

The anterior portion of the endodermal gut, lying immediately posterior to the mouth cavity, expands laterally as the pharynx. The lateral pockets of the pharyngeal cavity, called the pharyngeal pouches, perforate the mesodermal layer, reach the ectoderm, and break through to form pharyngeal, or gill, clefts (Figure 13). In fishes and larvae of amphibians, these clefts develop gills and become respiratory organs. Pharyngeal pouches develop in the early embryos of all vertebrates, including the air-breathing terrestrial reptiles, birds, and mammals. The number of pouches has been reduced in the course of evolution from six or more to four in tetrapods, and the posterior pouches may not actually break through.

The consistent development of pharyngeal pouches and clefts indicates their importance in vertebrate development. Many parts of the vertebrate body are derived from, or dependent on, the pharyngeal pouches; for example, the aortic arches—the most important blood vessels of a vertebrate—develop between successive pharyngeal pouches (Figure 14). Skeletal visceral arches also occur between consecutive pharyngeal pouches (they do not develop if the pharyngeal pouches are prevented from developing). In adult terrestrial vertebrates, parts of the visceral arches are transformed into the hyoid apparatus, supporting the tongue, the auditory ossicles, and parts of the larynx and trachea. Furthermore, some of the material of the pharyngeal pouches is utilized for the formation of the parathyroid glands and the thymus; the former are indispensable glands of internal secretion, and the latter are a source, in mammals, of cells that produce antibodies. The pharynx also produces the rudiment of the thyroid gland as a ventral outgrowth.

### THE LIVER, PANCREAS, AND L U J

Three additional important organs develop from the endoderm: the liver, the pancreas, and the lungs. The liver develops as a ventral outgrowth of the endodermal gut just posterior to the section that will become the stomach. Initially, the liver takes the form of a tubular gland, but it soon acquires a close relationship to the blood sinuses and capillaries, forming lobules around blood vessels rather than around glandular ducts. The pancreas develops from three independent rudiments: two ventral ones, formed just posterior to the liver rudiment, and a dorsal one. The ventral and the dorsal rudiments fuse in most vertebrates to form one organ with a complicated system of ducts opening into the duodenum, a portion of the small intestine. The lungs develop from a ventral hollow outgrowth of the gut, just posterior to the pharyngeal region; the outgrowth branches into a right and left trunk that grow posteriorly beside the esophagus and then expand into hollow sacs, in lower terrestrial vertebrates, or into a system of tubes, in birds and mammals.

The endodermal parts of the alimentary system are, along their entire length, encased by the splanchnic mesoderm of the lateral plates. The coelomic cavities of the right and left sides fuse ventral to the gut but remain separated dorsally by their respective walls, which form the dorsal mesentery—a double membrane by which the gut is suspended from the dorsal side of the body cavity and through which blood vessels and nerves reach the gut (Figure 11). The layer of splanchnic mesoderm next to the endoderm produces the connective tissue and muscular layers of the gut. During development of the glands of the alimentary canal (*e.g.*, pancreas, salivary glands), the mesoderm forms a connective tissue capsule around the branching tubules of the gland. The development of the tubules is dependent on this mesodermal capsule and cannot proceed without it.

## VII. Postembryonic development

After partially developing within the egg membranes or within the maternal body, the newly formed individual emerges. The new animal is then born (ejected from the mother's body) or hatched from the egg. The condition of the new organism at the time of birth or hatching differs in various groups of animals, and even among ani-

Formation  
of  
vertebrate  
mouth

Develop-  
ment of  
lungs

mals within a particular group. In sea urchins, for example, the embryo emerges soon after fertilization, in the blastula stage. Covered with cilia, the sea-urchin blastula swims in the water and proceeds with gastrulation. Frog embryos emerge from the egg membranes when the main organs have already begun to develop, but functional differentiation of the tissues is unfinished; for instance, the components of the eyes and ears are far from complete, the mouth is not yet open, and the gut is filled with yolk-laden cells. Certain birds (called precocial) emerge from the egg covered with downy feathers and can run about soon after hatching, whereas others (altricial) hatch naked, with only rudiments of feathers, and are quite unable to move around. Among mammals there is a great range in the degree of development at birth. In marsupials, such as opossums and kangaroos, the young are born incompletely developed and very small; the young are then kept for a long time in the pouch of the mother, all the while firmly attached to the teats and suckling. Many small mammals are helpless at birth. Mice are born naked and blind; puppies and kittens are born covered with fur but with unopened eyes. Newborn human babies have their eyes open but cannot move themselves about for several months. Hoofed mammals, on the other hand, bear young that can stand up and run after their mothers within a few hours of birth.

Egg tooth  
of birds

In birds the hard shell is broken by the hatchling's beak, which is provided with a sharp tubercle on its top. A similar "egg tooth" appears on the tip of the snout of hatching reptiles. Many arthropods have a preformed line of fragility that allows part of the eggshell to be burst open like a lid, allowing the young to emerge. Birth in mammals is effected through the contraction of smooth muscles of the uterus.

#### THE LARVAL PHASE AND METAMORPHOSIS

The organism emerging from the egg or from the maternal body, apart from being incompletely developed, may have an organization more or less different from that of an adult. In some cases the difference is so great that, without knowing the origin of the eggs or without following the young through their full course of development, it would be impossible to know that the young and the adult are of the same animal species. Such young, called larvae, transform into the adult form by a process of metamorphosis. The term larva also applies to young that resemble the adult form but differ from it in some substantial respect, as in possessing organs not present in the adult or in lacking an important structure (apart from sex glands and associated parts, which tend to develop later in life in most animals). Larvae in different animals have special names given to them, such as the tadpole of frogs, the caterpillar of butterflies, and the fry of fishes.

Advantages  
of larvae

The development of the embryo into a larva rather than directly into an organism similar to the adult has various advantages. At the time of emergence from the egg, the new individual is relatively small, and the organization that enables the adult to lead a particular mode of life may not be suitable for a miniature copy of the adult. The larva may have to procure food for itself and, being small, may not be able to feed in the same way as the adult. It also may not be able to use effectively the same defense mechanisms the adult possesses. The larval stage enables an animal to avoid such hazards; it provides a mode of life and corresponding organization better suited to the smaller size of the newly emerged organism. Another advantage is that the larva may be able to exploit an entirely different environment because its organization is very different from that of the adults. A terrestrial adult may have aquatic larvae, a flying adult may have burrowing larvae, and a parasitic adult may have a free-living larva. A third advantage of a larval stage emerges in animals whose adult stages are sessile or restricted in their movements; the larvae can move freely, either of their own accord or on water currents. In this way the larvae of sedentary animals serve for the dispersal of the species. Lastly, the larval stage is of great advantage for certain internal parasites, which, once inside a host, cannot transfer to another. New hosts are infected instead

by the larval stages. (The usual means of attaining this end is for the parasite to produce enormous quantities of eggs and rely on the passive entry of the eggs into the new host with food. A more efficient way, however, is for a mobile larva to enter the new host actively.)

A large number of marine invertebrates possess floating larvae that have hairlike projections (cilia) as their means of locomotion. There are three main types of larvae, characteristic of large subdivisions of the animal kingdom.

The planula larva of coelenterates has an elongated shape and cilia covering its entire surface. The internal organization is simple, hardly beyond differentiation into ectoderm and endoderm in the interior. The larva does not feed but serves only for dispersal.

The trochophore larva is found in many marine invertebrates. Typically, as in polychaetes, it has an alimentary canal with mouth and anus and a ring of ciliated cells arranged anterior to the mouth. It also possesses a sensory organ and rudiments of mesoderm. Cilia around the mouth bring in food—unicellular plants and other small particles. The larva thus not only serves for dispersal but also feeds and grows before it transforms into an adult worm. Other trochophore larvae are found in marine mollusks and in certain marine worms. The larva of echinoderms is similar to the trochophore in possessing a gut and a ciliary band, but the arrangement of the latter is different. The echinoderm larva also feeds and grows as well as serves for dispersal.

Larvae of very different kinds are found in many arthropods. In crustaceans the larva, called nauplius, does not differ substantially in mode of life or means of locomotion from the adult but has fewer appendages than the adult. A typical crustacean nauplius has three pairs of legs and an unpaired simple eye. Additional pairs of appendages and paired compound eyes appear in the course of a sometimes prolonged development. In insects the larva differs from the adult by the absence of wings but, in addition, may have a different mode of life and different way of feeding. Among chordates the tunicates (sea squirts) deserve attention; the larval form is a free-swimming creature, showing unmistakable relation to vertebrates, but the adult is sedentary, with much reduced nervous and muscular systems. The tadpole of a frog differs from the adult in being totally aquatic, in possessing a tail and gills for respiration, and in having a mouth adapted for feeding on plants. The adult frog is adapted to land life, except for reproductive periods, has no tail and no gills, and is an active predator.

Metamorphosis, the transformation of the larva into an adult, is a more or less complicated process depending on the degree of difference between the two forms. The transformation may be gradual, extend over a long period, and involve a number of intermediate stages; alternatively, the transformation may be achieved in one step. In the latter case, especially if the difference between the larva and adult is great, large parts of the body of the larva, including all the specifically larval organs, disintegrate (necrobiotic metamorphosis). At the same time, organs of the adult are built up, sometimes from reserve groups of cells that remain undifferentiated or nonfunctional in the larva. A good illustration of the distinction between gradual and abrupt metamorphosis occurs among the insects. In more primitive insects, such as cockroaches and grasshoppers, metamorphosis is gradual. The larva, often referred to as a nymph, has more or less the same organization as the adult, or imago; it feeds in a similar way but differs from the adults in lacking wings and in having incomplete sex organs. The wings appear in later stages of larval life; they are small at first but increase with each molt, and they attain full size and functional capacity at the last (imaginal) one. The larva of other insects, such as beetles, butterflies, and wasps, is a grub or caterpillar, a wormlike creature not even remotely resembling the adult. The difference in organization is so profound that the transformation cannot be achieved gradually, and an intermediate resting, or pupal, stage is interposed between the larva and imago. The pupa neither feeds nor moves,

Types of  
meta-  
morphosis

as the larval organs inside are destroyed and replaced with organs of the adult, including wings and sex organs. Eventually, when formation of the adult organs is complete, the pupal skin is cast off, and the adult emerges. The destruction of the larval parts may be far reaching and include even the skin and most of the alimentary canal. The tissues of the adult are formed from groups of reserve cells that were present all along in the larva as imaginal disks.

Necrobiotic metamorphosis is observed in the tunicate larva, in which the tail, including notochord, nerve cord, and muscles, and most of the brain, including eye and statocyst, are destroyed at the same time that the large pharyngeal cavity of the adult develops. A tadpole metamorphosing into an adult frog loses its tail—the cells of which are destroyed and devoured by phagocytic cells—its gills, and its larval mouthparts; concurrently the legs of the adult frog develop progressively, the structure of the mouth and alimentary canal change, and the skin acquires a bony (keratinized) layer and a system of subcutaneous glands (Figure 17).

*Hormonal function in metamorphosis.* The complicated changes taking place during metamorphosis, especially in the case of necrobiotic metamorphosis, must be performed in a coordinated way. So that no changes are made prematurely and no organ systems are left behind in the general transformation, some common signal for the change must be provided. For both insect and amphibian metamorphoses, which have been the most extensively studied, the signal is a hormonal one, sent in the blood to all the cells and tissues of the body.

Metamorphosis in an insect is complicated by the fact that the rigid cuticle covering its body is very restrictive; new features can appear only after a molt, when the old cuticle is replaced by a newly formed one. Molting in insects is caused by the action of two hormones. In the brain of insects, several groups of neurosecretory cells produce the first hormone. This brain hormone does not itself affect molting but stimulates the prothoracic gland, a loose mass of secretory cells situated in the thorax in close association with tracheal tubes. In response to the stimulation by the brain hormone, the prothoracic gland releases into the blood a second hormone, the molting hormone, or ecdysone. Under the influence of ecdysone, the tissues of the body produce a new cuticle under the old one, after which the old cuticle is shed (the actual molting). The new cuticle embodies any new developmental features that were scheduled to appear. The kind of feature that emerges after a molt is controlled by a third organ of internal secretion, the corpora allata, secretory tissue situated posterior to the brain, near or around the dorsal aorta. The corpora allata emit the juvenile hormone, which, as long as it circulates in the blood, acts to perpetuate the larval form. As the larva approaches the end of its development, however, the corpora allata stop producing juvenile hormone or reduce its quantity; whereupon, the larva, at the next molt, metamorphoses into an adult. Withdrawal of the juvenile hormone is the immediate cause of metamorphosis, in conjunction with the brain hormone and ecdysone, which are responsible for the shedding of the larval cuticle and for the production of the new cuticle embodying the

From E. Witschi, *Development of Vertebrates* (1956); W.B. Saunders Company. Philadelphia

Figure 17: Stages in the metamorphosis of the frog from aquatic tadpole to terrestrial adult frog, including details of development of the hind leg.

features of the imago. Metamorphosis through the stage of the pupa is effected by diminishing levels of juvenile hormone, which determine first the transformation of the larva into a pupa and, with further reduction of the juvenile-hormone level, the final step of transformation of the pupa into the adult.

The metamorphosis of a tadpole into a frog also depends upon two hormones: one initiating the process and the other directly influencing the tissues involved in the change. The first hormone is the thyrotropic hormone, produced by the hypophysis. It has no immediate effect on the tissues of the body but activates the thyroid gland to produce several substances, the most important of which is thyroxine. Thyroxine and other iodine-containing compounds circulate in the blood and cause changes that, in their entirety, constitute the process of metamorphosis. It is remarkable that different tissues react in different ways to the presence of thyroxine. The muscles of the tadpole's tail degenerate, whereas the muscles of the trunk and legs are not affected; in fact, the growth and development of limbs are stimulated as a part of metamorphosis. The effect of the hormone depends on the nature of the reacting cells and tissues—*i.e.*, on their competence—just as the embryonic inductor in the earlier stages of development influences only cells with the competence for a particular kind of reaction.

#### DIRECT DEVELOPMENT

If an animal after birth or emergence from an egg differs from the adult in comparatively minor details (apart from not having functional sex organs), the development is said to be direct. There is no larval stage and no metamorphosis. Direct development does not mean, however, that no changes occur between birth and adulthood. One very obvious change is the growth of the animal.

The rate of growth—not absolute increase—is highest in the early stages of postembryonic life; subsequently, growth continues to slow, ceasing completely at the attainment of adulthood. The rate of growth is dependent on many factors, both external (feeding, temperature) and internal. Of the internal factors, the most important are hormones, especially the growth hormone produced by the hypophysis. If the growth hormone is produced in insufficient quantities, the result is dwarfism; if it is produced in excessive quantities, the result is gigantism.

In the case of direct development, the most important change is the attainment of sexual maturity, which is achieved in several steps and involves the action of several hormones. The gonad rudiments and rudiments of the supporting parts of the reproductive system remain inactive long after birth. At the approach of adulthood, however, two sets of hormones come into action: hypophyseal hormones stimulate the gonads to activity, and gonadal hormones (produced by the gonads) cause the supporting sex organs and other sex characters to become fully developed. To become functional, the gonads must be acted upon by secretions from the hypophysis. In immature females the follicle-stimulating hormone, which alone causes the egg follicles and the oocytes to grow, and the luteinizing hormone stimulate the follicle cells to produce the female sex hormone, estrogen, which effects the development of the uterus, the milk glands, and other characteristics of the female sex. In the male, the same hypophyseal hormones are produced, with the result that the testes start to produce sperm and to secrete the male sex hormone, androgen. It appears that the luteinizing hormone is the more active in the male sex, being able to cause both spermatogenesis and androgen secretion. Androgen, in turn, brings about the development of the penis, the descent of the testicles, the appearance of typical male hair growth, and other secondary sex characteristics.

#### VIII. Maturity and death

Sexual maturity and the ensuing reproductive activity mark the pinnacle of development and morphogenesis and, for many animals, herald the end of life. The biological goal of the entire process is achieved with the launching of the next generation, and the life cycle that

runs from the formation of gametes by one generation to the formation of gametes by the next generation is completed. In many animals the females die after laying their eggs; the males may have died earlier, after pairing. Indeed, some males (spiders, praying mantises) are eaten by the females immediately after copulation.

The developmental period can only truly be said to end with the termination of an organism, for much activity continues to unfold new developmental sequences, not all of them progressive and favourable, to be sure. Senescence, or a decline in abilities, signals advancing age in mammals but is not a general occurrence in the animal kingdom. Far more animals continue to function at near-peak capacity well into old age. And even among those species—salmons, eels, many moths—whose members die after a single reproductive act, death is relatively swift and not accompanied by a prolonged period of deterioration.

In most animals the reproductive potential is not exhausted in a single act of gamete production, but the sexually mature individuals remain alive and reproduce repeatedly. In these cases life may extend long beyond the first attainment of reproductive ability and be accompanied by further growth of the individuals, as occurs in most fishes, amphibians, and reptiles, and also in mollusks and certain other invertebrates. In the case of prolonged life-spans, however, reproductive activity may cease with advancing age, and a senile involution take place, as is observed mainly in mammals and, particularly, in man. The changes taking place may be described as regressive development. In most animals, however, the end of life is not preceded by any overt traces of senility. As a general rule, then, the attainment of reproductive ability may be said to be the final phase of progressive development among animals.

A gradual loss of alertness and vigour is typical of the aging pattern of primates and is especially important to man. For additional information, the following articles will be helpful: LIFE-SPAN, for a consideration of the expectation of life for many organisms, including man; AGING, for the mental and physical changes that accompany the passage of time; and DEATH, for the culminative act of a lifetime of development.

**BIBLIOGRAPHY.** General textbooks covering the whole subject of animal development include: B.I. BALINSKY, *An Introduction to Embryology*, 3rd ed. (1970); C.W. BODMER, *Modern Embryology* (1968); and F.G. GILCHRIST, *A Survey of Embryology* (1968).

Theoretical considerations of embryonic development are found in: H. SPEMANN, *Experimentelle Beiträge zu einer Theorie der Entwicklung* (1936; Eng. trans., *Embryonic Development and Induction*, 1938, reprinted 1962), a classic exposition of the experimental method in embryology; J.T. BONNER, *The Evolution of Development* (1958); J. BONNER, *The Molecular Biology of Development* (1965); and C.H. Waddington, *Principles of Embryology* (1956).

Descriptions of the morphological aspects of embryonic development are found in: L.B. AREY, *Developmental Anatomy: A Textbook and Laboratory Manual of Embryology*, 7th ed. (1965); and B.M. PATTEN, *Foundations of Embryology*, 2nd ed. (1964).

Physiological and analytical studies of embryonic development are treated in: L.J. BARTH, *Development: Selected Topics* (1964); E.M. DEUCHAR, *Biochemical Aspects of Amphibian Development* (1966); R.A. FLICKINGER (comp.), *Developmental Biology* (1966); J. NEEDHAM, *Biochemistry and Morphogenesis* (1942); L. SAXEN and S. TOIVONEN, *Primary Embryonic Induction* (1962); and J.P. TRINKAUS, *Cells into Organs: The Forces that Shape the Embryo* (1969).

Specific treatments of embryonic adaptations in a wide range of animals are considered in: W.J. HAMILTON, J.D. BOYD, and H.W. MOSSMAN, *Human Embryology*, 3rd ed. (1962), deals with the prenatal development of form and function in man; O.E. NELSEN, *Comparative Embryology of the Vertebrates* (1953); and M. KUME and K. DAN (eds.), *Invertebrate Embryology* (1968; orig. pub. in Japanese, 1957).

Books dealing with metamorphosis and senescence include the following: W. EIKIN, "Metamorphosis," in J.A. MOORE (ed.), *Physiology of the Amphibia*, ch. 8 (1964); V.B. WIGGLESWORTH, *The Physiology of Insect Metamorphosis* (1954); and A. COMFORT, *Ageing: The Biology of Senescence*, rev. ed. (1964).

(B.I.B.)

## Development, Biological

Development in its most general meaning refers to any process of progressive change. In this sense, most modern philosophical outlooks would consider that development of some kind or other characterizes all things, in both the physical and biological worlds. Such points of view go back to the very earliest days of philosophy.

### GENERAL FEATURES

**Philosophical basis.** Among the pre-Socratic philosophers of Greek Ionia, half a millennium before Christ, some, like Heracleitus, believed that all natural things are constantly changing. In contrast, others, of whom Democritus is perhaps the prime example, suggested that the world is made up by the changing combinations of atoms, which themselves remain unaltered, not subject to change or development. The early period of post-Renaissance European science may be regarded as dominated by this latter atomistic view, which reached its fullest development in the period between Newton's laws of physics and Dalton's atomic theory of chemistry in the early 19th century. This outlook was never easily reconciled with the observations of biologists, and in the last hundred years a series of discoveries in the physical sciences have combined to swing opinion back toward the Heracleitan emphasis on the importance of process and development. The atom, which seemed so unalterable to Dalton, has proved to be divisible after all, and to maintain its identity only by processes of interaction between a number of component subatomic particles, which themselves must in certain aspects be regarded as processes rather than matter. Albert Einstein's theory of relativity showed that time and space are united in continuum, which implies that all things are involved in time; that is to say, in development.

The philosophers who charted the transition from the nondevelopmental view, for which time was an accidental and inessential element, were Henri Bergson and, in particular, Alfred North Whitehead. Karl Marx and Friedrich Engels, with their insistence on the difference between dialectical and mechanical materialism, may be regarded as other important innovators of this trend, although the generality of their philosophy was somewhat compromised by the political context in which it was placed and the rigidity with which their later followers have interpreted it.

Philosophies of the Heracleitan type, which emphasize process and development, provide much more appropriate frameworks for biology than do philosophies of the atomistic kind. Living organisms confront biologists with changes of various kinds, all of which could be regarded as in some sense developmental; however, biologists have found it convenient to distinguish the changes and to use the word development for only one of them. Biological development can be defined as the series of progressive, nonrepetitive changes that occur during the life history of an organism. The kernel of this definition is to contrast development with, on the one hand, the essentially repetitive chemical changes involved in the maintenance of the body, which constitute "metabolism," and on the other hand, with the longer term changes, which, while nonrepetitive, involve the sequence of several or many life histories, and which constitute evolution.

As with most formal definitions, these distinctions cannot always be applied strictly to the real world. In the viruses, for instance, and even in bacteria, it is difficult to make a distinction between metabolism and development, since the metabolic activity of a virus particle consists of little more than the development of new virus particles. In certain other cases, the distinction between development and evolution becomes blurred: the concept of an individual organism with a definite life history may be very difficult to apply in plants that reproduce by vegetative division, the breaking off of a part that can grow into another complete plant. The possibilities for debate that arise in these special cases, however, do not in any way invalidate the general usefulness of the distinctions as conventionally made in biology.

The scope of development. All organisms, including the very simplest, consist of two components, distinguished by a German biologist, August Weismann, at the end of the 19th century, as the "germ plasm" and the "soma." The germ plasm consists of the essential elements, or genes, passed on from one generation to the next, and the soma consists of the body that may be produced as the organism develops (Figure 1). In more

2nd ed. (1968); Rand McNally & Company

Figure 1: Weismann's concept of the continuity of the germ plasm.

modern terms, Weismann's germ plasm is identified with DNA (deoxyribonucleic acid), which carries, encoded in the complex structure of its molecule, the instructions necessary for the synthesis of the other compounds of the organism and their assembly into the appropriate structures. It is this whole collection of other compounds (proteins, fats, carbohydrates, and others) and their arrangement as a metabolically functioning organism that constitutes the soma. Biological development encompasses, therefore, all the processes concerned with implementing the instructions contained in the DNA. Those instructions can only be carried out by an appropriate executive machinery, the first phase of which is provided by the cell that carries the DNA into the next generation: in animals and plants by the fertilized egg cell; in viruses by the cell infected. In life histories that have more than

The blurring of distinctions in nature

a minimal degree of complexity, the executive machinery itself becomes modified as the genetic instructions are gradually put into operation, and new mechanisms of protein synthesis are brought into functional condition. The fundamental problem of developmental biology is to understand the interplay between the genetic instructions and the mechanisms by which those instructions are carried out.

Genotype  
versus  
phenotype

In the language of genetics the word genotype is used to indicate the hereditary instructions passed on from one generation to another in the genes, while phenotype is the term given to the functioning organisms produced by those instructions. Biological development, therefore, consists in the production of phenotypes. The point made in the last paragraph is that the formation of the phenotype of one generation depends on the functioning of part of the phenotype of the previous generation (e.g., egg cell), as the mechanism that begins the interpretation of the instructions contained in the new organism's genotype.

Types of development. In the entire realm of organisms, many different modes of development are found, the most important categories of which can be discussed as pairs of contrasting types.

**Quantitative and qualitative development.** Development may amount to no more than a quantitative change (usually an increase) in a system that remains essentially unaltered. Qualitative development involves an alteration in the nature of the system. Pure examples of the first type are difficult to find. Approximations to it occur when an animal or plant has attained a structure with the full complement of organs; it then appears to increase only in size, that is to say, quantitatively. This would be a period of simple growth. A closer examination nearly always shows that the system is also undergoing some qualitative change, however. A human infant at birth, for example, already has its full complement of organs, but the ensuing developmental period up to adulthood involves not only growth but also processes of maturation that involve qualitative as well as quantitative changes. Perhaps the most uncomplicated examples of quantitative development occur in certain simple plants and animals. Flatworms, for example, may become reduced in size when starved but increase in size again when provided with suitable nutrition; they thus undergo quantitative changes. Even in these cases, however, it is found the constituent organs do not always merely become reduced in size but may actually suffer the loss of certain parts.

**Progressive and regressive development.** The normal processes of development in the majority of plants and animals may be considered progressive since they lead to increases in size and complexity and to the addition of new elements to the system. As already indicated, some organisms, when placed in adverse conditions, may undergo regressive changes, both in size and complexity. Such regressive changes are a part of the normal life history of certain organisms. Characteristically, these are species in which the organism at an early stage develops a relatively complex structure that enables it to be motile, and later adopts a form of life for which motility is no longer a necessity. A good example is that of the barnacles, a group of marine crustaceans in which the egg at first develops into a motile larva that soon settles down and becomes firmly attached to a solid underwater surface. The barnacle then loses many of the organs characteristic of the motile phase and develops into its familiar stationary form.

There are a number of other examples, particularly in groups in which the adults adopt a parasitic form of life, especially within the digestive system or other tissues of a host animal, from which they have only to absorb their nutriment without having to move or to possess suitable organs for capturing prey. In such cases the early developmental period is characterized by progression toward more complex forms followed by a period of regression in which many of these organs may be lost. During this regressive period certain components of the organism (i.e., those concerned with functioning as a sessile or par-

The adapt-  
ability of  
regression

asitic form) may undergo progressive development at the same time as the other organs are regressing.

**Single-phase and multiphase development.** The most familiar organisms, including man, undergo a **single-phase** development; the organs that appear at early stages persist throughout the whole of life. There are many kinds of animals that develop one or more larval stages adapted to a life different from that of the adult. Perhaps the best known of these is the common frog. The egg first develops into a tadpole, which is provided with a large muscular tail by which it swims. The tadpole eventually undergoes a change of form, or metamorphosis. This involves the regression and resorption of the tail and the growth of the limbs. During this time the rest of the body of the tadpole undergoes less profound changes; the organs persist but undergo relatively far-reaching progressive changes. In other animals, the alteration between the larval and the adult forms may be much more drastic. The egg of a sea urchin, for instance, at first develops to a small larva (the pluteus), which is completely unlike that of the adult. During metamorphosis nearly all the structures of the pluteus disappear; the five-rayed adult develops from a very small rudiment within the larva. In other groups of marine invertebrates, there may be successive larval stages before the adult form appears.

Plants in general appear to exhibit a type of development related in a general way to the multiphased development just discussed in animals, although rather different from it in essence. This is called the "alternation of generations" (Figure 2). The majority of higher plants

Alterna-  
tion of  
genera-  
tions

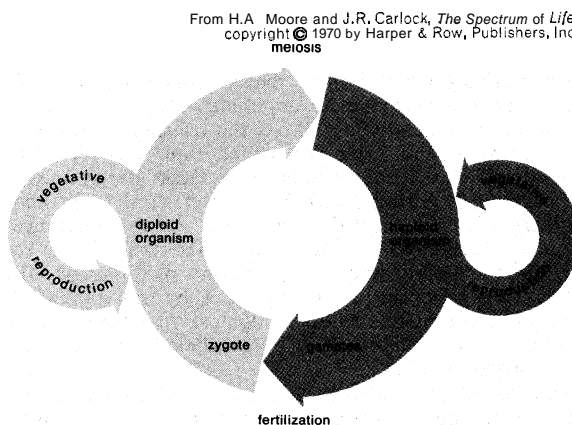

Figure 2: Generalized life cycle showing alternation of generations.

possess two sets of similar chromosomes in each of their cells, that is to say they are diploid ( $2n$ ), as are most higher animals. But in sexual reproduction, diploid cells undergo a reduction division so as to form precursors of the sex cells, which are **haploid**—i.e., they contain only one set of chromosomes. In animals these cells develop directly into the sex cells—egg and sperm—which unite in fertilization. In plants the haploid cells undergo some developmental processes before the functioning sex cells are produced. The products of this development are spoken of as the "haploid generation." In most higher plants the haploid development is quite reduced, so that the haploid individuals contain only a few nuclei—those associated with the pollen tube on the male side and a few associated with the egg on the female side. In some lower plants, however, such as mosses and ferns, the haploid development may be much more extensive and give rise to quite sizable separate plants. In such cases a species contains two kinds of individuals, produced by different types of developmental processes controlled, however, by the same **genotype**. This may be compared with the **multiphasing development** of larval forms in animals. The situation in plants, however, is characterized by the two forms of the organism having different chromosomal constitutions—haploid and diploid—whereas the larval forms and the adult of an animal species have the same chromosomal constitution.

*Structural and functional development.* These two categories cannot be regarded as a pair of opposites as were the previous pairs in this list; rather, they are two aspects of all processes of biological development and can be separated only conceptually, and for purposes of convenience of description. Function is the capacity of the biological system to carry out operations. At the level of the organism, these operations include walking, swimming, eating, digesting, etc.; at the cell level, typical functions are respiring, contracting, conducting nervous impulses, secreting hormones, etc.; and at the molecular level, all functions depend on the production of enzymes, coded by particular genes. Structure encompasses all parts of the organism capable of carrying out functions localized within the body of the organism and arranged in some particular spatial pattern. Contractile cells, for example, are grouped together to form muscle, and other cells are grouped together to form elements of the skeleton; both the muscles and the skeletal elements have definite spatial relations to each other.

These two aspects of development—function and structure—are not opposed to each other in any way. On the contrary, it is obvious that the higher level functions are clearly dependent on the proper structural relations and functions of cell systems. Even at the basic cellular or molecular levels, secretion or nervous conduction essentially depends upon the proper structural relation of the subcellular elements. It is, however, often convenient to focus discussion on one or other of these two aspects of development; for instance, a study may be made into the developmental processes that bring about the production of hemoglobin or insulin by a certain kind of cell, without at the moment being concerned with structural problems. Or again, the focus may be on the results of a certain process by which a mass of cells develops into a typical hand with five digits. In such an inquiry the structural aspects are paramount.

*Normal and abnormal development.* If a number of fertilized eggs of a given species are provided with conditions that enable them to develop at all, they will, with extraordinary regularity, develop into exceedingly similar adult organisms. The range of conditions they can tolerate is rather wide, and the similarity of the end products surprisingly complete. There are, indeed, good grounds for recognizing what must be considered normal development. The situation is perhaps more marked in animals than in plants, since the plants produced from a given batch of seed under a variety of environmental conditions often present considerably greater variation than is commonly found among animals. Even among plants, however, the differences produced by different conditions of cultivation are usually no more than quantitative differences in size and number of such organs as leaves and flowers, so that an individual can be described as well or poorly developed rather than as normally or abnormally developed. It is only in relatively few cases that a plant develops in quite different ways under two different conditions, neither of which can be considered abnormal or normal. In certain aquatic plants, for instance, the shape of the emergent leaves is different from the leaves that develop underwater. In such cases the plant actually has two normal forms of development.

It is possible, of course, to produce abnormal organisms by submitting a developing system to stimuli not usually encountered in normal environment, such as certain chemicals. The presence of unusual genes also may result in deviations from the normal processes of development. In the vast majority of cases such abnormalities can be regarded as resulting from failure to carry out fully the normal processes of development. Functional abnormality in the adult consists in the failure of the system to produce a certain enzyme or functional cell type; a structural abnormality consists in the unusual appearance of certain component elements or in their arrangement in incompletely realized patterns. It is extremely rare to find examples in which the abnormality consists in the addition of a new enzyme not produced in normal development, or the formation of a new structural pattern of the elements.

One very important type of development that, from some points of view, can be considered as an exception to the rule that abnormal development is nearly always retrogressive, is carcinogenesis, the production of tumours. Carcinogenesis involves a change in the developmental behaviour of a group of cells. Initially, it often involves a loss of some of the functional and structural characteristics that previously appeared in the cells. It is commonly followed, however, by the assumption of new properties, which however untoward they may be for the host animal, must be considered as a progressive type: the cells often grow faster and multiply sooner than the noncancerous cells, for example. Furthermore, the cells may undergo a sequence of changes in character and in their arrangement within the tumour. All these features can be regarded in a developmental sense as progressive.

In view of the great rarity of cases of abnormal development that lead to progressive changes, it seems to follow that the organs produced during the normal development of any given species actually exhaust all the potentialities of its genotype for the production of orderly functional structures. It appears that the only abnormal developments that can be produced are either displacements of normal organs, or inadequacies in carrying out normal processes, or the initiation of progressive but quite disorderly processes, as in the production of tumours (see MALFORMATION, BIOLOGICAL).

#### GENERAL SYSTEMS OF DEVELOPMENT

**Development of single-celled organisms.** In viruses, activities consist in the production, aided by the machinery of a host cell, of units for building new virus or phage particles: development is simply the assemblage of these constituent units.

In the next higher grade of biological organization, the organism consists of a single cell. Many single-celled algae produce special forms of cells that correspond to the sex cells, or gametes; these cells may unite in fertilization, the resulting fertilized egg, or zygote, undergoing a short period of development. In many other single-celled organisms, however, reproduction takes place by the simple division of an original cell into two daughter cells. In such forms, development normally is part of the process of subdivision. It involves the remodelling of the parent cell into two smaller cells, which are then separated by the division. Something similar must, of course, be involved in the division of cells of higher organisms also. In many single-celled organisms, however, the cell contains a number of defined parts, which are arranged in very definite ways, so that the process of remodelling is very striking and easily observed. This is so, for instance, with ciliated protozoans, in which the cortex is provided with a large number of hairlike cilia or other appendages, arranged in precise patterns, and often with such other structures as a mouth or a gullet. These structures are reproduced in two identical but smaller copies during cell division. This does not necessarily imply that no other developmental processes are possible. The process of regeneration of parts removed occurs quite independently of cell division, for example.

**Open and closed systems of development.** There is a marked difference between the general system of development in multicellular plants and multicellular animals. In a plant, certain groups of cells retain throughout the whole life of the plant an embryonic capability to give rise to many types of cells. These regions, known as meristems, occur at the growing tips of branches and roots and as a cylindrical sheath around the stem. They consist of rapidly dividing cells capable of assembling into groups that form buds from which may arise new stems, leaves, flowers, or roots.

By contrast, most animals have no special regions that retain an embryonic character. In most forms, the whole egg, and the whole collection of cells immediately derived from it, take part in the developmental processes and form parts of the developing embryo. In some forms that go through a number of larval stages, the development of certain cells is interrupted at an early stage, and they are set aside and resume their development to form

Cancerous growth as progressive

The latitude of normal development

Continued embryonic development in plants

a later type of larva, or to form the adult after the larval stages are completed. An example would be the imaginal buds of some insects. The cells of these buds cannot be regarded as retaining a fully embryonic character comparable to that of the plant meristems, since they cannot perform all the developmental processes but **only** those involved in the production of the particular late-larval or adult structure for which they have been set aside. In general, then, plants remain embryonic in character, capable as it were of starting again from the beginning to carry out the entire developmental process. Their development is, in this sense, "open." Most animals, on the other hand, lack persistently embryonic cells of this kind, and their development may be characterized as "closed." (There may be certain exceptions to this in very simple forms, such as flatworms, in which certain cells called neoblasts seem able to participate in any type of development; these cells are usually scattered throughout the body, and the major developmental processes that bring into being the general form of the organism cannot be attributed to them, as the development of the plant can be attributed to the meristems.)

**Blastogenesis** versus embryogenesis. Some animals possess a second system of development, in contrast to the "closed" embryonic system emphasized in the last section. In its most fully developed form, this system consists in remodelling a portion of the parental body into a new organism without any involvement of eggs or sperm. In an adult hydra, a microscopic aquatic animal, a portion of the body may begin to grow exceptionally fast; its cells differentiate into the various cell types and become molded into the constituent organs to build up a new individual identical to the parent. The group of cells responsible for this behaviour is, in its early stages, referred to as a bud, or blastema. Before they become activated these cells may appear quite indistinguishable from the other cells of the body and betray no embryonic capability comparable to the meristems of plants.

In some higher organisms, including certain insects, reptiles, and amphibians, incomplete but still fairly extensive new developments of a similar kind may take place. They require the stimulus of an injury, however, which may involve the removal of part of the normal body. The usual result is a new development to regenerate, or replace, the missing part. The first stage in such regenerative processes consists in the formation of a blastema, that is, a group of rapidly dividing cells that shows little sign of cellular specialization. The evidence indicates that they may not arise, as was once thought, from persisting embryonic cells scattered within the adult body, but instead are formed of cells near the position of the injury. These cells lose their normal adult character and become capable of developing into most of the tissues required to replace the parts removed by the injury (see **REGENERATION, BIOLOGICAL**).

Development from a blastema, or blastogenesis, presents many contrasts to embryogenesis, the normal form of development from a fertilized egg. In blastogenesis, tissues that, during embryonic development, appear in sequence one after another, may be formed simultaneously and without any obvious sequential relations. Very little, however, is as yet understood about the mechanisms by which the various tissues within the blastema become differentiated from one another. It may well be that these mechanisms are more similar to those found in embryonic development than appears at first sight.

#### CONSTITUENT PROCESSES OF DEVELOPMENT

**Growth.** As was pointed out earlier, developing systems normally increase in size, at least during part of their development. "Growth" is a general term used to cover this phenomenon. It comprises two main aspects: (1) increase in cell numbers by cell division and (2) increase in cell size. These two processes may in some examples occur quite separately from each other; for instance, cells in certain rapidly growing tissues (*e.g.*, the connective tissue or blood-forming systems in vertebrates) may increase greatly in number, while the cells remain approximately the same size. Alternatively, in some

organs (*e.g.*, the salivary glands of insects) the cells may increase greatly while remaining the same in number, each cell becoming enlarged, or hypertrophied. In such greatly enlarged cells there is often duplication of the genes, involving an increase in the DNA content of the nucleus, although no cell division takes place, and the nucleus continues as a single body, although with a multiplied, or "polyploid," set of chromosomes.

In very many cases, however, the growth of an organ depends on increases both in cell number and in cell size. The relative importance of these two processes has yet to be properly investigated. One case that has been well studied is the size of the wings of the fruit fly *Drosophila*. The number of cells in the wing can be easily determined, since each bears a single hair that can be seen and counted in simple microscopic preparations. It has been found that there is an accommodation of factors: if there is an unusually large number of cells, these may be somewhat smaller than usual, so that the total size of the wing remains relatively unchanged.

Perhaps the major theoretical difficulty in the concept of growth is that it is a quantitative notion attached to an ill-defined entity. Growth is an increase in size; but size of what? If a cell or organ increases in volume merely by the absorption of water, or by the laying down of a mineral substance such as calcium carbonate, is this to be regarded as growth or not?

**Morphogenesis.** As was pointed out earlier, morphogenesis refers to all those processes by which parts of a developing system come to have a definite shape or to occupy particular relative positions in space. It may be regarded as the architecture of development. Morphogenetic processes involve the movement of parts of the developing system from one place to another in space, and therefore involve the action of physical forces, in contrast to processes of differentiation (see below), which require only chemical operations. Although in practice the physical and chemical processes of development normally proceed in close connection, for purposes of discussion it is often convenient to make an artificial separation between them.

There is an enormous variety of different kinds of structures within living organisms. They occur at all levels of size, from an elephant's trunk to organelles within a cell, visible only with the electron microscope. There is still no satisfactory classification of the great range of processes by which these structures are brought into being. The following paragraphs constitute a tentative categorization that seems appropriate for the present state of biological thought on this topic.

**Morphogenesis by differential growth.** After their initiation, the various organs and regions of an organism may increase in size at different rates. Such processes of differential growth will change the overall shape of the body in which they occur. Processes of this kind take place very commonly in animals, particularly in the later stages of development. They are of major importance in the morphogenesis of plants, where the overall shape of the plant, the shape of individual leaves, and so on, depends primarily on the rates of growth of such component elements as the stems, the lateral shoots, and the vein and intervein material in leaves. In both animals and plants, such growth processes are greatly influenced by a variety of hormones. It is probable that factors internal to individual cells also always play a role.

Although differential growth may produce striking alterations in the general shape of organisms, these effects should probably be considered as somewhat superficial, since they only modify a basic pattern laid down by other processes. In a plant, for instance, the fundamental pattern is determined by the arrangement of the lateral buds around the central growing stem; whether these buds then grow fast or slowly relative to the stem is a secondary matter, however striking its results may be.

**Morphogenetic fields.** Many fundamental processes of pattern formation (*e.g.*, the arrangement of lateral buds in growing plants) occur within areas or three-dimensional masses of tissue that show no obvious indications of where the various elements in the pattern will arise

The appearance of pattern

until they actually appear. Such masses of tissue, in which a pattern appears, have been spoken of as "fields." This word was originally used in the early years of the 20th century by German authors who suggested an analogy between biological morphogenetic fields and such physical entities as magnetic or electromagnetic fields. The biological field is a description, but not an explanation, of the way in which the developing system behaves. The system develops as though each cell or subunit within it possessed "positional information" that specifies its location within the field and a set of instructions that lays down the developmental behaviour appropriate to each position.

There have been several attempts to account for the nature of the positional information and of the corresponding instructions. The oldest and best known of these is the gradient hypothesis. In many fields there is some region that is in some way "dominant," so that the field appears as though organized around it. It is suggested that this region has a high concentration of some substance or activity, which falls off in a graded way throughout the rest of the field. The main deficiency of the hypothesis is that no one has yet succeeded in identifying satisfactorily the variables distributed in the gradients. Attempts to suppose that they are gradients of metabolic activity have, on investigation, always run into difficulties that can only be solved by defining metabolic activity in terms that reduce the hypothesis to a circular one in which metabolic activity is defined as that which is distributed in the gradient.

Recently, a new suggestion has been advanced concerning positional information. Most processes within cells normally involve negative feedback control systems. These systems have a tendency to oscillate, or fluctuate regularly (in fact, any aspect of cell metabolism may be basically oscillatory in character). The cycle of cell growth and division may be only one example of a much more widespread phenomenon. The substances involved in these oscillations are likely to include diffusible molecules capable of influencing the behaviour of nearby cells. It is easy to envisage the possibility that there might be localized regions with oscillations of higher frequency or greater amplitude that act as centres from which trains of waves are radiated in all directions. It has been suggested that positional information is specified in terms of differences in phase between two or more such trains of transmitted oscillations.

Certain types of field phenomenon may involve an amplification of stochastic (random) variations. In systems containing a number of substances, with certain suitable rates of reaction and diffusion, chance variation on either side of an initial condition of equilibrium may become amplified both in amplitude and in the area involved. In this way, the processes may give rise to a pattern of differentiated areas, distributed in arrangements that depend on the boundary conditions.

*Morphogenesis by the self-assembly of units.* Complex structures may arise from the interaction between units that have characteristics such that they can fit together in a certain way. This is particularly appropriate for morphogenesis at the simple level of molecules or cells. Units such as the atoms of carbon, hydrogen, oxygen, nitrogen, and so on, can assemble themselves into orderly molecular structures, and larger molecules, such as those of tropocollagen, or protein subunits in general, can assemble themselves into complexes whose structure is dependent on localized and directional intermolecular forces. It seems that such comparatively large entities as the units that come together to form the head structures of bacteriophages or bacterial flagella are capable of orderly self-assembly, but the chemical forces that give rise to the interunit bonds are still little understood.

Processes that fall into the same general category as self-assembly may occur within aggregates of cells. The units that self-assemble are the cells themselves. Interaction and aggregation may be allowed to occur in assemblages of cells of one or more different kinds. In such cases it is commonly found that the originally isolated cells tend to adhere to one another, at first more or less

at random and independently of their character, but later they become rearranged into a number of regions consisting of cells of a single kind. When the cells in the initial collection differ in two different characteristics, for instance in species and organ of origin, the assortment in some cases brings together cells from the same organ, in other cases cells from the same species. Mixtures of chick and mouse cells, for instance, reassort themselves into groups derived from the same organ, whereas cells from two different species of amphibia sort out into groups from the same species more or less independently of organ type.

This morphogenetic process probably has only a restricted application to the formation of structures in normal development, in which only in a few tissues (*e.g.*, the connective system) do cells ever pass through a free stage in which they are not in intimate contact with other cells, and cells of different origin do not normally become intermingled so as to call for processes of reassortment. To explain normal morphogenetic processes of plants and animals one must look to the results that can be produced by the differential behaviour of cells that remain in constant close contact with one another. Several authors have shown how striking morphogenetic changes could be produced within a mass of cells that remain in contact, but that undergo changes in the intensity of adhesion between neighbouring cells, in the area of surface in the proportion to cell volume, and so on.

*Differentiation.* Differentiation is simply the process of becoming different. If, in connection with biological development, morphogenesis is set aside as a component for separate consideration, there are two distinct types of differentiation. In the first type, a part of a developing system will change in character as time passes; for instance, a part of the mesoderm, starting as embryonic cells with little internal features, gradually develops striated myofilaments, and with a lapse of time develops into a fully formed muscle fibre. In the second type, space rather than time is considered; for instance, other cells within the same mass of embryonic mesoderm may start to lay down an external matrix around them and eventually develop into cartilage. In development, differentiation in time involves the production of the characteristic features of the adult tissues, and is referred to as histogenesis. Differentiation in space involves an initially similar (homogeneous) mass of tissue becoming separated into different regions and is referred to as regionalization.

Histogenesis involves the synthesis of a number of new protein species according to an appropriate timetable. The most easily characterized are those proteins formed in a relatively late stage of histogenesis, such as myosin and actin in muscle cells. The synthesis of proteins is under the control of genes, and the problem of histogenesis essentially reduces to that of the genetic mechanisms that direct protein synthesis.

Regionalization is concerned with the appearance of differences between various parts of what is at first a homogeneous, or nearly homogeneous, mass. It is a prelude to histogenesis, which then proceeds in various directions in the different regions so demarcated. The processes by which the different regions acquire distinct contrasting characteristics must be related to some of the processes discussed under morphogenesis. Unlike morphogenesis, regionalization need not involve any change in the overall spatial shape of the tissues undergoing it. Regionalization falls rather into the type of process for which field theories have been invoked.

#### CONTROL AND INTEGRATION OF DEVELOPMENT

*Phenomenological aspects.* One of the most striking characteristics of all developmental systems is a tendency to produce a normal end result in spite of injuries or abnormalities that may have affected the system in earlier stages. In many cases, perhaps in most, only injuries inflicted during a certain restricted period of development can be fully compensated for. During such periods the system is said to be capable of regulation or the restoration of normality.

Tissues and regions

Molecular assembly

Developmental regulation is often discussed in terms of homeostasis, or regulatory mechanisms. Many systems, including biological ones, exhibit a tendency to return to initial equilibrium once it is diverted from it. A developing system is, by definition, always changing in time, moving along some defined time trajectory, from an initial stage, such as a fertilized egg, through various larval stages to adulthood, and finally to senescence. The regulation that occurs in such systems is a regulation not back to an initial stable equilibrium, as in homeostasis, but to some future stretch of the time trajectory. The appropriate word to describe this process is homeorhesis, which means the restoration of a flow.

A second major phenomenological characteristic of development is that the end state attained is not unitary but can be analyzed into a number of different organs and tissues. The overall time trajectory of this system can, therefore, also be analyzed into a number of component trajectories, each leading to one or another of the end products that can be distinguished in the later stages. A major discovery of the early experiments on developing systems was that, in many cases at least, the different time trajectories diverge from one another relatively suddenly during some short period of development, which usually occurs well before any visible signs of divergence can be seen microscopically or by any other available means of analysis. The most dramatic and influential example of this was provided by studies on the development of the amphibian egg at the time of gastrulation, or formation of a hollow ball of cells. At this time the lower hemisphere of the embryo will be pushed inward (invaginated) to develop into the mesoderm and endoderm, and the upper hemisphere will remain on the surface, expanding in area to cover the whole embryo. Approximately one-third of the upper hemisphere will develop into the nervous system and the remainder into the skin. During the period when these morphogenetic movements of invagination and expansion are occurring, a process takes place by which a portion of the upper hemisphere enters a trajectory toward neural tissue and another part enters a trajectory leading to epidermal development. This process of determination of developmental pathways happens relatively quickly, during a period when the cells of the two different regions appear superficially alike. The occurrence of the determination can in fact be demonstrated only experimentally. Before it occurs, any part of the hemisphere can develop either into neural tissue or into skin. After it has happened, each part can develop only into one or the other of these alternatives.

It is clear that an adequate theory of development has to account not only for the processes by which a developing system moves along its appropriate time trajectory, but also for the nature of the processes by which the trajectories diverge from one another and become fixed or determined in the developing cells.

The determined state can be transmitted through many cell generations. An example of this transmission can be seen in *Drosophila* flies. The imaginal buds of *Drosophila* are small packets of cells that become separated from the main body of the embryo in the early stages of development. They persist throughout larval life and then enter into the differentiation of adult characteristics when stimulated to do so by the hormones secreted at the time of pupation. These pupation hormones disappear from the body of the adult insect, and imaginal buds transplanted into the body cavity of an adult undergo many cell generations, but they do not show any signs of differentiating into the specific tissues of the corresponding adult organ. After many generations of proliferation, however, the cells can be transplanted back into a larva ready to pupate; they thus submit to the pupation hormones and differentiation occurs. Through many generations of proliferation the cells have retained the determination as to which adult organ they will develop into when the pupation hormones become available.

Attempts to identify the determining agent have not yet been successful. Experiments on amphibian eggs, however, have given rise to one important general conclusion; namely, that the process of determination can take

place only during a certain period of development, in which the cells of the upper half of the amphibian egg are poised between the two alternatives of development into neural tissue or into skin. They are said at this time to be "competent" for one or the other of these types of development. While they are in this state, and only while they are in it, a variety of external agents can switch them into one or the other of the possible pathways. Such a situation may be contrasted with one in which the cells were neutral, or featureless, and required then an external agent to transmit to them the quality of becoming nervous tissue or of becoming skin. This would mean that the reacting cells required information or instructions to be added to them from outside. Such a situation is not characteristic of biological development. Both in highly developed organisms such as amphibians and in simpler ones such as bacteria, the external agents act only as a releaser that switches on one or another process for which all of the necessary information is already incorporated in the cells concerned.

Analytical aspects. The existence of these developmental phenomena was realized in the first third of this century. During this period, biologists had no clear notion of the fundamental concepts needed to explain development. Developmental biologists, or embryologists, attempted to account for their observations by means of ill-defined notions, such as "potencies" or "organ-forming substances," or by referring to cellular properties that are real enough but obviously in themselves complex and essentially secondary in nature, such as cellular adhesiveness, the capacity of cell surfaces to differentially absorb certain substances, and so on. It was only gradually that developmental biologists came to realize the importance of the demonstration by genetics that nearly all the instructions required for the building of a new organism are contained in the genes that come together during fertilization, and that the small additional amount of information, contained primarily in the ovum, is itself a product of genetic instructions provided in the body of the mother in which the ovum is produced. The fundamental problems of the theory of development are, therefore, to understand how these units interact with one another to form more complex mechanisms that bring about the cellular or tissue behaviours of the different types of developing systems.

In the development of the neural system of vertebrates, for example, a great many genes must be active in controlling the synthesis of particular proteins. In the formation of the wing of a *Drosophila*, the activity of some 20 or 30 genes has been definitely demonstrated, and certainly many more are involved. The action of all these genes, however, must be considered to form a network involving many types of feedback and other interactive loops, the overall result of which is a product in which many components are present in precisely defined concentrations; and further, the developmental process leading to this end result must be buffered or stabilized, in the sense that if the process is diverted from its normal course at an early stage, it returns to some later stage of the normal trajectory. Such a buffered time trajectory has been called a chreod, a word meaning "a necessary path." The realization that the basic units of development are genes and that a chreod involves the action of tens, if not hundreds, of genes forces one to conceive of chreods as structures within a multidimensional space. The realization that biological development is fundamentally an expression of the controlled activities of genes has finally resolved one of the old philosophical controversies about the nature of development, between preformation and epigenesis. The former supposed that, at the initiation of development, for instance in the fertilized egg, the system already contained some representative of every organ that would eventually put in an appearance. The vindicated theory of epigenesis, on the other hand, supposed that later appearing entities were produced during the course of development.

The modern interpretation of epigenesis is that the initial stage of development does contain certain entities with well-defined properties, namely the genes. These do

The genes as repositories of developmental instructions

Determination

not, however, represent directly the later formed organs, which arise by the gradual interaction and progressive unfolding of the properties of groups of genes.

One of the major problems confronting modern developmental biology—namely, the nature of "determination"—requires an understanding of how genes are "primed" to enter into activity when an appropriate stimulus is given. The state of priming presumably has to apply to quite a large number of genes, though perhaps not to all that will be involved in the chreod, since some may be brought into activity by the operation of the earlier active ones. The priming, moreover, has to be able to persist through cell division and be capable of transmission through many generations of cell proliferation. Few concrete suggestions as to the mechanism have yet been made. One is that the primed genes are already producing the ribonucleic acid molecules, called messenger RNA's, which direct protein synthesis in the cell, but that these messengers are in some way inactivated or prevented from activating the protein-synthesizing machinery; this is known as the "masked messenger" hypothesis. Arguments in favour of this hypothesis are, however, circumstantial rather than direct. In some cases, for instance that of the *Drosophila* imaginal buds, there is direct evidence against it. Another hypothesis, perhaps more attractive, but much vaguer, is that the determination or priming involves the intervention of some of the large amounts of reiterated DNA known to be present in the cells of higher organisms. At the present time, however, biology lacks any convincing theory of determination in terms of gene action.

It appears at first sight that more is known about actual differentiation than initial determination. Actual differentiation must involve the controlled synthesis of particular proteins, coded for by specific genes. Certainly, a great deal is known about the mechanisms that control the action of genes in directing the synthesis of proteins in simple organisms such as viruses and bacteria. It is tempting to suppose that similar systems operate in controlling the synthetic activities of genes in higher organisms. Unfortunately, no single case of an exactly similar controlling system has ever been discovered in higher organisms, in spite of an intense search for it. It may in fact be suggested that until there is a fuller understanding of the mechanism of "priming" genes at the time of determination, there can scarcely be an adequate account of the way in which the activity of these genes is controlled at later stages.

#### DEVELOPMENT AND EVOLUTION

Evolution is carried out by a process dependent on mutation and natural selection. Expositions of this thesis, however, tend to overlook the fact that mutation occurs in the genotype, whereas natural selection acts only on the phenotype, the organism produced. It follows from this that the theory of evolution requires as one of its essential parts a consideration of the developmental or epigenetic processes by which the genotype becomes translated into the phenotype. The consequences of such considerations are discussed in the following sections.

**Effect on life histories.** *Length and timing of the reproductive phase.* Natural selection results in the production by one generation of offspring that are able to survive and reproduce themselves to form a further generation. The time unit appropriate to natural selection is therefore the generation interval. There will always be some natural selective pressure for the shortening of the generation interval, simply out of a natural economy, and for an increase of the number of offspring produced by any reproducing individual. One of the ways in which such an increase could be assured would be the lengthening of the reproductive phase in the life history; another would be an increase in the number of offspring produced.

These are, of course, not the only natural selective pressures that operate. It is clear enough that, in evolution, they have often been overcome by other pressures. There is another natural selective pressure of more general importance. This is the pressure to restrict the length of the

reproductive period, and indeed to remove reproductive individuals, in order to make room for the maturation of a new generation in which new genetic combinations can be tried out for their fitness. A species whose individuals were immortal would exhaust its possibilities for future evolution as soon as its numbers saturated all the ecological niches suitable for its way of life. Death is a necessary condition for the trying out of new genetic combinations in later generations. It is usually brought about, in great part at least, by combinations of two processes: restriction of the period of effective reproduction to a certain portion of a life history, and as a necessary consequence of this, the absence of natural selection for genetic mutations that would be effective in preserving life after reproduction has ceased. In some organisms—for instance, long-lived trees—there may be no restriction of reproduction to a particular period in the life history, but their development involves the gradual accumulation of larger and larger quantities of nonliving materials, such as dead wood, which presents a growing handicap, in the face of which the organism cannot indefinitely maintain itself against the inevitable hazards of existence. It is still something of a question whether these natural selective forces are sufficient in themselves to account for the phenomena of senescence, aging, and eventual death, which are found in various forms throughout nearly the whole biological kingdom (see AGING).

As was mentioned above, evolution has produced a number of the types of multiphasic development, in which the life history involves a succession of larval stages. Such types of development offer the possibility of changing the relative importance of the various stages in relation to the exploitation of resources and reproduction by the species. There are, for instance, many types of animals (particularly insects) in which nearly the whole life history is passed in a larval stage in which most of the feeding and growth of the organism is carried out, the final adult stage being short and used almost entirely for reproduction. Another evolutionary strategy has been to transfer the reproductive phase from the final stage of the life history to some earlier larval stage. This again has occurred in certain insects. If such a process is carried to its logical evolutionary conclusion, the final previously adult stage of the life history may totally disappear, the larval stage of the earlier evolutionary form becoming the adult stage of the later derivative of it. An example in which this process is at least partially accomplished is in the axolotl, a salamander that reproduces in a larval stage and in nature rarely if ever metamorphoses into the adult, but can be persuaded to do so if injected with extra supplies of the hormone thyroxine. It has been suggested that such processes of neoteny (the retention of some juvenile characteristics in adulthood) have played a decisive role in certain earlier phases of evolution, evidence of which is now lost. It has been argued that the whole vertebrate phylum may have originated from modifications of one of the larval stages of an invertebrate group.

*Recapitulation of ancestral stages.* The modifications of life histories just mentioned are aspects of a more general situation; namely, that the only variations that can become available for natural selection to operate on are those that can be produced by alterations of the developmental or epigenetic system of an existing organism. Any new mutant gene can cause a change only in a pre-existing set of developmental interactions; the phenotypes to which it can give rise are limited by the nature of the system that it will modify. One immediate result of this situation is that the development of a later evolved form will retain many features from the development of its ancestors: most evolutionary developments are likely to be additions to the previous organization. Since there is evolutionary pressure to reduce the length of time between generations, the addition of a new feature to development is likely to be accompanied by a speeding up of the older stages, and probably omission of certain of them.

To repeat, the development of a late-evolved form retains those aspects of earlier life histories that are essential for the building up of later developmental stages that

The evolutionary significance of death

The role of neoteny in evolution

The "masked messenger" hypothesis

may be important for natural selection. In the vertebrates, for instance, highly evolved types such as mammals and birds produce during their early development remnants of the primitive kidneys (pronephros and mesonephros) that functioned as excretory organs in their evolutionary ancestors. Although these organs no longer perform their physiological functions in later organisms, they play an essential role during the formative processes of embryonic development. Some structures characteristic of evolutionary ancestors may be retained for relatively short evolutionary periods after they have lost their original function simply because there is not sufficient natural selective pressure to bring about their elimination when they no longer have any obvious function, either physiologically or epigenetically; the human appendix is an example.

Adaptability and the canalization of development. A developing organism is subjected to natural selection by its particular environment. The environment is not the same for all individuals of a population, nor does it necessarily remain the same throughout evolutionary periods of time. An organism can be regarded as having to meet environmental changes that are unpredictable. There are basically two different types of strategy employed, in various proportions in different organisms, to meet this situation. One, perhaps the more obvious, is to evolve a high capacity for modification by environmental circumstances in ways that increase fitness in the environment in question; this is the strategy of increasing adaptability. It is probably true to say that all organisms show some capacity for adaptation, either short-term (physiological) or longer term (developmental), to their environments. In most organisms, however, particularly in most higher organisms, there is considerable development of the alternative strategy, which is to build up well-buffered or channelled developmental chreods, which lead to the production of a relatively predictable invariant end result in the face of very diverse environments. The second strategy is likely to be followed in situations in which the environment is likely to change markedly during the course of the organism's life.

Whether or not this is the main reason for the evolution of channelled, or canalized, developmental systems, a considerable degree of canalization is very common. It is relatively rare to find instances in which the form of an animal is highly dependent on the early environment, although such dependence is common enough among plants. Much more frequently, situations such as that typified by the house mouse are encountered: the mouse develops into an almost identical form whether it lives in the tropics or in a cold-storage depot.

This canalization of development severely restricts the phenotypic effects that can be produced by mutations. In particular, many new mutations occurring in a single dose in a diploid organism are found to be recessive, or ineffective in causing any alteration in the phenotype. As this discussion makes clear, canalization should not be considered as a relation involving only the normal and mutated forms of a particular gene, but rather the result of the interaction of many genes.

Genetic assimilation. A long-standing controversy in biology has been concerned with whether phenotypic modifications produced by abnormal environments are heritable in the sense that they can be produced by later generations in the absence of the original environmental stress. The hypothesis that they are heritable was advanced by the French evolutionist Lamarck in the 18th century and is generally known as the "inheritance of acquired characters." It found some supporters among biologists, some of whom used it as an argument against the Darwinian theory of evolution. In a broad sense, all characters are to some extent inherited, in that they depend on the genotype of the organism, and to some extent acquired, since development is also affected by the environment. In a stricter sense, however, Lamarck's hypothesis suggests that there is some inherent biological property that enables organisms to pass on physical modifications to their descendants, independently of a Darwinian mechanism of selection.

The combination of adaptability and canalization in development can explain such phenomena in strictly Darwinian rather than Lamarckian terms. The abnormal environment acting during development may succeed in modifying even a well-canalized development system. If the modification is of an adaptive kind and increases the fitness of the individuals in the unusual environment, it will be favoured by natural selection. The development of the selected individuals will, however, also show some properties of canalization, that is to say, resistance to further environmental changes. This invariance may be sufficient to prevent offspring of the selected individuals from reverting completely to the original phenotype even if they are removed from the abnormal environment. After selection for an adaptive modification in an abnormal environment has proceeded for many generations, a form may be produced whose canalization is strong enough to maintain the new phenotype almost unaltered when the environment reverts to what it was before the abnormality occurred. This process, which has been demonstrated in a number of laboratory experiments, is known as genetic assimilation. It produces exactly the same results as those emphasized by advocates of the Lamarckian inheritance of acquired characters, but it produces them by an orthodox Darwinian mechanism operating on developmental systems that have the common properties of canalization and adaptability. It provides the most convincing explanation for the evolution of organisms that are physiologically or functionally adapted to the demands their way of life will make.

**BIBLIOGRAPHY.** Classical works that laid the foundation for the modern interpretation of development in terms of gene activities include: T.H. MORGAN, *Embryology and Genetics* (1934); R. GOLDSCHMIDT, *Physiologische Theorie der Vererbung* (1927); C.H. WADDINGTON, *Organisers and Gene* (1940); D.W. THOMPSON, *On Growth and Form*, rev. ed. (1942). A few more recent books, which include the theoretical as well as empirical aspects of development are: C.W. WARDLAW, *Organization and Evolution in Plants* (1965); J.T. BONNER, *Morphogenesis* (1952); E.W. SINNOTT, *The Problem of Organic Form* (1963). Probably the best general account of modern experimental work is A. KUHN, *Entwicklungsphysiologie*, 2nd ed. (1965). Less up to date is C.H. WADDINGTON, *Principles of Embryology* (1956). Shorter and less comprehensive works are: J.D. EBERT, *Interacting Systems in Development* (1965); and C.H. WADDINGTON, *New Patterns in Genetics and Development* (1962). A number of essays on the theory of development may be found in *Towards a Theoretical Biology*, 3 vol., ed. by C.H. WADDINGTON (1968-70), see particularly the essays by Goodwin, Thom, Wolpert, and Waddington.

(C.H.W.)

## Development, Human

This article is concerned with the physical growth of a child from birth into maturity. Development before birth receives its principal treatment in the article EMBRYOLOGY, HUMAN.

Growth is far from being a simple and uniform process of becoming taller or larger. As a child gets bigger, there are changes in shape and in tissue composition and distribution. In the newborn infant the head represents about a quarter of the total length; in the adult it represents about one-seventh. In the newborn infant the muscles constitute a much smaller percentage of the total body mass than in the young adult. In most tissues, growth consists both of the formation of new cells and the packing in of more protein or other material into cells already present; early in development cell division predominates and later cell filling.

### TYPES AND RATES OF HUMAN GROWTH

Different tissues and different regions of the body mature at different rates, and the growth and development of a child consists of a highly complex series of changes. It is like the weaving of a cloth whose pattern never repeats itself. The underlying threads, each coming off its reel at its own rhythm, interact with one another continuously, in a manner always highly regulated and controlled. The fundamental questions of growth relate to these processes of regulation, to the program that controls the loom, a

subject as yet little understood. Meanwhile, height is in most circumstances the best single index of growth, being a measure of a single tissue (that of the skeleton; weight is a mixture of all tissues, and this makes it a less useful parameter in a long-term following of a child's growth). In this article, the height curves of girls and boys are considered in the three chief phases of growth; that is (briefly) from conception to birth, from birth until puberty, and during puberty. Also described are the ways in which other organs and tissues, such as fat, lymphoid tissue, and the brain, differ from height in their growth curves. There is a brief discussion of some of the problems that beset the investigator in gathering and analyzing data about growth of children, of the genetic and environmental factors that affect rate of growth and final size, and of the way hormones act at the various phases of the growth process. Lastly, there is a brief look at disorders of growth. Throughout, the emphasis is on ways in which individuals differ in their rates of growth and development.

Growth  
as distance  
and  
velocity

The changes in height of the developing child can be thought of in two different ways: the height attained at successive ages and the increments in height from one age to the next, expressed as rate of growth per year. If growth is thought of as a form of motion, the height attained at successive ages can be considered the distance travelled, and the rate of growth, the velocity. The velocity or rate of growth reflects the child's state at any particular time better than does the height attained, which depends largely on how much the child has grown in all preceding years. The blood and tissue concentrations of those substances whose amounts change with age are thus more likely to run parallel to the velocity rather than to the distance curve. In some circumstances, indeed, it is the acceleration rather than the velocity curve that best reflects physiological events.

In general, the velocity of growth decreases from birth onward (and actually from as early as the fourth month of fetal life; see below), but this decrease is interrupted shortly before the end of the growth period. At this time, in boys from about 13 to 15 years (Figure 3), there is marked acceleration of growth, called the adolescent growth spurt. From birth until age four or five, the rate of growth in height declines rapidly, and then the decline, or deceleration, gets gradually less, so that in some children the velocity is practically constant from five or six up to the beginning of the adolescent spurt. A slight increase in velocity is sometimes said to occur between about six and eight years.

**Prenatal growth.** This general velocity curve of growth in height begins a considerable time before birth. Figure 1 shows the distance and velocity curves for body length in the prenatal period and first two postnatal years. The peak velocity of length is reached at about four months after the mother's last menstruation. (Age in the fetal period is usually reckoned from the first day of the last menstrual period, an average of two weeks before actual fertilization, but, as a rule, the only locatable landmark.)

Growth in weight of the fetus follows the same general pattern as growth in length, except that the peak velocity is reached much later, at approximately 34 weeks after the mother's last menstrual period.

There is considerable evidence that from about 34 to 36 weeks onward the rate of growth of the fetus slows down because of the influence of the maternal uterus, whose available space is by then becoming fully occupied. Twins slow down earlier, when their combined weight is approximately the 36-week weight of the single fetus. Babies who are held back in this way grow rapidly as soon as they have emerged from the uterus. Thus there is a significant negative association between weight of a baby at birth and weight increment during the first year; in general, larger babies grow less, the smaller more. For the same reason there is practically no relation between adult size and the size of that person at birth, but a considerable relation has developed by the time the person is two years old. This slowing-down mechanism enables a genetically large child developing in the uterus of a small mother to be delivered successfully. It operates in many

Rapid

Figure 1: Curves indicating (above) growth attained and (below) velocity of growth during prenatal and early postnatal periods. The dashed line in the lower chart represents a smoothing out of the curve between points.

From D. Thompson, *Growth and Form*, 2nd ed. (1963); Cambridge University Press

species of animal; the most dramatic demonstration was by crossing reciprocally a large Shire horse and a small Shetland pony. The pair in which the mother was a Shire had a large newborn foal, and the pair in which the mother was Shetland had a small foal. But both foals were the same size after a few months, and when fully grown both were about halfway between their parents. The same has been shown in cattle crosses.

Poor environmental circumstances, especially of nutrition, result in lowered birth weight in the human being. This seems chiefly to be caused by a reduced rate of growth in the last two to four weeks of fetal life, for weights of babies born in 36 or 38 weeks in various parts of the world in various circumstances are said to be similar. Mothers who, because of adverse circumstances in their own childhood, have not achieved their full growth potential may produce smaller fetuses than they would have, had they grown up in better circumstances. Thus two generations or even more may be needed to undo the effect of poor environmental circumstances on birth weight.

The great rate of growth of the fetus compared with that of the child is largely due to the fact that cells are still multiplying. The proportion of cells undergoing mitosis (the ordinary process of cell multiplication by splitting) in any tissue becomes progressively less as the fetus gets older, and it is generally thought that few if any new nerve cells (apart from the cells in the supporting tissue, or neuroglia) and only a limited proportion of new muscle cells appear after six postmenstrual months, the time when the velocity in linear dimensions is dropping sharply.

The muscle and nerve cells of the fetus are considerably different in appearance from those of the child or adult. Both have little cytoplasm (cell substance) around the nucleus. In the muscle there is a great amount of intercellular substance and a much higher proportion of water than in mature muscle. The later fetal and the postnatal growth of the muscle consists chiefly of building up the cytoplasm of the muscle cells; salts are incorporated and the contractile proteins formed. The cells become bigger, the intercellular substance largely disappears, and the concentration of water decreases. This process continues quite actively up to about three years of age and slowly

Prenatal  
and  
postnatal  
growth  
contrasted

thereafter; at adolescence it briefly speeds up again, particularly in boys, under the influence of androgenic (male sex) hormones. In the nerve cells cytoplasm is added and elaborated, and extensions grow that carry impulses from and to the cells—the axons and dendrites, respectively. Thus postnatal growth, for at least some tissues, is chiefly a period of development and enlargement of existing cells, while early fetal life is a period of division and addition of new cells.

**Types of growth data.** Growth is in general a regular process. Contrary to what is said in some of the older textbooks, growth in height does not proceed by fits and starts, nor does growth in upward dimensions alternate with growth in transverse ones. The more carefully measurements are taken, with precautions, for example, to minimize the decrease in height that occurs during the day for postural reasons, the more regular does the succession of points in a graph of growth become. Many attempts have been made at finding mathematical curves that fit, and thus summarize, human growth data. What is needed is a curve or curves with relatively few constants, each capable of being interpreted in a biologically meaningful way. Yet the fit to empirical data must be adequate within the limits of measuring error. The problem is difficult, partly because the measurements usually taken are themselves biologically complex. Stature, for example, consists of leg length and trunk length and head height, all of which have rather different growth curves. Even with relatively homogeneous dimensions such as the length of the radius bone in the forearm, or width of an arm muscle, it is not clear what purely biological assumptions should be made as the basis for the form of the curve. The assumption that cells are continuously dividing leads to a different formulation from the assumption that cells are adding constant amounts of nondividing material or amounts of nondividing material at rates varying from one age period to another.

Fitting a curve to the individual values, however, is the only way of extracting the maximum information from an individual's measurement data. More than one curve is needed to fit the postnatal age range. It seems that two curves may suffice, at least for many measurements such as height and weight—one curve for the period from a few months after birth to the beginning of adolescence and a different type of curve for the adolescent spurt.

Such curves have to be fitted to data on single individuals. Yearly averages derived from different children each measured only once do not, in general, give the same curve. Thus the distinction between the two sorts of investigation is important. When the same child at each age is used, the study is called longitudinal; when different children at each age are used, it is called cross-sectional. In a cross-sectional study all of the children at age eight, for example, are different from those at age seven. A study may be longitudinal over any number of years; there are short-term longitudinal studies extending from age four to six, for instance, and full birth-to-maturity longitudinal studies in which the children may be examined once, twice, or more times every year from birth until 20 or over. Mixed longitudinal studies are those in which children join and leave the group studied at varying intervals. Both cross-sectional and longitudinal studies have their uses, but they do not give the same information, and the same statistical methods cannot be used for the two types of study. Cross-sectional surveys are obviously cheaper and more quickly done and can include much larger numbers of children. Periodic cross-sectional surveys are valuable in assessing the nutritional progress of a country or a socio-economic group and the health of the child population as a whole. But they never reveal individual differences in rate of growth or in the timing of particular phases such as the adolescent growth spurt. It is these individual rate differences that throw light on the genetic control of growth and on the correlation of growth with psychological development, educational achievement, and social behaviour.

Longitudinal studies are laborious and time-consuming; they demand great perseverance on the part of those who make them and those who take part in them; and they de-

mand high technical standards, since in the calculation of a growth increment from one occasion to the next opportunities for two errors of measurement occur. In spite of these problems, longitudinal studies are the indispensable base on which the diagnosis and treatment of disorders of growth rest, for the clinical approach is a longitudinal one; and each child treated with human growth hormone, or with other hormones that affect growth, represents an attempt to alter an individual pattern of growth velocity.

Averages simply computed from cross-sectional data inevitably produce velocity curves that are flatter and broader than the curve for an individual and hence not a proper basis for clinical standards. It is possible to construct curves, however, whose 50th percentile (or average) represents the actual growth of a typical individual, by taking the shape of the curve from individual longitudinal data and the absolute values for the beginning and end from large cross-sectional surveys. Figures 2 and

Figure 2: Individual height curves for British boys and girls in 1965 (see text).

3 show height-attained and height-velocity curves for the "typical" boy and girl in Britain in 1965, determined in this way. By "typical" is meant that boy or girl who has the mean (average) birth length, grows always at the mean velocity, has the peak of the adolescent growth spurt at the mean age, and finally reaches the mean adult height at the mean age of cessation of growth. Practically no individual follows the 50th percentile curve of Figure 2, but most have curves of the same shape. Standards for height for clinical use are constructed around these curves.

**Boys' and girls' height curves.** Figures 2 and 3 show the height curves from birth to maturity. Up to age two, the child is measured lying on his back. One examiner holds his head in contact with a fixed board, and a second person stretches him out to his maximum length and then brings a moving board into contact with his heels. This measurement, called supine length, averages about one centimetre more than the measurement of standing height taken on the same child, hence the break in the line in Figure 2 at age two. This occurs even when, as in the best techniques, the child is urged to stretch upwards to the full and is aided in doing so by a measurer's applying gentle upward pressure to his mastoid processes.

Figure 2 shows the typical girl as slightly shorter than the typical boy at all ages until adolescence. She becomes taller shortly after age 11 because her adolescent spurt takes place two years earlier than the boy's. At age 14 she is surpassed again in height by the typical boy, whose

the child's  
height

Advantages in  
longitudi-  
nal and  
cross-  
sectional  
studies

adolescent spurt has now started, while hers is nearly finished. In the same way, the typical girl weighs a little less than the boy at birth, equals him at age 8, becomes heavier at age 9 or 10, and remains so until about age 14½.

The velocity curves given in Figure 3 show these processes more clearly. At birth the typical boy is growing slightly faster than the typical girl, but the velocities become equal at about seven months, and then the girl

Figure 3: Typical velocity curves for supine length or height in British boys and girls in 1965 (see text).

grows faster until four years. From then until adolescence no differences in velocity can be detected. The sex difference is best thought of, perhaps, in terms of acceleration, the boy decelerating harder than the girl over the first four years.

**Different tissues and parts of the body.** The majority of skeletal and muscular dimensions follow approximately the growth curve described for height, and so also do the dimensions of the internal organs such as the liver, the spleen, and the kidneys. But some exceptions exist, most notably the brain and skull, the reproductive organs, the lymphoid tissue of the tonsils, adenoids, and intestines, and the subcutaneous fat.

In Figure 4 these differences are shown; the size attained by various tissues is given as a percentage of the birth-to-maturity increment. Height follows the "general" curve. The reproductive organs, internal and external, have a slow prepubescent growth, followed by a large adolescent spurt; they are less sensitive than the skeleton to one set of hormones and more sensitive to another.

The brain, together with the skull covering it and the eyes and ears, develops earlier than any other part of the body and thus has a characteristic postnatal curve. At birth it is already 25 percent of its adult weight, at age five about 90 percent, and at age 10 about 95 percent. Thus if the brain has any adolescent spurt at all, it is a small one. A small but definite spurt occurs in head length and breadth, but all or most of this is due to thickening of the skull bones and the scalp, together with development of the air sinuses.

The dimensions of the face follow a path somewhat closer to the general curve. There is a considerable adolescent spurt, especially in the lower jaw, or mandible, resulting in the jaw's becoming longer and more projecting, the profile straighter, and the chin more pointed. As always in growth, there are considerable individual differ-

Figure 4: Major types of postnatal growth of parts and organs of the body (see text).

From J. Tanner, *Growth at Adolescence* (1962); Blackwell Scientific Publications, after Scammon

ences, to the point that a few children have no detectable spurt at all in some face measurements.

The eye probably has a slight adolescent spurt, which is probably responsible for the increase in frequency of short-sightedness in children that occurs at the time of puberty. Though the degree of myopia increases continuously from at least age six to maturity, a particularly rapid rate of change occurs at about 11 to 12 in girls and 13 to 14 in boys, and this would be expected if there was a rather greater spurt in the axial dimension (the dimension from front to back) of the eye than in its vertical dimension.

The lymphoid tissue has quite a different growth curve from the rest. It reaches its maximum amount before adolescence and then, probably under the direct influence of sex hormones, declines to its adult value.

The subcutaneous fat layer also has a curve of its own, of a slightly complicated sort. Its thickness can be measured either by X-rays or, more simply, at certain sites in the body, by picking up a fold of skin and fat between the thumb and forefinger and measuring its thickness with a special, constant-pressure caliper. Figure 5 shows the distance curves of skin folds taken halfway down the back

Development of fat

Figure 5: Amount of subcutaneous fat on the back of the arm (triceps) and the back of the body (subscapular) from birth to 16 years (see text).

Growth of the brain, the skull, and the face

of the upper arm (the triceps) and on the body just below the angle of the shoulder blade, or scapula. Subcutaneous fat begins to be laid down in the fetus at about 34 weeks postmenstrual age, increases from then until birth and from birth onward until about nine months. (This is in the average child; the peak may be reached as early as six months or as late as 12 or 15.) After nine months, when the velocity of fat gain is zero, the fat usually decreases (that is, it has a negative velocity) until age six to eight, when it begins to increase once more. Girls have a little more fat than boys at birth, and the difference becomes more marked during the period of loss, since girls lose less than boys. From eight years on, the curves for girls and boys diverge more radically, as do the curves for limb and body fat. At adolescence the limb fat in boys decreases, while the body fat shows a temporary slowing down of gain but no actual loss. In girls there is a slight halting of the limb-fat gain at adolescence, but no loss; the trunk fat shows only a steady rise until adolescence.

**Development at puberty.** *Growth.* At puberty, a considerable alteration in growth rate occurs. There is a swift increase in body size, a change in shape and composition of the body, and a rapid development of the gonads, or sex glands—the reproductive organs and the characters signalling sexual maturity. Some of these changes are common to both sexes, but most are sex-specific. Boys have a great increase in muscle size and strength, together with a series of physiological changes making them capable of doing heavier physical work than girls and of running faster and longer. These changes all specifically adapt the male to his primitive primate role of dominating, fighting, and foraging. Such adolescent changes occur generally in primates (that is, men, apes, and monkeys) but are more marked in some species than in others. Man lies at about the middle of the primate range, as regards both adolescent size increase and degree of sexual differentiation.

During the adolescent spurt in height, for a year or more, the velocity of growth approximately doubles; a boy is likely to be growing again at the rate he last experienced about age two. The peak velocity of height (P.H.V., a point much used in growth studies) averages about 10.5 centimetres per year in boys and 9.0 centimetres in girls (about 4 and 3.4 inches, respectively), but this is the "instantaneous" peak given by a smooth curve drawn through the observations. The velocity over the whole year encompassing the six months before and after the peak is naturally somewhat less. During this year a boy usually grows between 7 and 12 centimetres (2.75 and 4.75 inches) and a girl between 6 and 11 centimetres (2.35 and 4.35 inches). Children who have their peak early reach a somewhat higher peak than those who have it late.

The average age at which the peak is reached depends on the nature and circumstances of the group studied more, probably, than does the height of the peak. In moderately well-off British or North American children at present the peak occurs on average at about 14.0 years in boys and 12.0 years in girls. Though the absolute average ages differ from population to population, the two-year sex difference always persists.

Practically all skeletal and muscular dimensions take part in the spurt, though not to an equal degree. Most of the spurt in height is due to acceleration of trunk length rather than of length of legs. There is a fairly regular order in which the dimensions accelerate; leg length as a rule reaches its peak first, followed by the body breadths, with shoulder width last. The earliest structures to reach their adult status are the head, hands, and feet.

The spurt in muscle, of both limbs and heart, coincides with the spurt in skeletal growth, for both are caused by the same hormones. Boys' muscle widths reach a peak velocity of growth that is greater than that reached by girls. But, since girls have their spurt earlier, there is actually a period, from about 12% to 13½%, when girls on average have larger muscles than boys of the same age, as well as being taller (Figure 2). Simultaneously with the spurt there is a loss of fat, as described above.

The marked increase in muscle size in boys at adolescence leads to an increase in strength, illustrated in Figure 6. Before adolescence, boys and girls are similar in

Figure 6: Strength of arm pull and thrust for boys and girls.

strength for a given body size and shape; after, boys have much greater strength, probably due to development of more force per gram of muscle as well as to absolutely larger muscles. They also develop larger hearts and lungs relative to their size, a higher systolic blood pressure (the pressure resulting from a heart contraction), a lower resting heart rate, a greater capacity for carrying oxygen in the blood with more hemoglobin, and a greater power for neutralizing the chemical products of muscular exercise such as lactic acid. In short, the male becomes at adolescence more adapted for the tasks of hunting, fighting, and manipulating all sorts of heavy objects, as is necessary in some forms of food-gathering.

It is as a direct result of these anatomical and physiological changes that athletic ability increases so much in boys at adolescence. The popular notion of a boy's "outgrowing his strength" at this time has little scientific support. It is true that the peak velocity of strength is reached a year or so later than that of height, so that a short period may exist when the adolescent, having completed his skeletal and probably also his muscular growth, still does not have the strength of a young adult of the same body size and shape. But this is a temporary phase; considered absolutely, power, athletic skill, and physical endurance all increase progressively and rapidly throughout adolescence.

**Reproductive system.** The adolescent spurt in skeletal and muscular dimensions is closely related to the rapid development of the reproductive system that takes place at this time. The course of this development is outlined diagrammatically in Figure 7. The bar marked "breast" in the chart for the girls and the bars marked "penis" and "testis" in the chart for the boys represent the periods of accelerated growth of these organs. Other bars indicate the genitalia rating and the advent and development of the pubic hair. The sequence and timings that are given represent in each case average values for British boys and girls; the North American average is within two or three months of this. To give an idea of the individual departures from the average, figures for the range of age at which the various events begin and end are inserted under the first and last point of the bars. The acceleration of penis growth, for example, begins on average at about age 12½ years, but sometimes as early as 10% and sometimes as late as 14½. The completion of penis development usually occurs at about age 14½, but in some boys is at 12% and in others at 16%. There are a few boys, it will be noticed, who do not begin their spurts in

Adolescent increase in strength

Development of reproductive organs

The adolescent spurt in height

Figure 7: Sequence of events at adolescence for average British boys and girls. Range of ages within which each event may begin and end is given by the figures placed directly below its start and finish. The numbers 2 to 5 within the bars indicate stage of maturity, 5 being full maturity and 2 the beginning of adolescence (see text)

W. Marshall and J. Tanner, *Archives of Disease in Childhood* (February 1970); British Medical Association

height or penis development until the earliest maturers have entirely completed theirs. At ages 13, 14, and 15 there is an enormous variability among any group of boys, who range all the way from practically complete maturity to absolute preadolescence. The same is true of girls aged 11, 12, and 13.

The psychological and social importance of this difference in the tempo of development, as it has been called, is great, particularly in boys. Boys who are advanced in development are likely to dominate their contemporaries in athletic achievement and sexual interest alike. Conversely the late developer is the one who all too often loses out in the rough and tumble of the adolescent world, and he may begin to wonder whether he will ever develop his body properly or be as well endowed sexually as those others whom he has seen developing around him. An important part of the educationist's and the doctor's task at this time is to provide information about growth and its variability to preadolescents and adolescents and to give sympathetic support and reassurance to those who need it.

The sequence of events, though not exactly the same for each boy or girl, is much less variable than the age at which the events occur. The first sign of puberty in the boy is usually an acceleration of the growth of the testes and scrotum with reddening and wrinkling of the scrotal skin. Slight growth of pubic hair may begin about the same time but is usually a trifle later. The spurts in height and penis growth begin on average about a year after the first testicular acceleration. Concomitantly with the growth of the penis, and under the same stimulus, the seminal vesicles, the prostate, and the bulbo-urethral glands, all of which contribute their secretions to the seminal fluid, enlarge and develop. The time of the first ejaculation of seminal fluid is to some extent culturally as well as biologically determined but as a rule is during adolescence and about a year after the beginning of accelerated penis growth.

Axillary (armpit) hair appears on average some two years after the beginning of pubic hair growth; that is, when pubic hair is reaching stage 4 (Figure 7). There is

enough variability and dissociation in these events, so that a very few children's axillary hair actually appears first. In boys, facial hair begins to grow at about the time that the axillary hair appears. There is a definite order in which the hairs of moustache and beard appear: first at the corners of the upper lip, then over all the upper lip, then at the upper part of the cheeks, in the midline below the lower lip, and, finally, along the sides and lower borders of the chin. The remainder of the body hair appears from about the time of first axillary hair development until a considerable time after puberty. The ultimate amount of body hair that an individual develops seems to depend largely on heredity, though whether because of the kinds and amounts of hormones secreted or because of variations in the reactivity of the end organs is not known.

Breaking of the voice occurs relatively late in adolescence. The change in pitch accompanies enlargement of the larynx and lengthening of the vocal cords, caused by the action of the male hormone testosterone on the laryngeal cartilages. There is also a change in *quality* that distinguishes the voice (more particularly the vowel sounds) of both male and female adults from that of children. This is caused by the enlargement of the resonating spaces above the larynx, as a result of the rapid growth of the mouth, nose, and maxilla (upper jaw).

In the skin, particularly of the armpits and the genital and anal regions, the sebaceous and apocrine sweat glands develop rapidly during puberty and give rise to a characteristic odour; the changes occur in both sexes but are more marked in the male. Enlargement of the pores at the root of the nose and the appearance of comedones (blackheads) and acne, while likely to occur in either sex, are considerably more common in adolescent boys than girls, since the underlying skin changes are the result of androgenic (male sex hormone) activity.

During adolescence the male breast undergoes changes, some temporary and some permanent. The diameter of the areola, which is equal in both sexes before puberty, increases considerably, though less than it does in girls. In some boys (between a fifth and a third of most groups studied) there is a distinct enlargement of the breast (sometimes unilaterally) about midway through adolescence. This usually regresses again after about one year.

In girls the start of breast enlargement—the appearance of the “breast bud”—is as a rule the first sign of puberty, though the appearance of pubic hair precedes it in about one-third. The uterus and vagina develop simultaneously with the breast. The labia and clitoris also enlarge. Menarche, the first menstrual period, is a late event in the sequence. It occurs almost invariably after the peak of the height spurt has been passed. Though it marks a definitive and probably mature stage of uterine development, it does not usually signify the attainment of full reproductive function. The early cycles may be more irregular than later ones and in some girls, but by no means all, are accompanied by discomfort. They are often anovulatory; that is, without the shedding of an egg. Thus there is frequently a period of adolescent sterility lasting a year to 18 months after menarche, but it cannot be relied on in the individual case. Similar considerations may apply to the male, but there is no reliable information about this. On average, girls grow about six centimetres (about 2.4 inches) more after menarche, though gains of up to twice this amount may occur. The gain is practically independent of whether menarche occurs early or late.

*Normal variations.* Children vary a great deal both in the rapidity with which they pass through the various stages of puberty and in the closeness with which the various events are linked together. At one extreme one may find a perfectly healthy girl who has not yet menstruated though her breasts and pubic hair are characteristic of the adult and she is already two years past her peak height velocity; and at the other, a girl who has passed all the stages of puberty within the space of two years.

In girls the interval from the first sign of puberty to complete maturity varies from 18 months to six years. The period from the moment when the breast bud first

First signs of puberty in the girl

The first sign of puberty in the boy

appears to **menarche** averages 2% years but may be as little as six months or as much as 5% years. The rapidity with which a child passes through puberty seems to be independent of whether puberty is occurring early or late. **Menarche** invariably occurs after peak height velocity is passed, so that the tall girl can be reassured about future growth if her menstrual periods have begun.

In boys a similar variability occurs. The genitalia may take between two and five years to attain full development, and some boys complete the whole process before others have moved from the first to the second stage.

The height spurt occurs relatively later in boys than in girls. Thus there is a difference between the average boy and girl of two years in age of peak height velocity but of only one year in the first appearance of pubic hair. Indeed, in some girls the acceleration in height is the first sign of puberty; this is never so in boys. A small boy whose genitalia are just beginning to develop can be unequivocally reassured that an acceleration in height is soon to take place, but a girl in the corresponding situation may already have had her height spurt.

**Sex dimorphism.** The differential effects on the growth of bone, muscle, and fat at puberty increase considerably the difference in body composition between the sexes. Boys have a greater increase not only in stature but especially in breadth of shoulders; girls have a greater relative increase in width of hips. These differences are produced chiefly by the changes of puberty, but other sex differentiations arise before that time. Some, like the external genital difference itself, develop during fetal life. Others develop continuously throughout the whole growth period by a sustained differential growth rate. An example of this is the greater relative length and breadth of the forearm in the male when compared with whole arm length or whole body length.

Part of the sex difference in pelvic shape antedates puberty. Girls at birth already have a wider pelvic outlet. Thus the adaptation for childbearing is present from an early age. The changes at puberty are concerned more with widening the pelvic inlet and broadening the much more noticeable hips. It seems likely that these changes are more important in attracting the males' attention than in dealing with its ultimate product.

**Physical and behavioral interaction.** Children vary greatly in their tempo of growth. The effects are most dramatically seen at adolescence, but they are present at all ages from birth and even before.

The concept of developmental age, as opposed to chronological age, is an important one. To measure developmental age, there is need of some way of determining how far along his own path to maturity a given child has gone. Thus there is need of a measure in which everyone at maturity ends up the same (not different as in height). The usual measure used is skeletal maturity or bone age. This is measured by taking an X-ray of the hand and wrist (using the same radiation exposure that a child inevitably gets, and to more sensitive areas, by spending a week on holiday in the mountains). The appearances of the developing bones can be rated and formed into a scale; the scale is applicable to boys and girls of all genetic backgrounds, though girls on average reach any given score at a younger age than boys; and blacks on average, at least in the first few years after birth, reach a given score younger than do whites. Other areas of the body may be used if required. Skeletal maturity is closely related to the age at which adolescence occurs; that is, to maturity measured by some sex character developments. Thus the range of the chronological age within which **menarche** may normally fall is about 10 to 16½, but the corresponding range of bone age for **menarche** is only 12 to 14%. Evidently the physiological processes controlling progression of skeletal development are in most instances closely linked with those that initiate the events of adolescence. Furthermore, children tend to be consistently advanced or retarded during their whole growth period, at any rate after about age three.

There is little doubt that being an early or a late maturer may have repercussions on behaviour and that in some children these repercussions may be considerable.

There is little enough solid information on the relation between emotional and physiological development, but what there is supports the common-sense notion that emotional attitudes are clearly related to physiological events. Boys who are advanced in development, not only at puberty but before as well, are more likely than others to be leaders. Indeed, this is reinforced by the fact that muscular, powerful boys on average mature earlier than others and have an early adolescent growth spurt. The athletically built boy not only tends to dominate his fellows before puberty but, by getting an early start, is in a good position to continue that domination. The unathletic, linear boy, unable, perhaps, to hold his own in the preadolescent rough-and-tumble, gets still further pushed to the wall at adolescence, as he sees others shoot up while he remains nearly stationary in growth. Even boys several years younger now suddenly surpass him in size, athletic skill, and perhaps in social graces also.

**Larger size and earlier maturation.** The rate of maturing and the age of onset of puberty are dependent on a complex interaction of genetic and environmental factors. Where the environment is good, most of the variability in age at **menarche** in a population is due to genetic differences. In France in the 1950s, the mean difference for identical twins was two months, while that between nonidentical twin sisters was eight months. In many societies puberty occurs later in the poorly off, and, in most societies investigated, children with many siblings grow more slowly than children with few.

During the last hundred years there has been a striking tendency for children to become progressively larger at all ages. This is known as the "secular trend." The magnitude of the trend in Europe and America is such that it dwarfs the differences between socio-economic classes.

The data from Europe and America agree well: from about 1900, or a little earlier, to the present, children in average economic circumstances have increased in height at age five to seven by about one to two centimetres (0.4 to 0.8 inch) per decade, and at 10 to 14 by two to three centimetres (0.8 to 1.2 inches) each decade. Preschool data show that the trend starts directly after birth and may, indeed, be relatively greater from age two to five than afterwards. The trend started, at least in Britain, as early as 1850.

Most of the trend toward greater size in children reflects a more rapid maturation; only a minor part reflects a greater ultimate size. The trend toward earlier maturing is best shown in the statistics on age at **menarche**. A selection of the best data is illustrated in Figure 8. The trend is between three and four months per decade since 1850 in average sections of western European populations. Well-off persons show a trend of about half of this

Modern tendency toward earlier maturity

Developmental and chronological ages

Effects of late and early maturity

Figure 8: Secular trend in age at menarche. 1830-1960.

magnitude, having never been so retarded in **menarche** as the worse off. The causes of the secular trend are probably multiple. Certainly better nutrition is a major one and perhaps in particular more protein and calories in early infancy. A lessening of disease may also have contributed. Hot climates used to be cited as a potent cause of early menarche, but it seems that their effect, if any, is considerably less than that of nutrition. Some authors have supposed that the increased psychosexual stimulation consequent on modern urban living has contributed, but there is no positive evidence for this.

#### HORMONES AND GROWTH

The main hormones concerned with growth are pituitary growth hormone, thyroid hormone, the sex hormones testosterone and estrogen, and the pituitary gonadotropic (sex-gland-stimulating) hormones.

**Pituitary growth hormone.** Pituitary growth hormone, a protein with molecular weight of 21,600 and of known amino-acid composition, is secreted by the pituitary gland throughout life. Exactly what its function is in the adult is not clear, but in the child it is necessary for growth; without it dwarfism results. During fetal life it seems not to be necessary, though normally present. It is not secreted at a constant rate all day but in small bursts of activity. Secretion by the pituitary is controlled by a substance sent to it from an adjacent part of the brain. The normal stimulus for secretion is not certain, but a sharp and "unnatural" lowering of blood sugar will cause growth hormone to be secreted, and this is used as a test. The hormone decreases the amount of fat and causes protein to be laid down in muscles and viscera. Children who lack it are fat as well as small; when given it by injection, they lose fat and grow rapidly.

The hormone is peculiar in being species-specific; that is, only growth hormone from human glands is active in man. Supplies of the hormone for treating children who need it are obtained at autopsy, and supply has been limited by this. The hormone has been made synthetically, but the processes for its manufacture have not yet been adopted for commercial production.

**Thyroid hormone.** Thyroid hormone from the thyroid gland in the neck is necessary for normal growth, though it does not itself stimulate growth, for example in the absence of pituitary growth hormone. Without thyroid hormone, however, cells do not develop and function properly, especially in the brain. Babies who lack thyroid hormone at birth are small and have insufficiently developed brains; they are known as cretins. Frequently, if the condition is diagnosed and they are treated with thyroid hormone at once, they recover completely; the longer they go without treatment, the more likely it is that the brain damage will be permanent.

Thyroid lack may also develop later in childhood, when it causes a slowing of growth rate; full catch-up follows prompt treatment.

**Sex hormones.** Testosterone, secreted by the interstitial cells of the testis, is important not only at puberty but before. Its secretion by the fetal testis cells is responsible for the development of certain parts of the male genital apparatus and for fixing the brain into the male pattern, which cannot later, it seems, be altered. If testosterone is not secreted at a particular and circumscribed time, the genitalia and the brain develop into the female form.

Only small amounts of testosterone circulate between birth and puberty, but at puberty the interstitial cells develop greatly in response to pituitary luteinizing hormone (see below), and testosterone is secreted in large amounts, bringing about most of the changes of male puberty. It acts on a widespread series of receptors—for example, the cells of the penis, the muscles, the skin of the face, the cartilages of the shoulder, and certain parts of the brain. Most of the adolescent growth spurt is due to testosterone.

The female sex hormones, collectively called estrogens, are first secreted in quantity at puberty by cells in the ovary. They cause growth of the uterus, vagina, and breast; they act also on the bones of the hip, causing the specifically female widening. The adolescent growth

spurt in the female is probably caused by **testosterone-like substances** (androgens) secreted by the adrenal gland in both male and female.

**Pituitary gonadotropins and initiation of puberty.** The pituitary secretes two other hormones concerned in development: one, follicle-stimulating hormone (**FSH**), causes growth of the main portions of the ovary in the female and the sperm-producing cells in the testis of the male; the other, luteinizing hormone (**LH**), causes growth and secretion of the testosterone-secreting cells of the male and has an action in controlling the menstrual cycle in the female. The pituitary is caused to secrete gonadotropins by substances called releasing factors that come to it from adjacent areas of the brain, where they are made. Certain children develop all the changes of puberty, up to and including sperm production or ovulation, at an early age, either as the result of a brain lesion or as an isolated developmental, sometimes genetic, defect. The youngest mother on record was such a child; she gave birth to a full-term healthy infant by cesarean section at the age of five years and eight months. The existence of precocious puberty and the results of accidental ingestion by small children of male or female sex hormones indicate that breasts, uterus, and penis will respond to hormonal stimulation long before puberty. Evidently an increased end-organ sensitivity plays at most a minor part in puberal events.

The signal to start the sequence of events is given by the brain, not the pituitary. Just as the brain holds the information on sex, so it holds information on maturity. The pituitary gland of a newborn rat successfully grafted in place of an adult pituitary begins at once to function in an adult fashion and does not have to wait until its normal age of maturation has been reached. It is the hypothalamus in the brain, not the pituitary, that must mature before puberty begins. Small amounts of sex hormones circulate from the time of birth, and these appear to inhibit the **prepuberal** hypothalamus from producing gonadotropin releasers. At puberty the hypothalamic cells become less sensitive to sex hormones. The small amount of sex hormones circulating then fails to inhibit the hypothalamus; gonadotropins are released, and these stimulate the production of testosterone by the testis or estrogen by the ovary. The level of the sex hormone rises until the same feedback circuit is re-established but now at a higher level of gonadotropins and sex hormones. The sex hormones are now high enough to stimulate the growth of secondary sex characters and to support mating behaviour.

#### DISORDERS OF GROWTH

**Short stature.** There are a number of causes of short stature (a term much preferable to dwarfism). The most common of them is simple inheritance with or without a greater-than-usual delay in the tempo of growth. Given a reasonably good environment, a child's height is chiefly controlled by the genes that he inherited from his parents. The control depends on many genes, each of small effect, and, in the average case, depends equally on the father and the mother. Thus two small parents, unless they are small because stunted by chronic malnutrition in their childhood, can expect to have mostly small children. Charts are now available giving the normality of a child's height when its parents' heights are known.

Secondly, the child may be simply delayed in growth. This can be established by estimating his bone age or by seeing whether his height is within normal limits for the bone age rather than the chronological age. In boys with delayed growth, testosterone or one of its derivatives can be given if psychological problems become great at an age when the majority of boys are entering puberty; however, unless the bone age is extremely retarded, one runs the risk of diminishing the final adult height through maturing the skeleton too rapidly, so that the treatment should be given only by persons with considerable experience of it.

Neither hereditary small stature nor delayed maturation is a disorder, of course, but the extreme of normal variation.

Youngest mother on record

Action of growth hormone

Effects of sex hormones on growth

**Growth hormone deficiency.** There may be a deficiency of growth hormone alone, with other pituitary functions normal, or there may also be deficiencies of the other hormones secreted by the pituitary, such as thyroid-stimulating hormone, adrenocorticotrophic hormone (ACTH), and gonadotropins.

The isolated growth hormone deficiency is more common in boys than in girls and usually is manifested by a reduced growth rate from birth onward. The size at birth is typically close to normal. Usually the child is fat and has a delayed bone age; the diagnosis is clinched by an inability to secrete growth hormone on a stimulation test. Treatment with human growth hormone is usually successful, a rapid rate of growth being induced in the first year of treatment. Even if the same dose is maintained, the response becomes less as the child approaches normal size for his age. In rare cases antibodies to HGH develop, and treatment has to be abandoned.

Panhypopituitarism, deficiency of all the pituitary hormones, most commonly follows the removal of a craniopharyngioma, a benign tumour of a part of the brain close to the pituitary gland. For this condition other hormones, notably thyroid and cortisone, may have to be given as well as HGH. Results are usually good.

**Hypothyroidism.** Lack of a properly functioning thyroid gland will, among other things, cause a decreased rate of growth. Bone age is delayed more than in HGH deficiency. Treatment with thyroid hormone is usually effective.

**Steroid (cortisone) excess.** Hormones of the type of cortisone have a powerful growth-stopping effect, and short stature follows administration of cortisone and similar drugs, if these are given in more than extremely small doses. This may have to be done for really intractable asthma or rheumatoid arthritis in a child but should be avoided to the utmost. Cushing's disease is a state of excess secretion of cortisone by the adrenal gland; this causes short stature, delayed bone age, and fatness.

**Gonadal dysgenesis (Turner's syndrome).** The sex chromosomes in females are normally XX, in contrast to the male XY configuration. In Turner's syndrome, in girls, the configuration is XO (that is, there is only one sex chromosome, an X-chromosome), or XX/XO. Short stature is characteristic, for unknown reasons. The ovaries fail to develop, so that no enlargement of the breasts or uterus occurs at puberty and the affected persons are sterile. The diagnosis is made by examination of the chromosomes.

**Low birth weight and short stature.** A proportion of children born with abnormally low birth weight, usually accompanied by a characteristic facial appearance, lack of fat, and often asymmetry of the body, remain small throughout their lives. They have normal amounts of thyroid and growth hormone and undergo a normal puberty. Injections of growth hormone are ineffective. It seems likely that the basic defect is a lack of the normal complement of cells. The disorder is called Silver's syndrome or Russell's syndrome.

**Psychosocial short stature.** Certain children who are subjected to psychological stress by an inimical home environment appear to react by not growing normally. This is not simple starvation or refusal to eat; on the contrary, the eating pattern often is bizarre and obsessive, food being eaten from time to time voraciously or taken from a dog's dish or a garbage can. These children tend to be fat, like those with growth hormone deficiency. Giving human growth hormone is ineffective, but removal of the children from their surroundings usually results in a catch-up in growth.

**Malabsorption, starvation.** Chronic starvation causes short stature, as does chronic malabsorption.

**Bone disorders.** The most common bone disorders causing short stature are achondroplasia and its near but distinct relative hypochondroplasia. In both there is shortening of the legs and arms relative to the trunk; in particular, the upper arm and the thigh are shortened. In achondroplasia there is also a characteristic facial appearance with prominent forehead and snub nose; in hypochondroplasia the face is normal. The disorder is one

of bone, and no treatment is currently effective. The state is inherited, but most cases are due to fresh mutations and do not have a family history. There are numerous rarer bone diseases causing short stature.

**Metabolic and other diseases.** A number of metabolic diseases, all relatively rare, cause short stature; they include certain diseases of the kidneys, the connective tissue, and the liver. Some children with congenital heart disease and some with bronchiectasis (inflammation and dilation of the bronchial tubes) are short. Children with various forms of mental defect are frequently small, for unknown reasons.

**Tall stature.** The majority of tall children simply inherit their size from tall parents. Two forms of pathological gigantism occur, however. One is caused by over-secretion of pituitary growth hormone, often due to a pituitary tumour, and the other, called cerebral gigantism, is of unknown cause. In the latter condition the tall size is associated with a characteristic head and face, clumsiness, and often some degree of mental defect.

## Development, Plant

Development refers to the sequence of changes undergone by an organism from the time of its origin until its senescence and death. It encompasses all aspects of growth and differentiation of parts. The potentiality for development is inherited in the genes in the form of information coded in molecules of deoxyribonucleic acid (DNA). Although both plants and animals share this chemical basis of inheritance and of translation of the code into structural units called proteins, plant development differs from that of animals in several important ways. Higher plants sustain growth throughout life and, in this sense, are perpetually embryonic; animals, on the other hand, generally have a determinate period of growth, after which they are considered mature. Furthermore, both growth and organ formation in plants are influenced by their possession of a rigid cell wall and a fluid-filled space called the vacuole, two features unique to the plant cell. Conversely, certain features of animal cells are absent in plants. Notable is the lack of cellular movements and fusions that play an important part in tissue and organ development in higher animals.

This article is divided into the following major sections:

- I. General features
  - Life cycles
  - Body plans
  - Preparatory events

Hormonal causes of short stature

Other causes of short stature

Uniqueness of plant development

- II. Early development: from zygote to seedling
  - Embryo formation
  - Germination and early growth
- III. Later development: the sporophyte plant body
  - Continuation of organ formation
  - The shoot system and its derivatives
  - The root system and its derivatives
- IV. Correlations in plant development
  - Coordination of shoot and root development
  - Determination of mature form
  - Seasonal adaptations
  - Senescence and death

## I. General features

### LIFE CYCLES

The life cycle of all tracheophytes (vascular plants), bryophytes (mosses and liverworts), and many algae and fungi is based on an alternation of generations, or different life phases: the gametophyte, which produces gametes, or sex cells, alternating with the sporophyte, which produces spores. Gametophytes develop from a fertilized egg, or zygote, that results from the fusion of gametes (fertilization) formed by the gametophytes; they are accordingly haploid (*i.e.*, each cell has two sets of chromosomes). Although the two generations are phases of one life cycle, they have independent developmental histories; each begins life as a single cell and passes through a juvenile period before reaching maturity and giving rise to the alternate phase.

In various algae and fungi the two generations are alike in form (*i.e.*, are isomorphic), and, despite the difference in chromosome number, their development follows essentially identical pathways. More commonly, however, the alternating generations have different forms (*i.e.*, are heteromorphic); this is true for the bryophytes and for all vascular plants, both angiosperms (flowering plants) and gymnosperms (conifers and allies). General rules for vascular plants are that the sporophyte generation is physically the larger, has a more complex developmental history, produces a greater range of cell types, and expresses a more diverse biochemistry; the gametophyte is often diminutive, reduced in the case of the angiosperms to a mere few cells. In the bryophytes, the gametophyte generation, rather than the sporophyte, is the more conspicuous.

Although the gametophyte generation in vascular plants is small and has limited physiological capabilities, its cells must convey genes capable of directing the sporophytic developmental pattern, because the pattern is transmitted through the gametes to the zygote (Figure 1). The expression of "sporophytic" genes must therefore be repressed in the gametophyte, probably from the time of spore formation (sporogenesis). Correspondingly, events associated with gamete formation (gametogenesis) or fertilization must somehow free the sporophytic genes and thus permit the zygote to enter the sporophytic developmental pattern. Although it might be supposed that the "switch" is associated with the difference in chromosome number between the haploid spore (a single set) and the diploid zygote (a double set), this has been shown not to be the determining factor.

The alternation of generations illustrates an important principle, namely that cell lineages arising from single parental cells containing the same genetic potentiality may pursue mutually exclusive developmental patterns. Channelling, or canalizing, events of this nature occur repeatedly in the course of development of an individual plant, beginning with the pattern of cell division from the very first cleavage of the zygote cell.

### BODY PLANS

Collectively plants manifest a wide range of body plans, ranging from the single cell (or unicell), with a single nucleus, through various types of colonial and filamentous forms to massive multicellular structures. (Algae, including the single-celled forms, have a great deal in common in structure and biochemistry with vascular plants. Bacteria and fungi stand somewhat apart, but be-

Figure 1: Stages in the fertilization and seed formation of a dicot.

From C.A. Villée, *Biology*, 6th ed. (1972); W.B. Saunders Co.

cause of their various plantlike qualities they are taken as plants for the purposes of this article.)

For the unicell, development is the same as cell differentiation. Although many unicellular fungi and algae show little differentiation other than that connected with reproduction, others undergo elaborate structural changes that illustrate many principles basic to development in multicellular plants. An important example is the green alga *Acetabularia*. This alga first produces a rootlike system and stalk and then, later, a flattened umbrella-like cap. The developmental potentialities of this unicell, with its single nucleus, are, however, limited; in order for there to be any advance beyond the state seen in *Acetabularia*, with the development of greater body mass and a division of labour among different parts, an increase in the number of participating nuclei seems obligatory.

One method of providing more nuclei is by nuclear division without a corresponding cell division; the result is a coenocytic structure. Plants with this type of multinucleate organization show considerable diversity; examples are found in both algae and fungi. Growth occurs by the extension of the cell wall in certain zones, usually at the tips of filaments, and structural differentiation results from branching and the specialization of parts for particular functions. The aggregation of coenocytic filaments can lead to the development of a three-dimensional body, or thallus, but plants with this type of organization have not achieved great size.

A more significant type of body plan, one based on the multicellular filament, is found in its most simple form in certain algae known as diatoms, in which chains of cells of indefinite length arise, although the cells show no evidence of interaction. More advanced is the condition of many other algae, in which there occur branches that may either be identical with the original filament or show structural or physiological specialization. This condition occurs in certain green algae, in which the main branches creep and the lateral branches grow erect; such diversification represents an important developmental innovation and, possibly, the evolutionary beginnings of organ specialization in plants.

Three-dimensional body forms may evolve from the association of cells in colonies. Cells among the colonial

**Multicellularity:** an advance in development

Conveying the genes through alternate generations

green algae are of definite number; each component cell resembles a free-living unicell, but all are united by cellular connections, or plasmodesmata, which may be important in coordinating the development of the colony. Colonies are often of precise geometric shape, forming either a circular plate or a sphere. In elaborate ones, certain cells are specialized for reproduction, and others are concerned primarily with movement.

Another developmental pathway resulting in more massive body structure is by the association of filaments. The reproductive structures of many fungi are composed of large numbers of closely interwoven filaments, which, although not physically connected, do interact in some way to produce structures such as the mushroom cap. Several filamentous body plans are found among the red algae. In one, a single main (axial) filament grows at one end, but, just behind its tip, cells divide to produce a number of lateral filaments that grow parallel with the axial filament. The older parts of the thallus, therefore, seem to be an aggregate of filaments. More massive structures are produced when there are several axial filaments; and, by branching, particularly when accompanied by fusion, dense tissues resembling the basic undifferentiated tissue (parenchyma) of higher plants are formed. In these algae, cellular connections occur between daughter cells of a filament, and others may develop secondarily between cells of neighbouring filaments.

The transition from a filamentous to a three-dimensional form appears most notably in the brown algae. In certain brown algae, growth is by an axial filament, but, behind the tipmost cell, divisions produce a denser tissue lacking evidence of filamentous organization. In the sporophytes of kelp, one of the largest and most complex of the algae, cell division often is restricted to areas comparable to the growing tips of vascular plants, and, although a filamentous organization may be evident in the centre of the thallus, the surrounding cortical regions are composed of a tissue that is essentially undifferentiated. (The gametophytes of kelp, however, have a simple filamentous organization).

Among nonvascular plants, true parenchyma is found in the bryophytes, in both the gametophyte and sporophyte phases. The development of the moss gametophyte illustrates the transition from a filamentous to a highly organized three-dimensional growth form. The moss spore germinates into a filamentous plant, the protonema, which later produces a leafy shoot. This type of transition from simple to more complex growth form is accompanied by the synthesis of new kinds of ribonucleic acids (RNA's), presumably through the activation of genes that were not expressed during the early growth of the gametophyte.

Much of the remainder of this article is concerned with the development of the complex body forms of vascular-plant sporophytes, which do not normally pass through any filamentous stages. It may be noted, however, that, in the course of evolution, the capacity for this type of growth has not been lost, since it may be adopted by cells grown in tissue cultures in the laboratory.

#### PREPARATORY EVENTS

The sporophytes of all vascular plants produce cells called spore mother cells—since they will give rise to spores—in spore cases (sporangia). Spore mother cells are usually surrounded, during development, by a special nutritive tissue. In the more primitive groups each sporangium holds many mother cells. This is true also in the pollen-producing sporangia of gymnosperms and angiosperms but not in the egg-producing sporangia (ovules), which usually have only one mother cell.

In certain lower vascular plants, typified by the club moss *Selaginella*, the gametophyte is formed **entirely**—or almost entirely—within the spore wall. Two kinds of gametophytes develop from the two kinds of spores produced by the sporophyte in different sporangia; the larger spore (megaspore) gives rise to the female gametophyte, the smaller spore (microspore) to the male. This condition is referred to as heterospory. The gametophytes, or prothalli, of other club mosses and most horse-

tails and ferns are sexually undifferentiated and arise from one kind of spore, a condition termed homospory.

In these groups the gametophytes develop as free-living and independent plants that ultimately produce the gametes. In general, the male gametes (antherozoids) are produced in globose structures (antheridia) that are either stalked or sunken in the gametophyte. The antherozoids, always many in number, develop from mother cells enclosed in the jacket of the antheridium. Each antherozoid can move by using its whiplike hairs, or flagella, two or three (in the lycopods) or many (in the horsetails and ferns). The female gametes are formed singly in flask-shaped structures (archegonia) that also are either stalked or sunken in the gametophyte. The neck of the flask is closed by neck canal cells, which later break down to permit the entry of the male gamete. The egg itself lies in the basal part, or venter, of the flask, with a ventral canal cell above it. When the male gametes, or antherozoids, are released by the rupture of the antheridium, they swim in a water film to the archegonia and effect fertilization.

Among the gymnosperms the male gametophyte is much reduced and is a parasite on the sporophyte for only a short time. Cell cleavages within the spore wall cut off a prothallial cell, which will give rise to the vegetative (*i.e.*, nonreproductive) part of the plant, and an antheridial cell, which divides into a tube cell and a generative cell. The male gametophyte so formed and contained within the spore wall is the pollen grain. After transfer to the ovule by wind, the pollen grain germinates to form a tube, and the generative cell divides into two cells, one of which forms the male gametes by further division. The gametes bear numerous spirally arranged flagella. The female gametophyte meanwhile develops entirely within the parent sporangium in the ovule. The size of the single functional spore increases greatly as the spore nucleus divides repeatedly to produce numerous free nuclei. Cell-wall formation then begins at the periphery, extending inward until the whole area is divided into cells. Up to four archegonia are formed, sunken in the tissue of the gametophyte, each with a female gamete, or egg.

The end of the gametophyte phase and the beginning of the sporophyte phase occur at fertilization, when one of the male gametes fuses with the female gamete to form the zygote, which will then develop as the sporophyte. (Development of the sporophyte can, in some cases, be triggered by means other than fertilization, in which case the organism is said to arise parthenogenetically.)

The male gametophyte of angiosperms is reduced to three cells, one so-called vegetative cell and two male gametes. The division producing the gametes may occur either before dispersal of the pollen grain or later, during the growth of the pollen tube. The female sporangium has one or two coats, or integuments, except for an opening (micropyle) at one end; the sporangium with an integument is called the ovule. The female gametophyte, known in this group as the embryo sac, develops from the parent spore while it is still retained in the **sporangium**. Three cell divisions result in eight nuclei, which arrange themselves so that three lie at each end and two lie in the centre. The cytoplasm then cleaves and three cells are formed at each pole, leaving two nuclei in a large central cell. The three cells at the micropylar pole (end toward the micropyle) form the egg apparatus. Two of these cells, called synergids, correspond to the neck cells of an archegonium; the third is the egg cell. The three cells at the opposite pole, the antipodals, play a part in embryo nutrition in certain genera. The two polar nuclei in the central cell ultimately unite, becoming the fusion nucleus. The pollen grain is transferred by various agencies (wind, water, animals) to the stigma of the female flower, and, as in the gymnosperms, it germinates to produce a tube. This tube grows through intervening tissues, through an opening (micropyle) of the egg, and enters a cell near the micropyle (synergid), in which the two male gametes are discharged. The unique feature of this phase of angiosperm development is that two fertilizations occur. One male gamete fuses with the

Fertilization: a change of generations

Three-dimensional body form

egg to give the diploid zygote; the other makes its way to the fusion nucleus in the central cell, already diploid, and by a second fusion gives a triploid primary endosperm nucleus, which is later concerned in the formation of the nutritive tissue, or endosperm.

## II. Early development: from zygote to seedling

### EMBRYO FORMATION

**Cleavage of the zygote.** In vascular plants embryo formation, or embryogenesis, usually occurs within a few hours after fertilization, with the first cell division that cleaves the zygote, or fertilized egg, into two daughter cells. Thereafter, rapid cell division provides the building blocks of the primary organs of the embryo sporophyte: the first root, first leaves, and the shoot apex. Temporary structures concerned with embryo nutrition—suspensor and foot—may also be produced. These organs originate in a polarization established at the time of zygote cleavage, but the details of their development vary widely among the different groups.

In the club mosses the zygote divides in a plane at right angles to the axis of the archegonium. The daughter cell toward the neck forms a short filament of cells, the suspensor; the inner cell gives rise to the other organs of the embryo, the shoot, root, and foot. The axis of the embryo is inclined to that of the archegonium and may be almost at right angles. This is in contrast to the behaviour of the true mosses, in which the embryo is oriented along the length of the archegonium, with the foot directed inward and the structures that are equivalent to the shoot, namely the spore capsule and its stalk, directed toward the neck.

A polarity like that of the mosses appears in the horse-tails, in which the zygote divides by transverse and longitudinal walls to form a group of four cells. Of these, the two cells toward the neck give rise to the shoot system; the inner two produce the foot and root.

The details of early embryogenesis in gymnosperms vary considerably. In the cycads and ginkgoes, the initial cleavage establishes a polarity opposite to that in the horse-tails, the inner cell giving rise to the shoot and the outer producing the root. Many conifers are unique in that the zygote undergoes a period of free-nuclear division without cell formation, producing usually four or eight nuclei, which move to the end of the zygote, away

from the neck cells, where cleavage begins. In the pines a further division gives four tiers of four cells. The intermediate tiers extend greatly to form a suspensor; each of the four cells at the lower pole may act as the parent cell of an embryo, a condition sometimes referred to as polyembryony.

In contrast, there is no free-nuclear stage in angiosperm embryogenesis. The zygote cleaves by a wall more or less at right angles to the axis of the embryo sac. The daughter cell next to the micropyle (basal cell) produces a suspensor and contributes to the root; the inner (terminal) cell gives rise to the shoot system. (Angiosperm embryogenesis is more fully described in the following section dealing with the origin of primary organs.)

Notwithstanding the variation in the different groups, the pattern of development established in the early cell cleavages is consistent. The primary polarization of the zygote must necessarily be imposed by the adjacent tissues of the sporophyte, but thereafter the fate of daughter cells depends on control established within the young sporophyte itself.

Although it is often possible to specify the origin of the cell lineages contributing to the various organs and tissue layers, a geometric regularity in cell division is generally maintained through only the first few division cycles in the embryo. The final form of the embryo is thus determined not through the specification of a precise scheme of cell division, as in the development of colonial algae, but through an overall control in which cell and tissue interactions play an important part.

**Origin of the primary organs.** Angiosperm embryogenesis can be described in terms of a much studied flowering plant called shepherd's purse (*Capsella bursa-pastoris*). The zygote divides into two cells, the terminal cell and the basal cell. The terminal cell divides by a wall formed at right angles to the first cleavage wall and then again by a wall formed at right angles to this; a quadrant of cells is thus formed (Figure 2A-D). The partition of the quadrant cells in a transverse plane then produces an octant stage (Figure 2E). By transverse divisions, the basal cell forms a filament, the suspensor, of up to ten cells, the end cell of which swells to form an absorbing organ. The attachment cell, or hypophysis, adjoins the octants derived from the terminal cell (Figure 2F).

sperms

Figure 2: Development of the embryo in *Capsella bursa-pastoris* (see text; G and H less enlarged than A-F).

Establish-  
ing the  
embryo

At this time, the prospective future of each of the zones of the embryo can be specified. Four cells of the octant group will ultimately produce the seed leaves (cotyledons) and the shoot apex; the other four will form the hypocotyl, the part of the embryo between the cotyledons and the primary root (radicle). The hypophysis will give rise to the radicle and the root cap; the cells of the suspensor will degenerate as the embryo matures.

The zones of the embryo destined to form the principal organs are established by this first sequence of divisions, and tissue layers are defined during the ensuing divisions. The octant cells divide by curved walls parallel to the surface; in this way the outer layer responsible for producing the epidermis of the shoot system is defined. Divisions of a more irregular nature in the inner zone ultimately define the tissues from which the central cylinder and vascular core of the main axis of the shoot will develop. Simultaneously, the hypophysis forms a group of eight cells by three successive divisions, the planes of which are mutually at right angles. Of these eight cells, the outer four produce the root cap and epidermis; the inner four contribute to the radicle.

The embryo is at first globular (Figure 2F), but it soon becomes heart-shaped by a combination of numerous cell divisions and enlargement in two zones of the outer hemisphere (Figure 2G). In this manner two cotyledons form. The volume of tissue between the cotyledons is the prospective shoot apex. The characteristic form of the apex is not established until after germination.

As the cotyledons become extended, the embryo bends, because of physical restraints, to conform with the cavity of the embryo sac (Figure 2H). From the heart-shaped phase onward, the core of the hypocotyl and the radicle appears as a cylinder of narrow and elongated cells. This is the parent tissue of the vascular system of the seedling. The surrounding tissue contributes the cortex layer of the stem and root.

The embryogenesis of *Capsella* illustrates only one of several patterns found among flowering plants. Among dicotyledons, the planes of division of the terminal cell, the form of the suspensor, and the contribution made by the basal cell to the embryo all provide evidence used in determining the embryogenetic plan.

Monocotyledons, flowering plants the seeds of which contain only one cotyledon, share with dicotyledons such as *Capsella* the main features of early embryogenesis, including the possession of a suspensor and, in most cases, a fairly regular progression of cell divisions to the octant stage. Thereafter the symmetrical growth pattern is lost through the development of the single cotyledon. In the lily family (Liliaceae), generally accepted as a primitive family of monocotyledons, the cotyledon is derived from an octad of cells arising from the terminal cell. The hypocotyl and stem apex are derived from the proximal cell of a short filament formed by the basal cell, and the root comes from the pair of cells next to it. The suspensor forms from the distal cell or cells of the filament. In the more advanced families of monocotyledons, including the grasses (Gramineae) and orchids (Orchidaceae), embryogenesis is much less regular. The grass embryo possesses structures that do not occur in any other flowering plants, namely, the scutellum, an organ concerned with the nutrition of the seedling, and the coleoptile and coleorhiza, protective sheaths of the young shoot and the radicle. The scutellum arises from octant cells, which also contribute to the cotyledon. The basal cell forms part of the coleoptile and also gives rise to the shoot apex and the tissues of the root and coleorhiza. The embryo is asymmetrical, with the shoot apex lying on one side in a notch, ensheathed by the coleoptile.

In marked contrast, embryogenesis of the orchids is more simple. Except when a suspensor is formed, early cleavages follow no well-defined plan, and the product is an ovoid mass of tissue called the proembryo. No cotyledon, stem apex, or root apex is organized in this early period; these organs do not appear until after germination has occurred.

**Nutritional dependence of the embryo.** During their early growth, the embryos of all vascular plants exist as

virtual parasites depending for nutrition on either the gametophyte or the previous sporophyte generation through the agency of the gametophyte or, in the special case of the angiosperms, upon an initially triploid tissue, the endosperm, which is itself nourished by the parent sporophyte.

The early nutrition of the sporophyte in ferns, horse-tails, and club mosses such as *Lycopodium* is clearly provided by the gametophyte. In these groups the young sporophyte produces a multicellular structure, the foot, which remains embedded in the tissues of the gametophyte throughout early development withdrawing nutrients. Ultimately, both shoot and root of the sporophyte grow out from the gametophyte, but, even after the first leaf has begun to photosynthesize and thus to produce its own food, the gametophyte may persist.

In *Selaginella*, the gametophytes are sexually distinct. The female gametophyte develops within the wall of the megaspore. The archegonia are exposed after the megaspore wall splits, but the gametophyte never escapes completely. After fertilization, the zygote cleaves, and the outer cell produces a long suspensor that pushes the embryo deeply into the tissues of the gametophyte. A foot is then formed, as in *Lycopodium*, and further development of the embryo continues at the expense of reserves transferred to the megaspore from the preceding sporophyte generation.

There are superficial similarities between the nutritional history of the embryo in gymnosperms and in *Selaginella*, for, in each, the female gametophyte, dependent upon reserves derived from the sporophyte, acts as an intermediary between one sporophyte generation and the next.

In the pines, the female gametophyte develops within the tissues of the nucellus and acquires abundant food reserves. The proembryo forms after a period of free-nuclear division in the zygote, and the tier of cells above the basal four then elongates to form a suspensor, which pushes the embryonic group deep into the gametophyte (Figure 3). Secondary suspensor cells may form from the basal tier to continue the process. During embryogenesis, the gametophyte continues to grow and to accumulate food materials, which are transferred to the embryo or remain as reserves in the seed.

The female gametophyte of angiosperms never acquires copious reserves, although starch is frequently present in the central cell and sometimes in the egg itself. The unique feature, here, is that the embryo is nutritionally dependent upon the endosperm, a tissue that, in the genetical sense, constitutes a third organism—neither gametophyte nor sporophyte. Furthermore, as a tissue the endosperm manifests several other special characteristics. The nuclei have three chromosome sets and, therefore, three times the deoxyribonucleic acid (DNA) of haploid cells. As nuclear division ends, the amount of DNA per nucleus increases still further, a condition comparable with that in various plant- and animal-gland nuclei, presumably connected with the nutritional function of the endosperm. Nuclear division takes place at first without cell-wall formation so that a coenocyte is produced; later, partitioning of the cytoplasm results in a cellular tissue.

The reserves accumulated in the endosperm include carbohydrates (especially starch), lipids, and proteins. As reserves accumulate, the nuclei of the endosperm cells may undergo deformation and degeneration. In many plants the growing embryo consumes the endosperm before seed maturation; in others, the tissue persists in the seed, providing a reserve for the developing seedling after germination. Endosperm is not formed in certain angiosperms. In such cases the embryo depends on the transfer of nutrients directly from the sporophyte.

Tissues other than the endosperm may become specialized for the early nutrition of the embryo. The antipodal cells of the female gametophyte sometimes acquire glandular properties, as may cells of the nucellus surrounding the embryo sac. In some species the embryo itself develops a suspensor that penetrates the tissues of the parent sporophyte and acts as an absorbing organ.

**Dormancy of the embryo.** Among the lower pteropsids (club mosses, horsetails, and ferns), the principal agent of dispersal is the haploid spore and not, as in gymnosperms and angiosperms, the seed, the ripened ovule containing a dormant embryo. Since the embryo of lower pteropsids is not involved in dispersal, it does not usually undergo any marked period of dormancy after the differentiation of the primary organs. Development instead proceeds continuously through dependence upon the gametophyte until the young sporophyte is established as a physiologically independent plant. The embryos of gymnosperms and angiosperms pass into a state of dormancy soon after the differentiation of the primary organs and the sporophyte is dispersed in a seed.

In the period leading up to dormancy, several changes occur in the embryo. The accumulation of reserves in the cotyledons or elsewhere ceases, respiratory rate declines rapidly, and cell division, with associated protein and nucleic-acid synthesis, stops. Correlated with these events are cellular changes typical of tissues with low metabolic activity. Especially obvious is the general dehydration of the cells that constitute the seed and the thickening of the cell walls of the ovule to form the seed coat (testa). The product is a structure in which the embryo is protected from temperature extremes by its state of desiccation and is often guarded from further drying and from mechanical or biological degradation by the seed coats. The seed coat often contributes to the maintenance of dormancy by physically impeding the passage of water and gases to and from the embryo, by chemically inhibiting germination, and by mechanically restricting the growth of the embryo.

Role of the seed coat in dormancy

#### GERMINATION AND EARLY GROWTH

Dormancy is brief for some seeds, for example those of certain short-lived annual plants. After dispersal and under appropriate environmental conditions, such as suitable temperature and access to water and oxygen, the seed germinates, and the embryo resumes growth.

**The "breaking" of dormancy.** The seeds of many species do not germinate immediately after exposure to conditions generally favourable for plant growth but require a "breaking" of dormancy, which may be associated with change in the seed coats or with the state of the embryo itself. Commonly the embryo has no innate dormancy and will develop after the seed coat is removed or sufficiently damaged to allow water to enter. Germination in such cases depends upon rotting or abrasion of the seed coat in the soil. Inhibitors of germination must be either leached away by water or the tissues containing them destroyed before germination can occur. Mechanical restriction of the growth of the embryo is common only in species that have thick, tough seed coats. Germination then depends upon weakening of the coat by abrasion or decomposition.

In many seeds the embryo cannot germinate even under suitable conditions until a certain period of time has lapsed. The time may be required for continued embryonic development in the seed or for some necessary finishing process—"after ripening"—the nature of which remains obscure.

The seeds of many plants that endure cold winters will not germinate unless they experience a period of low temperature, usually somewhat above freezing. Otherwise germination fails or is much delayed, with the early growth of the seedling often abnormal. (This response of seeds to chilling has a parallel in the temperature control of dormancy in buds.) In some species, germination is promoted by exposure to light of appropriate wavelengths; in others, light inhibits germination. For the seeds of certain plants, germination is promoted by red light and inhibited by light of longer wavelength, in the "far red" range of the spectrum. The precise significance of this response is as yet unknown, but it may be a means of adjusting germination time to the season of the year, or of detecting the depth of the seed in the soil. Light sensitivity and temperature requirements often interact, the light requirement being entirely lost at certain temperatures.

Low temperatures and seed germination

In the process of germination, water is absorbed by the embryo, which results in the rehydration and expansion of the cells. Shortly after the beginning of water uptake, or imbibition, the rate of respiration increases, and various metabolic processes, suspended or much reduced during dormancy, resume. These events are associated with structural changes in the organelles (membranous bodies concerned with metabolism), in the cells of the embryo.

**The emergence of the seedling.** Active growth in the embryo, other than swelling resulting from imbibition, usually begins with the emergence of the primary root from the seed, although in some species (e.g., the coconut) the shoot emerges first. Early growth is dependent mainly upon cell expansion, but, within a short time, cell division begins in the radicle and young shoot; thereafter, growth and further organ formation (organogenesis) are based upon the usual combination of increase in cell number and enlargement of individual cells.

Until it becomes nutritionally self-supporting, the seedling depends upon reserves provided by the parent sporophyte. In angiosperms these reserves are found in the endosperm, residual tissues of the ovule, or in the body of the embryo, usually in the cotyledons. In gymnosperms, food materials are contained mainly in the female gametophyte. Since reserve materials are partly in insoluble form—as starch grains, protein granules, lipid droplets, and the like—much of the early metabolism of the seedling is concerned with mobilizing these materials and delivering, or translocating, the products to active areas. Reserves outside the embryo are digested by enzymes secreted by the embryo and, in some instances, also by special cells of the endosperm.

In some seeds (e.g., castor beans) absorption of nutrients

Orientation of the seedling

from reserves is through the cotyledons, which later expand in the light to become the first organs active in photosynthesis. When the reserves are stored in the cotyledons themselves, these organs may shrink after germination and die or develop chlorophyll and become photosynthetic.

Environmental factors play an important part not only in determining the orientation of the seedling during its establishment as a rooted plant but also in controlling some aspects of its development. The response of the seedling to gravity is important. The radicle, which normally grows downward into the soil, is said to be positively geotropic. The young shoot, or plumule, is said to be negatively geotropic, because it moves away from the soil; it rises by the extension of either the hypocotyl, the region between the radicle and the cotyledons, or the epicotyl, the segment above the level of the cotyledons. If the hypocotyl is extended, the cotyledons are carried out of the soil, but, if the epicotyl elongates, the cotyledons remain in the soil.

Light affects both the orientation of the seedling and its form. When a seed germinates below the soil surface, the plumule may emerge bent over, thus protecting its delicate tip, only to straighten out when exposed to light (the curvature is retained if the shoot emerges into darkness). Correspondingly, the young leaves of the plumule in such plants as the bean do not expand and become green except after exposure to light. These adaptive responses are known to be governed by reactions in which the light-sensitive pigment phytochrome plays a part. In most seedlings, the shoot shows a strong attraction to light, or a positive phototropism, which is most evident when the source of light is from one direction. Combined with the response to gravity, this positive phototropism maximizes the likelihood that the aerial parts of the plant will reach the environment most favourable for photosynthesis.

### III. Later development: the sporophyte plant body

#### CONTINUATION OF ORGAN FORMATION

Although it is convenient to refer to the early development of the plant sporophyte from the fertilized egg as embryogenesis, the process is never actually concluded as it is in the higher animals. In vascular plants, organ formation (organogenesis) is not confined to early life, and the processes of shoot, root, and leaf formation that occur first in the embryo are repeated, albeit in modified form, throughout the life of the plant. The life-span may be short and determinate, as in annual plants such as the cereals, or long, lasting for many years—indeed potentially indefinitely, except for limitations imposed by the environment and accidents—as in trees. The protracted growth of perennials, or plants that resume growth each growing season, tends to lead to increase in size, but bulk is not necessarily directly correlated with age, because individual leaves, flowers, and even whole limbs continuously die and are shed. Some long-lived plants, however, do reach a point at which losses of body mass balance the increase resulting from continued growth and organ formation.

The activity of meristems. Characteristically, vascular plants grow and develop through the activity of organ-forming regions, the growing points. The mechanical support and additional conductive pathways needed by increased bulk are provided by the enlargement of the older parts of the shoot and root axes. New cells are added through the activity of special tissues called meristems, the cells of which are small, intensely active metabolically, and densely packed with organelles and membranes, but usually lacking the fluid-filled sacs called vacuoles. Meristems may be classified according to their location in the plant and their special functions. One important distinction is between persistent meristems, typified by those of the growing points, and meristems with a limited life, those associated with organs, such as the leaf, of determinate growth. The regions of rapid cell division at the tips (apices) of the stem and the root are terminal meristems. In the stem apex, the uppermost part is the promeristem, below which is a zone of transversely oriented early cell walls, the file, or

rib, meristem. The procambium is a meristematic tissue concerned with providing the primary tissues of the vascular system; the cambium proper is the continuous cylinder of meristematic cells responsible for producing the new vascular tissues in mature stems and roots. The cork cambium, or phellogen, produces the protective outer layers of the bark.

Among meristems of limited existence is the marginal, or plate, meristem responsible for the increase in surface area of a leaf; it contributes new cells mainly in one plane. Another type of meristem of limited life is called intercalary; it is responsible for the extension of some stems (as in the grasses) by the addition of new tissues remote from the growing points.

The number of dividing cells in persistent meristems remains roughly constant, with one of the daughter cells of each division remaining meristematic and the other differentiating as a component of a developing organ. The geometrical arrangements in the particular organ determine the way in which this occurs, but in general the consequence is that the meristem is continuously moving away from the maturing tissue as growth continues. It remains, therefore, a localized zone of specialized tissue, never becoming diluted by the interposition of expanding or differentiating cells. In organs such as leaves, flowers, and fruits, in which the growth is determinate, the divisions of meristematic cells become more widely scattered, and the frequency progressively falls as the proportion of the daughter cells that differentiate increases. Ultimately, at maturity, no localized meristem remains.

The contribution of cells and tissues. The two major factors determining the forms of plant tissues and organs are the orientation of the planes of cell division and the shapes assumed by the cells as they enlarge. Clearly, if the division planes in a cell mass are randomly oriented and individual cells expand uniformly, the tissue will enlarge as a sphere. On the other hand, if cell division planes are oriented regularly or the expansion of individual cells is directional, the tissue can assume any of a number of shapes. In a stem, for example, the cell division planes of the promeristem are oriented at various angles to the stem axis, so that new cells produced contribute to both width and length. Below this region, in the rib meristem, the proportion of divisions with the cell plate at right angles to the axis increases, so that the cells tend to be oriented in files. The cells in these files expand vertically more than they do horizontally, and, accordingly, the stem develops as a cylinder.

The factors that control the orientation of cell division planes in meristems are largely unknown. Cell interactions, however, are presumed to coordinate the distribution and orientation of the divisions. In each cell microtubules in the cytoplasm help to orient the nucleus before it divides. Then, at the time of the division, other microtubules arranged in a spindle-shaped figure (the mitotic spindle) are involved in separating the daughter chromosomes and moving them to opposite ends of the parent cell. Thereafter, the residual part of the spindle helps to locate the plate that separates the two daughter cells. Microtubules are also concerned in determining the direction of growth in expanding cells, since they appear to influence the construction of the cell wall by controlling the way cellulose is laid down in it.

Although change in shape is a form of cell differentiation, the term in the more general sense refers to a change in function, usually accompanied by specialization and the loss of the capacity for further division. Biochemical differentiation often involves a change in the character of the cell organelles—as when a generalized potential pigment body (proplastid) matures as a chloroplast, a chlorophyll-containing plastid. But it may also involve structural changes at a subcellular level, as when organelles change their character in cells engaged in intense metabolic activity.

The differentiation of plant cells for the movement of materials and the provision of mechanical support or protection invariably depends upon modification of the walls. This usually entails the accretion of new kinds of

Influence of the mitotic spindle

Classification of meristems

wall materials, such as lignin in woody tissue and cutin and suberin in epidermal tissues and cork. The accompanying structural changes must be controlled, for the wall materials are not applied at random but according to a pattern appropriate to the particular cell or tissue. The development of patterns during cell-wall growth depends not only on the cytoplasmic microtubules, as in the construction of the cells that will give rise to the water-conducting vessels (xylem elements), but also on cytoplasmic membranes, as in the formation of sieve-like end walls (sieve plates) in the cells that will give rise to food-conducting vessels (phloem elements).

The differentiation of xylem culminates in the death of the participating cells, and the vessels are formed of chains of empty walls. This is an example of "programmed death," not an uncommon phenomenon in plant and animal development.

#### THE SHOOT SYSTEM AND ITS DERIVATIVES

**The shoot tip.** The gametophytes of mosses and liverworts and the sporophytes of many higher plants have a shoot, or early stem, with a single cell at its tip, or apex, from which all the tissues of the stem arise. This apical cell is usually four-sided (tetrahedral), with three faces directed downward, and the fourth capping the apex. Daughter cells are continually cut off sequentially from the three inner faces, the apical cell preserving its tetrahedral shape. In cell lineages derived from the daughter cells, the division planes may remain oriented in a more or less regular manner, so that, for some distance below the apex, the three sectors can be recognized in the stem. This basic pattern occurs in the arrangement of the "leaves" of some mosses, which lie in three ranks. In many plants, however, division planes in the lower part of the apex show no particular correlation with the planes of cleavage of the apical cell, and the lateral appendages do not reflect any three-part arrangement.

Gymnosperm and angiosperm apices do not possess apical cells. The generative role is discharged by an ill-defined zone of tissue called the *promeristem*. Regularities may appear in the distribution of division planes only in the extreme tip region. Over the outer part of the apex, the cells often appear to lie in one to three layers, which constitute the *tunica* (Figure 4). Enclosed by the tunica lies a core of cells that exhibit no distinct layering: this zone is the *corpus*. The layers of the tunica normally contribute to the surface layers of the plant, and the corpus provides the deeper lying tissues.

The tunica–corpus analysis emphasizes the orientation of division planes, but apices can be examined from other points of view—the sizes of cells, the degree of vacuolation, and the concentration of various cell constituents, especially ribonucleic acid (RNA), vary through the apex and this sometimes results in more or less distinctive zones. Both gymnosperm and angiosperm apices have been classified on the bases of such zonal patterns, but the validity of this approach, as well as its usefulness for understanding the function of the apex as a morphogenetic centre, has been questioned.

Since 1950, a theory of angiosperm apical zonation developed by French and Belgian botanists has been gaining support. This theory proposes that the central region of the apical dome constitutes a mass of cells with relatively low division rates, the *méristème d'attente*, or "waiting meristem." Surrounding this region is an annular zone of cells with higher division rates, the *anneau initial*, or "initiating ring." Features other than division rates characterize these zones: RNA and protein content are lower in the *me'ristkme d'attente* than in the *anneau initial*, and the nucleoli are smaller. In longitudinal section, the differences contribute to the patterns distinguishable in apices, some of which have been used as bases for structural classification. The main contention of the Franco-Belgian school, however, is that the zonation represents a functional difference. The *méristème d'attente* is regarded as a region mainly concerned with controlling the geometry of the apex. The cells have a restricted metabolism concerned primarily in maintaining a low rate of increase in cell number, and they them-

selves, as well as their immediate derivatives, take no part in organogenesis or associated differentiation. The *anneau initial*, by contrast, is that part of the apex that produces the beginnings, or primordia, of lateral organs. Not only is the division rate higher, but the tissue as a whole is involved in metabolic syntheses that precede morphogenesis.

One difficulty in investigating the stem apex arises from the uncertainty about which aspects are important for the overall function: division planes, division frequency, metabolic patterns, or some combination of these. Still another complication results because the apex is in a state of constant change during the growth of the plant. A long-term developmental trend begins after the definition of the growing point in early embryogenesis and continues thereafter through juvenility and the period of vegetative growth into the reproductive phase. Superimposed on this trend is a cyclical change reflecting the periodic generation of the primordia of leaves and lateral shoots in the region immediately under the apex.

**The production of leaves.** Leaves originate on the flanks of the shoot apex. A local concentration of cell divisions marks the very beginning of a leaf; these cells then enlarge so as to form a nipple-shaped structure called the leaf buttress. The cells of the leaf buttress may be derived from the tunica alone or from both the tunica and the corpus.

In the early growth of the leaf primordium, new cells are contributed mainly by meristematic activity at the pole directed away from the stem, so that the buttress extends in length. The subsequent distribution of growth varies among the different groups of vascular plants ac-

cording to the shape of the mature leaf. In considering the angiosperms, a broad-leaved dicotyledon (tobacco) and a narrow-leaved monocotyledon (maize [corn]) will serve as examples (Figure 5).

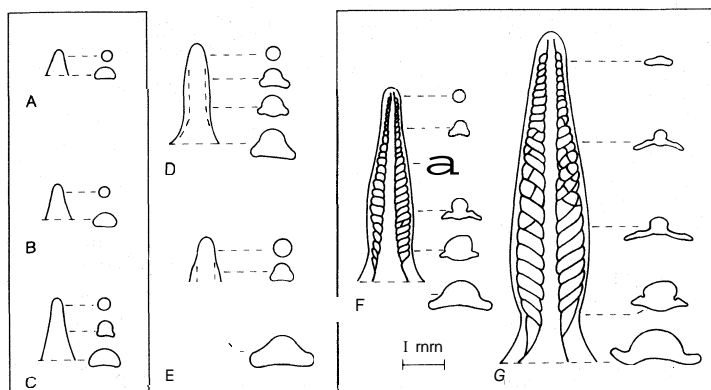

Figure 5: Longitudinal and transverse sections of tobacco foliage leaf primordia in successive stages of development. (A,B) The primordium in early development. (C) The small lateral ridges appearing about midway on the primordium are forerunners of the lamina. (D) Development of the lamina started. (E) Further expansion of the lamina and the beginning of development of the main lateral veins. (F) Primordium five millimetres in length showing development toward the base, of the network of provascular strands. (G) Primordium with the development of the lamina and system of venation well started. Dotted lines in C-E represent external boundaries of midrib and lateral veins and not the provascular portion.

The tobacco leaf as an example

Apical growth dominates in the tobacco-leaf primordium until a height of about 0.5 millimetre (0.02 inch) is reached. Thereafter, the buttress becomes more and more flattened in the transverse plane by laterally oriented cell divisions and further expansion growth on either side. The dividing zones are the marginal meristems, through the activity of which the leaf gains its laminate form. In each meristem the outer file of cells, or marginal initials, contributes the epidermal layers by continued division. The cells below, the submarginal initials, provide the tissue of the inner part of the leaf. Usually a certain number of cell layers is defined in the mesophyll. Cell division is not limited to the region of the marginal meristems but continues throughout the leaf in each of the layers, always in the same plane, until the final cell number is approached. The rate then declines, ceasing in the different layers at different times. Divisions usually end first in the epidermis, then in the lower mesophyll layers of a leaf such as that of tobacco, and last in the main photosynthetic tissue, the palisade layer, just beneath the upper epidermis.

The vascular pattern in a tobacco leaf is determined early in the development of the vessel primordium. A procambial strand is formed by the elongation of narrow axial cells, and this extends both toward the base and toward the apex, eventually linking with the procambium of the stem. When the marginal meristems become active, the lateral veins of the leaf are initiated first, followed by the third and later order branchings that give the characteristic network of veins in the mature leaf.

Although the differentiation of the cells of the vascular system begins at the base, the epidermal and mesophyll cells mature from the tip inward toward the stem. The palisade cells elongate in a plane at right angles to the epidermis; those of the lower mesophyll expand irregularly to give lobed forms. The cells of the epidermis, shaped like irregular paving stones, continue to expand in the plane of the leaf after growth ceases in the mesophyll, so that the cells of the internal tissues are pulled apart to form the system of air spaces found in the mature leaf.

Dicotyledonous leaves are folded in various ways in the bud, the patterns being determined by differential growth in the tissues of the upper and lower surfaces (laminae) of the young leaves. Differential growth may cause the

lamina either to roll or fold toward the leaf midrib or to fold near lateral veins, thus pleating the lamina. The folds in the bud are, of course, eliminated during the final phase of leaf expansion.

In the development of the maize leaf, the primordium arises first as a prominence some distance below the apical dome. The zone of division and growth extends laterally around the apex so that a complete collar forms; then the margins overlap. Meanwhile the original tip zone continues to elongate, eventually surpassing the stem apex. Tip growth declines thereafter, and further increase in cell number results from meristematic activity at the base. The early development of the vascular system is unlike that in dicotyledons, for several parallel procambial strands, rather than a single midrib, are initiated. The first of these grow toward the apex, but, as tip growth ceases, procambial strands form above and extend toward the base, passing through the node, or point of insertion of the leaf primordium, and into the stem below. As the leaf extends in length, the tissues begin to mature first at the tip, and a wave of differentiation passes down toward the base, where cell division and extension growth may continue long after the tip of the leaf is mature. Protection for this immature and succulent tissue of the leaf base is afforded by the sheaths of older leaves surrounding it.

These examples illustrate the principles involved in leaf development, but there are many deviations associated with variations in leaf form. Lobing and toothiness result from the persistence of cell division and growth in particular stretches of the margin after growth ceases in between. Carried to the extreme, this localized growth gives the feather-like pinnate leaf. Many monocotyledons form cylindrical leaves as a result of a fusion of the margins of the primordium after it has encircled the stem.

**Branching of the shoot.** The shoots of most vascular plants branch according to a consistent plan, with each new axis arising in the angle between a leaf and a stem—that is, in a leaf axil. In some plants, buds may also form from the older parts of shoot or root remote from the main apices; these buds, termed adventitious, do not conform to the general plan.

A lateral shoot apex is initiated on the flanks of the main apex but at some distance below the point of emergence of the youngest leaf primordium. As in the origin of a leaf, generally the outer cell layers contribute to the surface tissues of the new apex by maintaining a consistent pattern of divisions. In some species a tunica of more than one cell layer quickly forms, so that the new apex appears as a miniature version of the main one; alternatively, the differentiation may not become apparent until the new primordium has attained considerable bulk. In all cases, the new apex must reach a minimal volume before it in turn can begin to form its own lateral primordia and to organize true axillary buds. As this volume is attained, *meristème d'attente-anneau initial* zonation appears. As in the main apex, the formation of new primordia is associated with the annular zone.

From this point on, the development of the lateral shoot is the same as that of the main shoot, except that growth may not be as rapid because the main apex, or leading bud, dominates and absorbs much of the available nutrient. The early growth of the axillary bud proceeds quite vigorously until a certain number of leaf primordia has been formed; then apical activity slows. Cell division gradually stops, and with it the associated syntheses; thus there is no increase in the DNA of the nuclei of the meristem after the last division. The bud, in effect, passes into a state of dormancy, even though the external conditions for growth are propitious. This phenomenon is known as correlative bud inhibition, since it is determined by the activity of the leading bud of the shoot. If the leading bud is removed, the inhibited lateral buds resume growth, and with it the associated syntheses.

**Vascular development.** Cell division planes in the zone just below the apex of the shoot tend to be oriented so that vertical files of cells are formed. This is more evident in the central core than in the surrounding cortical region, for the pattern is not disturbed by the insertion of

Variations in leaves

The  
"cylinder"  
of vessels

lateral members. The first signs of the differentiation of the vascular system appear some distance below the apex, in a zone of tissue distinguishable by the smaller cross-sectional area of individual cells. These cells, forming the procambium zone, arise by divisions oriented at right angles to the axis and may form a complete cylinder; generally, however, interruptions occur, the segments being related to the uppermost leaf primordia. In a dicotyledon such as tobacco, the cylinder at its highest level consists of strands running upward toward the points of insertion of the primordia. Thus, as the site of each primordium is determined, a strand forming in the adjacent region of the stem will contribute to the cylinder, but at a higher level than the preceding strand. The link with the earlier formed procambium is not simple, however. The strand passing upward toward a leaf primordium usually is composed of branches arising from strands that enter the two nearest older leaves below it. Because it in turn will contribute a branch for the next leaf, the cylinder is really a hollow network, the "gaps," or leaf traces, marking the points of departure of the leaf veins.

During subsequent development, the strands, or vascular bundles, increase in thickness by further cell divisions, and connections form with the vascular systems of axillary buds. The cells differentiate to give the characteristic tissues of the vascular system: phloem vessels (conducting tissue), phloem parenchyma (packing tissue), and phloem fibres (supporting tissue) toward the outside and xylem vessels (woody conducting tissue) toward the inside. The differentiation occurs in an upward direction, so that the maturation of the vascular tissues follows at a more or less constant distance behind the apex.

Although details differ, the above account of the origin of the primary vascular system is broadly applicable to gymnosperms and many ferns. Vascular development differs somewhat in certain flowering plants. In many monocotyledons, such as maize, the several vascular strands that pass down from each leaf primordium into the stem do not contribute to a single cylinder but are scattered in the ground tissue, or parenchyma, of the stem. Lateral interconnections form principally at the nodes.

Increase in stem diameter is accomplished in the older stems of dicotyledons by the activity of the cambium, which produces secondary vascular tissue. This meristem, a relic of the procambium, is composed of thin-walled cells, is flattened in the radial plane, and persists between primary vascular tissue, the differentiated outer phloem, and the inner xylem. When secondary thickening begins, the parenchymatous cells between the vascular bundles also resume division, ultimately forming a cambium cylinder. The cells of the cambium divide, producing initial phloem cells toward the outside and initial xylem cells within. Files of cells are also cut off among the initial phloem and xylem cells that remain parenchymatous and are called phloem and xylem rays.

As in the apical meristem, the number of dividing cells in the cambium remains constant, except that more cells occasionally are added by divisions in the radial plane so that the girth of the cambial cylinder expands in pace with the growth of the xylem within. The addition of new phloem toward the outside compresses the primary phloem and the cortical tissues in a radial direction while stretching them tangentially. These primary tissues do not persist, however. As the girth of the stem increases, the epidermis is disrupted, and the outer layers of the cortex become meristematic, giving rise to the cork cambium, which generates cork cells on the outside. The cork layer, or bark, then takes over the protective function of the epidermis.

#### THE ROOT SYSTEM AND ITS DERIVATIVES

**The root tip.** Plants that have a single apical cell in the shoot also have a single apical cell in the root. The cell is again tetrahedral, but sometimes daughter cells are cut off from all four faces, with the face directed away from the axis producing the cells of the root cap. The cells derived from the other faces continue to divide mostly by forming transverse walls, but occasionally al-

so in the longitudinal plane. In this way vertical columns of cells form—tending, because of their mode of origin, to be disposed in three sectors.

In the roots of gymnosperms, angiosperms, and some lower plants, there is no single apical cell. Again, as with the shoot, such root apices can be analyzed in different ways. Perhaps the most useful approach is based upon tracing the sources of the main tissues in the apical region. Such an analysis has led to the histogen theory, which proposes that the three principal tissues of the root—vascular cylinder, cortex, and epidermis—originate from three groups of initial cells, or histogens, in the apical meristem—plerome, periblem, and dermatogen respectively. A fourth histogen, the calyptragen, produces the root cap. The histogens have been thought to lie in linear order in the apex, with the initial cells of the vascular system toward the older part of the root, and those of the cap toward the tip.

The histogen theory is difficult to apply to some types of roots, and there has been uncertainty about the numbers of histogens. The discovery of the "quiescent centre" in the root apex has clarified many features, however. The quiescent centre is a group of cells, up to 1,000 in number, in the form of a hemisphere, with the flat face toward the root tip; it lies at the centre of the meristem, in much the same position, in fact, as the tetrahedral apical cell in certain lower plants (Figure 6). The

The  
histogen  
theory of  
root-tissue  
origin

Figure 6: Median section of root apex of *Zea mays*.

cells of the quiescent centre are unusual in that their division rate is lower than that in the surrounding meristem. The cells of the centre have other distinctive features as well, notably a lower rate of protein synthesis than that of neighbouring cells.

The quiescent centre is surrounded by actively dividing cells of the promeristem that are the initial cells of the various tissues of the root. Those abutting the flat, tip-directed face contribute to the root cap; those above the quiescent centre are distributed in a cup shape. The cells in the centre of the cup produce the procambium and so, ultimately, give rise to the vascular cylinder. The annular zone of cells surrounding this central group forms the initials of the cortex; surrounding this, in turn, a ring of initial cells forms the protoderm, the layer corresponding to the epidermis at this level of the root.

The quiescent centre, a constant feature of the root tip, is apparently generally present in angiosperms and prob-

ably also in gymnosperms. The quiescent centre probably plays a role comparable with that of the apical cell in some lower plant roots, maintaining the geometry of the system. It has also been suggested that it may be concerned with the synthesis of growth hormones, although no direct evidence exists. When roots are damaged mechanically or by radiation, the cells of the centre can resume a rapid division rate, and they then participate in regeneration.

The zone of cell division extends some distance along the length of the root above the tip region. Although the girth may increase by longitudinal divisions and the widening of the daughter cells, most divisions occur in the transverse plane resulting in the formation of longitudinal files of cells.

In longitudinal section, the tissue zones become progressively better defined away from the tip. An internal protective band, the endodermis, becomes conspicuous as a single sheath of cells, surrounding the procambium. The phloem procambium, recognizable by its narrow cells, begins to differentiate in the lower part of the region of elongation. The xylem also becomes distinct, the thickenings appearing first in the upper part of the extension zone. Differentiation keeps pace with the advance of the root tip as new cells are added in the promeristem. When xylem occupies the core, there is no pith as in the shoot, but the cells of the outermost layers of the vascular cylinder remain undifferentiated, forming the pericycle, a tissue important in the formation of lateral roots. Within the bounds of the pericycle, the xylem is star-shaped in section, with the first-formed xylem elements (proto-xylem) occupying the ridges. The phloem lies in the intervening grooves. Outside of the endodermis, the cortical cells elongate but remain thin-walled. Above the level of the root-cap sheath, the epidermis forms the outer layer of the root, and, beyond the extension zone, its cells begin to develop root hairs.

A more complete account can be given for the mechanics of development of the root apex than for that of the stem, mainly because of its greater simplicity. An important difference lies in the absence of a mechanism for the cyclical production of lateral organs at the apex itself.

**Branching of the root.** The branching of the root takes place in the older parts and does not directly involve the apical meristem. The tissues concerned are the endodermis and the layer immediately beneath it, the pericycle. The endodermis participates in root branching in certain lower plants with apical cells. A cell of this layer enlarges and forms a tetrahedral cell, which becomes the new apical cell; by further divisions a hemispherical volume of tissue forms around it—the whole constituting a new apex.

In many other plants, including gymnosperms and angiosperms, the lateral roots develop from the pericycle. Cells in this layer enlarge and begin to divide until a dome of tissue develops. Called the incipient apex, the dome pushes out the surrounding endodermis, which may itself resume divisions, its daughter cells enlarging to create a sheath around the new root tip. During further growth, the dome assumes an organization like that of the primary root apex. At first, all cells are **meristematic**; then, while the primordium is still small, cells in the central zone cease DNA synthesis, and this zone becomes the new quiescent centre. Beyond it, the root cap is produced, and, at the base, initial cells begin to develop the cell files that become the vascular cylinder, cortex, and epidermis. The vascular tissues differentiate from the base outward, and link eventually with xylem and phloem of the parent root. All this development occurs before the tip of the new root emerges from the tissues of the parent root. The growth of the new tip into the cortex first pushes out the endodermal sheath, if one is present, and then bursts it. The cortical cells are themselves crushed and probably resorbed as the root grows on, until finally the tip breaks through the epidermis.

In most roots, new laterals are initiated in the pericycle opposite to the protoxylem ridges. They tend accordingly to form vertical ranks along the length of the root, re-

flecting the number of bands of protoxylem. Although lateral roots arise in quite a different way from leaves and axillary shoots at the stem apex, there are certain common features. Pericycle cells about to produce a root primordium synthesize ribonucleic acid, in anticipation of the period of growth and morphogenesis that will result in a new apex. The same behavior is seen in the cells of the annular zone, from which leaf primordia arise at the stem apex, and also in the axillary zones at a slightly lower level, from which new stem apices develop.

**Later growth.** In the secondary growth of the root, cell division in the primary xylem produces a cambium, which abuts the pericycle over the protoxylem ridges and passes between the phloem strands and the xylem in the grooves. Activity of the root cambium is comparable with that of the stem cambium; phloem elements are cut off outward, and xylem elements are cut off within. With continued growth in thickness, the star-shaped figure of the primary xylem is lost, and the cambium eventually forms a cylindrical sheath. Again, as in the stem, the protective function of the epidermis is ultimately taken over by cork layers produced by a cork cambium in the outer cortex.

#### IV. Correlations in plant development

##### COORDINATION OF SHOOT AND ROOT DEVELOPMENT

Although the structural organization of the vascular plant is comparatively loose, development of the various parts is well coordinated. Control is dependent upon the movement of chemical substances, including both nutrients and hormones.

An example of correlation is the growth of shoot and root. The enlargement of aerial parts is accompanied by increased demands for water, minerals, and mechanical support that are met by coordinated growth of the root system. Several factors apparently are concerned with control, because shoot and root affect each other reciprocally. The root depends on the shoot for organic nutrients, just as the shoot depends on the root for water and inorganic nutrients and the flow of ordinary nutrients must, therefore, play some part. More specific control, however, may be provided by the supply of nutrients required in very small amounts. The root depends on the shoot for certain vitamins, and variation in the supply, reflecting the metabolic state of the aerial parts, may also influence root growth. In addition, hormonal factors affecting cell division pass upward from the root into the stem; although the exact role of the hormones has not yet been established with certainty, they may provide one way by which the root system can influence the activity of the shoot apex.

The control of secondary thickening is another important example of growth correlation. As the size of the shoot system increases, the need for both greater mechanical support and increased transport of water, minerals, and manufactured food is met by an increase in stem girth through the activity of the vascular cambium. Generally, the cambium of trees in temperate zones is most active in the spring, when buds open and shoots extend, creating a demand for nutrients. Cell division begins near the bud in each shoot and then spreads away from it. The terminal bud stimulates the cambium to divide rapidly through the action of two groups of hormones: auxins and gibberellins.

The inhibition of lateral buds, another example of correlated growth response, illustrates a reaction opposite to that occurring in the control of cambial activity. Lateral buds are inhibited in general because axillary shoots grow more slowly or not at all, while the terminal bud is active. This so-called apical dominance is responsible for the characteristic single trunk growth seen in many conifers and in herbaceous plants such as the hollyhock. Weaker dominance results in a bushy growth form with repeated branching. The fact that lateral, or axillary, buds become more active when the terminal bud is removed suggests that hormonal control is involved.

The flow of auxin from the shoot tip is, in part, responsible for inhibiting axillary buds. The nutritional status of the plant also plays a role, apical dominance being

Meeting demands for food and support

Generation of lateral roots

strongest when mineral supply and light are inadequate. Because axillary buds are released from inhibition when treated with cell-division promoting substances (cytokinins), it has been suggested that these substances are also concerned in regulating axillary-bud activity.

#### DETERMINATION OF MATURE FORM

After its establishment as an independent plant, the sporophyte passes through a juvenile period before reaching maturity and becoming reproductive. Juvenility may be brief or, as in the case of trees, may extend over several years. The duration is determined partly by internal factors and partly by environmental controls related to the seasons.

In some ways juvenility is a continuation of developmental trends initiated in the embryo. In many plants, new organs are produced sequentially through early life, each of progressively more mature form. The first leaf of the young fern sporophyte, for example, is small and relatively simple, and the vascular system consists of a few forked strands. As growth proceeds, succeeding new leaves are of increasing complexity, and the shape begins to resemble that typical of the reproductive frond; in addition, vasculature shifts to the mature pattern, often one with a network of veins. Comparable trends occur in flowering plants, in which leaves at successive levels of plant maturity often show a progressive increase in the complexity of lobing or toothiness.

Some of the changes associated with the juvenile period can be attributed to the gradual enlargement of the growing point, necessarily small in the embryo; its volume increases progressively with development. This increase in cell number is usually associated with the emergence of a "mature" zonation pattern. The typical internal structure of the shoot apex does not develop until a specific number of leaves form.

Gradual structural change in the growing point, however, does not adequately account for all aspects of juvenility. Sometimes, the transition from juvenile to adult leaf form is not graded but sudden. The juvenile leaves of species of the gymnosperm *Chamaecyparis*, for example, are needlelike and spreading; the adult leaves are scalelike and lie close to the stem. Among flowering plants, various species of *Eucalyptus* have juvenile leaves that are ovate and mature leaves that are sickle-shaped.

Such sudden transitions from juvenile to adult form, referred to as phase change, seem to depend not on slow shifts in the apex but on some determinative event or correlated group of events. The two forms are relatively stable and tend to resist change; for example, cultured tissues taken from the juvenile (ivy-leaved) parts of ivy plants maintain a higher rate of cell division, and portions, or cuttings, taken from these parts tend to form roots more readily than those from the adult (simple-leaved) parts.

The establishment of these relatively stable but not wholly irreversible states is comparable with the determination of shoot and root poles during embryogenesis and, indeed, with the alternation of generations itself. The transmission of differentiated states through cell lineages presumably reflects the action of "switching" devices controlling the expression of different parts of the genetic complement. In this sense, phase change and related phenomena do not differ essentially from those of differentiation and organogenesis in general.

The transition in plants to the reproductive state is an example of a developmental event with some of the characteristics of phase change. Among seed plants, the reproductive structures are transformed shoots—strobili (including cones) of various kinds in the gymnosperms and flowers in angiosperms.

From a developmental point of view, the flower can be regarded as a shoot axis of determinate growth, with the lateral members occupying the sites of leaves differentiating as floral organs—sepals, petals, stamens, and pistils. In the transition to flowering, the stem apex undergoes distinctive changes, the most conspicuous of which is in the shape of the apical region, which is related to the kind of structure to be formed, whether a single

flower, as in the tulip, or a cluster of flowers (an inflorescence), as in the lilac. The region of cell division extends over the entire apex, and the ribonucleic acid content of terminal cells increases. When a single flower forms, lateral primordia emerge at higher and higher levels on the flanks of the apical dome, and the entire apex is absorbed in the process, after which apical growth ceases. When an inflorescence forms, early changes are generally comparable to that for the single flower with one major difference—axillary primordia emerge that either become floral meristems or develop as secondary inflorescence branches. These primordia appear closer to the apex than do those of axillary buds on a vegetative shoot. In grasses, the activation of axillary meristems is the most notable early indication of the passage into flowering.

The rate of maturation and the timing of the transition to the reproductive phase are sometimes governed by internal controls and thus are relatively insensitive to the environment, provided conditions are generally favourable for growth. Frequently, however, the developmental rate is affected profoundly by recurring cycles in the environment, particularly those of temperature and of day length. In effect, these cycles provide a timetable for the plant, thus adjusting flowering, fruiting, and seed dispersal to the season and increasing the chances for successful propagation.

The control of the developmental rate by temperature is especially evident in many herbaceous plants of temperate climates. These plants, as indicated earlier, often must experience cold, either as seeds or as young plants, before they can begin flower production; otherwise they undergo an excessively long period of leafy, or vegetative, growth. After the cold experience, which can be given artificially, the plant is said to have been vernalized, or brought to the spring condition. Again the response is akin to a determination, because the condition attained is transmitted through subsequent cell divisions. Furthermore, there are indications that vernalization induces a persistent modification in the metabolism of apical cells and their derivatives. Ingenious theoretical schemes, offered to explain the apparent paradox that low temperature should actually accelerate a developmental process, are based mostly upon the proposition that a special vernalization hormone (vernalin) is involved. Although little direct evidence for the existence of vernalin exists, a class of hormones found in certain plant species, the gibberellins, does participate. The cold requirements of some species, such as the carrot, can be eliminated by the application of gibberellin, although the amounts needed are substantial.

The annual cycle of changing day length obviously provides the best of all "clocks" for the regulation of plant development. The effect of day length (or rather length of continuous darkness) on the transition to flowering is part of the general phenomenon of photoperiodism. Certain plants, called short-day plants, grow vegetatively when the nights are shorter than a critical minimum period (days long); exposure to longer nights (days short), however, accelerates development and brings on early flowering. Conversely, long-day plants develop very slowly toward flowering during daily cycles with longer than a minimum of darkness (days short), and are accelerated by exposure to short nights (days long). Other plants either require days of intermediate length for flowering or respond to a sequence of different photoperiods.

The leaf, rather than the stem apex, is the light-receiving organ in the photoperiodic reaction, although it is at the apex that subsequent developmental changes occur. One commonly accepted view is that, as a consequence of the photoperiodic experience, a specific flower-inducing hormone (as yet not isolated but referred to as "florigen") is synthesized in the leaf and translocated to the apex. As in the case of vernalization, photoperiod undoubtedly affects the metabolism of the known plant hormones, and so influences many other developmental responses apart from flowering. The effect of the duration of illumination on the carbohydrate balance of the plant may also be important. Nutritional effects on flowering

The duration of a juvenile phase

Phase change

Vernalization of the seed

Photoperiod as a trigger for flowering

are well-known in many species — certain fruit trees, for example.

Whether or not environmental factors influence the passage into a reproductive state of a plant, the transition must be looked upon as part of the general developmental trend from juvenility to maturity: in this sense, flowering does not represent a radical alternative to vegetative growth but merely its culmination. Yet, entirely new organ types are produced at the flowering apex, presumably under the influence of genes that are not active during vegetative growth.

#### SEASONAL ADAPTATIONS

Certain plants are perennial and survive from year to year by matching their growth to the progression of the seasons or by suspending growth altogether during unfavourable times, such as winter or a dry season.

Response  
to an ap-  
proaching  
unfavour-  
able season

In the temperate zone, some time before winter begins, growth ceases in the shoots of woody plants, resting buds are formed, and deciduous trees lose their leaves. The resting bud consists of short axis, with the stem apex surrounded by modified unexpanded leaves, which protect the stem, especially from drying. The cells show marked frost resistance, similar to that of the embryo of the seed. Corresponding changes occur in herbaceous plants, in which the preparation for winter may involve the dying back of aerial parts altogether, leaving protected organs at or below the soil surface.

Growth sometimes ceases, even under favourable conditions, as a result of internal changes in the plant. This is true for some trees, which cease growth in midsummer. The passage into winter dormancy, however, is often controlled by the shortening of day length at the end of the growing season; in some plants decreasing night temperature also plays a part. Most temperate zone trees cease growth and form resting buds when the day length falls below a critical minimum.

Photoperiodic control seems to involve the formation of inhibitor compounds. In birches, for example, the leaf perceives the day length "signal" and transmits inhibitory materials to the apex, thus bringing growth to a stop and inducing the formation of a resting bud. The dormancy hormone, abscisic acid, may be concerned in this response and also in leaf abscission.

Budbreak in certain trees is controlled by photoperiod, growth resuming in the lengthening days of spring; light-perceptive organs are probably the young leaves inside the bud scales. Sometimes budbreak depends only on temperature increases that occur in spring, as in certain plants of Mediterranean climates.

The resumption of development in buds may result from a change in the balance of growth-inhibiting substances, such as abscisic acid, and growth promoters, notably the gibberellins. Buds can be caused to open prematurely by gibberellin treatment, which, as in the case of vernalization, can sometimes replace a cold experience; moreover, the gibberellin content in the buds of certain woody plants increases during chilling. Other hormones are probably also involved, however, for budbreak in plants such as the grapevine can be promoted by cytokinins, the plant cell-division factors.

An important general feature of adaptive periodicities is that the developmental changes anticipate the conditions for which they will ultimately provide the appropriate physiological or morphological adjustment. The ability of plants to utilize environmental indicators such as temperature and day-length changes is vital for the survival of plants. The production of such adaptive devices is made possible by the state of continuous embryogeny, already stressed as one of the most important characteristics of plant growth.

#### SENESCENCE AND DEATH

The growth of the vascular plant depends upon the activity of meristems, which are, in a sense, always embryonic. Continued indefinitely, this mode of growth could mean immortality; indeed, the longest lived individual organisms ever to have existed on earth have been certain species of trees. Plants and plant parts, however, do die,

and death is often not the consequence of accident or environmental stress but of physiological decline—aging, or senescence.

Various kinds of physiological senescence and death occur and may affect particular cells, tissues, organs, or the whole plant. In the formation of the vessels of the xylem, cells conclude their differentiation by dying and contribute their empty walls to the conducting tissue. Individual organs such as leaves usually have a limited life-span. Entire shoot systems may gradually die back in the aerial parts of perennial plants, which overwinter underground. And, finally, the whole plant may die after a limited period of growth and the completion of reproduction. This behaviour is found in many annual plants, which complete their life cycle in a single growing season. The life-span may extend to two years, as in biennial plants, or longer, as in banana and certain bamboos, which die after flowering and fruiting.

In the examples cited above, the death of cells, organs, or individual plants appears to be "programmed" and, in some sense, adaptive. This is clearly so with the death of individual cells during differentiation, when residual products contribute to the effective function of the entire plant body. The death of leaves and of shoot systems is part of the plant's adaptation to the cycle of the seasons. In annual species, the death of the whole individual may be viewed in a similar way. The succession of generations in this case is carried on by seeds; the sacrifice of the parent plant may, in fact, contribute to the success of the seedling by making available to the seed a pool of reserves derived from the breakdown of parent tissues.

Certain features characterize the onset of senescence. The cells show degenerative changes often associated with the accumulation of breakdown products. Metabolic changes accompany the degeneration. Respiration may increase for a period, but the rate ultimately declines as the cellular apparatus degenerates. Synthesis of proteins and nucleic acids ceases, and, in some instances, disintegration of cells has been associated with the release of enzymes through the disruption of membrane-bounded bodies called lysosomes.

The death of individual cells in tissues such as the xylem appears to be governed by internal factors, but senescence often depends upon interaction of tissues and organs. The presence of young developing leaves often accelerates the aging of older leaves; removal of the younger leaves retards the senescence of the older ones, suggesting control by competition for nutrients. A similar effect is seen in annual plants, in which the development of fruits and seeds is associated with the senescence and, ultimately, the death of the rest of the plant; the removal of reproductive structures slows the rate of aging. In these instances competition obviously has some effect, but it does not sufficiently explain why older, mature organs suffer in competition with those still in active development. The link may lie partly in the capacity of developing organs to draw nutrients to themselves, even from older parts of the plant. Developing organs thus provide "sinks" toward which nutrients tend to move. The senescence of organs drained in this way could result from the progressive loss of certain key constituents; should leaf viretine, for example, turn over by breakdown of proteins to their amino-acid constituents and then be resynthesized, a steady drain of amino acids from the leaf would progressively deplete the proteins in the leaf.

"Sinks" can be only part of the explanation, however, for in detached leaves of plants such as tobacco, protein synthesis decreases, and protein content falls, while the amino-acid content actually rises. Senescence in such instances can hardly depend on the withdrawal of nutrients. Furthermore, leaf senescence can be retarded locally by the application of cytokinins, hormones that stimulate plant cell division. Parallel effects have been demonstrated with growth substances of the auxin type in other plant systems. In the same way that active buds and fruits form sinks for nutrients from elsewhere in the plant, a cytokinin-treated area of a leaf attracts nutrients from other parts of the leaf. Although the metabolism of isolated leaves may differ in many respects from

Pro-  
grammed  
death of  
plant cells

Nutritional  
"sinks"

Daily  
length of  
darkness

that of attached leaves, leaf senescence probably does not result only from nutrient drainage but also from the synthetic activity of leaf tissues, which may be under-hormonal control from other parts of the plant. The root may be important, for roots are known to export cytokinins to the shoot.

Environmental factors, primarily photoperiod (daily length of darkness) and temperature, play important parts in governing senescence and death in plants. In annual plants, death is the natural conclusion of development; thus, conditions accelerating development automatically advance senescence. This is readily seen in short-day plants, in which precocious reproduction upon exposure to long dark periods is followed by early death. Senescence may be retarded in these cases, however, by hormonal treatments of the kind known to delay degeneration and death in detached leaves. Competition for nutrients between vegetative and reproductive structures cannot be the primary cause of death, for, in species such as hemp, the male plants—which do not produce seeds—die earlier than the females under short-day (long-night) conditions.

In perennial plants, leaf fall is associated with approaching winter dormancy. In many trees leaf senescence is brought about by declining day length and falling temperature toward the end of the growing season. Chlorophyll, the green pigment in plants, is lost; yellow and orange pigments called carotenoids become more conspicuous; and, in some species, anthocyanin pigments accumulate. These changes are responsible for the autumn colours of leaves. There are some indications that day length may control leaf senescence in deciduous trees through its effect on hormone metabolism, for both gibberellins and auxins have been shown to retard leaf fall and to preserve the greenness of leaves under the short-day conditions of autumn.

From the foregoing it may be seen that senescence and death are important in the general economy of plants. The paradox that death contributes to survival is resolved when it is understood that the death of the part contributes to the better adaptation of the whole—whether organ, individual, or species. Viewed in this way, death is no more than another—albeit the ultimate—manifestation of development.

**BIBLIOGRAPHY.** Developmental topics were taken up in many older botanical works, and special mention may be made of KARL COEBEL, *Organographie der Pflanzen*, 2 pt. (1898–1901; Eng. trans., *Organography of Plants*, 1900–05). Several modern texts on plant anatomy and morphology deal descriptively with development, including A.S. FOSTER and E.M. GIFFORD, *Comparative Morphology of Vascular Plants* (1959); K. ESAU, *Anatomy of Seed Plants* (1960) and *Plant Anatomy*, 2nd ed. (1965); and ABRAHAM FAHN, *Plant Anatomy* (1967; orig. pub. in Hebrew, 1962). For cryptogams, general surveys of development appear in G.M. SMITH, *Cryptogamic Botany*, 2nd ed., vol. 1, *Algae and Fungi*, and vol. 2, *Bryophytes and Pteridophytes* (1955).

Morphogenesis in plant development is treated in E.W. SINNOTT, *Plant Morphogenesis* (1960); and C.W. WARDLAW, *Morphogenesis in Plants* (1968). Many recent books are devoted to physiological and biochemical aspects. Introductory treatments are provided by A.C. LEOPOLD, *Plant Growth and Development* (1964); J.G. TORREY, *Development in Flowering Plants* (1967); and P.F. WAREING and I.D.J. PHILLIPS, *The Control of Growth and Differentiation in Plants* (1970). More advanced coverage of certain parts of the subject may be found in F.C. STEWARD, *Growth and Organization in Plants* (1968); W.M. LAETSCH and R.E. CLELAND (eds.), *Papers on Plant Growth and Development* (1967); and M.B. WILKINS (ed.), *The Physiology of Plant Growth and Development* (1969).

Many important topics in plant development are best approached through specialized monographs. The following are recommended: PANCHANAN MAHESHWARI, *An Introduction to the Embryology of Angiosperms* (1950); L.J. AUDUS, *Plant Growth Substances*, 2nd ed. (1959); F.A.L. CLOWES, *Apical Meristems* (1961); and W.S. HILLMAN, *The Physiology of Flowering* (1962). Sections are devoted to development and differentiation in each volume of the *Annual Review of Plant Physiology* (1950– ). The articles are advanced and require background knowledge for proper appreciation.

(J.H.-H.)

## Devonian Period

The Devonian Period is a time interval of the Paleozoic Era during which rocks of the Devonian System were formed (345,000,000 to 395,000,000 years ago). Rocks of Devonian age are known on all continents. The rocks show evidence of the earliest widespread continental and desert conditions, as in the Old Red Sandstone areas of Europe, for example, but marine deposits typically are more widespread. Sediments of this period contain the earliest abundant remains of vascular plants and of fishes of bizarre types, and four-footed vertebrates or tetrapods are contained in Late Devonian rocks. Insects are first known in the Devonian, and other invertebrates are abundant and varied. Devonian rocks crop out over wide areas and are locally of considerable economic importance in the production of building stone, cement rock, refractory and building brick, roof slate, glass sand, abrasives, and rock salt.

Sedimentary iron ore, particularly in Germany, formerly was of great importance. Lodes of tin, zinc, and copper occur in Devonian rocks. These deposits formerly were of considerable economic importance in Devon and Cornwall and were responsible for bringing trade in the Bronze Age. These deposits also later attracted the Phoenicians and Romans. Oil and gas have been produced for many years from Devonian rocks in New York and Pennsylvania.

Recently, more spectacular discoveries have been made. In 1944 oil was found in Middle and Upper Devonian sandstones in the Ural-Volga region of the U.S.S.R., and this area is the most important oil-producing area in the U.S.S.R. at present. In 1947 oil was discovered in an Upper Devonian reef at Leduc, Alberta, and this was followed by vigorous exploration. Ten years later Alberta accounted for over 95 percent of the Canadian output of crude petroleum.

Another spectacular discovery was that of the concealed Middle Devonian evaporites, anhydrite and halite, located in southern Saskatchewan. These were estimated to contain potash reserves that would last for eight centuries at current rates of consumption. Extraction there is of growing importance.

This article treats the rocks, life, and environment of the Devonian Period. For information on conditions before and after Devonian time, see SILURIAN PERIOD and CARBONIFEROUS PERIOD, LOWER. See also PALEOZOIC ERA, UPPER for an overview and STRATIGRAPHIC BOUNDARIES and FOSSIL RECORD for general, informative discussions of topics that are relevant to Devonian stratigraphy and paleontology.

### DEVONIAN STANDARD SECTION

The Devonian Period was first named in 1839 by Adam Sedgwick and Sir Roderick Impey Murchison following studies in Devon and Cornwall in southwestern England. In Wales and in Scotland, deposits called the Old Red Sandstone composed of land and lake sediments had long been known between the Silurian System below and the Lower Carboniferous (Mississippian) System above. As a result of studies of fossil corals from Devon, William Lonsdale first suggested that the Devon and Cornish rocks might be the marine equivalents of the Old Red Sandstone to the north, and it was largely on this evidence that Sedgwick and Murchison proposed the Devonian System. Although recently much better understood, the rocks of Devon were for many years much more poorly known than the extremely fossiliferous and little disturbed Devonian rocks in the Ardennes in Belgium and the Eifel and Rheinisches Schiefergebirge areas in Germany.

In practice, these areas have become the world standard and have provided the names of the stages that form the subdivisions of the period. James Hall, in 1843, published a monumental account of the Devonian equivalents in New York State, which form the North American standard. The standard series of stages for the Devonian System is as follows:

Upper Devonian	Famennian (named from Famennes, Belgium) Frasnian (named from Frasnies, Belgium)
Middle Devonian	Givetian (named from Givet, N. France) Eifelian (named from Eifel, Germany)
Lower Devonian	Emsian (named from Ems, Germany) Siegenian (named from Siegen, Germany) Gedinnian (named from Gedinne, Belgium)

Among French-speaking geologists the stage name *Couvinian* (from Couvin in Belgium) is often used in place of Eifelian, although the lower boundary is within the upper Emsian of the German usage. The term "Coblentzian" was in use formerly and comprised the Siegenian and Emsian stages combined. As is usual, this type sequence is completely in marine rocks that consist mostly of limestones, sandstones, and shales.

Stratigraphic boundaries within the Devonian System are defined and correlated using various fossil groups. Within the Devonian the ammonoids, conodonts, brachiopods, and corals are particularly useful, and in non-marine deposits fish and spores are used. There has been great difficulty in correlating the Silurian-Devonian boundary and until recently substantial errors were made, related to the erroneous supposition that graptolites became extinct at the boundary; they are now known to range well up into the Devonian. The graptolite zone of *Monograptus uniformis* is by international agreement taken as the base. The top of the system, by international agreement, is taken at the base of the ammonoid cephalopod *Gattendorfia* zone.

Radiometric evidence suggests this time interval began about 400,000,000 years ago and ended about 350,000,000 years ago. Convincing evidence for assigning precise dates has not yet been established, but two recent estimates give the beginning as  $413,000,000 \pm 5,000,000$  years and the close at  $362,000,000 \pm 6,000,000$  years. In practice, the evolution of fossil groups is used to subdivide and correlate rocks of the Devonian System; although this scale gives relative time only, precision in correlation is to an accuracy of about 1,000,000 years in some parts of the period.

#### DEVONIAN ROCKS

It generally is considered that Europe and North America were much closer together during the Devonian Period and probably were united approximately along the

present continental slope margins (see CONTINENTAL DRIFT). At the close of the Silurian, and continuing in the Lower Devonian, considerable igneous activity occurred in the belt including New England, Nova Scotia, Newfoundland, Scotland, Scandinavia, and eastern Greenland. With North America and Europe united as described, the belt thus indicated formed a mountain tract of active uplift. This is the Caledonian mountain belt resulting from the Caledonian orogeny. The deposits of the Old Red Sandstones appear to be the detritus resulting from erosion of these mountain areas. The marine Devonian rocks of western Canada and those in a belt from Montana to New York in North America, in Europe from Devon to the Holy Cross Mountains of Poland, on the Russian Platform and Novaya Zemlya, and, again, in the Arctic islands of Canada appear to provide evidence that marine waters encircled the Old Red Sandstone continent.

To the south, the supposed union of the southern continents in the Devonian formed the area called **Gondwanaland**; this provided another land area, comprising parts of present continental South America, Africa, the Antarctic, India, and Australia. The evidence regarding the distribution of terrestrial rocks here is far less clear than in the Northern Hemisphere and, apart from the Early Devonian, the marine record is also poor. Other significant land areas were in central Siberia and northern China.

The accompanying world map (Figure 1) shows the distribution of most of the major outcrops of Devonian rocks. In many areas the Devonian rocks have been much disturbed tectonically by subsequent deformation. These fold belts may be distinguished from cratonic areas where sediments remain much as they were when formed. The main fold belts in North America are the western Cordillera and Rocky Mountains and eastern Appalachian belts. In contrast, the Devonian of the Midwest and adjoining areas is flat lying. In South America, the main fold belt is the Andes and sub-Andes, and east of this line the Devonian rocks are little disturbed. In Australia the main fold belt is in the east from Queensland to Tasmania. In Europe the Armorican fold belt stretches eastward from Cornwall and Brittany. To the south of this line from the Pyrenees to Malaysia, Devonian rocks are caught up in the Alpine-Himalayan fold belt. Similarly, the Devonian of the Urals of the U.S.S.R. is disturbed, whereas to the west, on the Russian Platform, and to the east there is less deformation. In all these cases the folding occurred well after the Devonian, but there

Absolute  
age of  
rocks

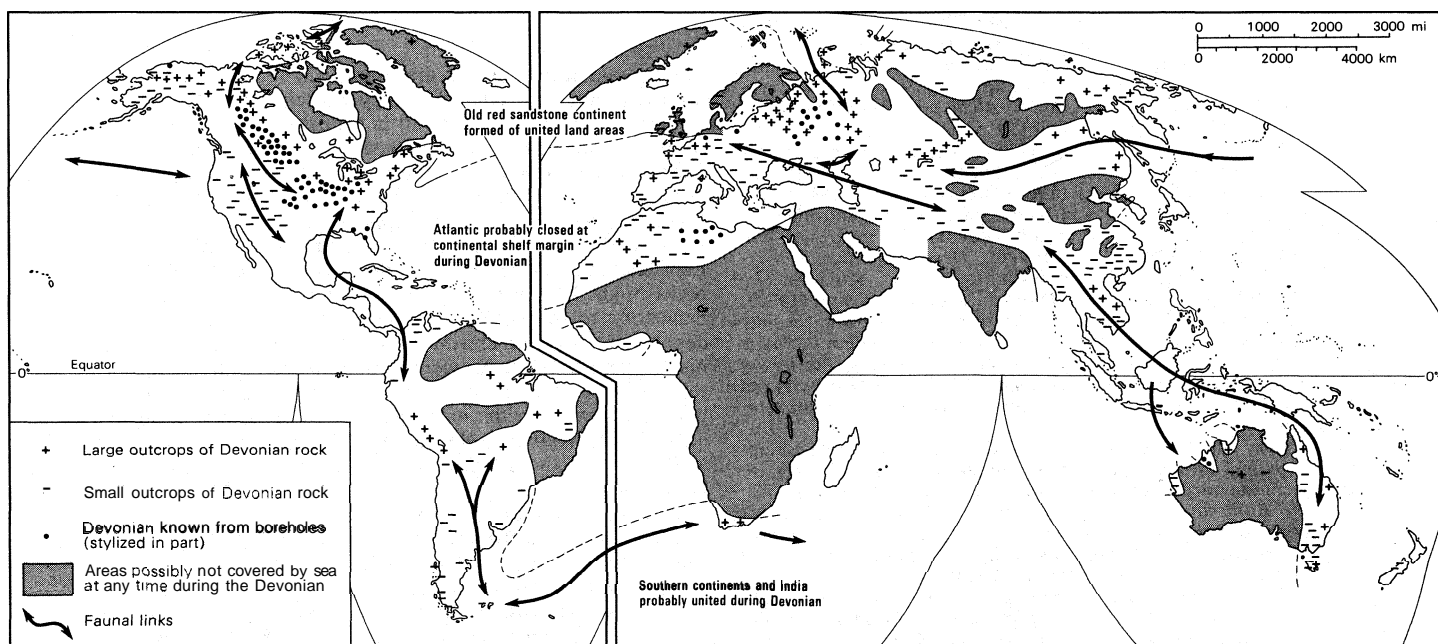

Figure 1: Devonian outcrops, inferred land areas, and faunal links.

is evidence that Devonian sedimentation contributed to the geosynclinal belts that were sites of the later mountain building.

In the regions that have suffered severe deformation, the Devonian sediments are frequently metamorphosed into slates and schists and often lose all the characters by which they may be dated. In areas where little change has taken place, all rock lithologies occur, from those characteristic of continental and desert conditions to the varied lithologies associated with shelf and deep sea accumulation. Contemporary igneous activity is widespread, both in the form of extrusive lavas, submarine pillow lavas, tuffs, agglomerates, and bentonites and also igneous intrusion. Extrusive activity is found in both continental and marine environments, whereas plutonic intrusions are usually linked with areas of uplift such as the Caledonian and Acadian belts of Europe and eastern North America.

Particular types of sediment characterize various areas of continental and marine environment and these give distinctive rock types. Considering continental areas first, the fluvial sediments are those deposited usually by water, either in flash floods in desert areas or by rivers and streams. To these may be added the aeolian sand dunes and breccias resulting from arid erosion. All are represented in rocks of the Old Red Sandstone type. Lacustrine sedimentation, in freshwater to supersaline lakes is another type that is well represented by some Scottish sediments.

The Devonian marine lithologies are not dissimilar to those of other periods, but certain features are worthy of comment. Thick, fine-grained, dark-gray, or black shales and slates have characterized sedimentation to a significant extent. The Late Devonian **Antrim**, New Albany, and Chattanooga Shales in the Midwest of North America are an example; the German **Wissenbacher-schiefer** is another. By contrast, very fine limestone reefs are known, and those of the Jasper National Park in Alberta and in western Australia must be among the best documented of any era.

For convenience in description this account will commence with a brief review of the European and North African sequences and then pass eastward to the Soviet Union, China, and Malaysia. Treatment of the southern continents from New Zealand to South America will follow, and North America will be considered last. Occurrences of various units are presented in Tables 1 and 2.

A line passing from the Bristol Channel eastward to northern Belgium and Germany roughly demarcates the Devonian marine area south of the Old Red Sandstone continental deposits, which characteristically are red stained with iron oxide. The continental deposits extend also to Greenland, Spitsbergen, Bear Island, and Norway. Robert Jameson coined the term "Old Red Sandstone" in 1808, mistakenly thinking it to be Werner's "Aelter Rother Sandstein," now known to be of Permian age. The rocks of this wide area have a remarkable affinity both in fauna and rock type and usually are considered to have united in Devonian times. The relations with the underlying Silurian System are seen in the classic Welsh Borderlands, where the Ludlow Bone Bed was taken as the boundary until international agreement placed it somewhat higher. In Wales, southern Ireland, and in the Scottish Lowlands, thicknesses of detritus, chiefly sandstones, accumulated to as much as 20,000 feet in places; and widespread volcanics occur in Scotland. These sediments are rich in fish and plants, as are the east Greenland and Norwegian deposits.

Devonian rocks in Devon and Cornwall are mostly marine, but there are intercalations of terrestrial deposits from the north. In north Devon at least 12,000 feet of shales, thin limestones, sandstones, and conglomerates occur; the latter two lithologies typical of the **Hangman Grits** and **Pickwell Down Sandstones**, which are the main terrestrial intercalations. But in south Devon reef limestones are in the Middle Devonian, and the Late Devonian locally shows very thin sequences formed on submarine rises and contemporary pillow lavas in basinal

areas. In north Cornwall both the Middle and Upper Devonian are primarily in slate facies. Fossils found in these rocks have permitted detailed correlations with the Belgian and German sequences.

Devonian of mixed terrestrial and marine type is known from boreholes under London, and these form a link with the Pas de Calais outcrops and to the classic areas of the Ardennes. There, between the Dinant Basin and Namur Basin to the north is evidence of a northward land mass, as in Devon. Both the Lower and Upper Devonian consist of nearshore and terrigenous sediments that reach thicknesses of 9,000 feet and 1,500 feet, respectively. But the Middle Devonian and early Upper Devonian (that is, the Couvinian, Givetian, and Frasnian stages whose type sections are here) are mainly limestones and shales and reach at least 5,000 feet in the south. Reefs are especially well developed in the Frasnian and occur as isolated masses, usually less than one-half mile in length, separated by shales. Equivalents to the north show red and green silts and shales of marginal continental marine type. Because the Belgian Devonian rocks are well exposed along a north-south line, their changes in thickness, lithology, and fauna have been well documented.

The Eifel forms a natural eastern extension of the Ardennes, and a somewhat similar succession is known. The Early Devonian is nonmarine and the Middle Devonian and Frasnian have a poor reef development, but the calcareous shales and limestones carry a rich and famous fauna. The uppermost Devonian is not preserved.

The Rhine Valley along with the **Rheinisches Schiefergebirge** to the east, has been, since the early days of geology, the subject of immense study by the numerous German universities that surround it. Again a northern sediment source generally is indicated, but a borehole near Münster, well to the north, has encountered Middle and early Upper Devonian marine limestones. To the south also, approaching the **Hunsrück-Taunus** mountains, there is evidence of a land mass. Between these areas a rich Devonian sequence is exposed in folded terrain. The maximum thickness is 30,000 feet. The Early Devonian consists of slates and sandstones. The slate has been much worked to clad houses and castles. A ledge of Emsian sandstone in the Rhine Gorge is the setting for the Lorelei legend. Limestones are common in the **Givetian** and are termed **Massenkalk**. Middle and Upper Devonian areas of thin sedimentation, as in Devon, are interpreted as deposits on submarine ridges. These are commonly nodular limestones rich in cephalopods that occur between thick shale sequences. Evidence of volcanic activity is common, and this has been invoked to explain the concentrations of sedimentary hematite iron ores in the **Givetian** and Frasnian. The Harz Mountains show a more calcareous Early Devonian section. Here copper, lead, and zinc are exploited from lodes in the famous Wissenbach Slate.

A calcareous Lower Devonian succession, the Bohemian facies, occurs in the Prague Basin of Czechoslovakia. A continuous marine succession formed from the Silurian into the Devonian, and the boundary is drawn at the top of the Pridoli Formation with *Scyphocrinites*. The overlying Lochkovian and Pragian formations include the Koneprusy Limestone with substantial reefs. The Upper Devonian is not preserved. In Moravia complete successions of calcareous and basinal volcanic sediments occur.

Devonian rocks of a type analogous to southern England and the Ardennes crop out in Brittany. Farther south in Europe outcrops occur in Spain and Portugal. The successions of the Pyrenees, Montagne Noire, and Carnic Alps all include deepwater limestones; and marine deposits are known in Yugoslavia, Macedonia, and Romania. Devonian rocks are widely distributed in North Africa and have been recoded at depth in boreholes in the Sahara during oil exploration. The southern Polish outcrops of the Holy Cross Mountains are especially famous and include a lower marine and continental series with a calcareous Middle Devonian and an Upper

Europe

U.S.S.R.  
and Asia

Devonian of reefs and shales rich in ammonoids and trilobites.

In Podolia, along the Dneister River, are fine marine sections going well up into the Lower Devonian and overlain by the Dneister Series of the Old Red Sandstone type. During the whole Devonian the Ural Mountains formed a geosynclinal trough linked northward to Novaya Zemlya and southward to the Crimea-Caucasian geosyncline that, with the southern European outcrops already mentioned, formed part of the original Tethyan sediments of the Alpine-Himalayan fold system of the present day. In European Russia, Old Red Sandstone conditions were general, but marine tongues stretched westward from the Urals to reach Moscow in the Middle Devonian and Leningrad in the early Upper Devonian. A remarkable series of boreholes revealed this great detail (Figure 2, top), and there is widespread evidence for salt lakes. Apart from the Leningrad outcrop and those along the Don south of Moscow, these are known from subsurface data only. Of economic importance here are the Timan-Pechora oil and gas field and the oil and potash of the Pripyat Marshes. Central Siberia was a land area, but Devonian rocks crop out around it, including rich Lower Devonian calcareous sequences in Salair and the full marine sequence in Altai. The Altai-Sayan area contains a wealth of Old Red Sandstone fish and plants. In northern and northeastern Siberia, in basins around the central platform, Devonian sequences are now well known as a result of recent work. These show a rich and varied fauna grading from marine to continental facies, with associated rich salt deposits. Devonian rocks occur on many of the Soviet Arctic islands.

The Great Khingan range recently has provided good evidence for marine Middle and Upper Devonian, the latter with ammonoids. Many scattered outcrops of Devonian are known in Mongolia and in many parts of China, but the lowest Devonian is poorly represented and often is in continental facies. The plant *Leptophloeum* has been widely traced. The western outcrops are thought to link southward with the Malaysian outcrops. These rocks and those of India, Afghanistan, and Iran form part of the primitive Tethyan or Alpine-Himalayan geosyncline. Devonian rocks with Middle Devonian corals occur in Korea; those in Japan contain *Leptophloeum*.

In New Zealand the Lower Devonian is known in the Reefton and Baton River areas. The brachiopods in the fauna include European elements and have few typical austral types.

Devonian rocks are known in eastern Australia in a belt from Queensland to Tasmania as part of the Tasman geosyncline. Fluvial sediments are found to the west. Thicknesses of 20,000 feet are known. *Leptophloeum* is found in the Late Devonian portion. Devonian rocks occur in central Australia in the Amadeus Basin and along the western coast in the Carnarvon, Canning, and Bonaparte Gulf basins. Complex facies changes are known, and the Canning Basin reef complexes show every detail of forereef, reef, and backreef structures exposed by modern erosion.

In the Antarctic both marine and continental Devonian occur, the latter rich in fish remains of European genera. The marine Early Devonian shows some affinity with the Bokkeveld in South Africa, which, in turn, has strong links with South America. No Devonian is known in Africa between Bokkeveld and the sections in Ghana and northwest Africa.

Early Devonian marine rocks are well developed in South America, but the Late Devonian is poorly documented. In the western geosyncline along the Andes and sub-Andes, remnants of Devonian are preserved from southern Chile north to Peru, Ecuador, Venezuela, and Colombia. The Devonian rocks of Uruguay, Argentina, and Brazil are thought to represent marine transgression from the west. Both continental and marine faunas are known. The fauna of the Falkland Islands and the Paraná and Parnaíba basins has many genera of brachiopods and trilobites that are common within the circum-Antarctic region but unknown in the Northern Hemisphere. In Venezuela and Colombia, however, faunas of Appalachian type dominate, although austral elements, such as *Australospirifer*, linger.

Belts of sediments down the Cordilleran region of western Canada and the eastern U.S. were linked by shallow shelf seas across central North America. The more rapidly subsiding Appalachian area received substantial clastic detritus from mountain ranges farther to the east and northeast. Evidence of their influence in forming the Catskill Delta is well seen in New York state. Thick sandstones and conglomerates that contain fish and plants thin westward along the Hudson River and pass into fully marine sequences (Figure 3). The rich faunas of the Devonian rocks of this area were published in a series of works by James Hall in the 19th century. In the Ontario, Michigan, and Indiana areas, early thin calcareous sequences give way to deeper water New Albany Shale, known farther south as the Chattanooga Shale.

Light gray areas represent red and green shales, sandstones, and conglomerates deposited in fresh or brackish water. Darker gray area represents dark gray or black shales and limestones with marine fossils. White areas indicate gray shales and siltstones with shallow-water marine organisms.

From M. House. *Continental Drift and the Devonian System*

Farther west, in Wyoming, Utah, and the Grand Canyon, terrestrial fish-bearing rocks occur locally. The Canadian Devonian has been vigorously studied since the discovery of oil in Alberta (see Figure 2, bottom), and considerable exploration of Alaska and the Canadian Arctic has been undertaken. The faunas of eastern North America show many links with Europe.

#### DEVONIAN LIFE

A highly varied invertebrate fauna derived from that of the Silurian continued in the Devonian, and most ecological niches of shallow and deep marine water were exploited. The remarkable proliferation of primitive fish, which has given the period the name the "Age of Fishes," occurred both in fresh and marine waters. Derivation of carnivorous fish from mud-eating forms occurred early in the period, and the four-footed tetrapods were derived from fish near the close of the period. Also remarkable is the rise to dominance of the vascular plants. By the mid-Devonian the first tree forests are known in place, but rich groves must have occurred earlier to provide the widespread plant debris.

The Devonian invertebrate faunas, in contrast to the record of the plants and vertebrates, are essentially of the type established by the Ordovician. In nearshore sandy and silty environments bivalves, burrowing organisms, brachiopods, and simple corals abound. In off-shore reefs, free from land detritus, biostromes and bioherms flourished, rich in corals, stromatoporoids, crinoids, brachiopods, trilobites, gastropods, and other forms. In deeper waters the cephalopod goniatites were abundant, one of the few new groups to appear; and there is evidence that the surface levels of these deep waters were occupied by small planktonic orthocones and by ostracods (arthropods) later in the period. Elements of these marine faunas are known on all continents of the world and have been much studied. They form the basis of the subdivision of the system and the most accurate means of correlating its members, and they enable paleoecological and paleogeographical reconstructions to be drawn with some assurance.

Both Foraminifera and Radiolaria among the Protozoa are well known, and sponges were locally abundant; the famous dictyosponges of New York are an example.

The corals and stromatoporoids among the coelenterate Hydrozoa were extremely important in the reef facies. Elsewhere, only simple corals are frequently found. The limestone reef and forereef facies and biostromal limestones are known in many areas of the world. The corals include tabulate corals, such as *Favosites* and *Alveolites*, but especially rugose corals, which have been used to establish correlations. *Amphipora* is a common rock-building type in the mid-Devonian of the Northern Hemisphere, and its twiglike form produces a "spaghetti" or "vermicelli" rock.

Bryozoa were especially common in shallow shelf seas of the period, and rich faunas are known from North America. Both stony (trepostomatous) and netted forms occurred; but the latter, the fenestellids, grow in importance during the period.

The brachiopods of the Devonian show great diversity.

The spire-bearing spiriferoids were perhaps the most common and have been used for zonation. Two groups of importance began here: the loop-bearing *terebratuloids* and the spiny, mud-dwelling productoids. A number of groups become extinct in the period, including a number of orthids and the pentamerids.

Molluscan groups were well represented. The marine clams (*Bivalvia*) increased greatly during the period, especially in the nearshore environments. The earliest freshwater bivalves appeared in the Upper Devonian. The gastropods were well diversified, especially in calcareous environments, but much less than in later periods. The Scaphopoda first appeared here. A significant Devonian event was the origin of the ammonoids from their continuing nautiloid ancestors. In the chambered shell of the ammonoids, the siphuncle is ventral or outermost in position (except in Late Devonian clymenids), and the septa commence the elaborate folded patterns that culminate in the ammonites of the Mesozoic. From their appearance, probably in the Siegenian, the evolution of the goniatites and later ammonites allows a detailed zonal subdivision to be established through the end of the Cretaceous. Devonian goniatites have been found on all continents except South America.

Among the Arthropoda the giant Eurypterida are found in the Old Red Sandstone facies. Some were predaceous carnivores and probably lived on fish. The first insect, a supposed collembolan, has been recorded from the Devonian of the U.S.S.R. Ostracods were locally very abundant; benthonic forms occur in shelf-sea deposits and planktonic forms in the Late Devonian, where their remains form the widespread ostracod-slate facies or cypridinenschiefer. The trilobites were well developed, in terms of size (some up to two feet long), variety, and distribution. Nearly all have clearly established Silurian ancestors. Commonest were the phacopids, which show a curious trend to blindness in the Late Devonian. Almost all of the diverse Lower Paleozoic trilobite stocks that entered the period were extinct before the close, and only the proetaceans survived into the Mississippian.

Among the Echinodermata, holothureans, asteroids, and ophiuroids are known, but they are rare. Crinoids were abundant, including free-living types with grapnel-shaped anchors. The blastoids diversified considerably, but the cystoids did not survive the period.

Conodonts, small toothlike structures usually less than one millimetre in size, had perhaps their greatest diversification during the Late Devonian and have proved of major importance for correlation.

Many groups of Devonian fish were heavily armoured, and this has led to their good representation in the fossil record. Fish remains are widespread in the Old Red Sandstone rocks of Europe, especially in the Welsh Borderland and Scottish areas; these are mostly associated with freshwater or estuarine deposits. In other areas marine fish are known and some of these, such as *Dunkleosteus* (*Dinichthys*) from the Late Devonian of Ohio may have reached 30 feet in length.

The earliest groups, comprising the Agnatha, were without jaws and presumably were mud eaters and scavengers. These are usually termed the ostracoderms, and they are thought to be the ancestors of the living lampreys and hagfish. Some, such as the osteostracan cephalaspids, had broad, platelike armour of varied form; and the brain and nerve structures in some of these are well known. The anaspids also were covered with armour in the form of scales. The heterostracans, which include the oldest known fish, have an anterior armour basically of upper (dorsal) and lower (ventral) plates; Pteraspis is an example. The Early Devonian saw the entry of jawed forms or gnathostomes, and the armoured forms of these, the Placodermi, characterize the period. The arthrodires with a hinged frontal armour in two portions and the grotesque antiarchs belong here. The close of the Devonian saw the diminution and extinction of most of these groups, but several other groups continued and have significant later history. Sharklike fish, the Chondrichthyes, have been found in the Middle Devonian. The bony fish,

Invertebrates

Vertebrates

Table 1: Devo i nPeriod Stage World

[illegible]

or Osteichthyes of current classification, include the climatioid acanthodeans, which had appeared before the period began; but the lungfish (Dipnoi), the coelacanth, and the rhiphidistid fish made their first appearance. The last group is thought to have given rise to the four-footed amphibians and all other higher groups of vertebrates.

These fossil fish have proved to be of great value to the geologist in correlating areas of Old Red Sandstone sedimentation and, more recently, in correlating such areas with marine deposits into which the fish often were washed.

Plants

In the history of vascular plants Devonian evidence is of fundamental importance because there was a remarkable initiation of vascular plants of diverse type. Their colonization formed the first forests such as the rich Gilboa forest of New York, of Middle-Late Devonian age. Much new information on spores is being provided by palynologists, and this may soon enable the antecedents of the Devonian flora to be established. Evidence of algae is common in the period, Bryophyta are first known here, and Charophyta are locally common. Freshwater algae and fungi are known in the Rhynie Chert of Scotland.

Some supposedly Silurian floras, such as that at Baragwanath, Victoria, Australia, are now known to be Early Devonian. The *Cooksonia* Late Silurian record of Czechoslovakia seems to be the earliest unquestionable evidence of vascular plants. By the Early Devonian a varied flora was established.

The Psilophytopsida is the most primitive group of the Pteridophyta; they did not survive the Late Devonian. *Cooksonia*, *Rhynia*, and others possessing a naked stem with terminal sporangia belong here. In other members, sporangia are borne laterally, but no true leaves were developed, and the branching was often of a primitive dichotomous type. The Psilophytopsida forms a basic stock from which other groups apparently evolved. *Asteroxylon*, known with *Rhynia* in the Lower Old Red Sandstone Rhynie Chert of Scotland, forms a link with the Lycopsidea by having lateral sporangia and a dense leafy stem. This group soon gave rise to treelike forms and later to the important lepidodendrids of the Carboniferous flora. Another apparent derivative, the Sphenopsidea, with jointed branches, is represented by *Hyeria* and *Pseudobornia*. This group became much more important after the Devonian and has descendants today in the scouring rushes (*Equisetum*). The Pteropsida also appeared in the Devonian. Primitive gymnosperms are known and drifted trunks of *Callixylon*, up to five feet in diameter, are common in Late Devonian deposits of the eastern United States and the Donetz Basin of the U.S.S.R.

The rich record of land plants may be related to the fact that the Old Red Sandstone represents the first widespread record of continental conditions. But the primitive nature of the stocks seen and the absence of a long earlier record, even of drifted fragments of vascular plants, suggest that the colonization and exploitation of this environment was a real Devonian event. Fortuitous finds, such as the silicified flora of the Rhynie Chert and the pyritized tissue from the Upper Devonian of New York, have enabled the intimate anatomy of many of these forms to be elucidated in a detail equivalent to that of modern forms.

Guide and index fossils

Most groups contribute to the establishment of the faunal and floral chronology that enables Devonian rocks to be correlated. For the continental deposits, fish and plant spores are most important. The fish give a very precise zonation in parts of the system. The Baltic Frasnian, for example, can be divided into at least five time zones using psammosteids (Agnatha), thus probably equalling the precision possible for the better-known marine Frasnian sequences. But many problems still remain in the correlation of the continental deposits with their marine equivalents.

The faunal succession in marine strata has been established for many groups, but only those of significance for international correlations will be mentioned here. Traditionally the goniatites and clymenids (ammonoid Cephalopoda) form the standard. The succession established first in Germany by Rudolf Wedekind has in 1917 been found to hold for all continents where representatives have been found. The index genera are shown in Table 3. All of these genus zones or *Stufen* are subdivisible into

tionally the goniatites and clymenids (ammonoid Cephalopoda) form the standard. The succession established first in Germany by Rudolf Wedekind has in 1917 been found to hold for all continents where representatives have been found. The index genera are shown in Table 3. All of these genus zones or *Stufen* are subdivisible into

species zones. Since this group possessed float chambers, their widespread dispersal was probably related to drifting after death.

Rivalling the ammonoids in parts of the Late Devonian and useful for defining the base of the system are the conodonts. The Late Devonian is characterized by a spectacular evolutionary radiation of *Palmatolepis* and its relatives. The widespread distribution of conodonts indicates that the unknown, soft-bodied organism to which they were attached was planktonic.

The brachiopods, although more restricted, are also important, especially the spiriferids of the Early Devonian, and the entry and evolution of the cyrtospiriferid types in the Late Devonian. The rhychonellids are of great value also in the subdivision of the Late Devonian. Some brachiopods, however, show diverse distribution patterns. *Stringocephalus*, a well-known Middle Devonian guide fossil in western U.S., Canada, Europe, and Asia, is entirely absent from the rich New York succession; yet *Tropidoleptus*, elsewhere confined to the Lower and Middle Devonian, ranges high in the Devonian of New York. Corals also have been used for correlation, but further work suggests they were particularly sensitive to changing local environments and thus are poor time indicators.

There is a marked similarity in the faunas and floras of the continental facies the world over. Recent records from such deposits in China containing Early Devonian *Cephalaspis* and *Pterichthys* or the widespread Australian records of *Bothriolepis* link closely with the Old Red Sandstone faunas of Europe. Yet when studied in more detail, specific differences become apparent. It has been suggested that the Baltic fish succession is so rich that it must have formed a migration centre. This may be so, but the wide distribution of supposed estuarine and freshwater fish raises many problems. Many of these can be resolved if the continents were closer together during the Devonian than at present.

The marine faunas of the Devonian give little evidence of faunal provinces. It is true that in the Lower Devonian the brachiopod *Australocoelia* has been recognized only in the Antarctic, the Falkland Islands, South America, South Africa, and Tasmania and that *Australospirifer*, *Scaphiocoelia*, and *Pleurothyrella* share parts of this distribution. These are not known in the marine Lower Devonian of northern continents, and this seems to establish an "Austral" fauna of limited circum-Antarctic distribution at this time (if the southern continents were then united as Gondwanaland). Elements of this fauna are often called "Malvinokaffric" after the Falkland (Malvinas) Islands and the South African Bokkeveld Beds. But at other levels in the Devonian provincial distinctions are not apparent, with the exception of local coral provinces that are distinguishable in the U.S.S.R.

Evidence is less ambiguous with regard to migration routes (Figure 1). The circum-Antarctic Lower Devonian fauna is linked perhaps to the north by *Leptocoelia* common in southern and eastern North American Devonian. *Leptocoelia* has not been recognized in Europe or Asia apart from Kazakhstan and farther east in the U.S.S.R. The faunas of the western U.S. and western

Faunal realms and migrations

Canada are firmly linked with the U.S.S.R. and Europe in the mid-Devonian and Late Devonian. There seems to be a circum-Arctic route around a united Old Red Sandstone continent linking the Cordilleran faunas with those of the Urals and Poland, Germany, and England. Evidence of this is forthcoming in the very rich records of *Stringocephalus*, *Manticoceras*, and *Amphipora* all along this line. Faunal links between the fine New York sequence and western Europe, however, are poor. The absence of many typical goniatite genera in New York, which are present in the western United States, and also the absence of *Stringocephalus* and strange ranges of *Paraspirifer*, *Tropidoleptus*, and *Cyrtospirifer* emphasize the dissimilarity. The Caledonian mountain chain, linked with the source of Appalachian sediments, must have provided an effective barrier even if North America and Europe, in pre-drift positions, were close together. It has been claimed that American faunal types occur in north-west Africa, and some European-type goniatites occur in the Middle Devonian of Virginia. But the general weakness of the transatlantic faunal ties is striking.

#### DEVONIAN ENVIRONMENTS

The evidence from the Devonian supports the belief that the present-day continents were formerly united in some way. In the Northern Hemisphere the linking of North America, Greenland, and Europe permits the postulation of a single Old Red Sandstone continent. In the Southern Hemisphere the closer union of Australia, Antarctica, South Africa, and South America would bring together the Austral elements previously mentioned, and for later periods this union is imperative to explain the distribution of glacial deposits.

There is no evidence that the orogenic phases of the Devonian were worldwide and synchronous. Mountain-building orogenies were often widespread in time. Thus, although the Caledonian orogeny was important in the north Atlantic area for initiating Old Red Sandstone conditions, both in the eastern United States (Middle Devonian-Acadian orogeny), southwestern United States (Antler orogeny), and in Greenland and Scotland, significant uplift and erosion occurred within the period. The same is true in other areas. Both volcanism and intrusion are associated with those orogenic phases. When regarded on a world scale, it is clear that volcanism in the Devonian is associated with the belts described as geosynclinal and to areas immediately adjacent where antipathetic uplift was occurring. Broad areas of cratonic and shelf sedimentation rarely exhibit volcanic deposits.

The wide distribution of evaporite basins in the Northern Hemisphere, of coals in Arctic Canada and Spitsbergen, of desert conditions, and of widespread marine faunas and carbonate reefs, suggests that warm and equable climates covered large areas. But from New York, where rich forests grew, *Callixylon* trunks with annual rings typical of the seasonal growth of higher latitudes are known. Studies of growth lines on Devonian corals indicate that the number of days in the Devonian year was in the order of 400 and that the lunar cycle was about 30½ days (see DATING, RELATIVE AND ABSOLUTE). The wide distribution of salt deposits suggests high evaporation and warm climates in many areas from western Canada to the Ukraine and Siberia and, again, locally in Australia. On the basis of paleomagnetic evidence from studies of rock magnetism, an Equator passed from California to Labrador and from Scotland to the Black Sea. By analogy with the glacial tillite distribution of the subsequent periods, the southern continents must have been near a pole. There is some evidence that the Austral province suffered glaciation in the Lower Devonian. The northern pole, paleomagnetic evidence suggests, may have lain in the north Pacific.

**BIBLIOGRAPHY.** The following collection of papers by international authorities is now the standard work for all aspects of the world Devonian: D.H. OSWALD (ed.), *International Symposium on the Devonian System*, 2 vol. (1967).

(M.R.H.)

## Dew

Dew is a deposit of waterdrops formed at night by the condensation of water vapour from the air onto the surface of objects freely exposed to the sky. It forms on clear nights when the air is calm or, preferably, when the wind is light. If the temperature of the surface is below the freezing point of water, the deposit takes the shape of hoarfrost (see FROST). Dew forms on clear nights because on such nights freely exposed surfaces lose heat to the sky by radiation. Unless this loss is offset by an efficient conduction of heat from the interior of the object, the surface will cool. Most objects, including grass blades, leaves, and petals, are much better radiators than air and, as a result, are usually colder at night than is the air. The cold surface cools the air in its vicinity, and if the air contains sufficient atmospheric humidity, it may cool below its dew point. When this happens, water vapour will condense out of the air onto the surface (see also MICROCLIMATES; HUMIDITY, ATMOSPHERIC).

The formation of dew is sustained by the diffusion of water vapour. Regarding the vertical diffusion of water vapour over soils carrying vegetation, there are two possible situations. First, there is the downward movement of water vapour from the atmosphere, which occurs when the water vapour content of the air increases with height. Second, there is the upward movement of water vapour, which occurs when the soil surface temperature is higher than that of the leaves. Accordingly, dew may be classified (1) as formed when water vapour diffuses downward in the air and (2) as formed from water vapour diffusing from the underlying soil surface. The name dewfall is proper to (1), and dew arising from (2) may be called distillation.

There have been various attempts to measure dew. Among the various instruments are R. Leick's porous gypsum plates and S. Duvdevani's dew gauge, consisting of a wooden slab treated with paint. To determine the amount of dew, Leick's plates are weighed, whereas Duvdevani's gauge involves the use of an optical dew scale. Other investigators (e.g., J.M. Craddock, E.G. Jennings, and J.L. Monteith) developed recording dew balances whose surface and exposure conform with the surrounding surface as far as possible. It is by means of such dew balances that one can best observe the phenomenon of distillation: on some occasions no gain in weight or even some loss in weight may be recorded despite the fact that dew had formed on the leaves. Clearly, this dew must be attributed to the diffusion of water vapour from one part of the weighed system to another; i.e., from soil to leaves.

The amount of dew formed on plants is not well known. It would appear that during dew nights the amounts vary from very small quantities to about 1/50 of an inch. G. Hofmann (*Die Thermodynamik der Taubildung*, Bad Kissingen, 1955) estimated that the maximum possible amount is about 3/100 of an inch for a ten-hour night, but such amounts would occur only under exceptional circumstances. Total annual dew precipitation may lie between about one-half inch in cold climates and in nearly arid warm climates, to about three inches in semi-humid warm climates. Because dew produced by distillation from the soil cannot be regarded as a gain of moisture, not all of the annual dew may be significant from a hydrological point of view. In some desert areas and semiarid regions the net gain may be a substantial fraction of the rainfall, however, and dew may be the principal moisture source for plants and animals. Under such conditions, it also may assume an important role in some aspects of rock weathering (q.v.). From the biological viewpoint, the usefulness of dew is doubtful as dew may stimulate the growth of fungi harmful to plants.

In ancient times it was believed that dewdrops fell from the sky. Aristotle suggested (in *Meteorologica*) that dew or hoarfrost was formed by the condensation of water vapour that had evaporated from the surface by day. Louis-Constant Prévost (*Recherches Physico-Mécaniques sur la Chaleur*, 1792) was probably the first to connect

dew with radiation losses from the surface. The first thorough investigation of dew, however, was made by Charles Wells, physician to St. Thomas's Hospital, London. He showed (*An Essay on Dew and Several Appearances Connected With It*, London, 1814) that dew was the result of cooling of the air at night. He also pointed out that although dew tended to form on windless nights, "a slight agitation of the air . . . when the air is pregnant with moisture . . . will render greater the quantity of dew" —the first statement appreciating the effect of slight turbulence on dew. In 1885 John Aitken (*Trans. Roy. Soc. Edinb.*, no. 33) published the results of his studies, which demonstrated, among other things, that trays of turf at times lost weight when dew formed on the blades. He interpreted this as the result of vapour diffusion from the soil. Aitken also made a distinction between dewdrops proper and drops of water that are formed by guttation; *i.e.*, the exudation of water from leaves under the action of root pressure.

**BIBLIOGRAPHY.** N.T. ZIKEEV, "Annotated Bibliography on Dew," *Met. Abstr. Bibliophy.*, 3:360–391 (1952), annotated listings from the year 1725 (a memoir by Robert Boyle) to the year 1951, encompassing 208 literature items; *Meteorological and Geostrophysical Abstracts* (monthly), publishes annotated items on dew as they appear in the scientific literature; J.L. MONTEITH, "Dew," *Q. Jl. R. Met. Soc.*, 83:322–341 (1957), a paper that describes the results of a thorough experimental study and treats the physical-theoretical aspects of dew formation, including heat balance and turbulent transport considerations; S. DUVDEVANI, "An Optical Method of Dew Estimation," *ibid.*, 73:282–296 (1947), a description of the author's optical dew gauge, widely used for routine measurements, with an evaluation of its relative merits.

(J.N.)

## Dewey, John

Almost equally famed as philosopher, psychologist, and educator, John Dewey shares with two fellow Americans (Charles Sanders Peirce and William James) the distinction of having founded the philosophical school of Pragmatism, is recognized as having helped establish the school of functional psychology, and is regarded as the outstanding thinker of the so-called progressive movement in American education and in educational reform during the first half of the 20th century. Dewey's political and social philosophy articulated and made more meaningful many of the ideals and deeper aspirations of the American people. He is generally recognized as an authentic voice of 20th-century American democracy. If there were such an office as that of national philosopher, writes Morris R. Cohen in his *American Thought*, Dewey is the person who could most properly be mentioned for it. When the University of Paris, in 1930, awarded him an honorary degree, it referred to him as "the most profound, most complete expression of American genius."

**Early life.** Dewey's family origins were modest. Three generations of his forebears were Vermont farmers, and both his parents were born and brought up on a Vermont farm. Archibald Dewey, John's father, when a young man broke with family tradition, however, and entered the grocery business in Burlington. Here many years later, at the age of 44, Archibald met and married Lucina Artemisa Rich, 20 years his junior. The couple had four sons, the first of whom died in infancy. John, the third child, was born on October 20, 1859, in a house that is still standing in Burlington.

The Burlington in which Dewey lived as a youth had a population of approximately 15,000, divided almost equally between native- and foreign-born; the latter came chiefly from Ireland and Quebec. The native-born included the "old Americans," descendants of middle class, Anglo-Saxon, Protestant families long established in Vermont or some other part of New England, and it was in the traditions of this group that Dewey was brought up.

Dewey attended the public schools of Burlington and there entered the University of Vermont. Particularly significant to him were the studies of the fourth year, designed to introduce the student to fundamental political, economic, philosophical, and religious theories and intended to be the capstone of the student's undergraduate

academic experience. Dewey found these courses interesting and provocative, and his thinking along broad intellectual and philosophical lines may be said to have started during his senior year in college.

Dewey's high school and college days marked the time when his intellectual interests were broadening and when he sought the company of books. He was, as he himself has written, a "voracious reader" at this time and found in books a source of deep satisfaction. His parents encouraged him in his reading, and Dewey was free to peruse almost any book which caught his fancy.

Interest in books, however, did not at this time crowd out other interests, as it threatened to do in Dewey's graduate-student years. He welcomed opportunities to swim and fish in Lake Champlain, only three blocks away from where he lived as a boy, and to hike, climb, and camp overnight in the Green Mountains. During the summer he was expected to work at a job, and this he did in the extensive lumber yards that at the time lined the shores of Burlington Bay.

Though he was allowed considerable freedom in his studies, reading, and recreational activities, Dewey was carefully restricted in other ways. His mother was deeply pious and required that her sons go to Sunday school, attend church services, and in other ways properly observe the sabbath. As they grew older she cautioned them against the temptations lurking in neighbourhoods bordering Burlington's industrial area on the lakefront, and when they had been out for an evening, upon their return, she would very likely question them as to where they had been and what they had done. In later years Dewey recalled with distaste this phase of his upbringing and recalled also the sense of guilt that this questioning evoked, even when there was nothing to be guilty about.

After finishing college, Dewey taught three years in high school and, in the fall of 1882, entered Johns Hopkins University, in Baltimore, for advanced study in philosophy. Here he came under the influence of George Sylvester Morris, visiting professor of philosophy from the University of Michigan and a leading exponent of Neo-Hegelianism, a revival of the thought of the 19th century German philosopher Hegel. Dewey found in this philosophy, with its emphasis on the spiritual and organic nature of the universe, what he had been vaguely groping for, and he eagerly embraced it.

While at Johns Hopkins, Dewey devoted himself almost exclusively to his studies and tended to neglect other activities. This preoccupation with study was noticed by the president of the university, who strongly advised him to study less and socialize more.

Upon being awarded the Ph.D. degree by Johns Hopkins University, in 1884, Dewey, in the fall of that year, went to the University of Michigan, where, at the urging of Morris, he had been appointed an instructor in philosophy and psychology. With the exception of the aca-

Influence  
of Hegel's  
philosophy

demical year 1888–89, when he served as professor of philosophy at the University of Minnesota, Dewey spent the next ten years at Michigan. During this time his philosophical endeavours were devoted mainly to an intensive study of Hegel and the British Neo-Hegelians and to the new experimental, physiological psychology then being advanced in the United States by G. Stanley Hall and William James.

Dewey's interest in education began during his years at Michigan. His readings and observations revealed that most schools were proceeding along lines set by early traditions and failed to adjust to the latest findings of child psychology and to the needs of a changing democratic social order. The search for a philosophy of education that would remedy these defects became a major concern for Dewey and added a new dimension to his thinking.

At the end of his second year at Michigan, Dewey married Harriet Alice Chipman of Fenton, Michigan. She had been a student in a number of Dewey's classes, and the friendship culminated in their marriage on July 28, 1886. Mrs. Dewey's academic interests centred mostly on social and educational problems, and it was in large measure because of her that Dewey's interests widened to include these. Alice had an outgoing personality, liked people, and helped her husband overcome the shyness with strangers that had troubled him since early adolescence. Both Alice and Dewey were fond of children and were pleased as their family grew to include three sons and three daughters. Two of the sons died in early childhood; and, to help soften their loss, the Deweys, while travelling in Italy, adopted an Italian boy near the age of one of the sons who had died. The adoption proved a happy one.

Career at the University of Chicago. Dewey left Michigan in 1894 to become professor of philosophy and chairman of the department of philosophy, psychology, and pedagogy at the University of Chicago. One feature of the new position that appealed to him was that the department was responsible for instruction not only in philosophy but also in psychology and pedagogy. Dewey saw in this arrangement an opportunity to unite these three disciplines and, more particularly, to bring pedagogy into closer relations with psychology and philosophy.

Dewey's achievements at the University of Chicago brought him national fame. The increasing dominance of evolutionary biology and psychology in his thinking led him to abandon the Hegelian theory of ideas, which views them as somehow mirroring the rational order of the universe, and to accept instead an instrumentalist theory of knowledge, which conceives ideas as tools or instruments in the solution of problems encountered in the environment. These same disciplines contributed somewhat later to his rejection of the Hegelian notion of an Absolute Mind manifesting itself as a rationally structured, material universe and as realizing its goals through a dialectic of ideas. Dewey found more acceptable a theory of reality that holds that nature, as encountered in scientific and ordinary experience, is the ultimate reality and that regards man as a product of nature who finds his meaning and goals in life here and now.

Since these doctrines, which were to remain at the centre of all of Dewey's future philosophizing, also furnished the framework in which Dewey's colleagues in the department carried on their research, a distinct school of philosophy was in operation. This was recognized by William James in 1903, when a collection of essays written by Dewey and seven of his associates in the department, *Studies in Logical Theory*, appeared. James hailed the book enthusiastically and declared that with its publication a new school of philosophy, the Chicago school, had made its appearance.

Dewey's contributions to psychology were also noteworthy. Many of the articles written at that time are now accepted as classics in psychological literature and assure him a secure place in the history of psychology. Most significant is the essay "The Reflex Arc Concept in Psy-

chology," generally taken to mark the beginnings of functional psychology—i.e., one that focusses on the total organism in its endeavours to adjust to the environment.

His writings on education, notably his *The School and Society* (1899) and *The Child and the Curriculum* (1902), presented and defended what were to remain the chief underlying tenets of Dewey's philosophy of education. These were that the educational process must begin with and build up on the interests of the child; that it must provide opportunity for the interplay of thinking and doing in the child's classroom experience; that the school should be organized as a "miniature community"; that the teacher should be a guide and coworker with the pupils, rather than a taskmaster assigning a fixed set of lessons and recitations; and that the goal of education is the growth of the child in all aspects of its being.

Among the results of Dewey's administrative efforts were the establishment of an independent department of pedagogy and of a laboratory school in which the educational theories and practices suggested by psychology and philosophy could be tested. The school, which began operations in January 1896, attracted wide attention and enhanced the reputation of the University of Chicago as a foremost centre of progressive educational thought.

The city of Chicago provided Dewey with an excellent opportunity to observe the operations of raw, unrestricted industrialism and to note its effects on large segments of the city's population. As a trustee of Hull House, a settlement house in a Chicago slum area, he became familiar with the exploitation of immigrant and minority groups and joined radicals and other liberals like himself in supporting legislation to aid the underprivileged, legalize labour unions, and curtail the power of monopolies. At Hull House, Dewey was introduced to Jane Addams, the distinguished founder of the organization. A warm and lasting friendship developed between them.

Career at Columbia University. The disagreement between President William Rainey Harper of the University of Chicago and Dewey concerning the administration and financing of the university's educational program led, in 1904, to Dewey's resignation of his posts and to his acceptance of a professorship of philosophy at Columbia University in New York City.

Dewey was associated with Columbia for 47 years, first as professor and then as professor emeritus of philosophy. During his 25 years of active teaching, his fame and the significance of what he had to say attracted thousands of students from at home and abroad to his classes, and he became one of the most widely known and influential teachers in America.

Dewey's scholarly output at Columbia was enormous; one bibliography devotes approximately 125 pages to listing the titles of his publications during these years. His thought covered a wide range of topics, including logic and theory of knowledge, psychology, education, social philosophy, fine arts, and religion. Major works dealing with each of these fields appeared over the years and clearly established Dewey as the foremost philosopher in America and as one of the nation's most productive scholars. His *Experience and Nature*, published in 1925, brings together in a systematic way the more important aspects of his philosophy and is generally regarded as his magnum opus.

His interest in current affairs prompted Dewey to contribute regularly to liberal periodicals, especially *The New Republic*. His articles focussed on domestic, foreign, and international developments and were designed to reach a wide reading public. Because of his skill in analyzing and interpreting events, he soon was rated as among the best of American commentators and social critics.

A man of action as well as of thought, Dewey gave generous amounts of time and energy to the support of organizations and causes in which he believed. After World War I, with S.O. Levinson, a Chicago attorney and long-time friend, he played an important role in the "outlawry of war" movement, which helped bring the Kellogg-Briand Pact of 1928 into existence. He was one of the founders and the first president of the American

ence and  
Nature*

Association of University Professors and was a charter member of the first teachers' union in New York City. He helped found the New School for Social Research in 1919 and the University-in-Exile in 1933, established for scholars being persecuted in countries under totalitarian regimes, and he held office in the American Civil Liberties Union, the League for Industrial Democracy, and the People's Lobby. He thought that the two major parties in Congress had failed to come to grips with the problems generated by the Depression of the 1930s, accused them both of being the "errand boys of big business," and took a leading part in an attempt to organize a third political party. In 1937, at age 78, he headed a commission of inquiry that went to Mexico City to hear Leon Trotsky's rebuttal of the charges made against him in the Moscow trials of 1936 and 1937.

His reputation brought Dewey invitations from a number of foreign countries, among them Japan, China, Turkey, Mexico, Russia, and South Africa. Russia, Mexico, China, and Turkey were undergoing social upheavals, which Dewey reported on in articles sent to *The New Republic*.

Great personal loss was suffered by Dewey when his wife died in 1927. The two had been unusually close, and her death left a void not easily filled. After her death Dewey shared an apartment with one or another of his children until 1946, when he married Roberta Lowitz Grant, whose parents he had known when Roberta was a child in her early teens. Dewey was 87 and Roberta 42 when they were married. Shortly after their marriage they adopted two small Belgian children, a sister and brother, made orphans by the war. The four quickly became a closely knit and affectionate family group.

Dewey was the recipient of many honours. He was awarded honorary degrees from at least 13 colleges and universities at home and abroad and was decorated with the Order of the Jade by the government of China in 1939 and the Order of Merit by the Chilean government in 1949. He was elected honorary president of the National Education Association in 1932, honorary president for life of the American Philosophical Association in 1938, and honorary vice president of the New York State Liberal Party in 1952. Meetings and dinners celebrating the anniversaries of his 70th, 80th, and 90th birthdays and attended by notables from all walks of life were held in his honour in cities throughout the nation.

During the last two decades of his life, Dewey's philosophy of education was the target of numerous and widespread attacks. Greatly agitated by the alleged failure of the schools to train pupils adequately in essential core subjects and in manners and discipline, critics blamed Dewey and his progressive ideas for these failures and in article after article made him the scapegoat of their grievances and frustrations.

Dewey enjoyed remarkably good health, and rarely during his long career was he forced to miss classes or cancel off-campus engagements because of illness. But his advancing years were exacting their toll, and during his 80s he required repeated hospital attention. He remained physically active, however, and participated in the celebration of his 90th birthday in New York City and in his native Burlington and also accepted in person the honorary degree awarded him by Yale University at its 250th commencement in June 1951.

In November 1951, Dewey broke his hip, and the failure of the bones to knit properly kept him weakened and confined to his apartment during the winter and spring of 1952. Yet he remained intellectually busy and continued to work on projects he had begun earlier, including a revised edition of his *Experience and Nature*. On May 31 he was stricken with pneumonia, from which he failed to recover. He died in the early evening of June 1, 1952.

#### MAJOR WORKS

EDUCATION: *The School and Society* (1899); *Democracy and Education* (1916); *Experience and Education* (1938).

PSYCHOLOGY AND PHILOSOPHY: *Psychology* (1887); *Studies in Logical Theory* (1903); *Ethics*, with James Tufts (1908); *How We Think* (1910); *Reconstruction in Philosophy* (1920);

*Human Nature and Conduct* (1922); *Experience and Nature* (1925); *The Public and Its Problems* (1927); *The Quest for Certainty* (1929); *Art As Experience* (1934); *A Common Faith* (1934); *Logic, the Theory of Inquiry* (1938); *Freedom and Culture* (1939); *Knowing and the Known*, with Arthur F. Bentley (1949).

MONTAGUE (eds.), *Contemporary American Philosophy: Personal Statements*, vol. 2, pp. 13–27 (1930), a sketch in which Dewey traces the stages of his intellectual development and the main influences encountered; JANE DEWEY (ed.), "Biography of John Dewey," in PAUL ARTHUR SCHILPP (ed.), *The Philosophy of John Dewey*, pp. 3–45 (1939), an account of Dewey's training, philosophical development, teaching positions, family and friendships, and travels; MAX EASTMAN, "John Dewey," *Atlantic Monthly*, 168:671–685 (1941), an account written by a friend who gives interesting details of the life of the Dewey family; GEORGE DYKHUIZEN, "John Dewey: The Vermont Years," *Journal of the History of Ideas*, 20:515–544 (1959); "John Dewey at Johns Hopkins (1882–1884)," *ibid.*, 22:103–116 (1961); "John Dewey and the University of Michigan," *ibid.*, 23:513–544 (1962); "John Dewey: The Chicago Years," *Journal of the History of Philosophy*, 2:227–253 (1964); and "John Dewey in Chicago: Some Biographical Notes," *ibid.*, 3:217–233 (1965), detailed accounts of Dewey's life during the period indicated; IRWIN EDMAN, *Philosopher's Holiday*, pp. 138–143 (1938), a fascinating account of Dewey as a teacher by a former student; SIDNEY HOOK, "Some Memories of John Dewey," *Commentary*, 14:245–253 (1952), an essay that gives an appreciative account of Dewey as a person, written by a former student and close friend; *John Dewey: An Intellectual Portrait* (1939), a very readable and authoritative account of the several aspects of Dewey's philosophy; GEORGE R. GEIGER, *John Dewey in Perspective* (1958), an exposition of Dewey's philosophy in the light of the misunderstandings and distortions which have centered about it; RICHARD J. BERSTEIN, *John Dewey* (1966), an illuminating study of the leading ideas of Dewey's philosophy; PAUL ARTHUR SCHILPP (ed.), *The Philosophy of John Dewey* (1939), contains in addition to a biographical sketch of Dewey, a collection of 17 essays by different authors, each a critical study of some aspect of Dewey's philosophy; a concluding essay by Dewey in response to his critics; and a bibliography of Dewey's writings to October 1939; JO-ANN BOYDSTON (ed.), *A Guide to the Works of John Dewey* (1970), a collection of essays by Deweyan scholars each introducing the reader to a particular area of Dewey's thought; MILTON HALSEY THOMAS, *John Dewey: A Centennial Bibliography* (1962), the most complete listing now available of writings by and about Dewey.

(G.Dy.)

## Diaghilev, Sergey

Promoter of the arts and founder of the Ballets Russes, Sergey Pavlovich Diaghilev revitalized the stereotyped form of ballet of the early 20th century. Integrating the ideals of other art forms—music, painting, drama—with those of the dance, he developed the ballet as a creative whole. As an innovator of artistic movements in Europe during the first quarter of the century and as the inspiring genius of musicians, painters, and dancers, he holds a unique place in the development of the arts in the 20th century.

Born in the province of Novgorod on March 19, 1872, Diaghilev was the son of a major general and a noblewoman, who died in childbirth. Diaghilev was remarkable for his large, dreamy eyes acquired from his mother, and perhaps he also inherited from her his craving for luxury in both the personal and artistic spheres. He repeatedly made it clear that he followed a purely hedonistic philosophy. From his stepmother, Helen Valerianova Panaieva, on the other hand, he acquired a sense of discipline and the instinct to dominate. Moreover, as a youth his artistic sensibilities were encouraged by her many musical connections. The piano lessons he took while still at school enabled him to play the **Schumann** concerto in public; as a child he also showed a gift for composition.

In 1890, while studying law at the University of St. Petersburg, he became associated with a group of friends interested in the social sciences, music, and painting—the first of a series of intellectual gatherings over which he presided throughout his life. Among his companions dur-

Diaghilev, c. 1916.

By courtesy of the Dance Collection, the New York Public Library at Lincoln Center, Aster, Lenox and Tilden Foundations

ing this period were the painters Alexander Benois and Léon Bakst, both of whom were later to contribute brilliantly to his productions. His first experience of ballet was, curiously enough, a disappointment. The work was Peter Ilich Tchaikovsky's *Sleeping Beauty*, which he saw with little enthusiasm at the Mariinsky Theatre in St. Petersburg about 1890. (The work was later to become one of Diaghilev's most successful productions.)

In 1893 he made his first journey abroad, visiting Germany, France, and Italy, where he met the distinguished French novelist Émile Zola and the opera composers Charles Gounod and Giuseppe Verdi. Even in his youth he sought out and was stimulated by the company of the great.

In 1896 Diaghilev graduated in law, but he was determined to follow a musical career. The composer Nikolay Rimsky-Korsakov, however, discouraged him from developing his talents as a composer, wisely no doubt, since a vocal work of Diaghilev that had been performed in public had left a poor impression. In Moscow he met the patron of the famed bass Fyodor Chaliapin and proposed revolutionary scenic ideas for productions of operas in which Chaliapin appeared. Although he was uncertain of his own artistic gifts, Diaghilev was convinced of his vocation: that of a great patron of the arts like the Roman Maecenas. His theatrical ventures in the sphere of opera and ballet and his literary projects, demanding huge investments, were hampered by the fact that he embarked on this career with no private income. Moreover, in 19th-century Russia, his homosexuality was a serious handicap in the development of his career. He had personal charm and audacity, however, and he used them to advantage.

In 1899 he realized the first of these international ventures when he founded, as editor in chief, the review *Mir Iskusstva* ("World of Art") which continued to appear until 1904. This was a counterpart of the London *Yellow Book*, reflecting the ideas of the graphic artist Aubrey Beardsley and the writer Oscar Wilde.

In 1902 Diaghilev published a monograph on the Russian portrait painter Dmitry Gregoryevich Levitsky (1735–1822), and three years later he organized a historic portrait exhibition of Russian art treasures at the Tauride Palace in St. Petersburg.

The great turning point in his life came when he left Russia for Paris in 1906. It was there that he helped to found what was later referred to as the Franco-Russian artistic alliance. He organized an exhibition of Russian art and then, in 1907, a series of historic concerts devoted to the work of the Russian nationalist composers.

In 1908 Modest Mussorgsky's opera *Boris Godunov* was produced in Russian by Diaghilev at the Paris Opéra with Chaliapin in the title role.

The time had arrived for him to launch the venture that was to fulfill his ideal of a combination or interpenetration of the arts. Appointed in 1899 as assistant to Prince Sergey Volkonsky, director of the Imperial Theatre, Diaghilev had met the dancer Michel Fokine, whose creative activity was powerfully influenced by the American dancer Isadora Duncan. Influenced by the dance innovations of Isadora Duncan, the ideas of composer Richard Wagner, and the theories of the poet Charles Baudelaire, Diaghilev opened his season of Ballets Russes at the Théâtre du Châtelet in Paris in 1909. The dancers Anna Pavlova, Vaslav Nijinsky, and Michel Fokine were in his company.

Before long it became clear that conventional choreography was to have no place in his novel spectacles. Mime or action dances were the aim of the choreographers who, largely under the influence of Fokine and Léonide Massine, were creating an entirely new tradition. The composers chosen to transform the old art forms were themselves inspired by the fantasies of painters and choreographers. This was Diaghilev's lofty creation, an ideal of artistic synthesis, based on an innate sense of taste. Diaghilev's art reached its height in the three early ballets of the young Russian composer Igor Stravinsky: *The Firebird* (1910), *Petrushka* (1911), and *The Rite of Spring* (1913). In *Petrushka*, perhaps the greatest of the Diaghilev ballets, Stravinsky, at Diaghilev's insistence, transformed a conventionally conceived piano concerto (on which he had been working) into a mimed ballet, bringing into real life the fantasy dramas of puppets at a showman's fair. The incident is indicative of the extraordinary psychological influence Diaghilev was able to exert over his collaborators. In *The Rite of Spring* Stravinsky produced one of the most explosive orchestral scores of the 20th century, and the production created an uproar in the Paris theatre at its first performance. The scandalous dissonances and rhythmic brutality of the music provoked among the fashionable audience such protestations that the dancers were unable to hear the orchestra in the nearby pit. They carried on, nevertheless, encouraged by the choreographer Nijinsky, standing on a chair in the wings, shouting out and miming the rhythm.

Diaghilev left his native Russia and never returned. An aristocrat, he carried on the revolution in the arts not in the Soviet Union, but in the intellectual circles of Paris. There he collaborated with the French poet Jean Cocteau, among others. He toured with his ballet throughout Europe, in the United States, and in South America. Despite his influence, however, Diaghilev was a lonely and dissatisfied man, impecunious and personally unhappy. He was an idealist, never realizing perfection and yet sowing the seed of an exploratory spirit. Seasons of the Diaghilev ballet were given uninterruptedly from 1909 to 1929. During his later seasons he introduced the works of forward-looking composers and painters from France, Italy, Great Britain, and the United States. Through Diaghilev's intuition they entered the world scene. Among the composers represented in his repertory were Richard Strauss, Claude Debussy, Maurice Ravel, and Sergey Prokofiev.

Diaghilev had long suffered from diabetes, and by the end of his brilliant 1929 season at Covent Garden, London, his health had gravely deteriorated. He nevertheless left for a holiday in Venice, where, following an alarming rise in temperature, he sank into a coma. He died there on August 19, 1929, and was buried in the island cemetery of San Michele.

**BIBLIOGRAPHY.** S. LIFAR, *Serge Diaghilev* (1940); and ARNOLD L. HASKELL and W. NOUVEL, *Diaghileff: His Artistic and Private Life* (1955), are authoritative biographies. S.L. GRIGORIEV, *The Diaghilev Ballet, 1909–1929* (Eng. trans. 1953), is a standard work on the Russian ballet; and JOHN PERCIVAL, *The World of Diaghilev* (1971), a succinct, popular study.

## Diagnosis

The term diagnosis refers either to an active process or to the conclusion reached by that process. Modern medical diagnosis in the active sense includes the process and art of using scientific methods to elucidate the whole compass of problems that influence a sick person. It includes the collection of all necessary facts and critical evaluation of every bit of evidence obtained from any and all sources by whatever method is useful. It is a lively art based on a sound and growing science. From the facts so obtained, and in the light of a knowledge of the principles of anatomy, physiology, and pathology, concepts of the causes of the trouble, the pathological lesions, and the disordered processes that make up the patient's disease are formed. From an array of possible hypotheses, the correct diagnosis is singled out as having the best fit with the findings. The process of selection is properly called differential diagnosis.

Diagnosis is ordinarily the forerunner of treatment, and treatment must be based on an understanding of diagnosis and of prognosis; that is, the outlook of a patient without treatment and with various kinds of treatment, including the accepted risks that certain treatments necessarily entail, whether the treatment be taking a pill, receiving an injection, or undergoing a surgical operation. The information upon which the diagnosis-prognosis-treatment continuum is based falls into three classes, each requiring a separate critical analysis for accuracy, error, and clinical significance for the particular patient involved. These classes are (1) facts obtained from the patient's story of his life, his health, his accidents, operations, and illnesses, as a specific unique member of society—the medical history; (2) facts obtained from the physical examination; and (3) data obtained from routine laboratory examinations and special tests. The next step is the development of the medical record—the recording of data followed by a codification of the important data and summary ordering of them in terms of their significance, from which a preliminary diagnosis is derived. This is then modified as further explicit tests are obtained to correct errors, solve puzzles, and measure degrees of abnormality more precisely. An estimate is made of prognosis. Treatment is then undertaken, with or without modification of the original diagnosis.

When the term diagnosis is used as a label, it refers to the conclusion that stems from the process of diagnosis. The conclusion cannot be considered final until after an examination of tissue specimens, surgical exploration, or autopsy, and even then the diagnosis is rarely a complete and total summary.

Any explanation of medical phenomena must be in terms of contemporary knowledge and thus must be provisional. It is based on the natural history of disease as determined by man's observing man in his environment. Historically, observation was, for a time, simply looking and seeing. The next development was the actual examination of the sick person, in which history taking, or seeking the seeds of the present trouble from the story of a patient's past health and disease, was a major factor. In the early historical period, and probably for ages before that, the examination was a bedside examination. One of the first advances from a mere bedside examination of the sick person was scrutiny of his urine by a physician-priest. Today, technical machinery and laboratory tests have created a myriad of instruments and procedures. Every day there are more kinds of scopes, electrical measurements, X-rays, and tolerance tests. In such a way, the physical examination carries the fluid secretions and excretions, groups of cells or bits of tissue, from the patient to the laboratory. Tumours and organs may be removed for examination.

Hippocrates knew the succussion splash; *i.e.*, the sound made when anyone (from a sick senator to a slave) with air and fluid free in the chest cavity was shaken. He heard and felt the sounds of the creaking of joints, intestinal rumblings, belching, and the expulsion of flatus. These were commonplace and treated by not being treated. But no man had real understanding of what went on inside

until the anatomists had paved the way for an Austrian physician, Leopold Auenbrugger, who developed the use of percussion (see below) in diagnosis and a French physician, René Laennec, who developed the stethoscope. William Harvey had added experimentation to biological observation and thus reduced the amount of time and energy wasted on speculation detached from data.

The introduction of active examination into a process that had been merely observation helped set modern medicine on its way. The success of the physical examination steadily improved when it became possible to correct findings by autopsy.

In the distant past, medicine was a matter of opinions supported by other opinions. It dealt in terms of myth that was ultimately modified, but neither organized nor stabilized, by astrology and alchemy.

Medical science could not exist until the body was first systematically dissected. Thus, among the sciences, anatomy came first. Perceptive men realized that there was a complementary relationship between structure and function. Ideas of the physiology of living functions began to develop. Next, pathology began to evolve on a sound anatomical basis, passing far beyond the primitive pathology of war wounds, injury, and the visible diseases of skin, bone, deformity, or ruin. A first order of understanding came with the disclosure in autopsy of such diseases as the fatal effect of spontaneous massive internal bleeding, or the mechanical ruin of various fabrics of the body by invasion of a destructive tumour. Partial or total mechanical obstruction of the body's pipes and tubes, a first comprehension of many of the mistakes of nature, deformities and inborn errors that were not immediately lethal, began to recall insights forgotten since the time of Alexandrian medicine.

With William Harvey's work on the circulation of the blood, physiology suddenly grew up. Experimental medicine, a twin of the revelation of the circulation, was born. With medicine's first understanding of the mechanics and hydraulics of the movement of blood, the function of the lungs could be seen as something other than a sophisticated cooling mechanism for the heart. Further advance in the workings of the lungs became possible only when the chemistry of gases had been understood.

Then came a series of advances unexpected and unorganized. The development of the microscope and the staining of tissues led scientists much deeper into the microcosm. Electrophysiology added yet another dimension. Observations that could not be clearly understood at the bedside were taken to the laboratory. Clues were brought back. They were tested. Some failed. A few worked. The process continued.

The natural history of disease has always provided the chemist with some of his most challenging opportunities. The American chemist Linus Pauling, who uncovered the nature of the physical flaw of the hemoglobin in sickle-cell anemia, for example, could not have done so if someone else had not first described and classified the anemia.

Just as certain elements that were typical of each stage and type of medical diagnosis are still used today—the mere observation, the careful examination coupled with the sick person's account of his present and past circumstances and ills, the laboratory and other tests—so too, traces of man's changing ideas of disease linger on: that disease is a magic spell or curse, a spirit that invades man's body; that disease is the experience of a particular person who can be observed, interrogated, and examined (the teachings of the Greek physician Hippocrates and his school); that there is no disease, just as there is no real external world, the Stoic concept; that disease is retribution and punishment; that the physical body and the cell are the seat of disease, the anatomic concept; that structure and function are both involved, the physiologic concept; that each disease has its own particular cause, the etiologic concept; that man is the source of his own ills, the psychologic concept; that disease is maladaptation to environment, the socioeconomic concept.

Finally, there emerges an ecologic concept, the understanding of a composite in which man and life are made up of many forces and entities interacting. Man's struc-

informa-  
tion  
leading to  
diagnosis

ture and function, as determined by his genetic legacy, become for each man a unique medley of nearly numberless possibilities. The accretions of changes from the physical events and memory traces of his own past and the race's past are continuously impinged upon by stimuli, great and small, sure and unsure, heard and unheard, inside and out. Life then becomes a process. It operates in time; goes on in a finite place. Man both reacts to and influences his environment. Both change. Disease, too, is a process. The body's functions fail or decay, the machinery rattles when adjustments are inadequate or the stimuli too great or too many. Disease results when adaptations, reactions, repair, and renewal diminish.

Today, disease is seen through a series of concepts, and vigilance must be exercised to keep separate the sometimes interchanged meaning of word, idea, and thing.

This article is divided into the following sections:

- I. Direct evidence from the patient
  - The medical history
  - Physical examination
- II. Biological, chemical, and radiological tests
  - Laboratory diagnosis
  - Multiphasic health screening
  - Use of radiations in diagnosis
- III. Other important considerations
  - Surgical diagnosis
  - The medical record
  - Sources of error in medical diagnosis

## I. Direct evidence from the patient

### THE MEDICAL HISTORY

The medical history, the information gleaned from the patient concerning everything that could have a direct or remote bearing on the present illness, must be as accurate and as exact as conditions permit. The excellence of the history depends on the patient's memory, his judgment, his present and past health, and his articulateness, and accuracy. The history must include vital statistics, dates, habits, occupation, and many points that may not bear immediately upon the problem at hand. Even when working with a well-informed and most articulate patient, the record may be poor if the physician who prepares it is hurried, careless, writes illegibly, fails to include pertinent material, or fails to become skilled in the use of the searching, carefully phrased question.

Most people are interested in talking about themselves. An unguided discourse is likely to be rambling, full of irrelevancies, and difficult to use or to learn from. It may blur the focus and distract the physician. Since the physician must take the patient's story apart and look at his dissection of it in terms of pathological physiology as indicative of departures from normal form and function, the skillful physician translates the ordinary patient's common speechways into what he understands as departures from normal function, on the basis of all the evidence that he can accumulate. He then translates these findings into a program of further diagnosis and therapy. The success of a physician, particularly in chronic illness, often will depend on a careful discussion and interpretation, in simple words that the patient can understand, of the nature of what is wrong, the necessity for therapy, and the nature of the therapeutic program.

**Present illness.** In obtaining information on the current state of the symptom complex called an illness, the physician guides the patient away from making diagnoses—she has seen a television program on cancer, perhaps; or a friend has died of it. At the same time, however, precise detail must be secured about the way the patient feels and the functions that seem to be or are out of kilter. Often the absence, the presence, or the degree of concomitant features will enable the interrogator to put the proper weight and significance upon each symptom.

Since the patient is likely to be frightened, worried, concerned, in pain, or uneasy, skilled physicians try to calm him by being calm, show interest by being interested, and exhibit genuine sympathy upon which not only successful diagnosis but successful management depend. The doctor has empathy and sympathy; he is neither overbearing nor oversolicitous.

Always a person's reason for seeing a physician is clear-

ly identified. In effect, the interview is opened by asking, "What may I do for you?" rather than, "What brought you here?" Few patients view their own problems unemotionally or even perceptively. After a patient has made his initial statement, the physician asks questions and keeps the focal point of the discussion on the patient's actual problems. While the physician must possess and exhibit genuine concern and care, he must avoid all moral judgment, favourable or unfavourable, upon the patient.

The value of a patient's story depends upon the assumption that it is truthful. Errors may occur from forgetfulness or a failure to understand the intent of a question. Occasionally there may be willful deceit out of fear or for ulterior motives such as the thought of compensation claims.

From the patient's history, clues for diagnosis will evolve. They may be only vaguely suggestive, or tantamount to a precise and complete diagnosis. Thus, as the physician accumulates information from which he derives medical data that are continually evaluated in the light of additional details of time, place, degree, and intensity, he begins to form a judgment of the credibility of the patient.

**Toward an analysis of pain.** As an example of the diagnostic query, the problem of pain looms large in medical experience. The physician usually wants to know several things about any particular pain. In order to experience pain, a person requires: (1) a stimulus; (2) a mechanism for transmission of the impulse; (3) an area in the higher levels of the central nervous system where perception occurs; (4) a state of conscious awareness. Diagnosis depends in part on a person's description of what he feels, and the description will be conditioned by the patient's intelligence, imagination, clarity of mental processes, earlier experiences with pain, and many other factors.

The first thing that the diagnostician must learn about pain is its location, first the general area in which it is felt and then the more precise localization in depth; *i.e.*, whether it is confined to an area that might be pointed to by a finger, the finger tips, the hand, both hands, or hands rubbed over the entire abdomen, and whether it is superficial or deep, or both. Next, the doctor is concerned with the extension of the pain by spread or irradiation, whether another pain, called referred pain, is felt simultaneously at a distance. Diagnostically it is important whether the pain extends from the point of origin over a continuous territory or is, for example, in the so-called ulnar portion of the left arm (that is, in the forearm on the side away from the thumb) and occurs simultaneously with separate pain under the breastbone, as occurs in angina pectoris, the suffering associated with the heart muscle's reception of insufficient oxygen.

Diagnosis is also concerned with the characteristics of the pain; the quantity and the quality of it, its severity, its character. All that can be learned of the character of a pain is learned from what the patient says by way of analogy with familiar experience. Thus, pain may be said to be burning, crushing, stinging, throbbing, or cramp-like. Such information needs to be considered with a clear understanding of whether the patient is ordinarily sensitive to pain, rather insensitive, or hypersensitive. His reaction to pain may be a hypochondriacal exaggeration or a stoical denial or downgrading of its severity.

The next series of diagnostic factors about pain are concerned with time, how long it lasts, whether it is a flash of lightning that appears for an instant and is gone, a slow but steadily intensifying sensation that builds up to a peak and then fades out, whether it is first established at an agonizing plateau of anguish and misery, is constant and enduring for hours, or brief—a crisis or a nuisance.

The next factor is the frequency with which pain occurs, if it is a repeated experience, whether it is habitual and inveterate, comes every day or many times a day, or only occasionally and in unforeseen circumstances, is irregular or has happened only once.

The exact circumstances under which pain occurs are important and generally must be considered in terms of special influences on pain: whether or not these are fac-

Reliability of patient's story

Localization and extension of pain

Factors affecting quality of medical history

tors that induce or aggravate it; whether, for example, a specific degree of exercise invariably induces it, its relation to meals, whether it is provoked by motion of a particular joint or limb or by general exercise, whether it comes only in circumstances charged with emotion or on the basis of season or weather.

The circumstances that aggravate a pain when it exists may be different from those that induce it, though they tend to be similar or identical.

Diagnosis is concerned with such pain-attending manifestations as shortness of breath; faintness; eructation; belching; passing of flatus; abdominal rumblings; flushing; a sense of dying, *angor animi*.

While a patient's story is the first and most important source of clues about pain, it must be related to what is learned in the examination of the patient. Much referred pain is interpreted by the brain as coming from sensitive structures innervated by the same segment of the spinal cord that is connected to nerves through the autonomic nervous system. Referred pain may be intense when an organ in the body proper is disturbed. The supporting structures of the skeleton must be considered—*i.e.*, bones with the membrane, the periosteum, that encloses them and tendons and ligaments with their attachments. The muscle mass, which, with all of the muscles taken together, is the largest organ in the body, may be the site of referred pain or may have pain associated with insufficient blood supply, spasm, injury, cuts, bumps, bruises, or encroachment or invasion by bleeding, tumour, or other abnormal material.

Next, the sensory nerves themselves may have lesions. It is diagnostically critical that a disease affecting the peripheral nerves of infectious, toxic, or metabolic origin may itself be responsible for sometimes bewildering pains.

Pain in the chest, in addition to coming from the supporting structures of skeleton, muscle, ligament, and skin, may come from a bewildering variety of abnormalities that affect the internal structures. The diaphragm (the muscular partition between the chest and the abdomen), for example, may be injured or irritated by disturbances of the upper portion of the abdomen by such phenomena as hiccups, spasms, or the stitch in the side that occurs when running. In diaphragmatic irritation, pain may be felt at the base of the neck because the central diaphragmatic muscle mass migrated down from the region of the neck in embryonic life after the nerves had formed their attachments, taking the nerves with them.

The examining physician must be aware that pain in the chest may come from a variety of disorders of the alimentary canal, which include diverticula (abnormal pouches) of the esophagus, spasm, failure of the sphincters to open properly, ulceration of the esophagus, and hiatal hernia—protrusion of the stomach through the esophageal opening in the diaphragm; and that pain in the lower chest may be provoked by peptic ulcer (ulceration of stomach or intestinal lining), inflammation of the pancreas, gallbladder disease, and even insufficient blood supply to the intestine—*ischemia*. Nearly all the organs and structures in the chest must be considered.

Evaluation of pain leads the examiner to questioning based on knowledge of the anatomical structures that may themselves give rise to pain or may be important in conveying the nerve impulses correlated with pain. The heart is not only symbolically but actually the site of disorders that commonly give rise to chest pains. The coronary arteries, the arteries that supply the heart, are the seat of blood vessel disease that is often responsible.

In addition, one may have pain caused by general body states such as thyrotoxicosis, or overactivity of the thyroid; polycythemia, or too many red cells; and anemia, or too few red cells. Finally, pains occur in tense, nervous people for reasons that are obscure.

Formulation and critique. The skillful physician must extract from the patient a description of symptoms that explains what the underlying facts are when the patient says, "I feel sick," "I'm breathless," "I'm weak," "I have a pain," or "I have an ache," or "I'm dizzy," statements so vague in themselves as to provide little help.

Thus, a complaint of weakness may suggest disease of the central nervous system, inflammation of the peripheral nerves, chronic intoxications, undernutrition, vitamin deficiency, fatigue from overwork, or almost any chronic severe debilitating disease. Difficult breathing or shortness of breath needs to be investigated along lines similar to those used in the investigation of pain. In the complaint of swelling of the ankles, one needs to know whether it is firm, red, hot, tender, or painful; whether it leaves an indentation on pressure; tends to diminish or disappear overnight only to reaccumulate during the subsequent day's activity.

In confirmed alcoholics, the quantity and kind of drinking the patient has done is hard to determine. His own statement may vary substantially from that of his cronies or his wife. A sense of guilt or shame may diminish the apparent extent of drinking; or, in an occasional patient, a sense of bravado may lead to exaggeration.

The actual colour of the urine, the colour of feces, the actual amount of blood coughed or vomited is diagnostically important. In judging the severity of hemorrhage, the patient's impressions may be exaggerated by terror or by objects, clothing or bedclothes, that have spread a little blood a long way. The occurrence of yawning, dizziness, tendency to black out, actual fainting, sensation of the heart racing, palpitation, and drenching sweat may be more helpful in arriving at an estimate of the degree of blood loss.

The physician will be helped in working out the chronology of a disease if the patient can tie in an episode or feature of an illness with a specific event, a happening, a journey on a specific date. Especially in long-drawn-out diseases, reference to old hospital records or physician's notes, or a diary, or letters may highlight a specially important event with enhanced accuracy.

In evaluating the impact of the illness on the patient's life, a physician will need to know whether the illness confined the patient to bed, kept him from work, or merely distracted him while he went through the day's usual routines. Thus a patient who complains of fearful pain but continues the routine of daily activity has presented conflicting testimony that needs to be judged. Again, the physician is aided in estimating from his character or nature. He knows, or should know, whether the patient is easily upset, exaggerates complaints, or is stoical; whether an illness or symptom can be used consciously or unconsciously by the patient to gain some objective—release from work, getting attention from an inattentive spouse, love and care from family, or sympathy from neighbours.

When a patient presents a long, complex medical history, actual records and reports may be essential to a proper understanding of the problem. The physician will need to know how many medicines are currently being used, what ones had been used in the past, what idiosyncrasies or allergies a patient has. It is essential to know whether some regimen such as a program of rest, of exercise, of weight reduction, of shock therapy, or diabetic management has important bearings on a current condition.

**Past history.** Although the history of a patient's past health or medical problems is more likely to be of value in understanding his problem in illnesses that are chronic, an understanding of a current acute disturbance may occasionally be possible only with the knowledge of the past. An unexplained fever may move a step toward clarification when it is learned that the patient had rheumatic fever some years previously. A pain in the abdomen may be understood only in the light of knowledge of earlier operations.

The general health of a person is not likely to be learned from a diary. Growth curves and charts of weight rarely are available, though any precise information helps. Whether or not a change in body weight is associated with the present sickness may have to be understood in the light of past averages and extremes of body weight.

There is need to know where the patient has lived, whether overseas travel or military duty may have exposed him to exotic diseases, drugs, or injury; whether he

Referred  
pain

the chrono-  
logy of  
disease

has ever been a patient in a hospital for some disease, injury, or operation; has had examinations for military service, for work, or for insurance, and what the results of these examinations were.

Special diagnostic procedures and specialty problems. An important part of the general history of a patient consists of the review of systems. Here, functional rather than structural characteristics of the body may reveal a pattern. In regard to many such systems, medical specialties have arisen, each with its own separate constitution and bylaws, its strong proprietary feelings, and its tendency to isolate itself from the central core of general medicine. The following list of systems is ordered alphabetically.

**Allergy and immune disorders.** An array of changes, many of them not belonging to a single medical domain, are grouped as allergic and immunological disorders. Sensitivity causes lesions in the skin, edema, and disorders of mucous membranes such as hay fever. Some doctors put migraine into this group. Pollens, danders, and easily discovered sensitizing agents are well known offenders.

**Bones.** The growth of bones, their shape, size, deformities such as the acquired ruin of rickets; perfect healing compared with the limping awkwardness of a misset fracture; congenital anomalies; the acquired overgrowth of hypertrophic osteoarthropathy are significant in diagnosis. The troubles in and around inflamed joints, the vast array of bone weakness from inadequate minerals or protein deficiency in osteoporosis and osteomalacia, bone cysts, tumours in bone and pathologic fractures add to the list of important metabolic and orthopedic problems.

**Cardiovascular system.** Since every cell in the body depends on the cardiovascular system for its successful birth, function, and survival, a complete understanding of it would require, and be equal to, the comprehension of all of the functions of physical life in health and disease. Since the time of Harvey, but not before, physicians have looked upon the heart as the essential element of this system, adding scientific validation about the heart to what folk speech had already kneaded into the language. For the diagnostician, a grossly abnormal functioning of the heart may call attention to its difficulties through pain in the chest, shortness of breath, palpitation, a quick beat or a sense of the heart's racing, or difficulty in breathing at night that makes one sit up, gasp for breath, and cough. Swelling of the ankles and the abdomen may occur next, as may faintness or fainting. The legs may signal circulatory deficiency in an intermittent limp and pain if there are large arterial impediments. Raynaud's phenomenon may blanch the fingers. The veins may become clogged and inflamed, or obstructed with the secret clot of phlebotrombosis, recognized only after detachment of the clot causes death of lung tissue.

The diagnostic story of cardiovascular trouble may include heart attacks, coronary artery trouble, angina pectoris, high blood pressure, rheumatic fever, congenital heart disease, traumatic lesions of the heart as well as systemic diseases such as diphtheria, syphilis, or muscle disorders.

**Endocrine system.** The hormones made by the body temper and modulate the sharper controlling actions of both the voluntary and the autonomic nervous systems. Growth, reproduction, body type, weight, size, hair, skin pigment, muscle strength; libido and potency or impotence; texture, moisture or dryness of skin and hair; tolerance to heat and cold; control of thirst; gluttony, sugar in the urine, loss of appetite; extraordinary ambiguities of physical sex characteristics; the diminuendoes of aging and senility—all form a heterogeneous endocrine-governed mixture. Errors of the system produce different forms of dwarfism and gigantism. Precocious senility is contrasted with the bewildering occurrence of puberty in those scarcely out of diapers.

**Gastrointestinal system.** Just as physicians who specialize in ailments of the nose and throat are said to be convinced that many, if not all, patients have trouble with the upper and lower respiratory tracts, so doctors

dealing with the alimentary canal may be convinced that this is, perhaps, the most fertile terrain for imperfect function and symptoms. Study of the alimentary canal includes an estimate of appetite, weight, the mechanics of eating, difficulty in swallowing, nausea, belching, flatulence, abdominal aches, pains or colic, vomiting, jaundice, and vomiting of blood. With jaundice, there may be fever, pain, or change in the colour of feces or urine.

A preoccupation of many people with alimentary complaints is called stool watching. Patients reporting their bowel movements to an examiner can give the most minute and detailed description of frequency, consistency, odour, gas, the effect and noneffect of cathartics, almost everything, including weighing the feces. The doctor must know about sphincter control, hemorrhoids, fistulas, bleeding, diarrhea, constipation, and bowel habits.

**Genetics.** A large group of physical and emotional difficulties may be determined by obvious chromosomal disorders or by mutations, which are getting increasing attention. They need to be known in order to be dealt with appropriately even in the afterthought of counseling. There is need to know whether any genetically determined disease is transmitted by a dominant or recessive mechanism, is a de novo sport or part of an ancient heritage.

**The hematopoietic system.** The bone marrow and sometimes, by a borrowed skill, the spleen and liver manufacture cellular and other constituents of circulating blood. "Anemia" is a general reference to numerous disorders with reduced hemoglobin and red cell constituents. Anemias fall into three large varieties with some crisscrossing and overlapping. A hypochromic microcytic anemia occurs when iron is not available in adequate amounts to manufacture hemoglobin, and the red cells are small and deficient in this protein, which is essential for the nearly instant transfer of oxygen and carbon dioxide. At the opposite extreme there are large cells full of hemoglobin but far too few of them. This form, called macrocytic hyperchromic anemia, results from inadequate function or supply of vitamin B<sub>12</sub> and folic acid. Pernicious anemia is the classical example of this disorder. Tropical or nontropical sprue with malabsorption cause the same morphologic change. Normochromic and normocytic anemias reflect a situation in which size and shape of red cells, and perhaps the function, are adequate, but there are not enough of them. This may occur shortly after a significant hemorrhage, in situations in which red cells are destroyed faster than they should be; and in some states that inhibit bone marrow and slow down the production of red cells. Too few cells are made, but the cells are not significantly abnormal.

**Lymphatic tissue.** The spleen and the liver may be enlarged in various tumours of lymphatic tissue (lymphomas) and leukemias. Peripheral lymph nodes become enlarged at the point at which infection invades the body. Tumours may develop. Infected lymph nodes may become swollen and painful or mat together. They may suppurate, forming abscesses and abnormal passages (fistulas). Lymph nodes play an important role in a wide range of disorders.

**Muscles.** The enlargement of the forearm of the traditional blacksmith, the rippling muscles of the gymnast and the weight lifter, have their opposite in various atrophies and muscle disorders that may be inborn or acquired from damage and destruction to motor nerve cells. The athlete's bruise, the stiffness of the sprain, and the harmless but miserable, sometimes wretchedly, painful nocturnal cramp of dowager, mountain climber, or sprint star may all be part of a diagnostic picture.

**Nervous system.** Diseases of the nervous system include those that belong to psychiatry and those that occur in the field of general neurology. Special and supplemental procedures and diagnostic procedures are required. The past history that is of concern to the neurologist includes the functions of speech and language, disorders of head and neck, the integrity and health of the cranial nerves, the whole motor system, coordination, the state of reflexes, the state of the sensory system, the spinal cord, as well as the gait, stance, and station of the

Types of  
anemiaNeuro-  
logical  
symptoms

patient. Special studies may be required for a comatose person, for children, for the very old, for those suspected of malingering, and for those who may be motivated by the hope of compensation and insurance payments. In the history of a patient with suspected neurological disease the physician needs to know about trouble with smelling, seeing, hearing, chewing, taste, equilibrium, speech, swallowing. The functions of urination, defecation, reactions to heat and cold, sweating, redness, pallor, and cyanosis are important, too.

**Obstetrics and gynecology.** For women such things as growth, age at **menarche** (the first menstrual period), regularity, duration, and frequency of menstrual periods, amount of flow, degree of comfort or discomfort, the exact date of the last normal period, occurrence of **leukorrhea** (whitish discharge from the vagina), unusual bleeding; premenopausal and postmenopausal events, and the menopause are all important. The whole medical and psychological story is necessary too.

The diagnostician will need to know of details of any communicable diseases, particularly German measles (rubella), the immunization record, inheritable diseases, kidney disease, diabetes, cardiac problems, and previous blood transfusions. He must know also of previous pregnancies, abortions, dates of delivery, method and ease of delivery, complications, weight of the child, condition at birth, and how the child developed.

When dealing with infertility problems, it is necessary to ascertain whether the uterine tubes are open; to make X-rays of the uterus; to examine a specimen of the uterine lining, just before the menstrual period, and to keep temperature graphs to see if ovulation can be detected; estrogen and other hormone levels must be investigated if any abnormal conditions are found.

**The skin.** Besides the colour of the **skin**, or the lack of it, the examiner needs to learn about changes in appearance that may range from the black of the black man to the noncolour of the albino; the acquired pigmentation of tanning or of Addison's disease (failure of the outer substance of the adrenal gland); tendency for the skin to be moist or dry, hot or cold, itching or comfortable, scaling or bleeding, easily bruised or weeping, wrinkled or fresh, distended by edema or shrivelled by malnutrition. Of the appendages of the skin, the most important are the hair and the nails. Also important are studies of the pattern of ridges and valleys that go to make up the fingerprint. Presence or absence of hair, its rate of growth, texture, the places it grows, and its colour must be noted. Whether it has disappeared or grows overabundantly, and where, may be critical. Generally neglected, the nails may give an intimate view of health, disease, growth, and aging. The spectacular changes of clubbing, the opposite alteration in spoon nails, pitting, colour changes, and the deformity produced by fungus infection or psoriasis make a gaudy and sometimes painful spectacle.

**Urinary system.** The urinary system, more likely to trouble old men than old women, may change the colour of the urine, increase excretion or reduce output, or manifest excessive urination at night and painful urination. The occurrence of pus or blood in the urine, frequency, colic from stones in the ureters or stones in the bladder, chancre, bubo (the inflammation of lymph nodes in the armpit or groin), and the urethral discharge of gonorrhea present a long trail of recurring disorders.

#### PHYSICAL EXAMINATION

The physical examination is a continuation of the exercise in diagnostic detective work. Any sensory function may be used by the physician as a legitimate means of getting information. The standard formal divisions of the physical examination are inspection, palpation, percussion, and auscultation (see below). Occasionally, smelling is of help in recognizing diabetic acidosis, uremic breath, fetor hepaticus, or lung abscess. Most physicians today doubt that old clinicians really could smell typhoid.

The physician working toward a diagnosis uses the same senses that everyone has. Because of his training, his perceptions have special meaning in terms of normal and

abnormal structure and function. A working diagnosis evolves on the basis of gathering and then interpreting the accumulated data. Even people who are tone deaf can become excellent at auscultation. It takes not so much talent as long practice to get accurate information from palpation and percussion.

**Inspection.** As for inspection, vision is so conditioned by training that most people see and perceive what they look *for* much better than they do what they look *at*. Inspection is the sheet anchor of physical diagnosis, and the hardest procedure to do well. Even so, correct diagnosis is probably made more often by inspection than by any other part of the physical examination. One sees what he can form a mental as well as a visual picture of—in short, what he understands. Looking, everyone can do; but seeing must be learned. The yield from inspection depends on the understanding and training of the observer. Within surprisingly broad limits, it depends little upon the acuity of vision as ordinarily measured, though good eyes and a good light always help.

Inspection in a sense goes on systematically during the entire time the patient is with the physician. It begins with greeting the patient and continues through taking the history. During the actual examination, it is concentrated. Everyone recognizes and identifies persons at a distance by their walk, their size, their shape, or their clothes. Their voice and manner may give further clues. Thus, one "diagnoses" the presence of a friend, an acquaintance, a relative, or a stranger. A layman seeing a person with heart failure might or might not know the significance of the bluish skin, the puffy ankles, the shortness of breath, though he would recognize that the person was in trouble.

In very gross abnormalities a quick diagnosis may be correct. Usually such a diagnosis results in fact from the compression in time of a multitude of steps that the diagnostician has taken unconsciously. There is no magic or sixth sense.

The importance of the examiner's concentrating his whole attention in diagnosis, both in controlling and in directing his thoughts, is illustrated by the experience almost everyone has had of looking at a watch to satisfy some particular need to know the time, only to realize on being asked what time it is that he has to look again because he was thinking not so much of actual time but rather in terms of some engagement, appointment, or plan.

Inspection of the body as a whole will reveal at once size, shape, skin colour, approximate age, gross deformity, sex, spontaneous motor activity, body build, and state of nutrition. Something is learned of manner, mood, posture, speech, and the subtle kaleidoscopic composite that helps tell whether the patient is sick with organs disabled or is anxious, worried, in pain, or in trouble, and, if so, to what degree. The symptoms may be just as real and as severe when the function of healthy organs is disordered as when they are physically diseased.

A region of the body may be inspected minutely or generally, for the body gives rise to hundreds of normal or abnormal physical signs. The initial and sometimes the only necessary diagnosis in skin diseases may be made by inspection. The tables of contents listing the illustrations in dermatological and in surgical textbooks of diagnosis give an indication of the importance of seeing to the understanding of such manifestations. Diagnostic inspection goes beneath the skin. Endoscopes, devices for viewing internal structures, may disclose a whole realm of internal structures from one end of the body to the other. Specialized instruments are available for viewing the interior of the eye, the nose, the ear, and so on. Beyond the eyes' unaided power, the microscope enables one to see tissues, cells, crystals, and so on. The X-ray discloses function and structure with fluoroscopic screen and films. The X-ray film may be in the form of a motion picture, a series taken in rapid sequence, or as the representation of a single moment.

**Palpation.** Palpation is investigation by means of tactile senses. Such senses may provide all kinds of information including **that** of touch, temperature, vibration,

Examina-  
tion of the  
body as a  
whole

shock, crepitation (grating) of a joint, vibration of moving fluid in an irregular conduit, and sense of position, location, or place. For the doctor, practice and experience add a keenness to the native sensory capacity, as he acquires a special skill.

The tips of the fingers are the most sensitive parts of the body for touch, as would be expected because of their constant use in exploration of the reachable environment. In growing children palpation appears better than vision in orientation, at least early in life. It includes not only examining and feeling objects but putting them in the mouth. Temperature is perceived most readily by the backs of the fingers and the back or the side of the hand where the skin is thin. Vibrations and thrills (tangible vibrations or pulsations) are felt best in the region of the palmar calluses where the fingers join the hand.

The tactile sense is used to some extent in testing strength of grip. The ideas imparted about the shape, consistency, and the mobility of an abdominal organ or mass are perceived by the simultaneous fusion of several aspects of touch.

Although palpation may be thought of mainly as the art of acquiring information about the external structures of the body, many internal organs can be felt indirectly, both in health and in disease. The sense of touch may be vital in finding abnormalities in the mouth, tongue, region of the tonsils, thyroid gland, rectal and pelvic structures, as well as in the external genitalia, skin, and hair. Abnormal masses or enlarged organs may be hard, soft, moveable, firm, or quiet; may pulsate, or crackle, as in the crepitus of joints. The crinkly, squashy feel of tissues into which air has escaped under skin or along fascial planes (sheets of fibrous tissue) where it does not belong is unpleasant. Thrills over turbulent flowing blood in aneurysms (local dilations of arteries with thinning of the vessel wall), arteries, or in the heart challenge the skill of the palpating hand. Useful information is imparted by the creaking, rubbing, leathery sensation over a point at which there is friction between two surfaces of the pleura, the membrane that encloses the lungs and lines the chest.

Surgeons have a special opportunity to become skilled in palpation. First they feel organs and masses through guarding muscle or intervening tissue; then at operation they feel the structures directly. This instructing, and at times correcting, experience gives the conscientious surgeon an intimate knowledge of lesions, tissues, and organs that other physicians may touch only at autopsy.

Percussion. Percussion is used in physical diagnosis to obtain information about what lies below the surface of the body, by striking it, setting up vibrations, and listening to the resulting sounds. It is a primitive form of echolocation. In addition, the practiced clinician obtains information in percussion from the sense of touch.

While, except when examining internal passages and structures, inspection is in the class of nonintervention, the manipulations of palpation and percussion represent an intrusion or an intervention, minor to be sure, in which the passive observational aspect of the diagnostic quest is replaced by a simple, gentle experiment. Auscultation (see below), as it is practiced with the stethoscope, also has an element of intervention as the physician puts the stethoscope in appropriate places and may instruct the patient about breathing or holding the breath or changing position.

Percussion may be direct or indirect. When it is direct, the tips of the fingers strike the chest. When a finger is interposed, the percussion is indirect and is called **bimanual** or **mediate** percussion. The finger that is placed upon the chest or abdomen is called the **pleximeter**. Only the terminal phalanx is applied, since the other fingers may damp out vibrations and sounds. The striking finger is called the **plexor**. Another form of percussion is done with the middle finger while the other fingers and thumb of the same hand are pressed firmly on the surface.

When percussion is desired, the examination begins with the patient lying on his back. After the front of the chest has been percussed in this position, the patient sits up and the borders of the lung, particularly the bases, are estimated and the outline of cardiac dullness is obtained.

Very ill patients remain in the recumbent position, and the front and back are examined with the patient lying on one side or the other.

Auscultation. Auscultation means listening and hearing. The body generates many noises, most of which come from air movement. A patient's breathing, voice, and manner of speaking, as well as what he has to say, are important. Coughing, sneezing, belching, the expulsion of flatus, the embarrassing sounds of the movement of air through the bowel within the abdomen are familiar. The cry, the snore, the groan, the shriek, the snort, the stertorous breathing (which may occur in heart failure or in brain disorders), regular-irregular stop and go breathing patterns all give diagnostic clues. But for practical purposes auscultation concerns what may be heard by the appropriate use of the stethoscope.

The stethoscope, beginning as a tightly rolled cylinder of paper first used by René-Théophile-Hyacinthe Laënnec, next became a solid cylinder, then a hollow cylinder, and finally a device with tips that fit snugly into the two ears. The stethoscope has even been modified in the **symballophone**, in which two terminal cups, or bells, simultaneously capture sounds from two different points, thus permitting an approach to three-dimensional localization of sounds.

Traditionally, the chief terrain of auscultation is the chest, to hear sounds generated by the heart and lungs. A broader understanding of disease and a great new variety of technique have broadened the uses and emphasized the value of auscultation.

The use of sound in diagnosis is complicated by the differences in sounds from person to person. The capacity of the listener to hear sounds is related in part to his perspective capacity, though, significant deafness aside, it is rare to find a person who cannot master the difficult art and science of auscultation.

The stethoscope employed today consists of two ear pieces, which fit snugly into the external ear, rubber tubing, and a chest piece. The tubing connects the ear pieces to the chest piece, which ordinarily includes a hollow bell and a wider flat cup. The cone of the bell, which transmits all sounds but is best for sounds of low pitch, has a rim of hard rubber or plastic around it. The wider flat cup is covered with a thin semirigid diaphragm of plastic to exclude low-pitched sounds so that isolated high-pitched sounds may be heard. Different forms of stethoscopes offer various advantages and disadvantages. The snugness of the fit in the ear is important for concentrating the sounds the doctor wishes to hear and excluding others.

Bakelite, or other plastics with proper acoustical properties, are necessary for the cup. When the diaphragm is used, it is pressed snugly against the surface. The bell is applied lightly but with an all-around contact to keep out extraneous sounds. If it is pressed lightly, the stretched skin acts as a diaphragm and blocks out low-pitched sounds.

**Examination of the chest.** When air flows at various rates through tubes of varying calibre, shape, or **angulation**, it is thrown into turbulence, setting up vibrations. The purpose of auscultation is to separate normal from abnormal sounds of breathing, after coughing, and by the transmission of the spoken or whispered voice through the lungs to the surface of the chest. When sounds are not heard, the physician assumes that part of the tube is blocked, that air is not reaching its proper destination, or that something is interposed between the air-containing lung and the surface at which the stethoscope is applied. This could be fluid, a solid mass of tissue, or air free in the chest cavity.

Ordinary breathing produces breath sounds, called **vesicular** breath sounds, which are longer in the inspiratory phase than in the expiratory phase. They can be heard over the lungs except where structures between the two lungs are in the way. If the stethoscope is placed over the trachea, bronchial breathing, breathing with a longer, louder expiratory phase and a short inspiratory phase is heard. When this breathing is heard over other parts of the lung, it means that sounds generated in the trachea

Develop-  
ment of  
the stetho-  
scope

Types of  
breathing

Import-  
ance of  
the sense  
of touch

Direct and  
indirect  
percussion

are being transmitted through consolidated (solidified) or compressed pulmonary tissue, as in pneumonia. Intermediate between bronchial and vesicular breathing is **bronchovesicular** breath, which usually indicates pulmonary consolidation of less extent than when bronchial breathing is heard.

The sound and time relationships may be changed completely in the breath sounds heard during an attack of bronchial asthma. The expiratory phase may be many times longer than the short gasping inspiratory phase. The pitch is high, sometimes amounting almost to a squeak. The sounds of this sort of breathing, called **amphoric**, resemble the noise produced by blowing over the mouth of an empty bottle.

Ordinary breathing does not produce loud sounds. Much louder ones are produced when a person whispers or speaks. Whispered sounds usually give better discrimination because they are not too loud. Consolidation increases the loudness of the sounds from the spoken or whispered voice. Egophony, the sound resembling the bleating of a goat, may be heard over areas of pulmonary compression, collapse, or consolidation.

### Rales

In addition to sounds produced by breathing or **phonation** the examiner may hear sounds called **rales**, or little rattles, which come from the turbulence set up by air going through constricted or distorted parts of the airways or over fluid or thicker secretions that do not completely plug the tube. The classification of rales is chaotic. The major designations concern whether the rales are moist or dry, the dry ones actually being produced by moist but viscid secretions. Large gurgles or rhonchi occur when the noise is generated in the trachea or larger bronchi. They occur especially in persons in coma. Rales occurring when death is approaching have been called the "death rattle."

Less impressive rales, called medium or crepitant, arise from the disturbance in the flow of air and vibration set up in smaller branches of the bronchial tree. They sound either like clicks or bubbles. Fine moist rales may be also called crackling or subcrepitant. They probably arise from air moving over fluid in the very small bronchioles. Dry rales have a musical or a sonorous quality, depending on whether they are high pitched or low pitched.

### Friction rubs

The diagnostician may hear friction rubs in pleurisy, injury, pulmonary infarction, or pneumonia. They are produced because the fibrinous surface of the **pleura**—membrane—covering the chest wall and that covering the lung are dry or sticky, and the movement between them, ordinarily gliding, is interrupted. The noise is said to resemble that made by rubbing two pieces of leather together. With free air and fluid in the pleural space, movement may cause a succussion splash, a very unpleasant sound.

A great variety of sounds may be heard over the heart in pericarditis, inflammation of the fibrous sac that encloses the heart. Even more astonishing ones are heard in the crunchy, crackly loud noises generated when air escapes from its normal tubular pathways in the lungs into the lung's free supporting tissues and fascial planes.

Information gained by auscultation must be considered in conjunction with what may be found by palpation and percussion. Percussion may disclose the hyperresonance of a pneumothorax, air free in the chest cavity, or the flat note of consolidation, fluid, or interposed tissue. Inspection may reveal bulges or an asymmetry in the respiratory movements of the two sides of the chest.

Variations in the amount of subcutaneous fat, in the thickness and muscularity of the chest wall, in the capacity of the patient to follow instructions in breathing, in the state of vigour and health of the patient, all introduce differences in sound produced that can be appreciated only with painstaking and prolonged practice and experience.

**Auscultation of the heart.** Normal sounds in the cardiac cycle are as follows: first, sudden contraction of the ventricles (the lower chambers of the heart) closes the atrio-ventricular valves, between the lower and the upper chambers, and opens the valves into the aorta and the pulmonary artery, transmitting vibrations to the chest

wall. This first heart sound is brief. The second heart sound occurs when the aortic and pulmonic valves snap closed at the beginning of diastole, the interval between the pumpings of blood out into the general circulation and to the lungs. If the right and left sides of the heart do not beat simultaneously, the cause may be abnormally high pressure in the pulmonary artery, narrowing of the valve into the pulmonary artery, or blocked conduction in the right bundle branch, a collection of modified heart muscle fibres that normally plays a part in conduction of impulses from the pacemaker of the heart, the sinoatrial node (see **CARDIOVASCULAR SYSTEM, HUMAN**).

A third and a fourth heart sound may be perceived. The third represents the ordinarily quiet opening of the aortic and pulmonary valves as blood leaves the ventricles, the lower chambers of the heart. The fourth, or atrial, heart sound is generally pathologic and represents overactivity of the atrial contraction or abnormality in the ventricle at the time it receives blood.

The use of the stethoscope enables the physician to make a tolerably accurate judgment about cardiac rhythm and irregularities, as well as an accurate count of the rate. In atrial fibrillation, the heart beats fast and irregularly and there may not be a pulse for each heartbeat. If the pause between beats has been short the amount of blood ejected by the heart is too small to propagate a pulse wave.

The ordinary heartbeat is characterized by the two sounds that repeat themselves continually. With irregularity, it is necessary to count the heart rate rather than feel the pulse. The difference between beats recorded over the heart and at the wrist is called the pulse deficit.

Counting the heart beat

After the rate per minute has been determined, the rhythm is studied. It may be entirely regular. There may be a slight slowing and speeding related to phases of respiration, an irregularity called sinus arrhythmia.

To the diagnostician anything that is regular at extremely rapid rates suggests a disorder of rhythm called atrial flutter. Regular impulses are generated in the pacemaker in the atrial wall at approximately 230–300 beats a minute, but protracted ventricular response at the rate of 200–300 beats a minute is incompatible with life. There may be a 2:1, 3:1, or 4:1 block, which means that only every other, every third, or every fourth atrial beat evolves a ventricular response.

The heart rate may be slow. When it is exceptionally slow, and regular, there may be a 2:1, 3:1, or 4:1 block. Very fast rates may occur with atrial fibrillation, atrial flutter, a simple rapid heartbeat (sinus tachycardia), or paroxysmal atrial flutter. Ventricular rates between 150 and 230 seem regular. In ventricular tachycardia, rates may vary from 150 to more than 250 per minute. Irregularity of rhythm causes changes in intensity of sounds because of variation in filling of the ventricles. Irregularities of rhythm may be erratic as with premature atrial or ventricular beats. Atrial fibrillation causes complete irregularity of ventricular activity.

Gallop rhythms are so named because of their resemblance to the rhythmic hoof beats of a galloping horse. The gallop of clinical significance heard early in diastole suggests an overfilled ventricle that is failing in its function as a pump.

All sounds generated from the heart result from vibrations being set in action. When blood flow is smooth, turbulence does not occur, and vibrations are not imparted to heart or vessel wall. Vibrations heard as murmurs are increased if blood is of low viscosity as in anemia, when the rate of the flow is rapid, or when the calibre of the vessel undergoes an abrupt change. The doctor can identify the time at which the murmurs occur with respect to the action of the heart, whether they are early, intermediate, or late with respect to the process of pumping blood into the system and the lungs (systole), or in the periods between pumping (diastole).

Cardiac murmurs

Murmurs, once identified in time, can be divided into those produced by organic lesions and those produced by abnormal function as in anemia or when the heart is dilated. Short systolic murmurs confined to early, middle,

or late phase systole are likely to be benign. All diastolic murmurs have pathologic significance.

Murmurs have pitch and quality, or timbre. This the physician recognizes as a musician identifies the same note produced by bass viol, violin, drum, or flute. Murmurs produced when the pressure is low are low-pitched; those coming from high pressure and narrow orifices are high-pitched. A cardiac murmur may be loud or faint, and loudness is not necessarily significant.

Whenever he hears an extraneous sound, the examiner must decide whether it is a murmur or not, whether it is generated in the heart or is outside it, as in a pericardial or pleural-pericardial friction rub. Ordinary heart sounds begin and end abruptly. Murmurs are less likely to do so. The bell and the diaphragm must be used to hear high- and low-pitched murmurs. The stethoscope must be moved to locate the region of greatest intensity that suggests that a particular valve is involved. The timing of the murmur, whether in early or late systole or diastole, must be determined.

Loudness is usually recorded on a scale of six. One is of small intensity and six is audible without a stethoscope away from the chest. A murmur may be loudest at the beginning, at the end, in the middle. The type of murmur depends on whether it is low-pitched and heard best with the diaphragm. Very low pitched noises may come from friction rubs and have puzzled even experienced clinicians.

Effect of  
position on  
heart  
murmur

Heart sounds and murmurs may be influenced by position—whether the patient is lying on his back, on his left side, is sitting upright, or is leaning forward. The phase of respiration is important, too, since the base of the heart is brought closer to the chest wall with full and held expiration. The presystolic murmur of mitral stenosis, the narrowing of the opening between the left atrium and ventricle (upper and lower chamber), may be heard in a small area while the patient is lying on his left side. Leaning forward may increase the loudness of the murmur of aortic stenosis, narrowing of the opening into the aorta. Exercise with faster flow of blood may bring out a murmur otherwise silent or increase the noise of a murmur.

Smell. While smell seems the least dignified of all the senses used in physical diagnosis and is rarely of critical value, its cultivation may be helpful in obscure problems and may solve a few.

The smell of the highly perfumed, pomaded, and pomandered male patient; the outdoors or barnyard smell of an unbathed worker in the fields; the rancid and fetid personal stalactites and stalagmites of the unkempt vagrant—hobo, hippie, or prisoner of war—are intrusive. In the more strictly medical application of the sense of smell there is much to learn after passing through the atmosphere of body odours. On the breath can be detected such things as the characteristic odour of the diabetic in coma; of someone with long-standing untreated kidney disease; the marshy, musty, swampy odour associated with liver disease; the fragrant, rancid, or vomity, alcoholic odour of the acutely ill or nearly dead drunkard.

A lung abscess may produce a powerful, sometimes nauseating odour, which is particularly distressing to the victim of the disease as well as to all within smelling range. The sputum may have a putrid odour, nauseating with its sickeningly sweet stench.

Poisons  
and  
fistulas

The breath may carry the odour of poisons, as may vomitus, which may smell of alcohol, lysol, and aromatic poisons. Fermenting or decayed food from a diverticulum or pouch in the esophagus (the passageway from throat to stomach) or a suddenly emptying pouch of intestine may have a bad odour. Though a fecal odour to vomitus may come from an abnormal opening between colon and stomach, so-called fecal vomiting may occur with peritonitis (inflammation of the membrane lining the abdomen or covering its organs) or may result from intestinal obstruction.

For thousands of years the body and excreta gave their smell to human habitation. The smell of feces is not generally diagnostic. It is particularly unpleasant in some

forms of malabsorption in which fats become rancid in the alimentary canal.

The odour of urine may be ammoniacal or nitrogenous. Sometimes it smells of the product of other forms of decomposition, usually microbial in origin, with yeasts, fungi, and bacteria doing their part. Pus may have a fecal odour when produced by protein-attacking bacteria from the gut. A sickeningly sweet smell may be associated with gas formation in gas gangrene. Smell, on the whole, is not a critical or often a valuable source of help in the diagnostic examination but may give an initial clue that suggests clinical changes.

Miscellaneous examinations. **Emergency physical examination.** An emergency may fall into a wide variety of categories. No specialty in medicine is without emergencies. The degree of emergency varies quantitatively as well as in terms of the kind of difficulty. The field of trauma has always been illustrated most vividly in warfare, where the form, variety, and severity of injury depend upon the sophistication of methods of destruction.

Outside the field of physical trauma, emergencies may be classified as arising in the natural history of a disease. This may be illustrated by massive internal or external bleeding, stroke, a ruptured intestine, or the anguish produced by efforts at the passage of a stone in ureter or bile duct. Intoxications from overwhelming poisoning, assault by radioactivity from a disaster in an atomic energy plant, or the multitudinous accidental or intentional poisonings make a long list. In fields of special concern, the anaphylactic shock of a bee sting may be promptly fatal. A myocardial infarction, death of a section of heart muscle, may be lethal instantly or within moments. The end stage of chronic undernutrition may present a lethal emergency as death approaches. In the field of nose and throat disorder, impaction of food caught in the windpipe or the clot formations in veins within the skull in connection with infections of the mastoid or petrous portion of the temporal bone may be critical emergencies. In endocrinology, though emergencies are much less common, severe insulin reactions or diabetic coma are examples. As for the eye, the acute foreign body injury, lacerations, burns, detached retina, or the tight eyeball crisis in glaucoma are serious emergencies. Besides bleeding of the alimentary canal, rupture of gullet, stomach, or other portions, peritonitis from appendicitis, and severe bleeding constitute examples. Some infections, stones, and obstructions make serious emergencies in the genitourinary system. In women, serious menstrual bleeding, pregnancies outside the uterus, and complications of labour are among the grave emergencies. In the field of infection, emergencies usually represent acute and overwhelming sepsis—poisoning from bacteria and their products—now that yellow fever, typhus, and plague are checkreined. A systemic *Meningococcus* infection may be fatal within 12 hours of the first sign or symptom. Rabies, tetanus, diphtheria, and poliomyelitis are emergencies. The nervous system has cerebral hemorrhage, clots, and meningitis (inflammation of the brain covering). As for psychiatric problems, profound depression with suicidal impulse or act, hysteria, and mania produce difficult emergency problems. The first sign of alcoholism that is noted may be a ruptured varix (dilated vein) of the esophagus, delirium tremens, or manicacal drunkenness.

Foreign  
bodies in  
the eye

Severe burns, decompression illness, electric shock, heat stroke, and sometimes dehydration exhaustion from heat may be critical emergency problems from environmental trauma. The doctor must consider poisonings of all sorts.

Burns,  
shock, and  
poisoning

The emergency patient may be encountered in combat, at the site of an automobile accident, in the home, in an ambulance, in a mobile coronary care unit, or in the emergency rooms of a hospital. The skill and equanimity of the physician in such cases are sorely tested, for he needs to make plans accurately and at once. He must know when instant action is required and when thoroughgoing treatment should be delayed.

For the severely injured patient, the diagnostician follows a sequence of priority that brings immediate attention to life-threatening injuries and leaves for later attention and definitive care less serious troubles. The

restitution of tissue continuity, the setting of fractures, the general support of cardiorespiratory activity, the appropriate use of antibiotics, and the comprehensive instant alerts of an intensive-care unit may mean the difference between survival and death.

In the cases of severe internal bleeding, it is important to know the exact site of bleeding, but transfusion and other supportive measures gain time for further studies. Though surgeons are uneasy about operating for bleeding from an unknown site in the alimentary canal, it is sometimes necessary if the bleeding goes on faster than transfusion can keep up safe blood volume.

**Toxicological examination.** A poisoned person may be a victim of homicidal or suicidal intent, accident, or assault from the environment or his occupation. He may be acutely overwhelmed or slowly stifled from chronic exposure. In chronic poisonings, detective work of all sorts is necessary with a thorough toxicological study of the home and work circumstances, the situation in which poisoning occurred, and the probable reasons for it. In acute poisoning, especially in a comatose person who can give no history, the doctor must proceed on the basis of what is analogous to the enlightened practice of veterinary medicine. The odour of the breath or vomitus, the identification of pills, capsules, or other recognizable material in the vomitus or stomach washings, the degree of diminution of consciousness, alterations in respiration, circulation, blood pressure, skin colour, temperature, all may be helpful. Twitchings, focal neurological changes, convulsions give important clues. When he suspects or is reasonably certain that a poison has been taken, the doctor will order the stomach to be washed out. Chemical studies of blood and body fluids, minerals, and gases may give diagnostic clues as to the nature of the intoxication. Many poisons can be tested for directly in vomitus, stool, urine, or blood. Any clues from recent history may be helpful—children climbing up to explore medicine cabinets, a telltale empty bottle—and real suicidal attempts must be distinguished from dramatic gestures in which the need and desire for attention and concern may evoke the demonstration.

**Diagnostic examination in obstetrics and gynecology.** The history of an obstetrical patient includes previous pregnancies and methods of delivery, complications, weight of child, condition at birth, subsequent development, abortions, miscarriages, date of last menstrual period, history of communicable diseases, especially rubella (German measles), and previous immunizations. Emphasis is given to the past history of blood transfusions, kidney disease, diabetes, and heart disease. In the examination, pelvic size and shape are recorded. Complete blood and urine studies are done, and tests for rubella antibody.

On later occasions blood pressure, the presence or absence of accumulations of fluid in the tissues, weight, and urinalysis for albumin and sugar are noted. The size of fetus, its position, and heart rate are recorded.

The main concern in the gynecological patient is menses: time of onset, interval, duration, flow, pain, last menstrual period, intermenstrual bleeding, leukorrhea (a white discharge from the vagina), recent cell smears, contraceptive techniques, previous pregnancies, abortions, operations, and children. The initial pelvic examination includes investigation of the external genitalia, the support of the outlet, and estimates, based on bimanual examinations, of the size, position, and mobility of the uterus and associated structures. The vagina and cervix are inspected.

**Neurological examinations.** Neurological examinations complement the general medical and psychiatric examinations. They are divided into five large headings: (1) history; (2) mental status; (3) neurological examination proper; (4) special situations; and (5) supplemental procedures as indicated. The mental status includes general appearance, behaviour, state and degree of consciousness, stream of thought, spontaneous speech, hallucinations, mood, affect, and functions of the intellect.

The neurological examination proper inquires into speech and language; functions of the head and neck; the

cranial nerves; the entire motor system, coordination, reflexes; the sensory system; the spinal column; and station and gait. Examination of comatose patients, infants, children, the elderly and senile, the person suspected of malingering, and the person with compensation or insurance ambitions requires special testing. Special diagnostic procedures include complete examination of cerebrospinal fluid, X-rays of the skull, the brain, the cerebral blood vessels, and recording of the brain-wave patterns by electroencephalography. Other procedures include psychological and personality tests and examination of specimens of muscle and nerve.

**Psychiatric diagnosis examination.** Experienced diagnosticians get much information, formally and informally, about mental status. The look of the patient, his age, grooming, posture, facial expressions, manner, and attitude; the spontaneous stream of his talk, its rate, form, and quantity; his psychomotor activity are all noted. Affectively, the whole emotional life is judged from observations and questions: whether the patient is composed, complacent, irritable, happy, angry, elated, suspicious, boastful, self-satisfied, expansive, distant, aloof, indifferent, dissociated, perplexed, fearful, tense, tormented, desperate; what the nature of the thought content may be; whether his attention flits about or he is phlegmatic; whether there are somatic expressions such as perspiration, flushing, fast heartbeat, tears, tics, grimaces, and moist palms; and whether his association and thinking are logical or autistic—given to self-centred fantasies and day dreams.

Feelings of unreality and depersonalization must be inquired into delicately. The doctor then must study carefully phobias, obsessions, compulsions, expansive moods, illusions, and hallucinations of various sorts. The patient's mental grasp and capacity and his orientation as to time, place, and person must be evaluated. His memory may be judged by the history of remote and recent events; his retention and recall of digits; his counting and calculation, simple multiplication, addition, subtraction, or division; his level of awareness; his intelligence; his judgment, as in terms of how he manages his business and family affairs. The doctor must know whether the patient's understanding is real or merely verbal; what plans he has for the future; what his insight is; whether he senses difficulty and is aware of real trouble.

**Urological examination.** In practice the most important part of the urological examination is the intravenous pyelogram (X-ray of the kidney and ureter after injection of a contrast medium into a vein). It may give an estimate of kidney size and function, the renal pelvis (the main cavity of the kidney), the ureters, urinary bladder, and urethra. The examination of the male is concerned with the glans, foreskin, body of the penis, scrotum, testicles, seminal vesicles, vas deferens (the seminal vesicle and the vas deferens join to form the ejaculatory duct), and a digital examination of the prostate through the rectum. Urethral discharge, swelling, redness, and any abnormality of external genitalia may disclose orchitis, inflammation of the testes, of the epididymis (a structure back of the testes), or of the prostate (a gland encircling the urethra). Massage of the prostate and examination of prostatic secretions are important. Detailed examination of the urine may include cultures. With the instrument called an endoscope, direct inspection of the lining of the bladder is possible. Examination of semen along with study of sex hormones and thyroid function may be needed in cases of sterility and impotence.

## II. Biological, chemical, and radiological tests

### LABORATORY DIAGNOSIS

Tasting a diabetic's urine and the detection of its sweetness may have been the first laboratory test. Out of the fields of physiological chemistry and biochemistry diverse laboratory tests have arisen. They are an extension of the physical examination and are increasingly a part of the professional consultations, which means that certain salient features about the patient are made known to those doing the tests. Tests are done on blood, urine, cerebrospinal fluid, feces, sputum, gastric contents, se-

Clues to  
mental  
status

Chronic  
and acute  
poisoning

men, and abnormal fluids obtained from the chest, the pericardium (the sac enclosing the heart), or the peritoneal (abdominal) cavity. Hair, nails, and skin scraping may also be tested. The usefulness of a test has a clear relationship to the speed with which the results are made available.

Routine  
and  
special  
tests

One of the critical problems of diagnosis today is determining what should be looked upon as a routine screening laboratory test and what should be a special test. Certain studies of blood, urine, and feces have become accepted as routine. Multiphasic screening, testing for several disorders simultaneously with a number of tests, is now broadening this base substantially. After whatever screening procedures have been done, the next stage in the examination is a critical planning based on all the information obtained. Availability, cost, physical and chemical principles, methods, error, and other limitations are related to final interpretation and application of the results.

**Blood.** A well equipped clinical laboratory is able to examine many constituents of blood. Organic chemicals normally occurring in the blood include glucose, acetone, lactic acid, pyruvic acid, uric acid, creatine, creatinine, and nitrogen in the form of urea nitrogen, nonprotein nitrogen, amino acid nitrogen, and ammonia. Minerals are tested to find out whether the concentration is high, low, or normal. These include sodium, chloride, calcium, phosphorus, potassium, carbonates, copper, lithium, magnesium, lead, and iron. Hormones and enzymes may be measured. Blood gases that can be measured include oxygen, carbon dioxide, and carbon monoxide. In addition to the usual blood proteins, albumin and globulin, ceruloplasmin (a globulin that transports most of the plasma copper) and cryoglobulins (proteins that precipitate or gel when cooled below body temperature) may be tested.

Drugs in  
the blood

Important drugs, used therapeutically or found in toxic levels from accident or attempted suicide, include barbiturates, bromide, ethyl alcohol, methyl alcohol, salicylate, and sulfonamide. Blood lipids are measured. Routine studies among the vitamins may determine levels of ascorbic acid, vitamin A, and the carotenoids, the precursors of vitamin A. Protein changes in the blood related to liver disease are measured. Testing bile pigments separates bilirubin into the varieties called direct reacting and indirect reacting, a test useful in classifying jaundice when it is present. Other properties of blood that may be tested include blood volume, degree of alkalinity, tolerance tests of various sorts, and the clearance rate for normal materials such as urea, creatinine, or a dye such as sulfobromophthalein.

**Urine.** The urine is examined by inspection as to its colour, which may be light or very dark from jaundice, breakdown of hemoglobin, or the dispersion of red cells through it. It may contain gravel, clots, pus, micro-organisms, and crystals. Most significant are casts of the urinary tubules (long microscopic tubes forming part of the functioning unit of the kidney, the nephron). The specific gravity is important as a measure of the concentration of the urine. The volume of urine is important also, particularly when there is any impairment of kidney function or any obstruction. Among chemicals that may be tested for in the urine are the sugars, acetone (suggestive of diabetes), various nitrogen compounds, hemoglobin and myoglobin (oxygen-carrying proteins of the blood and muscle), homogentisic acid present in the hereditary disease alkaptonuria, coproporphyrins (suggestive of lead poisoning), porphobilinogen (present in the metabolic disease porphyria), and urea and uric acid. Enzymes and hormones are tested for. A great variety of drugs can be detected in the urine; these are important in cases of overdosage, sensitivity, or suicidal attempts. **Urobilinogen** is the important bile derivative tested for chemically. Its high secretion suggests liver disorders; its absence, bile duct obstruction. Phenolsulfonphthalein concentration in the urine after intravenous injection is a good test of kidney function. Among the minerals tested for, calcium, phosphorus, copper, and lead are perhaps the most important.

**Stool.** Examination of feces includes a description of the form; the colour; whether the consistency is normal, diarrheal, or oily; and the occurrence of mucus or blood. The bulk of the feces averages 100 to 200 grams a day, of which about 30% is solid material and the rest water. The stools normally contain little protein. Up to 30% of the dry weight may consist of fat, 5% of which is fatty acid combined as soap. Free fatty acid usually runs about 5.5%, neutral fat about 40% of the total fat. Ordinarily, less than two grams of nitrogen are lost in the stool daily. The normal stool urobilinogen ranges from 40 to 280 milligrams per 24 hours.

**Other tests.** Gastric (stomach) juice is examined primarily for hydrochloric acid levels and the quantity of digestive enzymes (e.g., pepsin).

Studies of the cerebrospinal fluid include investigation of its appearance (it should not be cloudy); the number of cells present (abnormal increase suggests infection); and its protein levels (increased in a number of diseases). The fluid is also tested for syphilis.

A wide range of tests assess the functioning of a number of organs, including the heart, the lungs, the kidneys, the liver, the pancreas, and the thyroid.

#### MULTIPHASIC HEALTH SCREENING

It has been an accepted tenet of medical thought over the years that early detection would be beneficial in controlling and diminishing disease in the community, as well as in helping individual sick persons. Multiphasic health screening has been suggested as one way to detect cellular and biochemical changes that have not yet advanced to the stage of producing symptoms impressive enough to cause the patient to seek medical aid. The people affected by any health scheme include the well and the ill who have no symptoms, and the well and the ill who do.

Multiphasic health screening is a health examination for a wide range of variations and given large numbers of people. It has as its purpose the sorting out of the ill and the well, with and without symptoms. Most important is the detection of established disease and the prevention of its progress by finding it early. At the present time it is customary for the tests, examinations, questionnaires, and other procedures of mass screening to be applied or administered by technically trained assistants. Then the physician reviews all the data to make plans for further diagnostic and therapeutic moves.

In the period between the two world wars, and gaining momentum after World War II, screening programs were set up by public health organizations for the detection of specific diseases. Skin tests and massive X-ray surveys were done, for instance, to detect tuberculosis, and tests of large populations were done for syphilis. Extensive examinations have been conducted for admission into the armed services. These have detected, in various categories, an appalling degree of inadequacy, asymptomatic illness, or gross dysfunction about which nothing had been done by those examined.

The next step in multiphasic screening came with the development of equipment such as vacuum tubes for obtaining blood that permitted the introduction of multiphasic health screening in various demonstration centres throughout the country. Administrative complexity and lack of experience led to the accumulations of piles of paper and miscellaneous data. The high cost of discovering simple medical problems, or anyone who was seriously sick but salvageable, was discouraging. The result was substantial reduction of support for such pilot studies.

By the late 1950s, equipment was available to automate the chemical analysis of blood. When, nearly a decade later, such apparatus began to be tied into electronic data processing, the third chapter of the story began to unfold as automated multiphasic health testing linked computer technology and sundry automated equipment with clinical tests and procedures. Though this was hailed as the new salvation, few such combinations of systems give a comprehensive overview of health or illness. The ultimate objective of automated multiphasic health testing is to establish a total health profile of the person to aid his physician in the diagnosis of disease and its management.

Introduc-  
tion of  
automa-  
tion

The selection of screening-test procedures and the way in which electronic data processing is used vary widely among the different systems now in operation. The ground covered is much the same in most currently used batteries of screening tests. A representative one would certainly include information from the medical history; tests of visual acuity, body measurements, hearing tests, measurements of air breathed in and out, and measurement of pressure within the eye; X-ray of the chest; electrocardiogram (record of the electrical impulses from the heart muscle); determination of blood pressure; study of cells from the cervix to check for cancer; blood cell count; hematocrit (determination of the proportions of the blood volume accounted for by the red cells); and a variety of blood tests including tests for glucose, cholesterol, urea, sodium, and potassium. Other tests could easily be added. The procedures are usually partially or fully automated, and the emphasis is on using less highly trained people to do the tests and collect the data. Many currently operating facilities process data electronically. The report may consist of many pages or a one-page summary.

Such systems become more efficient as they approach the mass production practices of industry. The unit cost is reduced by increasing the number of patients processed. This is true whether the persons cared for constitute a prepayment group, physician referrals, self referrals, patient referrals, employees of a specific company, members of a labour union, identifiable members of an academic community or a geographical region, or mixtures of these.

The proponents of multiphasic health screening maintain that properly trained technicians, using automated equipment, can provide an adequate substitute for the traditional periodic health examination by the physician, with expenditure of only one-third the time.

Fears have been expressed that the mass of irrelevant data through which the physician will have to wade to find the initial clues, and the subsequent multiple diagnostic studies, will add to, rather than subtract from, the present demands for work. There is not yet enough evidence to know whether the machine's reduction of human error really provides better quality control or whether the false-positive or false-negative results that do occur will lead to mismanagement of the patient's problems. There is an as yet unresolved conflict between those who boast of the efficiency—getting everything done at once and in one place, instead of the seemingly endless procession of patients around, to, and from hospitals, clinics, offices, and laboratories—and those who fear that any kind of conveyor-belt machinery will further depersonalize the already strained patient-physician relations. In the matter of costs, multiphasic health screening as currently available costs approximately a third to a fourth of the cost of the same care in the traditional system. The advantages or disadvantages for individual physicians have scarcely been evaluated in any objective terms. Both advocates and opponents of the system have agreed that it has not been demonstrated scientifically that multiphasic health screening improves health or saves lives. Experience with the system must be expanded for really reliable testing of its contribution. Finally, there is no satisfactory formula for generalizing the cost-result relationship in achieving the objective of health. There is general expectation that a technical staff, using automation and computers, will play a significant role in the future achievement of those functions that lead to better health. Technical and functional capacities have demonstrated that such services are feasible. The real question is how the new technology can be introduced into the existing complicated system of health care for the good of the patient, of the larger community, and of the several elements of the health profession.

#### USE OF RADIATIONS IN DIAGNOSIS

**X-rays.** The discovery of the roentgen ray (X-ray) introduced a radical new improvement into medical diagnosis by making available an immediate and detailed view of internal structures. Originally, results were re-

corded on photographic film. The pattern of shadows cast was related to the density of the structures penetrated or partly penetrated by the X-rays. Bones, air, fluid, and solid structures were viewed in the living body. Modern techniques have permitted many advances. Fluoroscopy, which projects X-ray images upon a fluorescent screen, gives visualization of living, moving structures. Now accurate motion pictures with image intensifiers permit detailed studies of contrast material flowing through the coronary arteries in the beating heart. Many exciting observations have been made possible by perfecting methods of increasing the contrast of various pipes, tubes, and vessels and passageways in the body. Radiopaque material such as barium may be swallowed and its progress through the alimentary canal followed in detail; or it may be introduced in an enema. The functional capacity of organs such as the kidney and the liver to concentrate soluble radiopaque material permits getting a vivid picture of the outline of bile ducts, gallbladder, the larger renal (kidney) collecting system, the renal pelvis and calices (the largest cavity in the kidney and subdivisions of it), ureter, and bladder. Direct injection of soluble radiopaque material into artery and vein can be done selectively, to concentrate on a particular portion of the vascular tree or functional unit such as individual coronary artery or a renal artery. X-rays of veins may be obtained in the same selective way. A more recent development is the injection of material into lymphatic vessels, which permits mapping out normal and diseased tributary lymphatic structures and lymph nodes.

Another contrast method involves the use of air or rapidly absorbed gases such as carbon dioxide, which may be introduced into the abdomen; the chest; the fallopian tubes; or into the ventricles, or cavities, of the brain. An oily radiopaque material may be introduced into the bronchial tree to map out the shape, size, and distribution of nearly the whole of the tracheobronchial tree, the complete passageway for air except the nose and larynx.

The whole world of bone and joint defects may be demonstrated. The salivary duct system may be outlined. The vascular structures of spleen and portal system can be seen. X-rays of the spinal cord may reveal deformity or encroachment by tumour. Double contrast may be obtained by the use of a thin mixture of barium and air to outline irregularities or lesions of the mucous membrane of the intestine.

Stereoscopic studies of the chest are helpful in getting a three-dimensional view of the location of lesions in the lungs. A different technique, planigraphy and tomography, by rotating camera and film blurs out all but the focal point or plane under study, giving, in effect, a three-dimensional idea of solid lesions whose density differs from that of surrounding structures.

**Use of radioactive isotopes.** Radioactive isotopes, with their system of tagging, have been used in a number of ways for diagnostic purposes. (Isotopes of any element are forms of that element that are alike chemically but differ in mass of nucleus.) Two of these are illustrated briefly. The element iodine is absorbed from the alimentary canal, taken up in the circulation, and removed selectively by the thyroid gland for incorporation in active hormones. Thus, the state of function of the thyroid gland, its adequacy, overactivity, or failure, can be judged by giving the subject a drink of a dilute solution in water of iodine containing a small amount of the radioactive form of iodine, iodine-131. The concentration is then tested by putting a Geiger counter over the thyroid and measuring the radioactivity taken up by the end of four hours and of twenty-four hours.

Pernicious anemia, which is characterized, among other things, by a failure of the stomach to produce hydrochloric acid and an enzyme (called the intrinsic factor) that helps the digestion and assimilation of vitamin B<sub>12</sub>, may be studied by giving a large amount of vitamin B<sub>12</sub> containing radioactive cobalt. The subsequent excretion of radioactivity in the urine reveals how much vitamin B<sub>12</sub> has been absorbed, taken into the blood stream, and excreted in the urine. By measuring radioactivity of both urine and stool, one may find that all the radioactivity is

Fluoroscopy and moving X-ray pictures

Stereoscopic views

Criticisms of multiphasic screening

in the stool, that none has been absorbed, and that the patient has pernicious anemia or perhaps has had the whole stomach removed.

In tests that involve tagging by radioactive isotopes, it is possible to measure biologically active materials that exist in almost infinitesimally small concentrations in the body. While such studies have been more important in building an understanding of normal mechanisms in disease, they may become important in routine diagnostic work.

**Ultrasound.** Ultrasound (sound waves above the range audible to man) has been used routinely to measure the motion of the heart's valves and to determine the existence and degree of pericardial effusion, the collection of fluid in the space around the heart. The measurement of left ventricular wall thickness and of atrial tumours, and the study of the aortic root, have been made possible by more advanced techniques. Newer techniques have made it possible to measure the aortic arch, the right pulmonary artery, and the left atrium.

### III. Other important considerations

#### SURGICAL DIAGNOSIS

Surgical diagnosis includes routine and special diagnosis in patients who have problems amenable to surgical procedures and the use of surgical techniques for diagnosis. At times, for example, the problem of life-endangering bleeding from the alimentary canal from an undetermined site may require surgical intervention without knowledge of the bleeding area. In some situations such as obstructive jaundice, an operation may be made to determine whether there is a stone or remediable stricture (narrowing) or whether a tumour, operable or inoperable, is causing the trouble.

A further diagnostic aid during an operation is the pathologist's report from frozen sections of material obtained by the surgeon. Gross inspection and palpation may not disclose whether tumour or inflammatory reaction is responsible. Information from the pathologist may determine whether the operation proceeds with a radical destruction of tissue, mere palliation, or doing nothing.

Surgical means may be employed for obtaining tissue for diagnosis. This ranges from the gentle scraping of surface cells from the skin to get material for cultures of yeast and fungi, simple biopsy (removal of a specimen) of the skin, to biopsy of lymph nodes or tissue from organs. Washings or specimens of abnormal tissue may be obtained from the bronchi. Devices may be passed along the alimentary canal to obtain small bits of mucosal tissues. Culture and other analyses may be fruitful and helpful. The so-called Papanicolaou smear of cells from the cervix to test for cancer is another example of such procedures.

Somewhat intermediate between an operation that explores the abdominal cavity and the scraping of the skin are needle biopsies to obtain material from skin, muscle, liver, lung, and kidney. Such techniques, particularly with the employment of the electron microscope, have greatly advanced diagnosis.

#### THE MEDICAL RECORD

A patient's medical record in a doctor's office or in the hospital is a written, typewritten, or electronic record that contains the medical story of a person's health and disease, the findings from the physical examination, the reports of laboratory tests, the results of special examinations, the findings and opinions of consultants, and then the synthesis of these matters in the diagnoses made by the responsible physician. There follows a continuum of notes on treatment, tests, medicines, operations, radiation, physical therapy, and progress. It is a stage-by-stage summary of events by physicians, nurses, and others. To be helpful it must be completely accurate. To be good it must be brief.

The medical record should assist all responsible persons in the care and treatment of the patient. It must be a teaching record, a document for clinical research, and a source of statistics. The patient's medical record documents the criteria for insurance claims. It is the source of

legal proof in claims for injury, poisoning, homicide, or malpractice. A medical record must be up-to-date for the proper study and treatment of the patient. It has to be accurate for any subsequent use as a medical record.

It is essential that those who write in the record be identified: physician in charge, junior staff man, resident, intern, undergraduate student, nurse, or aide. For the record to reflect the essential moving picture, dates and times must be identified. Because the record is a privileged communication, it has to remain in the physician's locked files or in the hospital record room.

While the exact format of the recorded history may vary, the advance guard of medical teaching and care is collecting information to provide a data bank that becomes the basis for problem solving. The changing pattern of the disease and response to therapy is considered in the light of problems.

But the standard history, which is usually kept on one of a variety of forms, begins with complete identity of the patient. These are necessary vital statistics and vital signs; information about the informant if other than the patient; a statement of the main problem; and the present illness. The rest of the information in the history deals with past events. This includes general health, specific diseases, hospitalizations, operations and injuries, social history, family history, and a systematic review of the organs of the body and the identifiable functioning systems of the body. This gives an indication of their performance and functional state, past and present.

Many of the vital statistics are obtained by clerks. Some are entered on a plastic plate used to identify patient, tests, procedures, consultations, and charges.

#### SOURCES OF ERROR IN MEDICAL DIAGNOSIS

In analyzing the mistakes and false moves in the study of many patients whose problems ultimately came to solution, several sorts of errors are identified. Most important is failure to obtain available information because of improper history taking. Another is in the failure to understand the meaning of a patient's adequately elicited subjective complaints. Such flaws in the history produce more diagnostic error than failure to feel a mass, hear an abnormal heart sound, or obtain a useful laboratory test. Obviously, the whole of a person's past existence is likely to be more significant than his present state at an instant in time. The immediate past and recent events usually are more important than those in the distant past, but there are many exceptions.

In the communication systems required for the physical record of a patient, there may be errors in labelling samples of blood or urine, errors in recording the results of tests on laboratory reports, technical errors in the test procedure, errors in entering the results in the patient's record, and this may include mixups from similar or identical names, or a clerical error in picking up a wrong chart.

Many conditions—language barriers, coma, stupor or delirium, inability to articulate or recall—prevent the story of the past from being obtained. This makes diagnosis like trying to make a judgment of what has gone on in a play from seeing only a still photograph of a single scene.

Errors may occur when a doctor forgets to ask a question or to do an examination. Errors of omission are commoner than those of commission.

An understanding of the emotional and intellectual capacity and state of the patient is essential. It is as necessary to tone down the interminable complaints of the perennial complainer as it is to probe for information from a stoical, repressed, or reserved person.

Just as disease is an ever-changing process, so the diagnosis is the best approximation, in terms of structure, function, and malfunction, of those derangements and troubles that interfere with the patient's natural existence by causing pain, malfunction, or fear.

## Dialects

A dialect is a variety of a language. The word comes from the Ancient Greek *dialektos* "discourse, language, dialect," which is derived from *dialegethai* "to discourse, talk." A dialect may be distinguished from other dialects of the same language by features of any part of the linguistic structure—the phonology, morphology, or syntax. In the sound system of American English, for example, certain dialects distinguish the vowel in "caught" from that in "cot," while others do not, and in some dialects "greasy" is pronounced with an *s* sound and in others with a *z* sound. In morphology (word formation), various dialects in the Atlantic states have "clim," "clurn,"

"clome," or "cloome" instead of "climbed," and, in syntax, there are "sick to his stomach," "sick at his stomach," "sick in," "sick on," and "sick with." On the level of vocabulary, examples of dialectal differences include American English "subway," contrasting with British English "underground"; and "corn," which means "maize" in the U.S., Canada, and Australia, "wheat" in England, and "oats" in Scotland. Nevertheless, while dialects of the same language differ, they still possess a common core of features.

Frequently, the label dialect, or dialectal, is attached to substandard speech, language usage that deviates from the accepted norm; e.g., the speech of many of the heroes of Mark Twain's novels. On the other hand, the standard language can be regarded as one of the dialects of a given language. In a special historical sense, the term dialect applies to a language considered as one of a group deriving from a common ancestor; e.g., English, Swedish, and German are Germanic dialects.

There is often considerable difficulty in deciding whether two linguistic varieties are dialects of the same language or two separate but closely related languages; this is especially true of dialects of primitive societies, in which the difference is essentially one of degree. Many decisions regarding dialects versus languages must be arbitrary.

Normally, dialects of the same language are considered to be mutually intelligible, while different languages are not. Intelligibility between dialects is, however, almost never absolutely complete; on the other hand, speakers of closely related languages can still communicate to a certain extent when each uses his own mother tongue. Thus, the criterion of intelligibility is quite relative. In more developed societies, the distinction between dialects and related languages is easier to make because of the existence of standard languages and, in some cases, national consciousness.

Among the synonyms for dialect, the word idiom refers to any kind of dialect, or even language, whereas patois, a term from French, denotes rural or provincial dialects, often with a deprecatory connotation. An idiolect is the dialect of one individual person at one time. This term implies an awareness that no two persons speak in exactly the same way—i.e., without slight differences in vocabulary—and that each person's dialect is constantly undergoing change—e.g., by the introduction of newly acquired words. Most recent investigations emphasize the versatility of each person's speech habits according to levels or styles of language usage.

Another synonym for dialect is the term vernacular; it refers to the common, everyday speech of the ordinary people of a region. The word accent has numerous meanings; in addition to denoting the pronunciation of a person or a group of people ("a foreign accent," "a British accent," "a Southern accent"), it also refers to features of pitch or stress. In contrast to accent, the term dialect is used to refer not only to the sounds of language but also to grammar and vocabulary.

### VARIETIES OF DIALECTS

**Geographic dialects.** The most widespread type of dialectal differentiation is geographic. As a rule, the speech of one locality differs at least slightly from that of any other place. Differences between neighbouring local dialects are usually small, but, in travelling farther in the same direction, differences accumulate. Every dialectal feature has its own boundary line, called an isogloss (or sometimes heterogloss). Isoglosses of various linguistic phenomena rarely coincide completely, and by crossing and interweaving they constitute intricate patterns on dialect maps (see Figure 1). Frequently, however, several isoglosses are grouped approximately together into a bundle of isoglosses. This grouping is caused either by geographic obstacles that arrest the diffusion of a number of innovations along the same line or by historical circumstances, such as political borders of long standing, or by migrations that have brought into contact two populations whose dialects were developed in noncontiguous areas.

Dialects,  
patois,  
idiolects

#### Local and regional dialects

Geographic dialects include local ones (e.g., the Yankee English of Cape Cod or of Boston, the Russian of Moscow or of Smolensk) or regional ones, such as Delaware Valley English, Australian English, or Tuscan Italian. Such entities are of unequal rank; South Carolina English, for instance, is included in Southern American English. Regional dialects do have some internal variation, but the differences within a regional dialect are supposed to be smaller than differences between two regional dialects of the same rank. In a number of areas ("linguistic landscapes") where the dialectal differentiation is essentially even, it is hardly justified to speak of regional dialects. This uniformity has led many linguists to deny the meaningfulness of such a notion altogether; very frequently, however, bundles of isoglosses—or even a single isogloss of major importance—permit the division of a territory into regional dialects (see Figure 2 for the dialectal division of American English in the Atlantic states). The public is often aware of such divisions, usually associating them with names of geographic regions or provinces, or with some feature of pronunciation; e.g., Southern English or Russian o-dialects and a-dialects. Especially clear-cut cases of division are those in which geographic isolation has played the principal role; e.g., Australian English or Louisiana French.

**Social dialects.** Another important axis of differentiation is that of social strata. In many localities, dialectal differences are connected with social classes, educational levels, or both. More highly educated speakers and, often, those belonging to a higher social class tend to use more features belonging to the standard language, whereas the original dialect of the region is better preserved in the speech of the lower and less educated classes. In large urban centres, innovations unknown in the former dialect of the region frequently develop. Thus, in cities the social stratification of dialects is especially relevant and far reaching, whereas in rural areas, with a conservative way of life, the traditional geographic dialectal differentiation prevails.

Educational differences among speakers strongly affect the extent of their vocabulary. In addition, practically every profession has its own expressions, which include the technical terminology and sometimes also the casual words or idioms peculiar to the group. Slang, too, is characterized mainly by a specific vocabulary and is much more flexible than an ordinary dialect, as it is subject to fashion and depends strongly on the speaker's age

#### Technical terminology and slang

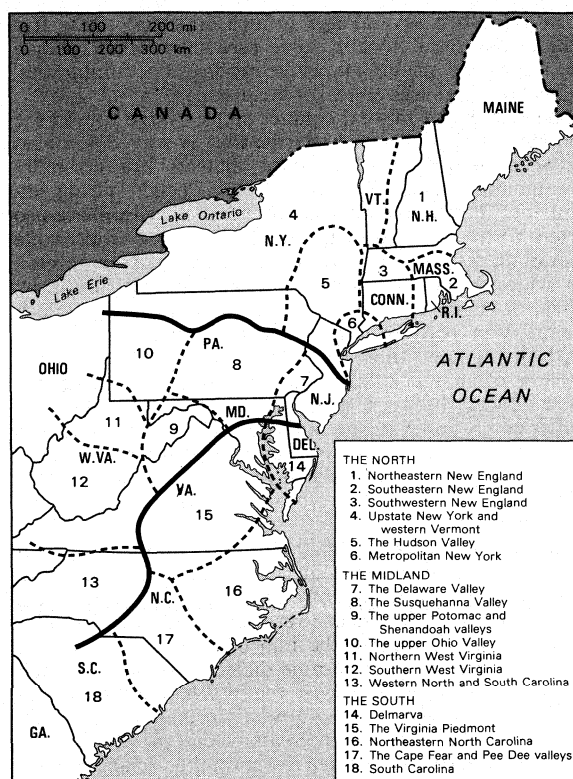

Figure 2: Dialect areas of the eastern United States.

Adapted from H. Kurath, *Word Geography of the Eastern United States*, The University of Michigan Press

group. Slang—just as a professional dialect—is used mainly by persons who are in a sense bidialectal; i.e., they speak some other dialect or the standard language, in addition to slang. Dialectal differences also often run parallel with the religious or racial division of the population.

#### DEVELOPMENT OF DIALECTS

The basic cause of dialectal differentiation is linguistic change. Every living language constantly undergoes changes in its various elements. Because languages are extremely complex systems of signs, it is almost inconceivable that linguistic evolution could affect the same elements and even transform them in the same way in all localities where one language is spoken and for all speakers in the same locality. At first glance, differences caused by linguistic change seem to be slight, but they inevitably accumulate with time (e.g., compare Chaucer's English with modern English or Latin with modern Italian, French, Spanish, or Romanian). Related languages usually begin as dialects of the same language.

**Dialectal change and diffusion.** When a change (an innovation) appears among only one section of the speakers of a language, this automatically creates a dialectal difference. Sometimes an innovation in dialect A contrasts with the unchanged usage (archaism) in dialect B. Sometimes a separate innovation occurs in each of the two dialects. Of course, different innovations will appear in different dialects, so that, in comparison with its contemporaries, no one dialect as a whole can be considered archaic in any absolute sense. A dialect may be characterized as relatively archaic, because it shows fewer innovations than the others; or it may be archaic in one feature only.

After the appearance of a new dialectal feature, interaction between speakers who have adopted this feature and those who have not leads to the expansion or the curtailment of its area or even to its disappearance. In a single social milieu (generally the inhabitants of the same locality, generation, and social class), the chance of the complete adoption or rejection of a new dialectal feature is very great; the intense contact and consciousness of membership within the social group fosters such uni-

formity. When several age groups or social strata live within the same locality and especially when people speaking the same language live in separate communities, dialectal differences are easily maintained.

The element of mutual contact plays a large role in the maintenance of speech patterns; that is why differences between geographically distant dialects are normally greater than those between dialects of neighbouring settlements. This also explains why bundles of isoglosses so often form along major natural barriers—impassable mountain ranges, deserts, uninhabited marshes or forests, or wide rivers—or along political borders. Similarly, racial or religious differences contribute to linguistic differentiation because contact between members of one faith or race and those of another within the same area is very often much more superficial and less frequent than contact between members of the same racial or religious group. An especially powerful influence is the relatively infrequent occurrence of intermarriages, thus preventing dialectal mixture at the point where it is most effective; namely, in the mother tongue learned by the child at home.

**Unifying influences on dialects.** Communication lines such as roads (if they are at least several centuries old), river valleys, or seacoasts often have a unifying influence. Also, important urban centres, such as Paris, Utrecht, or Cologne, often form the hub of a circular region in which approximately the same dialect is spoken. In such areas, the prestige dialect of the city has obviously expanded. As a general rule, those dialects, or at least certain dialectal features, with greater social prestige tend to replace those that are valued lower on the social scale.

In times of less frequent contact between populations, dialectal differences increase; in periods of greater contact, they diminish. The general trend in modern times is for dialectal differences to diminish, above all through the replacement of dialectal traits by those of the standard language. Mass literacy, schools, increased mobility of populations, and, in the last few decades, the ever-growing role of mass communications all contribute to this tendency. Naturally, the extent of such unifying action varies greatly in different linguistic domains, depending on the level of civilization. Nevertheless, the most thorough example of linguistic force exerted by a single dominating civilization belongs to ancient times: in the Hellenistic era, almost all ancient Greek dialects were replaced by the so-called koine, based on the dialect of Athens.

Mass migrations may also contribute to the formation of a more or less uniform dialect over broad geographic areas. Either the resulting dialect is that of the original homeland of a particular migrating population or it is a dialect mixture formed by the levelling of differences among migrants from more than one homeland. The degree of dialectal differentiation depends to a great extent on the length of time a certain population has remained in a certain place. Thus, it is understandable that the diversification of the English language is far greater in the British Isles than, for example, in North America (especially if the number of dialectal differences is considered on a comparable area basis, such as how many per 1,000 square miles). In the U.S. itself much greater diversity is evident among dialects in old colonial America—along the Atlantic coast—than among dialects west of the Appalachians. It is also typical that phonological differences are more far reaching in Switzerland among Swiss-German dialects than throughout the vast territory where the Russian language is spoken, extending from Leningrad to eastern Siberia. Such a situation results not only from migrations of the Russian population, (as compared to the centuries of Swiss stability) but also from the contrasting geographical configurations: in the U.S.S.R., there is unobstructed communication in all directions; in mountainous Switzerland, the territory is carved into small, isolated units.

Migrations and, more rarely, geographical phenomena may in some areas cause a much stronger dialectal differentiation in one direction than in others. Isoglosses in the U.S., for example, run predominantly in an east-west

direction, reflecting the westward stream of migration during the colonization of areas west of the Appalachians. Similarly, the majority of isoglosses in Russia follow latitude, but in the opposite (west-east) direction.

**Focal, relic, and transitional areas.** Dialectologists often distinguish between focal areas—which provide sources of numerous important innovations and usually coincide with centres of lively economic or cultural activity—and relic areas—places toward which such innovations are spreading but have not usually arrived. (Relic areas also have their own innovations, which, however, usually extend over a smaller geographical area.) Relic areas or relic phenomena are particularly common in out-of-the-way regional pockets or along the periphery of a particular language's geographical territory. An example of a focal area in the U.S. would be the Boston region, while rural Maine and New Hampshire and Cape Cod and Nantucket Island would be typical relic areas (see Figure 3).

Adapted from A.J. Bronstein, *The Pronunciation of American English—An Introduction to Phonetics* (1960), Appleton-Century-Crofts; with permission from the American Council of Learned Societies

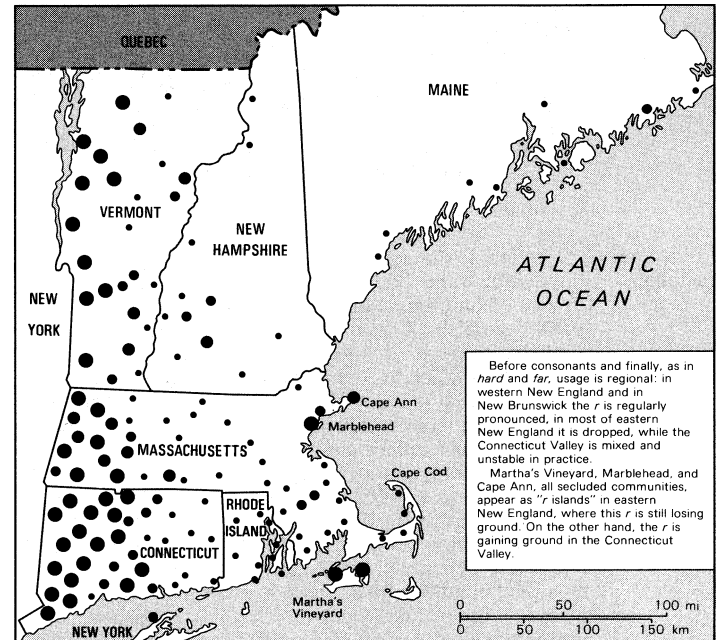

Figure 3: New England pronunciation of prenasal and final r. The largest circles indicate regular use of this r, the smallest ones sporadic use, and the two intermediate sizes rather evenly divided usage.

The borders of regional dialects often contain transitional areas that share some features with one neighbour and some with the other. Such mixtures result from unequal diffusion of innovations from both sides. Similar unequal diffusion in mixed dialects in any region also may be a consequence of population mixture created by migrations.

In regions with many bilingual speakers (*e.g.*, along the border between two languages) dialects of both languages will often undergo changes influenced by the other tongue. This is manifested not only in numerous loanwords but often also in the adoption of phonological or grammatical features. Such phenomena are particularly frequent in a population that once spoke one language and only later adopted the second language. In extreme cases, a so-called creolized language develops. (Creoles are pidgin languages that have become the only or major language of a speech community. See PIDGIN.)

**Standard languages.** Standard languages arise when a certain dialect begins to be used in written form, normally throughout a broader area than that of the dialect itself. The ways in which this language is used—in administrative matters, literature, economic life—lead to the minimization of linguistic variation. The social prestige attached to the speech of the richest, most powerful, and most highly educated members of a society trans-

Written form of dialects

Natural barriers and language change

Dialect differentiation and population movements

forms their language into a model for others; it also contributes to the elimination of deviating linguistic forms. Dictionaries and grammars help to stabilize linguistic norms, as do the activity of scholarly institutions and, sometimes, governmental intervention. The base dialect for a country's standard language is very often the original dialect of its capital — in France, Paris; in England, London; in Russia, Moscow. Or the base may be a strong economic and cultural centre — in Italy, Florence. Or the language may be a combination of several regional dialects; e.g., German or Polish.

Even a standard language that was originally based on one local dialect changes, however, as elements of other dialects infiltrate into it over the years. The actual development in any one linguistic area depends on historical events. Sometimes even the distribution of standard languages may not correspond to the dialectal situation. Dutch and Flemish dialects are a part of the Low German dialectal area, which embraces all of northern Germany, as well as the Netherlands and part of Belgium. In one part of the dialectal area, however, the standard language is based on High German, and, in the other part, the standard language is Dutch or Flemish, depending on the nationality of the respective populations. In the U.S., where there is no clearly dominant political or cultural centre — such as London or Paris — and where the territory is enormous, the so-called standard language shows perceptible regional variations in pronunciation.

In most developed countries, the majority of the population has an active (speaking, writing) or at least passive (understanding) command of the standard language. Very often the rural population, and not uncommonly the lower social strata of the urban population as well, are in reality bidialectal. They speak their maternal dialect at home and with friends and acquaintances in casual contacts, and they use the standard language in more formal situations. Even the educated urban population in some regions uses the so-called colloquial language informally. In the German-, Czech-, and Slovene-speaking areas of middle Europe, for example, a basically regional dialect from which the most striking local features have been eliminated is spoken. The use of this type of language is supported by psychological factors, such as feelings of solidarity with a certain region and pride in its traditions or the relaxed mood connected with informal behaviour.

#### DIALLECT GEOGRAPHY

Dialect study as a discipline — dialectology — dates from the first half of the 19th century, when local dialect dictionaries and dialect grammars first appeared in western Europe. Soon thereafter, dialect maps were developed; most often they depicted the division of a language's territory into regional dialects. The 19th-century Romantic view of dialects and folklore as manifestations of the ethnic soul furnished a great impetus for dialectology.

Early dialect studies. The first dialect dictionaries and grammars were most often written by scholars describing the dialect of their birthplace or by fieldworkers whose main method of investigation was free conversation with speakers of the dialect, usually older persons and, preferably, those who showed the least degree of literacy and who had travelled as little as possible. Many of these grammars and dictionaries recorded dialectal traits that deviated from the standard language. In the second half of the 19th century, when historical and comparative linguistic study was flourishing, it became customary to focus attention on the fate of particular elements of the archaic language in a given dialect; e.g., the changes that Latin vowels and consonants underwent when used in different positions in a particular Romance dialect.

With the accumulation of dialectal data, investigators became increasingly conscious of the inadequacy of viewing dialects as internally consistent units that were sharply differentiated from neighbouring dialects. It became more and more clear that each dialectal element or phenomenon refused to stay neatly within the borders of

a single dialect area and that each had its own **isogloss**; consequently, maps of dialects would have to be replaced by maps showing the distribution of each particular feature. While sound scientifically, the preparation and compilation of such maps, called linguistic atlases, is a difficult, costly, voluminous, and time-consuming job.

Dialect atlases. Dialect atlases are compiled on the basis of investigations of the dialects of a large number of places; a questionnaire provides uniform data. There are two basic methods of data collection: fieldwork and survey by correspondence. Fieldwork, in which a trained investigator transcribes dialectal forms directly (or on tape), affords more precise data and enables the questionnaire to include a greater number of diverse questions; but it implies a necessarily limited number of points to be covered. The advantage of the correspondence method lies in its ability to encompass more points at less cost and with less time expended in gathering the data. On the other hand, rural schoolteachers, normally the persons who complete such questionnaires, can answer only a relatively small number of questions and often imperfectly.

The first large-scale enterprise in linguistic geography was the preparation of the German linguistic atlas. In the 1880s, the initiator of this great undertaking, Georg Wenker, composed 40 test sentences that illustrated most of the important ways in which dialects differed and sent them to schoolmasters in over 40,000 places in the German Empire. The sentences were to be translated into the local dialect. Publication of the results was not begun until 1926; the main cause of the delay was the enormous quantity of material to be arranged and analyzed.

The famous French linguistic atlas of Jules Gilliéron and Edmond Edmont was based on a completely different concept. Using a questionnaire of about 2,000 words and phrases that Gilliéron had composed, Edmont surveyed 639 points in the French-speaking area. The atlas, compiled under the direction of Gilliéron, was published in fascicles from 1902 to 1912 and furnished both a strong stimulus and the basic model for work on linguistic atlases elsewhere in the world. European linguists, especially in Romance- and Germanic-speaking countries, were the first to participate in such atlas projects. One of the most significant contributions is the linguistic atlas of Italy and southern Switzerland by Karl Jaberg and Jakob Jud; it appeared from 1928 to 1940. Particularly noteworthy in its attention to precise definitions of meaning, this atlas often used illustrations and described objects and actions of village life denoted by the questionnaire's words.

At present, dialects of virtually all European languages have been treated in linguistic geography studies. In some countries, data are still being collected and classified and maps are being drawn, but in others a second generation of atlases is already underway. French dialectologists, for instance, are now working on regional atlases that will complement data contained in the *Atlas linguistique de la France*. In England, work began in 1946, under the direction of Harold Orton and Eugene Dieth; the first volume of the *Survey of English Dialects* was published in 1962. In Slavic-speaking countries, work is now underway both on atlases of separate Slavic languages and on the large general Slavic linguistic atlas that will cover nearly 1,000 locales in all parts of European territory where Slavic languages are spoken. Outside Europe, the greatest amount of work in linguistic geography has been completed in Japan and in the United States.

As early as 1905–06, a committee of Japanese dialectologists published the first linguistic atlas of Japan in two volumes, one devoted to phonology and one to morphology. Subsequent work has been done on a new atlas of Japan as a whole and on several regional atlases. The extensive activity of Chinese specialists has concentrated on descriptions of particular local and regional dialects. The Chinese situation is a peculiar one because of the enormous number of people who speak Chinese, the very significant dialectal differentiation (certain dialects, particularly those in the South of China, would be con-

The French atlas

19th-century impetus for dialect study

sidered by Western standards as separate languages), and the nature of the Chinese script. Chinese characters do not represent sounds but concepts. Because of this, the written language can be read without difficulty in many different dialect areas, although its spoken form varies greatly from one region to another.

Because of the enormous size of the U.S., atlas surveys were done by region. Between 1931 and 1933, fieldworkers under the direction of the linguist Hans Kurath surveyed 213 New England communities; the results were published in the *Linguistic Atlas of New England* (with 734 maps) in 1939–43. Based on the methodological experience of Jaberg and Jud in their atlas of Italy and southern Switzerland, this work involved systematic investigations not only among the relatively uneducated but also among better educated, more cultured informants and among the very well educated, cultured, and informed members of a community. Thus the dimension of social stratification of language was introduced into linguistic geography, and valuable material about regional linguistic standards became available.

After 1933, fieldwork was extended to the other Atlantic states. Lack of financial support, however, has hindered the publication of these atlases. Nevertheless, several works based on the material gathered have appeared, among them Kurath's *Word Geography of the Eastern United States*, E. Bagby Atwood's *Survey of Verb Forms in the Eastern United States*, and Kurath's and McDavid's *Pronunciation of English in the Atlantic States*. Independent work was carried out in other U.S. regions, mainly with an adapted form of the questionnaire developed for the Atlantic states; only introductions or summaries of material in the files have been published, however, because of lack of funds.

The most effective and thorough—as well as the most expensive—way of presenting data in linguistic atlases is by printing the actual responses to questionnaire items right on the maps. Phenomena of linguistic geography, however, are usually represented by geometric symbols or figures at the proper points on the map, or, even more summarily, by the drawing of isoglosses (linguistic boundaries) or by shading or colouring the areas of particular features.

Only dialect atlases can furnish the complexity of data of the major dialectal phenomena in a multitude of geographic locations in a manner that both assures commensurability of the data and allows a panoramic examination of the whole gamut of data. The inventory of linguistic phenomena is so rich, however, that no one questionnaire can encompass it all. Moreover, the use of a questionnaire unavoidably brings about a schematization of answers that is lacking in spontaneity. For these reasons, other kinds of publications, such as dialect dictionaries or monographs based on extensive free conversation with speakers of local dialects, are indispensable complements to linguistic atlases.

The value and applications of dialectology. The scientific interest of dialectology lies in the fact that dialects are a valuable source of information about popular culture. They reflect not only the history of a language but, to a great extent, the ethnic, cultural, and even political history of a people as well. A knowledge of dialectal facts provides practical guidance to school systems that are trying to teach the standard language to an ever greater number of pupils.

In the 1930s, the value of dialectology to the study of language types became apparent. Because dialects greatly outnumber standard languages, they provide a much greater variety of phenomena than languages and thus have become the main source of information about the types of phenomena possible in linguistic systems. Also, in some languages, but not in others, an extremely wide structural variation among dialects has been found. In Yugoslavia, where two closely related Slavic languages, Serbo-Croatian and Slovene, are spoken, dialects are found with synthetic declension (case endings, as in Latin) and analytic declension (use of prepositions and word order, as in English). In addition, there are among these dialects complex systems of verbal tenses contrasting

with simple ones, as well as dialects with or without the dual number or the neuter gender. The dialects of Serbo-Croatian and Slovene also exhibit almost every type of prosodic structure (e.g., tone, stress, length) found in European languages. Some dialects differentiate long and short vowels or rising and falling accents, while others do not; and in some, but not all of them, stress fulfills a grammatical function. Of the several dozen vowel and diphthong sounds that occur in these dialects, only five are common to all of them; all the rest are restricted to relatively small areas. All of this rich variety contrasts sharply with the relative structural uniformity of the English language—not only in the U.S. but wherever it is spoken. (The outstanding exceptions are the creolized dialects, which are distinguished by far-reaching structural peculiarities.)

#### SOCIAL DIALECTOLOGY

The methodology of generative grammar (see GRAMMAR) was first applied to dialectology in the 1960s, when the use of statistical means to measure the degree of similarity or difference between dialects also became increasingly common. The most important development of that time, however, was the rapid growth of methods for investigating the social variations of dialects; this type of variation, in contrast to geographical variation, is especially great in the U.S., above all in large urban centres. In cities such as New York, a whole scale of speech variations can be found to correlate with the social status and educational levels of the speakers. In addition, age groups exhibit different patterns, but such age-group patterns of variation differ from one social stratum to another. Still another dimension of variation, especially important in the U.S., is connected with the race and the ethnic origin of a speaker as well as his date of immigration. So-called Black English has been influenced by the fact that most of the black population in non-southern U.S. regions originally came from the southeastern states; thus, many Black English peculiarities are in reality transplanted southeastern dialectal traits.

Normally, speakers of one of the social dialects of a city possess at least some awareness of the other dialects. In this way, speech characteristics also become subjectively integrated into the system of signs indicating social status. And in seeking to enhance their social status, poorer and less educated speakers may try to acquire the dialect of the socially prestigious. Certain groups—e.g., blacks and the working class—however, will, under certain conditions, show a consciousness of solidarity and a tendency to reject members who imitate either the speech or other types of behaviour of models outside their own social group.

As a consequence of an individual's daily contacts with speakers of the various social dialects of a city, elements of the other dialects are imperceptibly drawn into his dialect. The collective result of such experiences is the spread of linguistic variables; i.e., groups of variants (sounds or grammatical phenomena) primarily determined by social (educational, racial, age, class) influences, an example being the existence of the two forms "He don't know" and the standard "He doesn't know." Traits representing variables in intergroup relations can become variable features in the speech of individuals as well; i.e., an individual may employ two or more variants for the same feature in his own speech, such as "seeing" and "seein'" or "he don't" and "he doesn't." The frequency of usage for each variable varies with the individual speaker as well as with the social group. There are intermediate stages of frequency between different social groups and entire scales of transitions between different age groups, thus creating even greater variation within the dialect of an individual. The variables also behave differently in the various styles of written or spoken language used by each speaker.

The study of variables is one of the central tasks of any investigation of the dialects of American cities. Applying the statistical methods of modern sociology, linguists have worked out investigative procedures sharply different from those of traditional dialectology. The chief

and  
Slovene  
dialects

contributor has been William Labov, the pioneer of social dialectology in the U.S. The basic task is to determine the correlation between a group of linguistic variables—such as the different ways of pronouncing a certain vowel—and extralinguistic variables, such as education, social status, age, and race. For a reasonable degree of statistical reliability, one must record a great number of speakers. In general, several examples of the same variable must be elicited from each individual in order to examine the frequency and probability of its usage. Accordingly, the number of linguistic variables that can be examined is quite limited, in comparison with the number of dialectal features normally recorded by traditional fieldworkers in rural communities; in these situations, the investigator is often satisfied with one or two responses for each feature.

A completely new, flexible, and imaginative method of interviewing is needed for such work in urban centres, as well as new ways of finding and making contact with informants. One example is Labov's method for testing the fate of final and preconsonantal *r* in speakers of different social levels. Choosing three New York City department stores, each oriented to a completely different social stratum, he approached a large number of salesladies, asking each of them about the location of a certain department that he knew to be on the fourth floor. Thus, their answers always contained two words with potential *r*'s—"fourth" and "floor." This shortcut enabled Labov to establish in a relatively short time that the salesladies in the store with richer customers clearly tended to use "r-full" forms, whereas those in the stores geared to the poorer social strata more commonly used "r-less" forms.

Social dialectology has focussed on the subjective evaluation of linguistic features and the degree of an individual's linguistic security, phenomena that have considerable influence on linguistic change. Linguistic scientists, in studying the mechanism of such change, have found that it seems to proceed gradually from one social group to another, always attaining greater frequency among the young. Social dialectology also has great relevance for a society as a whole, in that the data it furnishes will help deal with the extremely complex problems connected with the speech of the socially underprivileged, especially of minority groups. Thus, the recent emphasis on the speech of minority groups, such as the Black English of American cities, is not a chance phenomenon. Specific methods for such investigation are being developed, as well as ways of applying the results of such investigation to educational policies.

(1950), both in French. Among the atlases are: FERDINAND WREDE et al., *Deutscher Sprachatlas auf Grund des Sprachatlas des Deutschen Reichs von Georg Wenker* (1926–), which treats German dialects; JULES GILLIERON and EDMOND EDMONT, *Atlas linguistique de la France* (1902–12), a work on French dialects; KARL JABERG and JAKOB JUD, *Sprach- und Sachatlas Italiens und der Südschweiz*, dialect recordings by P. SCHEUERMEYER, G. ROHLFS, and M.L. WAGNER, 8 vol. (1928–40), which gives the linguistic geography of Italy (written in German). Atlases on English dialects include: HANS KURATH et al., *Linguistic Atlas of New England*, 3 vol. (1939–43); HANS KURATH and RAVEN I. MCDAVID, JR., *The Pronunciation of English in the Atlantic States* (1961); and HAROLD ORTON et al., *Survey of English Dialects*, 4 vol. (1962–67). The following books discuss American English dialects: CARROLL E. REED, *Dialects of American English* (1967); and WILLIAM LABOV, *The Social Stratification of English in New York City* (1966). Articles on dialectology appear in these collections: HAROLD B. ALLEN (ed.), *Readings in Applied English Linguistics*, 2nd ed. (1964), see esp. pt. 3, "Linguistic Geography"; and HAROLD HUNGERFORD, JAY ROBINSON, and JAMES SLEDD (eds.), *English Linguistics: An Introductory Reader* (1970), see esp. pt. 2, "Dialectology."

(P.I.)

## Dias, Bartolomeu

As leader of the first expedition to round the Cape of Good Hope, thus opening the seaway from Europe to

Asia, Bartolomeu Dias is usually considered to be the greatest of the Portuguese pioneers who explored the Atlantic in the 15th century.

Almost nothing is known of Dias' early life. His supposed descent from one of Prince Henry the Navigator's pilots is unproved, and his rank was the comparatively modest one of squire of the royal household. The name "Dias de Novais" does not appear in contemporary documents but only in the deed of appointment of his grandson as governor of Angola in 1571.

In 1474, King Afonso V entrusted his son, Prince John (later John II), with the supervision of Portugal's trade with Guinea and the exploration of the western coast of Africa. John sought to close the area to foreign shipping and after his accession in 1481 ordered new voyages of discovery to ascertain the southern limit of the African continent. The navigators were given stone pillars (*padrões*) to stake the claims of the Portuguese crown. Thus one of them, Diogo Cão, reached the Congo and sailed down the coast of Angola to Cape Santa Maria at 13°26' south, where he planted one of John's markers supposing that he had attained the southernmost tip of Africa. Cão was ennobled and rewarded and sailed again: this time he left a marker at 15°40' and another at Cape Cross, continuing to 22°10' south. Royal hopes that he would reach the Indian Ocean were disappointed, and nothing more is heard of Cão. John II entrusted command of a new expedition to Dias. In 1486 a Portuguese had heard of a great ruler, the Ogané, far to the east, who was identified with the legendary Christian ruler Prester John. John II then sent Pêro da Covilhã (q.v.) and one Afonso Paiva overland to locate India and Abyssinia and ordered Dias to find the southern limit of Africa.

Dias' fleet consisted of three ships, his own "São Cristóvão," the "São Pantaleão" under his associate João Infante, and a supply ship under Dias' brother, whose name is variously given as Pêro or Diogo. The company included some of the leading pilots of the day, among them Pêro de Alenquer and João de Santiago, who earlier had sailed with Cão. A 16th-century historian, João de Barros, places Dias' departure in August 1486 and says that he was away 16 months and 17 days, but since two other contemporaries, Duarte Pacheco and Christopher Columbus, put his return in December 1488, it is now usually supposed that he left in August 1487.

Dias passed Cão's marker, reaching the "Land of St. Barbara" on December 4, Walfisch Bay on December 8, and the "Gulf of St. Stephen" (Elizabeth Bay) on December 26. After January 6, 1488, he was prevented by storms from proceeding along the coast and sailed south out of sight of land for several days. When he again turned to port, no land appeared, and it was only on sailing north that he sighted land on February 3. He had thus rounded the Cape without having seen it. He called the spot Angra de São Brás ("Bay of St. Blaise," whose feast day it was) or the Bay of Cowherds, for the people he found there. Dias' Negro companions were unable to understand these people, who fled but later returned to attack the Portuguese. The expedition went on to Angra da Roca (present-day Algoa Bay). The crew was unwilling to continue, and Dias recorded the opinions of all his officers, who were unanimously in favour of returning. They agreed to go on for a few days, reaching Rio do Infante, named after the pilot of "São Pantaleão"; this is almost certainly the present Groot-Vis River.

It was now clear that India could be reached by the Cape route, and Dias turned back. He sighted the Cape itself in May. Barros says that he named it Cape of Storms and that John II renamed it Cape of Good Hope. Duarte Pacheco, however, attributes the present name to Dias himself, and this is likely since Pacheco joined Dias at the island of Principe. Little is known of the return journey, except that Dias touched at Principe, the Rio do Resgate (in the present Liberia), and the fortified trading post of Mina. One of Dias' markers, at Padrão de São Gregório, was retrieved from False Island, about 30 miles short of the Great Fish River, in 1938. Another marker formerly stood at the western end of the "Gulf of St. Christopher," now Dias Point.

Sighting of  
the Cape  
of Good  
Hope

Nothing is known of Dias' reception by John II. Although plans are said to have been made for a voyage to India, none was attempted for nine years, perhaps pending news of Pêro da Covilhã. John's successor, Manuel I, authorized Vasco da Gama's celebrated voyage of 1497. Bartolomeu Dias accompanied that expedition as far as Mina.

On Gama's return to Portugal, after successfully making contact with the seaports of western India, a further fleet was at once organized; it consisted of a dozen ships and was intended to impress the Indians and to open commerce on a large scale. The whole fleet was under Pedro Álvares Cabral, and Dias was given one of the smaller ships. The fleet sailed far into the western Atlantic on its way to the Cape and sighted land at Espirito Santo in Brazil. Thought to be an island, it was named the Land of the True Cross. Dias thus participated in the discovery of Brazil. He was lost at sea when they reached the Cape, thus perishing in the very waters he had been the first to navigate.

No portrait of Dias is known. He had a son, Antônio, and his grandson, Paulo Dias de Novais, governed Angola and became the founder of the first European city in southern Africa, São Paulo de Luanda, in 1576.

**BIBLIOGRAPHY.** Sources for Dias are the 16th-century historians: JOAO DE BARROS, GALVAO, and DUARTE PACHECO PEREIRA. See also ERIC AXELSON, *South-East Africa, 1488-1530* (1940).

(H.V.L.)

## Dice and Dice Games

Dice are small cubes used as implements for gambling and the playing of social games, each individual cube being called a die. Each side of a standard die is marked with from one to six small dots (spots). The spots are arranged in conventional patterns and placed so that the spots on the opposite sides always total seven: one and six, two and five, three and four. The combinations of the six spots plus the number of dice in play determine the mathematical probabilities.

In most games played with dice, the dice are thrown (rolled, flipped, shot, tossed, or cast) from the hand or from a receptacle called a dice cup, in such a way that they will fall at random. The spots that face upward when the dice come to rest are the deciding spots. The combination of the spots on the topmost surfaces of the dice decides, according to the rules of the game being played, whether the thrower (called the shooter) wins, loses, continues to throw, or loses possession of the dice.

### DICE AND THEIR USE: FROM ANCIENT TO MODERN TIMES

Sophocles reported that dice were invented by one Palamedes, a Greek, during the siege of Troy, while Herodotus maintained that they were invented by the Lydians in the days of King Atys. Both "inventions" have been discredited by numerous archaeological finds demonstrating that dice were used in many earlier societies. Dice, before they became gambling implements, were magical devices that primitive men used in *sortilege*, the casting of lots to divine the future. The probable forerunners of dice were knucklebones (the anklebones of sheep) marked on four faces. In Arabic, the word for knucklebone is the same as that for dice.

Primitive people all over the globe—the North American Indian, the Aztec and Maya, the South Sea islander, the Eskimo, the African—have gambled with dice of many materials and curious shapes and markings. They have used dice made of plum and peach stones, of seeds, of buffalo, caribou, and moose bone, of deer horn, of pebbles, of pottery, of walnut shells, and of beaver and woodchuck teeth. In later Greek and Roman times, although most dice were made of bone and ivory, others were of bronze, agate, rock crystal, onyx, jet, alabaster, marble, amber, porcelain, and other materials.

Man's earliest written records mention not only dice but crooked dice as well. Cubical dice with markings practically equivalent to those of modern dice have been found in Chinese excavations dated as early as 600 BC and in

Egyptian tombs dated earlier than 2000 BC. It is in India, more than 2,000 years ago, that the first written records of dice are found in the ancient Sanskrit epic, the *Mahābhārata*.

(Top) Egyptian die, reputed to be from the tomb of Osiris, Abydos, Egypt. (Bottom) Etruscan dice, c. 7-6th century BC, from Chiusi, Italy. In the Smithsonian Institution, Washington, D.C.

Dice in various forms are the oldest gaming implements known to man, and countless games are and have been played with them. Craps, the most popular gambling-house game, is played with two dice. Chuck-a-Luck, Hazard, and 4,5,6 are played with three dice. In more social play, there are many Poker Dice games played with five dice, and various counter and bar games such as Twenty-six played with ten. In Backgammon and hundreds of board games two or more dice are thrown to determine moves.

Modern dice are almost all made of a cellulose or other plastic material. There are two kinds, perfect or casino dice made by hand and true to a tolerance of 1/5,000 inch, which are used mostly in gambling casinos to play Craps, and round-cornered or imperfect dice called drugstore or candystore dice, which are machine made and are generally used to play social and board games. Modern casino dice are sawed from extruded plastic rods. The spots are drilled approximately 17/1,000 inch into the faces of the die. Then all recesses are filled with a paint the same weight as the plastic that has been drilled out. The dice are then buffed and polished, and since no recesses remain, they are known as flush-spot dice.

Most casinos use red flush-spot dice, which are transparent and come in sets of five; the standard size used in most casinos the world over is 0.750 inch. The dice edges are generally square and known as razor edge, or slightly turned and known as feather edge. Casino dice usually carry the casino's own special monogram and coded serial numbers as a means of thwarting dice cheats. Perfect dice used in various dice games range from a 0.250-inch celluloid or bone "Pee Wee" to an extra large size 0.770 inch. Perfect concave-spot dice, although still in use, are rarely seen in casinos.

Pyramidal, pentahedral, and octahedral dice with all sorts of face designs also are and have been used.

Dice specially made for cheating have been found in the tombs of ancient Egypt and the Orient and in prehistoric graves of North and South America. Any die that is not a perfect cube will not act according to correct mathematical odds and is called a shape. Shapes are cubes that have been shaved down on one or more sides so that they are slightly brick-shaped and will tend to settle down most often on their larger surfaces. Shapes are the most common of all crooked dice.

Loaded dice when measured with calipers may prove to be perfect cubes; but extra weight just below the surface

Crooked dice

Antiquity of dice

on some sides will make the opposite sides come up more often than they should.

Dice with one or more faces each duplicated on its opposite side and certain numbers omitted will tend to produce some numbers in disproportionate frequency and never to produce certain other numbers; for example, two dice marked respectively with duplicates of 3-4-5 and 1-5-6 can never produce combinations totalling 2, 3, 7 or 12, which are the only combinations with which one can lose in the game of Craps. Such dice, called tops and bottoms, are used as a rule only by accomplished dice cheats, who introduce them into the game by sleight of hand. Since it is impossible to see more than three sides of a cube at any one time, tops and bottoms are unlikely to be detected by the inexperienced gambler.

Cheating at dice is possible with honest dice also. The cheater throws the dice in a manner that causes one or two dice to spin instead of turning over at random so that a predetermined side or number will come to settle skyward.

Amateur cheats, using a blanket or soft surface to play on, roll one or both dice straight ahead in a spool-like fashion so that the two faces at the sides of each die cannot appear at the top—thus preventing certain combinations of numbers from appearing.

In many dice games, a person, usually the operator of the game, wins by no other expedient than offering bets at odds less favourable than those dictated by the theory of probability.

Probabilities

Assuming the use of perfect dice, skill in most dice games consists in knowing the mathematical probability that any total number will appear face up when two or more dice are thrown at random. Ultimate probabilities are subject to the laws of combinations and permutations, but in most dice games they can be ascertained by the application of simple arithmetic. The basic assumption is that any one side on each die is as likely as any other side to appear face up. With a symmetrical die of six sides each side has an equal chance with each of the others, so the expectation is for any one side to be thrown an average of once in six times. Hence its probability is  $1/6$ , which is to say that the odds are 5 to 1 against the appearance of any specified side on any one throw.

With two dice, each of the six sides of one die can be combined with each of the six sides of the other to form  $6 \times 6$  or 36 combinations. The chance that any combination of two like numbers such as two 6s, two 5s, etc., will appear in one throw is 1 in 36 or  $1/36$ , which is to say that the odds against the appearance of two 6s or any two like numbers in one throw is 35 to 1. When three dice are used, as in Chuck-a-Luck, the total combinations are  $6 \times 6 \times 6 = 216$ . When four dice are used the total combinations are  $6 \times 6 \times 6 \times 6 = 1,296$ , and so on. The chances of throwing a specific number in one throw of the dice is calculated by comparing the number of favourable chances with the number of unfavourable chances. For example, the only throws that will produce the total 5 with four dice is 1-1-1-2, 1-1-2-1, 1-2-1-1, and 2-1-1-1, so 5 can be expected to appear 4 times in 1,296 throws, making the odds 1,292 to 4, or 323 to 1, against such an event.

#### GAMES PLAYED WITH DICE

Hazard, sometimes now known as English Hazard, a two-dice game for two or more players, became a mania in London's swank gaming establishments in the 17th and 18th centuries. The name comes from the Spanish *azar*, unlucky throw at dice, misfortune, which, in turn, is derived from the Arabic *az-zahr*, the die. A Chuck-a-Luck variant, Grand Hazard or Three Dice Hazard, is sometimes also called Hazard (see below). The modern game of Craps was derived from the old English game, and its name from a nickname of the losing cast of 1-1 or 1-2, which was called Crabs at least as early as the 16th century.

In Hazard, after the bets are made, one player, the shooter, rolls the dice to determine the "main" point (any number from 5 through 9). This done, he then rolls

again, winning if he throws the main point or certain other numbers (11 if the main is 7, or 12 if it is 6 or 8), and losing if he throws certain others (crabs to any main; 11 to 5, 6, 8, or 9; or 12 to 7). If he throws any other number from 4 through 10 it becomes his "chance"; he continues to throw the dice until his chance comes up, when he wins, or the main comes up, when he loses. If there is a banker for the game the rules may differ.

Craps is of American origin. According to tradition, some time after 1800, blacks living around New Orleans tried their hands at Hazard, which the English sometimes nicknamed Crabs or Craps. In the course of time they modified the rules and playing procedure so greatly that they ended up inventing the game of Craps (in the U.S. idiom known as Crapshooting or Shooting Craps and here identified as Private Craps to distinguish it from Open Craps and the more formalized variants offered in gambling casinos). In 1907 John H. Winn, a New York City dice maker, became the first Craps bookmaker or banker in history. Winn invented the game of Open Craps, a game in which the players are permitted to bet among themselves or with a bookmaker, who charges a fee. They may bet that the shooter will win or lose, paying, for example, a quarter for a \$5 bet and 50 cents for a \$10 bet. Shortly afterward, Winn introduced Bank Craps, in which all bets must be made against the house, charging 5 percent of the amount of any bet. Later, other gamblers eliminated the direct charge, substituting shorter house odds, and added more bets to the layout.

Craps not only replaced Faro as the great American banking game but also outdistanced all other casino games in popularity. Since the legalization of gambling in Nevada in 1931, the Las Vegas version of Bank Craps has been introduced into countless casinos the world over, in the Caribbean, Europe, South America, Africa, and Asia. Its spread undoubtedly was encouraged by the belief of the various governments that Las Vegas Craps attracts American tourists. The popularity of the private game of Craps with the U.S. military personnel during World Wars I and II helped to spread that game to many parts of the world. There are four ways to play Craps. Private Craps is a friendly, social game that does not use a casino, Crap table, or banker. The only requisites for Private Craps are two or more persons with cash in their pockets and a pair of dice. It can be played on a street corner, in a back alley, private club, army barracks, living room—anywhere the players have room to roll the dice.

Bank Craps is played on a special table, similar to a billiard table, covered with a "Craps layout" divided into spaces representing the various bets that can be placed. Although there are various layouts, the actual differences among them are small. The layout is planned so that the house has a mathematical advantage on every bet.

From J. Scarne. *Scarne on Dice* (1945); Slackpole Books

Caribbean style double-side dealer layout on a Las Vegas dice table.

Open or Money Craps is a game in which players are permitted to bet among themselves, but a houseman called a banker or bookie is present to accept any bet within the house limit that a player is unable to place with another player. For this privilege, the player must pay the banker a charge, usually 5 percent of the amount wagered. New York Craps is a version of Bank Craps found in gambling houses in the eastern part of the United States, the Bahamas, and in England. The table and the layout differ from the Las Vegas or Bank Craps

Principles  
of Craps

table, known as a double-end dealer, and the dealer charges 5 percent of the amount wagered on the point numbers (4,5,6,8,9,10).

The following principles apply to all forms of Craps: A standard pair of dice is used. Any number may play. Any player, by consent of the others, may start the game by becoming the first shooter (person throwing the dice).

The dice are thrown by the shooter and the two numbers that face skyward when the dice come to rest, added together, are the deciding numbers. If on the first roll, the shooter throws a natural (7 or 11), it is a winning decision called a pass; if he throws a crap (2,3, or 12) it is a losing decision called a missout; if he throws a 4, 5, 6, 8, 9, or 10, that number becomes his point and he continues throwing until he either throws his point again (for a pass), or throws a 7 (for a missout). When the shooter fails to make his point, the dice pass to the next player on his left and it becomes his turn to shoot. The shooter also has the option of handing the dice to the next player after a pass if he wishes. The next player also may refuse to shoot in his turn and pass the dice on.

Chuck-a-Luck is a very old dice game originally called Sweat-cloth in England and known in the United States, where it appeared about 1800, as Sweat. Later it came to be known as Chucker-Luck and simply Chuck, and, more recently, as the Bird Cage. Chuck-a-Luck has disappeared from many gambling establishments and is played mainly at carnivals and bazaars. The standard equipment is simplicity itself: a cloth layout numbered from 1 to 6 inclusive, a table, and a 20-inch wire cage containing three dice. Players may bet any amount within agreed minimum and maximum limits on one or more of the six numbers. When all bets are down, the wire cage is inverted and the three dice tumble down and come to rest at the bottom of the cage. The faceup numbers of the three dice determine the outcome.

If, for example, one unit was bet on 6, then if there is one 6 up after the cage is inverted, the operator pays even money and will return two units for a net gain of one unit to the bettor; if two 6s are up, the operator will pay 2 to 1, or three units; and if all three dice show a 6, the operator pays 3 to 1, or four units. When one unit is wagered on each of the six numbers, the operator breaks even when three different numbers are thrown, makes a profit of one unit when a pair and a single are thrown, makes a profit of two units when three of a kind are thrown. The operator's overall advantage amounts to 7.87 percent on each unit bet.

Crown and Anchor, a variant of Chuck-a-Luck, played in England, Australia, and especially Canada, uses the same equipment as Chuck-a-Luck except that each of the three dice carries six symbols: crown, anchor, heart, spade, diamond, and club, instead of spots. The layout carries the same symbols. The players place their bets on the symbols on the layout and the banker throws three dice from a dice cup. The payoff and the advantage for the operator are the same as in Chuck-a-Luck.

Grand Hazard, another variant of Chuck-a-Luck, also known as Three-Dice Hazard or simply Hazard, was one of America's most popular gambling house games in the early 1930s. The three dice were dropped through a Hazard chute containing a series of inclined planes that tripped the dice as they fell, or they were thrown from a cup. The layout included, in addition to the six numbers, spaces for bets on high, low, odd, and even numbers, and on three of a kind (triplets or raffles); some layouts permitted bets on specific combinations of the dice.

Barbooth or Barbudi is a two-dice game of Middle Eastern origin. It is still being played in Greece, Turkey, and other countries of the Middle East and North Africa, including the United Arab Republic. In the United States and elsewhere it is played chiefly by persons of Greek, Jewish, and other Middle Eastern ancestry. It is often played in gambling houses for high stakes.

In Barbooth, unlike Craps, the shooter does not specify the amount of his wager. The player on his right sets the stakes, betting that the shooter will not win. The other players may make side bets on whether the shooter or the

fader will win. The game, which provides no mathematical advantage for either the shooter or fader, is known as a dead-even game. A house employee known as a cutter takes a percentage of each winning bet. A bookmaker or banker is usually available to accept side bets for a charge, which is divided equally between the bookmaker and house cutter.

The shooter and fader—beginning with the shooter—alternate throwing two pee wee dice from a dice cup until a decision has been achieved. If either the shooter or the fader throws one of four specified combinations (e.g., 3-3 or 5-6) he wins; if he throws one of four others (e.g., 1-1 or 1-2) he loses. All other throws are meaningless. After each decision the shooter retains or passes the dice according to specified winning or losing combinations.

Four-Five-Six, or See Low, is a popular gambling-house game in the U.S. Northwest, Western Canada, and Alaska. Three dice and a dice cup are used. Each player places the amount he desires to wager in front of him. The operator, or banker, then covers all bets and plays against each player in turn. The banker starts the game by throwing the dice from the cup once. If he throws any three of a kind (such as 1-1-1) or any pair plus 6 (such as 1-1-6), or the sequence, 4-5-6, he wins all bets. If he throws 1-2-3 or any pair plus 1 such as 2-2-1, he loses all bets. When any pair is thrown and the third die is a 2,3,4, or 5 (such as 1-1-2), the number on the third die becomes the point number. All combinations except the ones stated are meaningless and the banker throws again. If the banker throws a point number, each other player in turn to the banker's left throws the dice to determine the outcome against the banker. If the player fails to score a winning or losing decision and throws a point, the higher of the banker's or player's points wins. A tie is a standoff or no decision. When a player does not get a pair and does not throw either 4-5-6 or 1-2-3, the roll is meaningless, and he must continue throwing the dice until he wins, loses, or ties. The banker's advantage lies in the fact that there are more winning than losing combinations and he has the first chance to throw them.

One of the most popular U.S. bar and counter games is Poker Dice. It is usually played with five poker dice whose sides bear the playing card denominations: ace, king, queen, jack, ten, and nine, although the usual spotted dice are sometimes used. The ace is also sometimes played wild. Any number can play and each player throws one die to determine the order of play, highest man going first. The object is to throw the highest poker hand in either one or two throws as determined beforehand.

Indian dice, another popular bar and counter game, is played with five dice similar to poker dice, but in this game the player may take as many as three throws to score a hand.

Scarney Dice, a creation of John Scarne, author of *Scarne on Dice* and other works, is a poker-dice game played with a dice cup and five Scarney dice; that is, dice that are marked with the 1,3,4, and 6 spots plus the word "dead" on two opposite sides. (The usual spotted dice also may be used, with the 2 and 5 spots considered "dead.") A player may throw as many times as he wishes, providing he has not thrown five dead dice. After each throw, dead dice are put aside and the remaining dice are thrown again. On any throw made without a dead die, the total points facing up, plus any bonus, are credited to the shooter. Bonuses are awarded on a scale ranging from 10 points for any two pairs to 100 points for any five of a kind.

Yacht is another poker-dice variant, in which five dice are thrown from a cup and a score is kept. Each player in rotation may throw the dice three times in each of the 12 rounds. After each of his first two casts in each round, he may leave standing such dice as satisfy him and throw the rest. Various dice combinations (categories) are assigned scoring values, the highest being yacht (five of a kind) for 50 points. The other categories are big straight, little straight, full house, four of a kind, choice (any five

dice), and sixes, fives, threes, twos, and aces. Before each turn a player must select a category not previously selected.

Liar Dice, which approaches real poker with its element of bluffing, is popular in the U.S. Army. The shooter shakes five dice in a cup, turns the cup upside down and lifts it, shielding the dice from view with his hand. He then announces the best poker hand he can make, but his announcement need not be true. His opponent may either roll for a higher hand, or challenge the announcement by saying, "Liar," in which case, the player must reveal his dice. He wins if his announcement was correct, loses if it was not.

Aces is one of the most popular dice games played in the Far East by U.S. military personnel. Any number may play, but each player must have a dice cup and five dice. Each player puts an agreed stake into a pot and then throws his five dice—the player with the highest poker hand becoming the first shooter, the player throwing the second highest sits on his left and shoots second and so on; tying players throw again.

The first shooter begins by throwing his five dice. Each 1 is placed in the centre of the table; all 2s are passed to the player on his left; all 5s to the player on his right. The player continues to throw until he fails to throw a 1, a 2, or a 5, or until he has no dice left. The player on the left then begins his throw. Players with no dice are still in the game as they may receive dice from the players on either side of them. When all the dice but one have been placed in the centre of the table, the player throwing the last 1 with the last die is the winner and takes the pot.

In Buck Dice, any number can play and three dice are used. Each player throws the dice to determine the order of play, with the highest total first. The low man then throws one die and the number thrown becomes the point. The starter throws all three dice, scoring one point for each point number thrown. He continues to throw as long as he throws point numbers, which are added as he goes along. When he fails to throw a point number on any throw, the dice pass to the next player. The object is to score exactly 15 points, called buck or game. If a throw puts a player's score above 15, the throw does not count and he must throw again. As each player reaches that score he drops out until only one player remains; he is the loser and pays everyone a predetermined amount. Any three of a kind (not point numbers) is a little buck and counts five points. The point number on all three dice is big buck or the general, which counts 15 points and eliminates the player no matter what score he has previously made.

High Dice is a two-dice game also called Beat the Banker and Counter Klondike in which the banker and player each throw once, the banker first. The player must throw a higher number than the banker to win. The banker takes all ties.

In the 1950s 26 was a favourite counter game in many stores and taverns throughout the U.S. Midwest, in which customers would play for a fee such as 25 cents to win checks or tokens that could be cashed for drinks, cigarettes, or other merchandise. Federal and state anti-gambling drives during the late 1950s eliminated most of these games. A high rail dice board, score pad, dice cup, and ten dice are used. The player selects any number from 1 through 6 as his point. He throws the ten dice 13 times and totals the number of times he has thrown his point number. The object is to throw 26 or more point numbers.

Backgammon is the parent of all track board games and perhaps the oldest game with dice still being played. The French and Germans call it Tric-Trac, the Italians *Tavola reale* (royal table). The Romans who played it with three dice knew it as *ludus duodecim scripta* (game of the 12 lines). The derivation of the word Backgammon has been ascribed both to the Welsh words *back* and *gammon* (little battle) and to the Saxon *bac* and *gamen* (back game).

Two persons play and each has a pair of dice and a cup plus one doubling die. There are 30 playing counters

called men, 15 of one colour and 15 of another (usually black and white). The players sit on opposite sides of a board that contains 24 alternately coloured triangles called points, 12 opposite each player. A bar divides the board into two equal rectangles one of which, by agreement, is designated the inner, or home, table, and the other the outer table. The placement of the men on the backgammon board to start the game is shown in the figure below.

Modern Backgammon board at the beginning of play.

Each player throws one die from the cup. The player throwing the higher number plays first by using both his and his opponent's numbers. Thereafter, each player throws his own two dice. The numbers on the two dice, taken separately, show the number of points over which the men may be moved. When one man has been moved the number of points indicated by one die, the other number may be used either to move the same man farther or to move another man. The player must try to use both numbers. If he can use only one number he must use the higher number of the two if possible. When both dice show the same number, the player has thrown doublets and each number is played twice. Therefore if a double 3 is thrown it would be played the same as four 3s.

A single man on a point is a blot. When a man of the opposite colour lands on that point the blot is hit and the man that was originally there is taken off and placed on the bar. A man on the bar may enter again when a number is thrown on the dice that will place the man on an unoccupied point of his opponent's home table. All men on the bar must be re-entered before any other moves may be made.

When a player has two or more men on a point, it is said to be blocked and an opponent's man may not come to rest on that point although it can move past the blocked point. If a player blocks six adjacent points and has one or more of his opponent's men behind it, he has made a prime. If he blocks all six points of his home table when his opponent still has one or more men on the bar, he is said to have a shutout.

When a player's men have all reached his own home table, he begins removing them from the board. This is called bearing or bearing off the men. For each number thrown a man is removed from the corresponding point. On a throw of 5-3 for instance, one man is removed from the 5 and one from the 3 point. A throw of doublets allows the player to remove twice as many men. On a throw of double 3, four men may be taken from the 3 point. When the number thrown is higher than any point on which there are men, the player may remove a man from the next highest point. If low numbers are thrown and there are no men located on those points, men from higher points are moved down toward the one point according to the numbers thrown on the dice. Men may also be moved down instead of being borne off if desired.

The first player to bear off all his men wins a single game. If he bears off all men before his opponent has borne off any, he wins a double game or gammon and collects double stakes. If the loser has not borne off any men and still has one or more men in his opponent's

home table or on the bar, the winner has scored a triple game or backgammon and collects triple stakes.

At any time after his opponent has finished a throw a player may double the stake. If his opponent rejects the double, he forfeits the games and the stake. The privilege of making the next double falls to his opponent. There is no limit to the number of doubles that may be made but the option of offering doubles alternates between players.

Acey Deucey is the favourite Backgammon game of the U.S. Navy, Marine Corps, and Merchant Marine. The equipment and rules of play are similar to Backgammon except that the pieces (men) are not placed on the board at the start of the game but must be played onto the board, and when ace-deuce is thrown the player moves one man three spaces, or one man one space and another two spaces, and then also has the choice of any doublets and also may take an additional throw of the dice.

In Russian Backgammon, no men are placed upon the board at the start, but each player enters his men by throws of the dice—both players enter in the same home table and both move in the same direction around the board to the opposite table. Bearing off is the same as in Backgammon. After having entered two or more men, a player is at liberty either to continue entering his men with any subsequent throws, or to move the men already entered. When a blot is hit, the owner must re-enter it before he makes any other move. Except on a player's first throw of the game, doublets are used twice over. He not only can play the upper faces of the dice twice over, but the bottom (opposite) faces as well; he also can throw again before his opponent. After each thrown doublet the player continues to throw until he fails to throw a doublet, in which case he plays the numbers thrown and the throw passes to his opponent.

## Dickens, Charles

Generally regarded as the greatest English novelist, Charles Dickens enjoyed a wider popularity than any previous author had done during his lifetime. Much in his work could appeal to simple and sophisticated, to the poor and to the Queen, and technological developments as well as the qualities of his work enabled his fame to spread worldwide very quickly. His long career saw fluctuations in the reception and sales of individual novels, but none of them was negligible or uncharacteristic or disregarded, and, though he is now admired for aspects and phases of his work that were given less weight by his contemporaries, his popularity has never ceased and his present critical standing is higher than ever before. The most abundantly comic of English authors, he was much more than a great entertainer. The range, compassion, and intelligence of his apprehension of his society and its shortcomings enriched his novels and made him both one of the great forces in 19th-century literature and an influential spokesman of the conscience of his age.

### EARLY YEARS

Charles John Huffam Dickens was born February 7, 1812, in Portsmouth but left it in infancy. His happiest childhood years were spent in **Chatham** (1817–22), an area to which he often reverts in his fiction. From 1822 he lived in London, until, in 1860, he moved permanently to a country house, Gad's Hill, near **Chatham**. His origins were middle class, if of a newfound and precarious respectability; one grandfather had been a domestic servant, and the other an embezzler. His father, a clerk in the navy pay office, was well paid, but his extravagance and ineptitude often brought the family to financial embarrassment or disaster. (Some of his failings and his ebullience are dramatized in Mr. Micawber in the partly autobiographical *David Copperfield*.) In 1824 the family reached bottom. Charles, the eldest son, had been with-

Dickens, 1859.

By courtesy of the Gernsheim Collection, the University of Texas at Austin

drawn from school and was now set to manual work in a factory, and his father went to prison for debt. These shocks deeply affected Charles. Though abhorring this brief descent into the working class, he began to gain that sympathetic knowledge of their life and privations that informed his writings. Also, the images of the prison and of the lost, oppressed, or bewildered child recur in many novels. Much else in his character and art stems from this period, including, as the 20th-century novelist Angus Wilson has argued, his later difficulty, as man and author, in understanding women: this may be traced to his bitter resentment against his mother, who had, he felt, failed disastrously at this time to appreciate his sufferings. She had wanted him to stay at work when his father's release from prison and an improvement in the family's fortunes made the boy's return to school possible. Happily the father's view prevailed.

His schooling, interrupted and unimpressive, ended at 15. He became a clerk in a solicitor's office, then a shorthand reporter in the lawcourts (thus gaining a knowledge of the legal world often used in the novels), and finally, like other members of his family, a parliamentary and newspaper reporter. These years left him with a lasting affection for journalism and contempt both for the law and for Parliament. His coming to manhood in the reformist 1830s, and particularly his working on the Liberal Benthamite *Morning Chronicle* (1834–36), greatly affected his political outlook. Another influential event now was his rejection as suitor to Maria Beadnell because his family and prospects were unsatisfactory; his hopes of gaining and chagrin at losing her sharpened his determination to succeed. His feelings about Maria then and at her later brief and disillusioning re-entry into his life are reflected in David Copperfield's adoration of Dora Spenlow and in the middle-aged Arthur Clennam's discovery (in *Little Dorrit*) that Flora Finching, who had seemed enchanting years ago, was "diffuse and silly," that Flora "whom he had left a lily, had become a peony."

**Beginning of literary career.** Much drawn to the theatre, Dickens nearly became a professional actor in 1832. In 1833 he began contributing stories and descriptive essays to magazines and newspapers; these attracted attention and were reprinted as *Sketches* by "**Boz**" (February 1836). The same month, he was invited to provide a comic serial narrative to accompany engravings by a well-known artist; seven weeks later the first installment of *Pickwick Papers* appeared. Within a few months *Pickwick* was the rage and Dickens the most popular author of the day. During 1836 he also wrote two plays and a pamphlet on a topical issue (how the poor should be allowed to enjoy the Sabbath) and, resigning from his newspaper job, undertook to edit a monthly magazine, *Bentley's Miscellany*, in which he serialized *Oliver Twist*

Factory experiences

Early stories and essays

(1837–39). Thus, he had two serial installments to write every month. Already the first of his nine surviving children had been born; he had married (in April 1836) Catherine, eldest daughter of a respected Scottish journalist and man of letters, George Hogarth.

For several years his life continued at this intensity. Finding serialization congenial and profitable, he repeated the *Pickwick* pattern of 20 monthly parts in *Nicholas Nickleby* (1838–39); then he experimented with shorter weekly installments for *The Old Curiosity Shop* (1840–41) and *Barnaby Rudge* (1841). Exhausted at last, he then took a five-month vacation in America, touring strenuously and receiving quasi-royal honours as a literary celebrity but offending national sensibilities by protesting against the absence of copyright protection. A radical critic of British institutions, he had expected more from "the republic of my imagination," but he found more vulgarity and sharp practice to detest than social arrangements to admire. Some of these feelings appear in *American Notes* (1842) and *Martin Chuzzlewit* (1843–44).

**First novels.** His writing during these prolific years was remarkably various and, except for his plays, resourceful. *Pickwick* began as high-spirited farce and contained many conventional comic butts and traditional jokes; like other early works, it was manifestly indebted to the contemporary theatre, the 18th-century English novelists, and a few foreign classics, notably *Don Quixote*. But, besides giving new life to old stereotypes, *Pickwick* displayed, if sometimes in embryo, many of the features that were to be blended in varying proportions throughout his fiction: attacks, satirical or denunciatory, on social evils and inadequate institutions; topical references; an encyclopaedic knowledge of London (always his predominant fictional locale); pathos; a vein of the macabre; a delight in the demotic joys of Christmas; a pervasive spirit of benevolence and geniality; inexhaustible powers of character creation; a wonderful ear for characteristic speech, often imaginatively heightened; a strong narrative impulse; and a prose style that, if here overdependent on a few comic mannerisms, was highly individual and inventive. Rapidly improvised and written only weeks or days ahead of its serial publication, *Pickwick* contains weak and jejune passages and is an unsatisfactory whole—partly because Dickens was rapidly developing his craft as a novelist while writing and publishing it. What is remarkable is that a first novel, written in such circumstances, not only established him overnight and created a new tradition of popular literature but also survived, despite its crudities, as one of the best known novels in the world.

His self-assurance and artistic ambitiousness had appeared in *Oliver Twist*, where he rejected the temptation to repeat the successful *Pickwick* formula. Though containing much comedy still, *Oliver Twist* is more centrally concerned with social and moral evil (the workhouse and the criminal world); it culminates in Bill Sikes's murdering Nancy and Fagin's last night in the condemned cell at Newgate. The latter episode was memorably depicted in George Cruikshank's engraving; the imaginative potency of Dickens' characters and settings owes much, indeed, to his original illustrators (Cruikshank for *Sketches by "Boz"* and *Oliver Twist*, "Phiz" [Hablot K. Browne] for most of the other novels until the 1860s). The currency of his fiction owed much, too, to its being so easy to adapt into effective stage versions. Sometimes 20 London theatres simultaneously were producing adaptations of his latest story; so even nonreaders became acquainted with simplified versions of his works. The theatre was often a subject of his fiction, too, as in the Crummles troupe in *Nicholas Nickleby*. This novel reverted to the *Pickwick* shape and atmosphere, though the indictment of the brutal Yorkshire schools (Dotheboys Hall) continued the important innovation in English fiction seen in *Oliver Twist*—the spectacle of the lost or oppressed child as an occasion for pathos and social criticism. This was amplified in *The Old Curiosity Shop*, where the death of Little Nell was found overwhelmingly powerful at the time, though

a few decades later it became a byword for "Victorian sentimentality." In *Barnaby Rudge* he attempted another genre, the historical novel. Like his later attempt in this kind, *A Tale of Two Cities*, it was set in the late 18th century and presented with great vigour and understanding (and some ambivalence of attitude) the spectacle of large-scale mob violence.

To create an artistic unity out of the wide range of moods and materials included in every novel, with often several complicated plots involving scores of characters, was made even more difficult by Dickens' writing and publishing them serially. In *Martin Chuzzlewit* he tried "to resist the temptation of the current Monthly Number, and to keep a steadier eye upon the general purpose and design" (1844 Preface). Its American episodes had, however, been unpremeditated (he suddenly decided to boost the disappointing sales by some America-baiting and to revenge himself against insults and injuries from the American press). A concentration on "the general purpose and design" was more effective in the next novel, *Dombey and Son* (1846–48), though the experience of writing the shorter, and unserialized, Christmas books had helped him obtain greater coherence.

*A Christmas Carol* (1843), suddenly conceived and written in a few weeks, was the first of these Christmas books (a new literary genre thus created incidentally). Tossed off while he was amply engaged in writing *Chuzzlewit*, it was an extraordinary achievement—the one great Christmas myth of modern literature. His view of life was later to be described or dismissed as "Christmas philosophy," and he himself spoke of "*Carol* philosophy" as the basis of a projected work. His "philosophy," never very elaborated, involved more than wanting the Christmas spirit to prevail throughout the year, but his great attachment to Christmas (in his family life as well as his writings) is indeed significant and has contributed to his popularity. "Dickens dead?" exclaimed a London costermonger's girl in 1870. "Then will Father Christmas die too?"—a tribute both to his association with Christmas and to the mythological status of the man as well as in his work. The *Carol* immediately entered the general consciousness; Thackeray, in a review, called it "a national benefit, and to every man and woman who reads it a personal kindness." Further Christmas books, essays, and stories followed annually (except in 1847) through 1867. None equalled the *Carol* in potency, though some achieved great immediate popularity. Cumulatively they represent a celebration of Christmas attempted by no other great author.

How he struck his contemporaries in these early years appears in R.H. Horne's *New Spirit of the Age* (1844). Dickens occupied the first and longest chapter, as

... manifestly the product of his age . . . a genuine emanation from its aggregate and entire spirit. . . . He mixes extensively in society, and continually. Few public meetings in a benevolent cause are without him. He speaks effectively. . . . His influence upon his age is extensive—pleasurable, instructive, healthy, reformatory . . .

Mr. Dickens is, in private, very much what might be expected from his works. . . . His conversation is genial . . . [He] has singular personal activity, and is fond of games of practical skill. He is also a great walker, and very much given to dancing Sir Roger de Coverley. In private, the general impression of him is that of a first-rate practical intellect, with "no nonsense" about him.

He was indeed very much a public figure, actively and centrally involved in his world, and a man of confident presence. He was reckoned the best after-dinner speaker of the age; other superlatives he attracted included his having been the best shorthand reporter on the London press and his being the best amateur actor on the stage. Later he became one of the most successful periodical editors and the finest dramatic recitalist of the day. He was splendidly endowed with many skills. "Even irrespective of his literary genius," wrote an obituarist, "he was an able and strong-minded man, who would have succeeded in almost any profession to which he devoted himself" (*Times*, June 10, 1870). Few of his extraliterary skills and interests were irrelevant to the range and mode of his fiction.

Status as a public figure

American tour

Popularity of *Pickwick Papers*

Privately in these early years, he was both domestic and social. He loved home and family life and was a proud and efficient householder; he once contemplated writing a cookbook. To his many children, he was a devoted and delightful father, at least while they were young; relations with them proved less happy during their adolescence. Apart from periods in Italy (1844–45) and Switzerland and France (1846–47), he still lived in London, moving from an apartment in Furnival's Inn to larger houses as his income and family grew. Here he entertained his many friends, most of them popular authors, journalists, actors, or artists, though some came from the law and other professions or from commerce and a few from the aristocracy. Some friendships dating from his youth endured to the end, and, though often exasperated by the financial demands of his parents and other relatives, he was very fond of some of his family and loyal to most of the rest. Some literary squabbles came later, but he was on friendly terms with most of his fellow authors, of the older generation as well as his own. Necessarily solitary while writing and during the long walks (especially through the streets at night) that became essential to his creative processes, he was generally social at other times. He enjoyed society that was unpretentious and conversation that was genial and sensible but not too intellectualized or exclusively literary. High society he generally avoided, after a few early incursions into the great houses; he hated to be lionized or patronized.

He had about him "a sort of swell and overflow as of a prodigality of life," an American journalist said. Everyone was struck by the brilliance of his eyes and his smart, even dandyish, appearance ("I have the fondness of a savage for finery," he confessed). John Forster, his intimate friend and future biographer, recalled him at the *Pickwick* period:

the quickness, keenness, and practical power, the eager, restless, energetic outlook on each several feature [of his face] seemed to tell so little of a student or writer of books, and so much of a man of action and business in the world. Light and motion flashed from every part of it.

He was proud of his art and devoted to improving it and using it to good ends (his works would show, he wrote, that "Cheap Literature is not behind-hand with the Age, but holds its place, and strives to do its duty"), but his art never engaged all his formidable energies. He had no desire to be narrowly literary.

A notable, though unsuccessful, demonstration of this was his being founder-editor in 1846 of the *Daily News* (soon to become the leading Liberal newspaper). His journalistic origins, his political convictions and readiness to act as a leader of opinion, and his wish to secure a steady income independent of his literary creativity and of any shifts in novel readers' tastes made him attempt or plan several periodical ventures in the 1840s. The return to daily journalism soon proved a mistake—the biggest fiasco in a career that included few such misdirections or failures. A more limited but happier exercise of his practical talents began soon afterward: more than a decade he directed, energetically and with great insight and compassion, a reformatory home for young female delinquents, financed by his wealthy friend Angela Burdett-Coutts. The benevolent spirit apparent in his writings often found practical expression in his public speeches, fund-raising activities, and private acts of charity.

*Dombey and Son* (1846–48) was a crucial novel in his development, a product of more thorough planning and maturer thought and the first in which "a pervasive uneasiness about contemporary society takes the place of an intermittent concern with specific social wrongs" (Kathleen Tillotson). Using railways prominently and effectively, it was very up-to-date, though the questions posed included such perennial moral and religious challenges as are suggested by the child Paul's first words in the story: "Papa, what's money?" Some of the corruptions of money and pride of place and the limitations of "respectable" values are explored, virtue and human decency being discovered most often (as elsewhere in Dickens) among the poor, humble, and simple. In Paul's early death Dickens offered another famous pathetic

episode; in *Mr. Dombey* he made a more ambitious attempt than before at serious and internal characterization. *David Copperfield* (1849–50) has been described as a "holiday" from these larger social concerns and most notable for its childhood chapters, "an enchanting vein which he had never quite found before and which he was never to find again" (Edmund Wilson). Largely for this reason and for its autobiographical interest, it has always been among his most popular novels and was Dickens' own "favourite child." It incorporates material from the autobiography he had recently begun but soon abandoned and is written in the first person, a new technique for him. David differs from his creator in many ways, however, though Dickens uses many early experiences that had meant much to him—his period of work in the factory while his father was jailed, his schooling and reading, his passion for Maria Beadnell, and (more cursorily) his emergence from parliamentary reporting into successful novel writing. In *Micawber* the novel presents one of the "Dickens characters" whose imaginative potency extends far beyond the narratives in which they figure; *Pickwick* and *Sam Weller*, *Mrs. Gamp* and *Mr. Pecksniff*, and *Scrooge* are some others.

#### MIDDLE YEARS

**Journalism.** Dickens' journalistic ambitions at last found a permanent form in *Household Words* (1850–59) and its successor, *All the Year Round* (1859–88). Popular weekly miscellanies of fiction, poetry, and essays on a wide range of topics, these had substantial and increasing circulations, reaching 300,000 for some of the Christmas numbers. Dickens contributed some serials—the lamentable *Child's History of England* (1851–53), *Hard Times* (1854), *A Tale of Two Cities* (1859), and *Great Expectations* (1860–61)—and essays, some of which were collected in *Reprinted Pieces* (1858) and *The Uncommercial Traveller* (1861, later amplified). Particularly in 1850–52 and during the Crimean War, he contributed many items on current political and social affairs; in later years he wrote less—much less on politics—and the magazine was less political, too. Other distinguished novelists contributed serials, including Mrs. Gaskell, Wilkie Collins, Charles Reade, and Bulwer Lytton. The poetry was uniformly feeble; Dickens was imperceptive here. The reportage, often solidly based, was bright (sometimes painfully so) in manner. His conduct of these weeklies shows his many skills as editor and journalist but also some limitations in his tastes and intellectual ambitions. The contents are revealing in relation to his novels: he took responsibility for all the opinions expressed (for articles were anonymous) and selected and amended contributions accordingly; so comments on topical events and so on may generally be taken as representing his opinions, whether or not he wrote them. No English author of comparable status has devoted 20 years of his maturity to such unremitting editorial work, and the weeklies' success was due not only to his illustrious name but also to his practical sagacity and sustained industry. Even in his creative work, as his eldest son said,

No city clerk was ever more methodical or orderly than he; no humdrum, monotonous, conventional task could ever have been discharged with more punctuality, or with more businesslike regularity.

**Novels.** The novels of these years, *Bleak House* (1852–53), *Hard Times* (1854), and *Little Dorrit* (1855–57), were much "darker" than their predecessors. Presenting a remarkably inclusive and increasingly sombre picture of contemporary society, they were inevitably often seen at the time as fictionalized propaganda about ephemeral issues. They are much more than this, though it is never easy to state how Dickens' imagination transforms their many topicalities into an artistically coherent vision that transcends their immediate historical context. Similar questions are raised by his often basing fictional characters, places, and institutions on actual originals. He once spoke of his mind's taking "a fanciful photograph" of a scene, and there is a continual interplay between photographic realism and "fancy" (or imagination). "He describes London like a special correspondent

Autobiographical interest of *David Copperfield*

Unsuccessful journalistic ventures

Themes of the later novels

for posterity" (Walter Bagehot, 1858), and posterity has certainly found in his fiction the response of an acute, knowledgeable, and concerned observer to the social and political developments of "the moving age." In the novels of the 1850s, he is politically more despondent, emotionally more tragic. The satire is harsher, the humour less genial and abundant, the "happy endings" more subdued than in the early fiction. Technically, the later novels are more coherent, plots being more fully related to themes, and themes being often expressed through a more insistent use of imagery and symbols (grim symbols, too, such as the fog in *Bleak House* or the prison in *Little Dorrit*). His art here is more akin to poetry than to what is suggested by the photographic or journalistic comparisons. "Dickensian" characterization continues in the sharply defined and simplified grotesque or comic figures, such as Chadband in *Bleak House* or Mrs. Sparrit in *Hard Times*, but large-scale figures of this type are less frequent (the Gamps and Micawbers belong to the first half of his career). Characterization also has become more subordinate to "the general purpose and design"; moreover, Dickens is presenting characters of greater complexity, who provoke more complex responses in the reader (William Dorrit, for instance). Even the juvenile leads, who had usually been thinly conceived conventional figures, are now often more complicated in their make-up and less easily rewarded by good fortune. With his secular hopes diminishing, Dickens becomes more concerned with "the great final secret of all life"—a phrase from *Little Dorrit*, where the spiritual dimension of his work is most overt. Critics disagree as to how far so worldly a novelist succeeds artistically in enlarging his view to include the religious. These novels, too, being manifestly an ambitious attempt to explore the prospects of humanity at this time, raise questions, still much debated, about the intelligence and profundity of his understanding of society.

**Personal unhappiness.** Dickens' spirits and confidence in the future had indeed declined: 1855 was "a year of much unsettled discontent for him," his friend Forster recalled, partly for political reasons (or, as Forster hints, his political indignation was exacerbated by a "discontent" that had personal origins). The Crimean War, besides exposing governmental inefficiency, was distracting attention from the "poverty, hunger, and ignorant desperation" at home. In *Little Dorrit*, "I have been blowing off a little of indignant steam which would otherwise blow me up . . .," he wrote, "but I have no present political faith or hope—not a grain." Not only were the present government and Parliament contemptible but "representative government is become altogether a failure with us. . . the whole thing has broken down. . . and has no hope in it." Nor had he a coherent alternative to suggest. This desperation coincided with an acute state of personal unhappiness. The brief tragicomedy of Maria Beadnell's re-entry into his life, in 1855, finally destroyed one nostalgic illusion and also betrayed a perilous emotional immaturity and hunger. He now openly identified himself with some of the sorrows dramatized in the adult David Copperfield:

Why is it, that as with poor David, a sense comes always crushing on me, now, when I fall into low spirits, as of one happiness I have missed in life, and one friend and companion I have never made?

This comes from the correspondence with Forster in 1854–55, which contains the first admissions of his marital unhappiness; by 1856 he is writing, "I find the skeleton in my domestic closet is becoming a pretty big one"; by 1857–58, as Forster remarks, an "unsettled feeling" had become almost habitual with him, "and the satisfactions which home should have supplied, and which indeed were essential requirements of his nature, he had failed to find in his home." From May 1858, Catherine Dickens lived apart from him. A painful scandal arose, and Dickens did not act at this time with tact, patience, or consideration. The affair disrupted some of his friendships and narrowed his social circle, but surprisingly it seems not to have damaged his popularity with the public.

Catherine Dickens maintained a dignified silence, and

most of Dickens' family and friends, including his official biographer, Forster, were discreetly reticent about the separation. Not until 1939 did one of his children (Katey), speaking posthumously through conversations recorded by a friend, offer a candid inside account. It was discreditable to him, and his self-justifying letters must be viewed with caution. He there dated the unhappiness of his marriage back to 1838, attributed to his wife various "peculiarities" of temperament (including her sometimes labouring under "a mental disorder"), emphatically agreed with her (alleged) statement that "she felt herself unfit for the life she had to lead as my wife," and maintained that she never cared for the children nor they for her. In more temperate letters, where he acknowledged her "amiable and complying" qualities, he simply and more acceptably asserted that their temperaments were utterly incompatible. She was, apparently, pleasant but rather limited; such faults as she had were rather negative than positive, though family tradition from a household that knew the Dickenses well speaks of her as "a whiney woman" and as having little understanding of, or patience with, the artistic temperament.

Dickens' self-justifying letters lack candour in omitting to mention Ellen Ternan, an actress 27 years his junior, his passion for whom had precipitated the separation. Two months earlier he had written more frankly to an intimate friend:

The domestic unhappiness remains so strong upon me that I can't write, and (waking) can't rest, one minute. I have never known a moment's peace or content, since the last night of The Frozen Deep.

*The Frozen Deep* was a play in which he and Nelly (as Ellen was called) had performed together in August 1857. She was an intelligent girl, of an old theatrical family; reports speak of her as having "a pretty face and well-developed figure"—or "passably pretty and not much of an actress." She left the stage in 1860; after Dickens' death she married a clergyman and helped him run a school. The affair was hushed up until the 1930s, and evidence about it remains scanty, but every addition confirms that Dickens was deeply attached to her and that their relationship lasted until his death. It seems likely that she became his mistress, though probably not until the 1860s; assertions that a child, or children, resulted remain unproved. Similarly, suggestions that the anguish experienced by some of the lovers in the later novels may reflect Dickens' own feelings remain speculative. It is tempting, indeed, to associate Nelly with some of their heroines (who are more spirited and complex, less of the "legless angel," than most of their predecessors), especially as her given names, Ellen Lawless, seem to be echoed by those of heroines in the three final novels—Estella, Bella, and Helena Landless—but nothing definite is known about how she responded to Dickens, what she felt for him at the time, or how close any of these later love stories were to aspects or phases of their relationship.

"There is nothing very remarkable in the story," commented one early transmitter of it, and this seems just. Many middle-aged men feel an itch to renew their emotional lives with a pretty young girl, even if, unlike Dickens, they cannot plead indulgence for "the wayward and unsettled feeling which is part (I suppose) of the tenure on which one holds an imaginative life." But the eventual disclosure of this episode caused surprise, shock, or piquant satisfaction, being related of a man whose rebelliousness against his society had seemed to take only impeccably reformist shapes. A critic in 1851, listing the reasons for his unique popularity, had cited "above all, his deep reverence for the household sanctities, his enthusiastic worship of the household gods." After these disclosures he was, disconcertingly or intriguingly, a more complex man; and, partly as a consequence, Dickens the novelist also began to be seen as more complex, less conventional, than had been realized. The stimulus was important, though Nelly's significance, biographically and critically, has proved far from inextinguishable.

**Public readings.** In the longer term, Kathleen Tillotson's remark is more suggestive: "his lifelong love-affair

Friendship  
with Ellen  
Ternan

Marital  
grief

Histrionic  
talents

with his reading public, when all is said, is by far the most interesting love-affair of his life." This took a new form, about the time of Dickens' separation from his wife, in his giving public readings from his works, and it is significant that, when trying to justify this enterprise as certain to succeed, he referred to "that particular relation (personally affectionate and like no other man's) which subsists between me and the public." The remark suggests how much Dickens valued his public's affection, not only as a stimulus to his creativity and a condition for his commercial success but also as a substitute for the love he could not find at home. He had been toying with the idea of turning paid reader since 1853, when he began giving occasional readings in aid of charity. The paid series began in April 1858, the immediate impulse being to find some energetic distraction from his marital unhappiness. But the readings drew on more permanent elements in him and his art: his remarkable histrionic talents, his love of theatricals and of seeing and delighting an audience, and the eminently performable nature of his fiction. Moreover, he could earn more by reading than by writing, and more certainly; it was easier to force himself to repeat a performance than create a book.

His initial repertoire consisted entirely of Christmas books but was soon amplified by episodes from the novels and magazine Christmas stories. A performance usually consisted of two items; of the 16 eventually performed, the most popular were "The Trial from *Pickwick*" and the *Carol*. Comedy predominated, though pathos was important in the repertoire, and horrors were startlingly introduced in the last reading he devised, "Sikes and Nancy," with which he petrified his audiences and half killed himself. Intermittently, until shortly before his death, he gave seasons of readings in London and hardworking tours through the provinces and (in 1867–68) the United States. Altogether he performed about 471 times. He was a magnificent performer, and important elements in his art—the oral and dramatic qualities—were demonstrated in these renderings. His insight and skill revealed nuances in the narration and characterization that few readers had noticed. Naturally, such extracts or short stories, suitable for a two-hour entertainment, excluded some of his larger and deeper effects—notably, his social criticism and analysis—and his later novels were underrepresented. Dickens never mentions these inadequacies. He manifestly enjoyed the experience until, near the end, he was becoming ill and exhausted. He was writing much less in the 1860s. It is debatable how far this was because the readings exhausted his energies, while providing the income, creative satisfaction, and continuous contact with an audience that he had formerly obtained through the novels. He gloried in his audiences' admiration and love. Some friends thought this too crude a gratification, too easy a triumph, and a sad declension into a lesser and ephemeral art. However the episode is judged, it was characteristic of him—of his relationship with his public, his business sense, his stamina, his ostentatious display of supplementary skills: also of his originality, for no important author (at least since Homer, as reviewers said) and no English author since of anything like his stature has devoted so much time and energy to this activity. The only comparable figure is his contemporary, Mark Twain, who acknowledged Dickens as the pioneer.

#### LAST YEARS

**Final novels.** Tired and ailing though he was, he remained inventive and adventurous in his final novels. *A Tale of Two Cities* (1859) was an experiment, relying less than before on characterization, dialogue, and humour. An exciting and compact narrative, it lacks too many of his strengths to count among his major works. Sydney Carton's self-sacrifice was found deeply moving by Dickens and by many readers; Dr. Manette now seems a more impressive achievement in serious characterization. The French Revolution scenes are vivid, if superficial in historical understanding. *Great Expectations* (1860–61) resembles *Copperfield* in being a first-person narration and in drawing on parts of Dickens' personality and ex-

perience. Compact like its predecessor, it lacks the panoramic inclusiveness of *Bleak House*, *Little Dorrit*, and *Our Mutual Friend*, but, though not his most ambitious, it is his most finely achieved novel. The hero Pip's mind is explored with great subtlety, and his development through a childhood and youth beset with hard tests of character is traced critically but sympathetically. Various "great expectations" in the book proved ill founded—a comment as much on the values of the age as on the characters' weaknesses and misfortunes. *Our Mutual Friend* (1864–65), a large inclusive novel, continues this critique of monetary and class values. London is now grimmer than ever before, and the corruption, **complicity**, and superficiality of "respectable" society are fiercely attacked. Many new elements are introduced into Dickens' fictional world, but his handling of the old comic-eccentrics (such as Boffin, Wegg, and Venus) is sometimes tiresomely mechanical. How the unfinished *Edwin Drood* (1870) would have developed is uncertain. Here again Dickens left panoramic fiction to concentrate on a limited private action. The central figure was evidently to be John Jasper, whose eminent respectability as a cathedral organist was in extreme contrast to his haunting low opium dens and, out of violent sexual jealousy, murdering his nephew. It would have been his most elaborate treatment of the themes of crime, evil, and psychological abnormality that had recurred throughout his novels; a great celebrator of life, he was also obsessed with death.

How greatly Dickens personally had changed appears in remarks by friends who met him again, after many years, during the American reading tour in 1867–68. "I sometimes think . . ." wrote one, "I must have known two individuals bearing the same name, at various periods of my own life." But just as the fiction, despite many developments, still contained many stylistic and narrative features continuous with the earlier work, so, too, the man remained a "human hurricane," though he had aged considerably, his health had deteriorated, and his nerves had been jangled by travelling ever since his being in a railway accident in 1865. Other Americans noted that, though grizzled, he was "as quick and elastic in his movements as ever." His photographs, wrote a journalist after one of the readings, "give no idea of his genial expression. To us he appears like a hearty, companionable man, with a deal of fun in him." But that very day Dickens was writing, "I am nearly used up," and listing the afflictions now "telling heavily upon me." His pride and this old-trouper tradition made him conceal his sufferings. And, if sometimes by an effort of will, his old high spirits were often on display. "The cheerfullest man of his age," he was called by his American publisher, J.T. Fields; Fields's wife more perceptively noted, "Wonderful, the flow of spirits C.D. has for a sad man."

His fame remained undiminished, though critical opinion was increasingly hostile to him. Henry Wadsworth Longfellow, noting the immense enthusiasm for him during the American tour, remarked: "One can hardly take in the whole truth about it, and feel the universality of his fame." But in many respects he was "a sad man" in these later years. He never was tranquil or relaxed. Various old friends were now estranged or dead or for other reasons less available; he was now leading a less social life and spending more time with young friends of a calibre inferior to his former circle. His sons were causing much worry and disappointment; "all his fame goes for nothing," said a friend, "since he has not the one thing. He is very unhappy in his children." His life was not all dreary, however. He loved his country house, Gad's Hill, and he could still "warm the social atmosphere wherever he appeared with that summer glow which seemed to attend him." T.A. Trollope (contributor to Dickens' *All the Year Round* and brother of the novelist Anthony Trollope), who wrote that, despaired of giving people who had not met him any idea of

the general charm of his manner. . . . His laugh was brimful of enjoyment. . . . His enthusiasm was boundless. . . . He was a *hearty* man, a large-hearted man, . . . a strikingly manly man.

Change in  
Dickens'  
personality

Only a week before his death he was at the theatre, in high spirits, brim-full of *joie-de-vivre*. His talk had all the sparkle of champagne, and he himself kept laughing at the majesty of his own absurdities, as one droll thought followed another, . . . at times still so young and almost boyish in his gaiety. (Lord Redesdale, *Memories*, 1915)

Last  
speech

Farewell readings. His health remained precarious after the punishing American tour and was further impaired by his addiction to giving the strenuous "Sikes and Nancy" reading. His farewell readings tour was abandoned when, in April 1869, he collapsed. He began writing another novel and gave a short farewell season of readings in London, ending with the famous speech, "From these garish lights I vanish now for evermore . . ." — words repeated, less than three months later, on his funeral card. He died suddenly, on June 9, 1870, and was buried in Westminster Abbey. People all over the world mourned the loss of "a friend" as well as a great entertainer and creative artist and one of the acknowledged influences upon the spirit of the age.

#### ASSESSMENT

**Contemporary** opinion. Ralph Waldo Emerson, attending one of the readings in Boston, "laughed as if he must crumble to pieces," but, discussing Dickens afterward, he said:

I am afraid he has too much talent for his genius; it is a fearful locomotive to which he is bound and can never be free from it nor set to rest. . . . He daunts me! I have not the key.

There is no simple key to so prolific and multifarious an artist nor to the complexities of the man, and interpretation of both is made harder by his possessing and feeling the need to exercise so many talents besides his imagination. How his fiction is related to these talents — practical, journalistic, oratorical, histrionic — remains controversial. Also the geniality and unequalled comedy of the novels must be related to the sufferings, errors, and self-pity of their author and to his concern both for social evils and for the perennial griefs and limitations of humanity. The novels cover a wide range, social, moral, emotional, and psychological. Thus, he is much concerned with very ordinary people but also with abnormality (*e.g.*, eccentricity, depravity, madness, hallucinations, dream states). He is both the most imaginative and fantastic and the most topical and documentary of great novelists. He is unequal, too; a wonderfully inventive and poetic writer, he can also, even in his mature novels, write with a painfully slack conventionality.

Biographers have only recently known enough to explore the complexity of his nature. Critics have always been challenged by his art, though from the start it contained enough easily acceptable ingredients, evident skill and gusto, to ensure popularity. The earlier novels were and have mostly remained the most popular: *Pickwick*, *Oliver Twist*, *Chuzzlewit*, the *Carol*, *Copperfield*. Critics began to demur against the later novels, deploring the loss of the freer comic spirit, baffled by the more symbolic mode of his art, and uneasy when the simpler reformism over isolated issues became a more radical questioning of social assumptions and institutions. Dickens was never neglected or forgotten and never lost his popularity, but for 70 years after his death he received remarkably little serious attention (George Gissing, G.K. Chesterton, and George Bernard Shaw being notable exceptions). F.R. Leavis, later to revise his opinion, was speaking for many, in 1948, when he asserted that "the adult mind doesn't as a rule find in Dickens a challenge to an unusual and sustained seriousness"; Dickens was indeed a great genius, "but the genius was that of a great entertainer."

Modem criticism. Modern Dickens criticism dates from 1940–41, with the very different impulses given by George Orwell, Edmund Wilson, and Humphry House. In the 1950s, a substantial reassessment and re-editing of the works began, his finest artistry and greatest depth now being discovered in the later novels — *Bleak House*, *Little Dorrit*, and *Great Expectations* — and (less unani-

mously) in *Hard Times* and *Our Mutual Friend*. Scholars have explored his working methods, his relations with his public, and the ways in which he was simultaneously an eminently Victorian figure and an author "not of an age but for all time." Biographically, little had been added to Forster's massive and intelligent *Life* (1872–74), except the Ellen Ternan story, until Edgar Johnson's in 1952. Since then, no radically new view has emerged, though particular phases or aspects have received fuller attention. The centenary in 1970 demonstrated a critical consensus about his standing second only to William Shakespeare in English literature, which would have seemed incredible 40 or even 20 years earlier.

He was being compared to Shakespeare, for imaginative range and energy, while still in his twenties. He and Shakespeare are the two unique popular classics that England has given to the world, and they are alike in being remembered not for one masterpiece (as Dante, Cervantes, or John Milton are) but for a creative world, a plurality of works populated by a great variety of figures, in situations ranging from the sombre to the farcical. For the common reader, both Shakespeare and Dickens survive through their characterization, though they offer much else. Shakespeare ranges more deeply and widely. Dickens enjoys one temporary advantage in having lived when he did and thus being able to write of an urban industrial world, in which notions of representative government and social responsibility were current — a world containing many of the problems and hopes that persist a century after his death and far beyond the land of his birth.

#### MAJOR WORKS

**NOVELS:** *The Pickwick Papers* (1837); *Oliver Twist* (1838); *Nicholas Nickleby* (1839); *The Old Curiosity Shop* and *Barnaby Rudge* (1841), two novels first published in a "clock framework," later abandoned, under the title of *Master Humphrey's Clock*; *Martin Chuzzlewit* (1844); *Dombey and Son* (1848); *David Copperfield* (1850); *Bleak House* (1853); *Hard Times* (1854); *Little Dorrit* (1857); *A Tale of Two Cities* (1859); *Great Expectations* (1861); *Our Mutual Friend* (1865); *The Mystery of Edwin Drood* (1870, unfinished).

**CHRISTMAS BOOKS:** *A Christmas Carol* (1843); *The Chimes* (1845, for 1844); *The Cricket on the Hearth* (1846, for 1845); *The Battle of Life* (1846); *The Haunted Man* (1848).

**STORIES (CHRISTMAS STORIES):** The volume entitled *Christmas Stories* in collected editions includes "A Christmas Tree" (1850); "What Christmas Is as We Grow Older" (1851); "The Poor Relation's Story" (1852); "Nobody's Story" (1853); "The Seven Poor Travellers" (1854); "The Holly-Tree," sometimes called "The Holly-Tree Inn" (1855); "The Wreck of the Golden Mary" (1856); "The Perils of Certain English Prisoners" (1857); "Going into Society" (1858); "The Haunted House" (1859); "A Message from the Sea" (1860); "Tom Tiddler's Ground" (1861); "Somebody's Luggage" (1862); "Mrs. Lirriper's Lodgings" (1863); Mrs. Lirriper's Legacy" (1864); "Doctor Marigold" (1865); "Mugby Junction" (1866); "No Thoroughfare" (1867). (**OTHER STORIES:** in collected editions generally appended to the volume entitled *Reprinted Pieces*, ["The Lamplighter" (1841); "To Be Read at Dusk" (1852); "Hunted Down" (1859); "George Silverman's Explanation" (1867); "Holiday Romance" (1868; children's story in 4 parts; pt. 2, "The Magic Fishbone," often reprinted separately).

**OTHER WORKS:** *Sketches by "Boz,"* 2 series (1836, together, 1839, included Dickens' first published work, "A Dinner at Poplar Walk," 1833); *Sketches of Young Gentlemen* (1838) and *Sketches of Young Couples* (1840), both usually appended to the *Sketches by "Boz,"* volume, in collected editions, which also usually contains "The Mudfog Papers" (contributed to *Bentley's Miscellany*, 1837–38); *American Notes* (1842); *Pictures from Italy* (1846); *The Life of Our Lord* (completed 1849, for his children; published 1934); *A Child's History of England* (1852–54); "The Lazy Tour of Two Idle Apprentices" (with Wilkie Collins, contributed to *Household Words* [1857]; often included in the volume entitled *Christmas Stories*); *Reprinted Pieces* (1858; contributed to *Household Words*, 1850–56); *The Uncommercial Traveller* (1861, amplified 1868, 1875; contributed to *All the Year Round*, 1860–69); *Plays and Poems*, ed. by R.H. Shepherd (1885); *Miscellaneous Papers*, ed. by B.W. Matz (1908; the most substantial posthumous collection, mainly essays contributed to *Household Words*, 1850–59; 16 further items, in the volume retitled *Collected Papers*, in

*The Nonesuch Dickens*, 1937); *Uncollected Writings from Household Words 1850–1859*, ed. by Harry Stone (1968).

#### BIBLIOGRAPHY

*Bibliographies:* K.J. FIELDING, *Charles Dickens* (1953); ADA NISBET, "Charles Dickens," in LIONEL STEVENSON (ed.), *Victorian Fiction: A Guide to Research*, pp. 44–153 (1964), full discussion of materials for Dickens studies and of writings about him in many languages; PHILIP COLLINS, *A Dickens Bibliography* (1970), off printed from GEORGE WATSON (ed.), *New Cambridge Bibliography of English Literature*, vol. 3, col. 779–850.

Most of the manuscripts and proof sheets of the novels are in the Victoria and Albert Museum, London. Other important collections of manuscripts and letters are in Dickens House, London; the British Museum; New York Public Library; Pierpont Morgan Library, New York; Free Library of Philadelphia; Henry E. Huntington Library and Art Gallery, San Marino, California; the University of Texas Libraries; and Yale University Library. The Dickens Fellowship (Dickens House, London) has branches all over the world and publishes the *Dickensian* (3/yr.). *Dickens Studies Newsletter* (quarterly) and *Dickens Studies Annual* are published from Carbondale, Illinois, where the Dickens Society is based.

*Collected editions:* *The New Oxford Illustrated Dickens* (1947–58) is the most cited but will be replaced by the Clarendon edition (1966– ). See also *Speeches*, ed. by K.J. FIELDING (1960); and *Public Readings*, ed. by PHILIP COLLINS (forthcoming).

*Letters:* The most complete collection, *The Letters of Charles Dickens*, ed. by W. DEXTER, 3 vol. (1938), is being replaced by *The Letters of Charles Dickens*, ed. by M. HOUSE *et al.* (1965– ). See also *The Heart of Charles Dickens, As Revealed in His Letters to Angela Burdett-Coutts*, ed. by E. JOHNSON (1952).

*Biographies:* JOHN FORSTER, *The Life of Charles Dickens*, 3 vol. (1872–74), remains indispensable, though EDGAR JOHNSON, *Charles Dickens: His Tragedy and Triumph*, 2 vol. (1952, reprinted 1965), is now the standard biography.

*Criticism:* GEORGE R. GISSING, *Charles Dickens: A Critical Study* (1898); G.K. CHESTERTON, *Charles Dickens* (1906); GEORGE ORWELL, "Dickens," in *Critical Essays*, pp. 7–56 (1946); EDMUND WILSON, "Dickens: The Two Scrooges," in *The Wound and the Bow*, pp. 1–104 (1941); HUMPHRY HOUSE, *The Dickens World*, 2nd ed. (1960), the best discussion of Dickens and his age; G.H. FORD, *Dickens and His Readers* (1955); JOHN E. BUTT and KATHLEEN TILLOSON, *Dickens at Work* (1957); J. HILLIS MILLER, *Charles Dickens: The World of His Novels* (1958), the most influential critical study since Edmund Wilson's; PHILIP COLLINS, *Dickens and Crime* (1962); ROBERT GARIS, *The Dickens Theatre* (1965); ANGUS WILSON, *The World of Charles Dickens* (1970); FR. and Q.D. LEAVIS, *Dickens, the Novelist* (1971).

*Anthologies of Dickens criticism:* G.H. FORD and L. LANE (eds.), *The Dickens Critics* (1961); STEPHEN WALL (ed.), *Charles Dickens: A Critical Anthology* (1970); and PHILIP COLLINS (ed.), *Dickens, the Critical Heritage* (1971), on his reception 1836–82.

### Dickinson, Emily

Emily Dickinson is one of the world's masters of the short lyric poem. The subjects of her poems, expressed in intimate, domestic figures of speech, include love, death, and nature. The contrast between her quiet, secluded life in the house in which she was born and died, and the depth and intensity of her terse poems, has provoked much speculation about her personality and personal relationships. Her 1,775 poems and her letters, which survive in almost as great a number, reveal a passionate, witty woman and a scrupulous craftsman who made an art not only of her poetry but also of her correspondence and her life.

#### Early life

Emily Elizabeth Dickinson was born December 10, 1830, at Amherst, Massachusetts, the second of three children. The three remained close throughout their adult lives: her younger sister, Lavinia, stayed in the family home and did not marry, and her older brother, Austin, lived in the house next door after his marriage to a friend of Emily's. Her grandfather, Samuel Fowler Dickinson, had been one of the founders of Amherst College, and her father, Edward Dickinson, served as treasurer of the college from 1835 to 1872. A lawyer who served one term (1853–1855) in Congress, Edward Dickinson was an

austere and somewhat remote father, but not an unkind one. Emily's mother, too, was not close to her children.

Emily was educated at Amherst Academy and Mount Holyoke Female Seminary. Mount Holyoke, which she attended from 1847 to 1848, insisted on religious as well as intellectual growth, and Emily was under considerable pressure to become a professing Christian. She resisted, however, and although many of her poems deal with God, she remained all her life a skeptic. Despite her doubts, she continued to hold strong religious feelings, a conflict that lent tension to her writings.

Emily began to write verse about 1850, apparently while under the spell of the poems of Ralph Waldo Emerson and Emily Brontë, and under the tutelage of Benjamin F. Newton, a young man studying law in her father's office. Only a handful of her poems can be dated before 1858, when she began to collect them into small, handsewn booklets. Her letters of the 1850s reveal a vivacious, humorous, somewhat shy young woman. In 1855 Emily went to Washington, D.C., with her sister to visit their father, who was serving in Congress. During the trip they stopped off at Philadelphia, where she heard the preaching of the noted clergyman, the Rev. Charles Wadsworth, who was to become her "dearest earthly friend." He was something of a romantic figure: a man said to have known great sorrow, whose eloquence in the pulpit contrasted with his solitary broodings. He and Emily exchanged letters on spiritual matters, his Calvinist orthodoxy perhaps serving as a useful foil for her own speculative reasoning. She may also have found in his stern, rigorous beliefs a welcome corrective to the easy assumption of a benign universe made by Emerson and the other Transcendentalists.

In the 1850s Emily began two of her significant correspondences—with Dr. and Mrs. Josiah G. Holland and with Samuel Bowles. The two men were editors of the *Springfield (Massachusetts) Republican*, a paper that took an interest in literary matters and even published verse. The correspondence continued over the years, although in the case of the Hollands, most of the letters after the 1850s went to Mrs. Holland, a woman intelligent enough to comprehend Emily's subtleties and witticisms. Emily tried to interest Bowles in her poetry, and it was a crushing blow to her that he, a man of quick mind but conventional literary tastes, failed to appreciate it.

By the late 1850s, when she was writing poems at a steadily increasing pace, Emily Dickinson loved a man whom she called "Master" in three drafts of letters. "Master" does not exactly resemble any of Emily's known friends, but may have been Bowles or Wadsworth. This love shines forth in several lines from her poems: "I'm ceded—I've stopped being Theirs," "Tis so much joy! 'Tis so much joy," and "Dare you see a Soul at the White

Character  
of her  
poetry

*Heat?*" to name only a few. Other poems reveal the frustration of this love and its gradual sublimation into a love for Christ and a celestial marriage to him.

The poems of the 1850s are fairly conventional in sentiment and form, but beginning about 1860, they become experimental both in language and prosody, though they owe much to the metres of the English hymn writer Isaac Watts and to Shakespeare and the King James Version of the Bible. Emily's prevailing poetic form was the quatrain of three iambic feet, a type described in one of the books by Watts in the family library. She used many other forms as well, and to even the simpler hymnbook measures she gave complexity by constantly altering the metrical beat to fit her thought: now slow, now fast, now hesitant. She broke new ground in her wide use of off-rhymes, varying from the true in a variety of ways that also helped to convey her thought and its tensions. In striving for an epigrammatic conciseness, she stripped her language of superfluous words and saw to it that those that remained were vivid and exact. She tampered freely with syntax and liked to place a familiar word in an extraordinary context, shocking the reader to attention and discovery.

On April 15, 1862, Emily Dickinson wrote a letter, enclosing four poems, to a literary man, Thomas Wentworth Higginson, asking whether her poems were "alive." Higginson, although he advised Emily not to publish, recognized the originality of her poems and remained her "preceptor" for the rest of her life. After 1862 Emily Dickinson resisted all efforts by her friends to put her poems before the public. As a result, only seven poems by Emily Dickinson were published during her lifetime, five of them in the *Springfield Republican*.

Period of  
greatest  
creativity

The years of Emily Dickinson's greatest poetic output, about 800 poems, coincide with the Civil War. Although she looked inward and not to the war for the substance of her poetry, the tense atmosphere of the war years may have contributed to the urgency of her writing. The year of greatest stress was 1862, when distance and danger threatened Emily's friends—Samuel Bowles, in Europe for his health; Charles Wadsworth, who had moved to a new pastorate at the Calvary Church in San Francisco; and T.W. Higginson, serving as an officer in the Union Army. Emily also had persistent eye trouble, which led her, in 1864 and 1865, to spend several months in Cambridge, Massachusetts, for treatment. Once back in Amherst, she never travelled again, and after the late 1860s never left the boundaries of the family's property.

After the Civil War, Emily Dickinson's poetic tide ebbed, but she sought increasingly to regulate her life by the rules of art. Her letters, some of them equal in artistry to her poems, classicize daily experience in an epigrammatic style. For example, when a friend affronted Emily by sending a letter jointly to her and her sister, she replied: "A Mutual plum is not a plum. I was too respectful to take the pulp and do not like a stone." By 1870 Emily Dickinson dressed only in white and saw few of the callers who came to the homestead; her seclusion was fiercely guarded by her devoted sister. In August 1870, Higginson visited Amherst and described Emily as "a little plain woman" with reddish hair, dressed in white, bringing him flowers as her "introduction" and speaking in a "soft frightened breathless childlike voice."

Her later years were marked with sorrow at the deaths of many people she loved. The most prostrating of these were the deaths of her father in 1874 and her eight-year-old nephew Gilbert in 1883, which occasioned some of her finest letters. She also mourned the loss of Bowles in 1878, Holland in 1881, Charles Wadsworth and her mother in 1882, Otis P. Lord in 1884, and Helen Hunt Jackson in 1885. Lord, a judge from Salem, Massachusetts, with whom Emily fell in love about 1878, had been the closest friend of Emily's father. Emily's drafts of letters to Lord reveal a tender, mature love, which Lord returned. Mrs. Jackson, a poet and popular novelist, discerned the greatness of Emily's poetry and tried unsuccessfully to get her to publish it.

Emily Dickinson died on May 15, 1886. Soon after her death her sister Lavinia determined to have Emily's

poems published. In 1890 *Poems* by Emily Dickinson, edited by T.W. Higginson and Mabel Loomis Todd, appeared. Other volumes of Dickinson poems, edited chiefly by Mabel Loomis Todd, Martha Dickinson Bianchi (Emily's niece), and Millicent Todd Bingham, were published 1891–1945, and in 1955 Thomas H. Johnson edited all the surviving poems and their variant versions.

#### MAJOR WORKS

No collection of poems by Emily Dickinson was published in her lifetime. The first selection, *Poems by Emily Dickinson* (1890), was followed by *Poems: Second Series* (1891), and *Poems: Third Series* (1896). Additional poems were included in *Letters of Emily Dickinson*, 2 vol. (1894). Later volumes of poems were: *The Single Hound: Poems of a Lifetime* (1914), *Further Poems of Emily Dickinson: Withheld from Publication by Her Sister Lavinia* (1929), *Unpublished Poems of Emily Dickinson* (1935), and *Bolts of Melody: New Poems of Emily Dickinson* (1945).

**BIBLIOGRAPHY.** S.T. CLENNING, *Emily Dickinson: A Bibliography, 1850–1966* (1968), is the most recent and most comprehensive bibliography. The great majority of Dickinson manuscripts, both poems and letters, are in the libraries of Harvard University and Amherst College. Emily Dickinson's home, the property of Amherst College, contains some memorabilia. The basic text of the poems is *The Poems of Emily Dickinson, Including Variant Readings Critically Compared with All Known Manuscripts*, 3 vol., ed. by T.H. JOHNSON (1955); the most complete edition of the letters, *The Letters of Emily Dickinson*, 3 vol., ed. by T.H. JOHNSON and THEODORA WARD (1958). There is as yet no definitive biography of Emily Dickinson. Biographical studies include: M.T. BINGHAM, *Emily Dickinson's Home: Letters of Edward Dickinson and His Family* (1955), the best account to date of Emily Dickinson's early years; T.H. JOHNSON, *Emily Dickinson: An Interpretive Biography* (1955), an extended critical biography; and JAY LEMA, *The Years and Hours of Emily Dickinson*, 2 vol. (1960), a day-by-day guidebook to the life of Emily Dickinson. Two critical studies of the poems are C.R. ANDERSON, *Emily Dickinson's Poetry: Stairway of Surprise* (1960); and G.F. WHICHER, *This Was a Poet* (1938). Although Whicher's book is no longer wholly reliable as biography, both of these works are critically excellent.

(D.J.M.H.)

## Dictionary

The word "dictionary" is used to describe a wide variety of reference works. Basically, a dictionary lists a set of words with information about them. The list may attempt to be a complete inventory of a language or may be only a small segment of it. A short list, sometimes at the back of a book, is often called a glossary. When a word list is an index to a limited body of writing, with references to each passage, it is called a **concordance**. Theoretically, a **good dictionary** could be compiled by bringing together and organizing into one list a large number of concordances. When a word list is of geographic names only, it takes the special name **gazetteer**.

The word "lexicon" designates a wordbook, but it also has a special abstract meaning among linguists, referring to the body of separable structural units of which the language is made up. In this sense a preliterate culture has a lexicon long before its units are written down in a dictionary. Scholars in England sometimes use "lexis" to designate this lexical element of language.

The compilation of a dictionary is lexicography; lexicology is a branch of linguistics in which, with the utmost scientific rigour, the theories that lexicographers make use of in the solution of their problems are developed.

The common phrase "dictionary order" takes for granted that the alphabetical order will be followed, and yet the alphabetical order has been called a tyranny that makes dictionaries less useful than they might be if compiled in some other order. The assembling of words into groups related by some principle, as by their meanings, can be done, and such a work is often called a thesaurus or synonymy. But such works need an index for ease of reference, and it is unlikely that alphabetical order will be superseded except in specialized works.

The distinction between a dictionary and an encyclopaedia is easy to state but difficult to carry out in a practical way: a dictionary explains words, whereas an encyclopaedia explains things. Because words achieve

Distinction  
between  
dictionary  
and  
encyclo-  
paedia

their usefulness by referring to things, however, it is difficult to construct a dictionary without considerable attention to the objects and abstractions designated.

A monolingual dictionary has both the word list and the explanations in the same language, whereas bilingual or multilingual (polyglot) dictionaries have the explanations in another language or different languages. The word "dictionary" is also extended, in a loose sense, to reference books with entries in alphabetical order, such as a dictionary of biography, a dictionary of heraldry, or a dictionary of plastics.

The present article, after an account of the development of dictionaries from classical times to the recent past, treats the kinds of dictionaries and their features and problems. It concludes with a brief section on some of the major dictionaries that are available. Examples and illustrations for the sections on the types of dictionaries and on their features and problems are drawn primarily from the products of English lexicographers.

#### HISTORICAL BACKGROUND

From classical times to 1604. In the long perspective of human evolutionary development, dictionaries have been known through only a slight fraction of language history. People at first simply talked without having any authoritative backing from reference books. A short Akkadian word list, from central Mesopotamia, has survived from the 7th century BC. The Western tradition of dictionary making began among the Greeks, although not until the language had changed so much that explanations and commentaries were needed. After a 1st-century-AD lexicon by Pamphilus of Alexandria, many lexicons were compiled in Greek, the most important being those of the Atticists in the 2nd century, that of Hesychius of Alexandria in the 5th century, and those of Photius and Suidas in the Middle Ages. (The Atticists were compilers of lists of words and phrases thought to be in accord with the usage of the Athenians.)

Because Latin was a much-used language of great prestige well into modern times, its monumental dictionaries were important and later influenced English lexicography. In the 1st century BC, Marcus Terentius Varro wrote a treatise *De lingua Latina*; the extant books of its section of etymology are valuable for their citations from Latin poets. At least five medieval **scholastics**—Papias the Lombard, Alexander Neckam, Johannes de Garlandia (John Garland), Hugo of Pisa, and Giovanni Balbi of Genoa—turned their attention to dictionaries. The mammoth work of Ambrogio Calepino, published at Reggio (now Reggio nell'Emilia), in 1502, incorporating several other languages besides Latin, was so popular that "calepin" came to be an ordinary word for a dictionary. A Lancashire will of 1568 contained the provision: "I wyll that Henry Marrecrofte shall have my calapyne and my parafrasies." This is an early instance of the tendency that, several centuries later, caused people to say, "Look in Johnson" or "Look in Webster."

Because language problems within a single language do not loom so large to ordinary people as those that arise in the learning of a different language, the interlingual dictionaries developed early and had great importance. The corporation records of Boston, Lincolnshire, have the following entry for the year 1578:

That a dictionarye shall be bought for the scollers of the Free Scoole, and the same boke to be tyed in a cheyne, and set upon a deske in the scoole, whereunto any scoller may have accesse, as occasion shall serve.

The origin of the bilingual lists can be traced to a practice of the early Middle Ages, that of writing interlinear glosses—explanations of difficult words—in manuscripts. It is but a step for these glosses to be collected together at the back of a manuscript and then for the various lists—glossaries—to be assembled in another manuscript. Some of these have survived from the 7th and 8th centuries—and in some cases they preserve the earliest recorded forms in English.

The first bilingual glossary to find its way into print was a French–English vocabulary for the use of travellers, printed in England by William Caxton without a title

page, in 1480. The words and expressions appeared in parallel columns on 26 leaves. Next came a Latin–English vocabulary by a noted grammarian, John Stanbridge, published by Richard Pynson in 1496 and reprinted frequently. But far more substantial in character was an English–Latin vocabulary called the *Pronptorius puerorum* ("Storehouse [of words] for Children") brought out by Pynson in 1499. It is better known under its later title of *Promptorium parvulorum sive clericorum* ("Storehouse for Children or Clerics") commonly attributed to Geoffrey the Grammarian (Galfridus Grammaticus), a Dominican friar of Norfolk, who is thought to have composed it about 1440.

The next important dictionary to be published was an English–French one by John (or Jehan) Palsgrave in 1530, *Lesclaircissement de la langue françoise* ("Elucidation of the French Tongue"). Palsgrave was a tutor of French in London, and a letter has survived showing that he arranged with his printer that no copy should be sold without his permission,

lest his proffit by teaching the Frenche tonge myght be mynished by the sale of the same to suche persons as, besids hym, wern disposed to studye the sayd tongue.

A Welsh–English dictionary by William Salesbury in 1547 brought another language into requisition: *A Dictionary in Englyshe and Welshe moche necessary to all suche Welshemen as wil spedly learne the Englyshe tōgue*. The encouragement of Henry VIII was responsible for an important Latin–English dictionary that appeared in 1538 from the hand of Sir Thomas Elyot. Thomas Cooper enlarged it in subsequent editions and in 1565 brought out a new work based upon it—*Thesaurus Linguae Romanae et Britannicae* ("Thesaurus of the Roman Tongue and the British"). A hundred years later John Aubrey, in *Brief Lives*, recorded Cooper's misfortune while compiling it:

His wife . . . was irreconcilably angrie with him for sitting up late at night so, compiling his Dictionary. . . . When he had halfe-donne it, she had the opportunity to gett into his studie, tooke all his paines out in her lap, and threw it into the fire, and burnt it. Well, for all that, that good man had so great a zeale for the advancement of learning, that he began it again, and went through with it to that perfection that he hath left it to us, a most usefull worke.

More important still was Richard Huloet's work of 1552, *Abececlarium Anglo-Latinum*, for it contained a greater number of English words than had before appeared in any similar dictionary. In 1556 appeared the first edition by John Withals of *A shorte Dictionarie for Yonge Beginners*, which gained greater circulation (to judge by the frequency of editions) than any other book of its kind. Many other lexicographers contributed to the development of dictionaries. Certain dictionaries were more ambitious and included a number of languages, such as John Baret's work of 1573, *An Alvearie: or triple Dictionarie, in Englishe, Latin, and French*. In his preface Baret acknowledged that the work was brought together by his students in the course of their exercises, and the title *Alvearie* was to commemorate their "beehive" of industry. The first rhyming dictionary, by Peter Levens, was produced in 1570—*Manipulus Vocabulorum. A Dictionarie of English and Latine wordes, set forthe in suche order, as none heretofore hath ben*.

The interlingual dictionaries had a far greater stock of English words than were to be found in the earliest all-English dictionaries, and the compilers of the English dictionaries, strangely enough, never took full advantage of these sources. It may be surmised, however, that people in general sometimes consulted the interlingual dictionaries for the English vocabulary. The anonymous author of *The Arte of English Poesie*, thought to be George Puttenham, wrote, in 1589, concerning the adoption of southern speech as the standard:

herein we are already ruled by th' English Dictionaries and other bookes written by learned men, and therefore is needeth none other direction in that behalfe.

The mainstream of English lexicography is the word list explained in English. The first known English–English glossary grew out of the desire of the supporters of

Thomas  
Cooper  
and his  
*Thesaurus*

The first  
rhyming  
dictionary

dictionar-  
ies

the Reformation that even the most humble Englishman should be able to understand the Scriptures. William Tyndale, when he printed the Pentateuch on the Continent in 1530, included "A table expoundinge certeyne wordes." The following entries are typical:

Albe, a longe garment of white linnen.  
Boothe, an housse made of bowes.  
Brestlappe or brestflappe, is soche a flappe as thou seist in the brest or a cope.  
Consecrate, to apoynte a thinge to holy uses.  
Dedicate, purifie or sanctifie.  
Firmament: the skyes.  
Slyme was . . . a fattenesse that osed our of the erth lyke unto tarre/And thou mayst call it cement/if thou wilt.  
Tabernacle, an house made tentwise, or as a pavelion.  
Vapor/a dewymiste/as the smoke of a sethyng pot.

Spelling reformers long had a deep interest in producing English dictionaries. In 1569 one such reformer, John Hart, lamented that the "disorders and confusions" of spelling were so great that "there can be made no perfitte Dictionarie nor Grammer." But a few years later the phonetician William Bullokar promised to produce such a work and stated, "A dictionary and grammar may stay our speech in a perfect use for euer."

The schoolmasters also had a strong interest in the development of dictionaries. In 1582 Richard Mulcaster, of the Merchant Taylors' school and later of St. Paul's, expressed the wish that some learned and laborious man "wold gather all the words which we vse in our English tung," and in his book commonly referred to as *The Elementarie* he listed about 8,000 words, without definitions, in a section called "The General Table." Another schoolmaster, Edmund Cote, of Bury St. Edmund's, in 1596 brought out *The Englishe Scholemaister, teachinge all his schollars of what age soever the most easie short & perfect order of distinct readinge & true writinge our Englishe tonge*, with a table that consisted of about 1,400 words, sorted out by different typefaces on the basis of etymology. This is important, because what is known as the "first" English dictionary, eight years later, was merely an adaptation and enlargement of Cote's table.

**From 1604 to 1828.** In 1604 at London appeared the first purely English dictionary to be issued as a separate work, entitled *A Table Alphabeticall, conteyning and teaching the true writing and understanding of hard usuall English wordes, borrowed from the Hebrew, Greeke, Latine, or French &c.*, by Robert Cawdrey, who had been a schoolmaster at Oakham, Rutland, about 1580, and in 1604 was living at Coventry. He had the collaboration of his son Thomas, a schoolmaster in London. This work contained about 3,000 words but was so dependent upon three sources that it can rightly be called a plagiarism. The basic outline was taken over from Cote's work of 1596, with 87 percent of his word list adopted. Further material was taken from the Latin-English dictionary by Thomas Thomas, *Dictionarium linguae Latinae et Anglicanae* (1588). But the third source is most remarkable. In 1599 a Dutchman known only as A.M. translated from Latin into English a famous medical work by Oswald Gabelkhouer, *The Boock of Plzysicke*, published at Dort, in the Netherlands. As he had been away from England for many years and had forgotten much of his English, A.M. sometimes merely put English endings on Latin words. When friends told him that Englishmen would not understand them, he compiled a list of them, explained by a simpler synonym, and put it at the end of the book. Samples are: "Puluerisated, reade beaten; Frigifye, reade coole; Madefye, reade dipp; Calefye, reade heat; Circumligate, reade binde; Ebulliated, read boyled." Thus, the fumbings of a Dutchman who knew little English (in fact, his errata) were poured into Cawdrey's word list. But other editions of Cawdrey were called for—a second in 1609, a third in 1613, and a fourth in 1617.

The next dictionary, by John Bullokar, *An English Expositor*, is first heard of on May 25, 1610, when it was entered in the Stationers' Register (which established the printer's right to it), but it was not printed until six years later. Bullokar introduced many archaisms, marked with a star ("onely used of some ancient writers, and now

growne out of use"), such as "aye," "eld," "enewed," "fremd," "gab," and "glee." The work had 14 editions, the last as late as 1731.

Still in the tradition of hard words was the next work, in 1623, by Henry Cockeram, the first to have the word dictionary in its title: *The English Dictionarie: or, an Interpreter of hard English Words*. It added many words that have never appeared anywhere else—adpugne, adstupiate, bulbitate, catillate, fraxate, nixious, prodigity, vitulate, and so on. Much fuller than its predecessors was Thomas Blount's work of 1656, *Glossographia: or, a dictionary Interpreting all such hard words. . . as are now used in our refined English tongue*. He made an important forward step in lexicographical method by collecting words from his own reading that had given him trouble; and he often cited the source. Much of Blount's material was appropriated two years later by Edward Phillips, a nephew of the poet Milton, for a work called *The New World of English Words*, and Blount castigated him bitterly.

Thus far, the English lexicographers had all been men who made dictionaries in their leisure time or as an avocation, but in 1702 appeared a work by the first professional lexicographer, John Kersey the Younger. This work, *A New English Dictionary*, incorporated much from the tradition of spelling books and discarded most of the fantastic words that had beguiled earlier lexicographers. As a result, it served the reasonable needs of ordinary users of the language. Kersey later produced some bigger works, but all of these were superseded in the 1720s, when Nathan Bailey, a schoolmaster in Stepney, issued several innovative works. In 1721 he produced *An universal etymological English Dictionary*, which for the rest of the century was more popular even than Dr. Johnson's. A supplement in 1727 was the first dictionary to mark accents for pronunciation. Bailey's imposing *Dictionarium Britannicum* of 1730 was used by Samuel Johnson as a repository during the compilation of the monumental dictionary of 1755.

Many literary men felt the inadequacy of English dictionaries, particularly in view of the continental examples. The Accademia della Crusca, of Florence, founded in 1582, brought out its *Vocabolario* at Venice in 1612, filled with copious quotations from Italian literature. The Académie Française produced its dictionary in 1694, but two other French dictionaries were actually more scholarly—that of César-Pierre Richelet in 1680 and that of Antoine Furetière in 1690. In Spain the Royal Spanish Academy (Real Academia Española), founded in 1713, produced its *Diccionario de la lengua Castellana*, 1726–1739, in six thick volumes. The foundation work of German lexicography, by Johann Leonhard Frisch, *Deutsch-Lateinisches Wörterbuch*, in 1741, freely incorporated quotations in German. The Russian Academy of Arts (St. Petersburg) published the first edition of its dictionary somewhat later, from 1789 to 1794. Both the French and the Russian academies arranged the first editions of their dictionaries in etymological order but changed to alphabetical order in the second editions.

In England, in 1707, the antiquary Humphrey Wanley set down in a list of "good books wanted," which he hoped the Society of Antiquaries would undertake: "A dictionary for fixing the English language, as the French and Italian." A number of noted authors made plans to fulfill this aim (Joseph Addison, Ambrose Philips, Alexander Pope, and others), but it remained for a promising poet and critic, Samuel Johnson, to bring such a project to fulfillment. Five leading booksellers of London banded together to support his undertaking, and a contract was signed on June 18, 1746. Next year Johnson's *Plan* was printed, a prospectus of 34 pages, consisting of a discussion of language that can still be read as a masterpiece in its judicious consideration of linguistic problems.

With the aid of six amanuenses to copy quotations, Johnson read widely in the literature up to his time and gathered the central word-stock of the English language. He included about 43,500 words (a few more than the number in Bailey), but they were much better selected and represented the keen judgment of a man of letters.

Kersey's  
New  
English  
Dictionary

Samuel  
Johnson's  
Plan

First  
purely  
English  
dictionary

He was sympathetic to the desire of that age to "fix" the language, but he realized as he went ahead that "language is the work of man, of a being from whom permanence and stability cannot be derived." At most, he felt that he could curb "the lust for innovation."

The chief glory of Johnson's dictionary was its 118,000 illustrative quotations. No doubt some of these were included for their beauty, but mostly they served as the basis for his sense discriminations. No previous lexicographer had the temerity to divide the verb "take," transitive, into 113 senses and the intransitive into 21 more. The definitions often have a quaint ring to modern readers because the science of the age was either not well developed or was not available to him. But mostly the definitions show a sturdy common sense, except when Johnson used long words sportively. His etymologies reflect the state of philology in his age. Usually they were an improvement on those of his predecessors, because he had as a guide the *Etymologicum Anglicanum* of Francis Junius, as edited by Edward Lye, which became available in 1743 and which provided guidance for the important Germanic element of the language.

Four editions were issued during Dr. Johnson's lifetime, the fourth in 1773 having received much personal care in revision. The *Dictionary* retained its supremacy for many decades and received lavish praise, but some would-be rivals were bitter in criticism. A widely heralded work of the 1780s and 1790s was the projected dictionary of Herbert Croft, in a manuscript of 200 quarto volumes,

By courtesy of the Newberry Library, Chicago

to be called the *Oxford English Dictionary*. Croft was however, unable to get it into print.

The practice of marking word stress was taken over from the spelling books by Bailey in his *Dictionary* of 1727, but a full-fledged pronouncing dictionary was not produced until 1757, by James Buchanan; his was followed by those of William Kenrick (1773), William Perry (1775), Thomas Sheridan (1780), and John Walker (1791), whose decisions were regarded as authoritative, especially in the United States.

The attention to dictionaries was thoroughly established in U.S. schools in the 18th century. Benjamin Franklin, in 1751, in his pamphlet "Idea of the English School," said, "Each boy should have an English dictionary to help him over difficulties." The master of an English grammar school in New York in 1771, Hugh Hughes, announced: "Every one of this Class will have Johnson's Dictionary in Octavo." These were imported from England, because the earliest dictionary printed in the U.S. was in 1788, when Isaiah Thomas of Worcester, Massachusetts, issued an edition of Perry's *Royal Standard English Dictionary*. The first dictionary compiled in America was *A School Dictionary* by Samuel Johnson, Jr. (not a pen name), printed in New Haven, Connecticut, in 1798. Another, by Caleb Alexander, was called *The Columbian Dictionary of the English Language* (1800) and on the title page claimed that "many new words, peculiar to the United States," were inserted. It received abuse from critics who were not yet ready for the inclusion of American words.

In spite of such attitudes, Noah Webster, already well-known for his spelling books and political essays, embarked on a program of compiling three dictionaries of different sizes that included Americanisms. In his announcement on June 4, 1800, he entitled the largest one *A Dictionary of the American Language*. He brought out his small dictionary for schools, the *Compendious*, in 1806 but then engaged in a long course of research into the relation of languages, in order to strengthen his etymologies. At last, in 1828, at the age of 70, he published his master work, in two thick volumes, with the title *An American Dictionary of the English Language*. His change of title reflects his growing conservatism and his recognition of the fundamental unity of the English language. His selection of the word list and his well-phrased definitions made his work superior to previous works, although he did not give illustrative quotations but merely cited the names of authors. The dictionary's worth was recognized, although Webster himself was always at the centre of a whirlpool of controversy.

Since 1828. It was Noah Webster's misfortune to be superseded in his philology in the very decade that his masterpiece came out. He had spent many years in compiling a laborious "Synopsis" of 20 languages, but he lacked an awareness of the systematic relationships in the Indo-European family of languages. Germanic scholars such as Jacob Grimm, Franz Bopp, and Rasmus Rask had developed a rigorous science of "comparative philology," and a new era of dictionary making was called for. Even as early as 1812 Franz Passow had published an essay in which he set forth the canons of a new lexicography, stressing the importance of the use of quotations arranged chronologically in order to exhibit the history of each word. The brothers Jacob and Wilhelm Grimm developed these theories in their preparations for the *Deutsches Wörterbuch* in 1838. The first part of it was printed in 1852, but the end was not reached until more than a century later, in 1960. French scholarship was worthily represented by Maximilien-Paul-Émile Littré, who began working on his *Dictionnaire de la langue française* in 1844, but, with interruptions of the Revolution of 1848 and his philosophical studies, he did not complete it until 1873.

Among scholars in England the historical outlook took an important step forward in 1808 in the work of John Jamieson on the language of Scotland. Because he did not need to consider the "classical purity" of the language, he included quotations of humble origin; in his *Etymological Dictionary of the Scottish Language*, his use of

Pronouncing dictionary

**OA'TMEAL.** *n. f.* [*oat* and *meal*.] Flower made by grinding oats.

*Oatmeal* and butter, outwardly applied, dry the scab on the head. *Arbutnot on Aliment.*

Our neighbours tell me oft, in joking talk,

Of ashes, leather, *oatmeal*, bran, and chalk. *Gay.*

**OA'TMEAL.** *n. f.* An herb. *Ainsworth.*

**OATS.** *n. f.* [*aten*, Saxon.] A grain, which in England is generally given to horses, but in Scotland supports the people.

It is of the grafs leaved tribe; the flowers have no petals, and are disposed in a loose panicle: the grain is eatable. The meal makes tolerable good bread. *Miller.*

The *oats* have eaten the horses. *Shakespeare.*

It is bare mechanifm, no otherwife produced than the turning of a wild *oatbeard*, by the insinuation of the particles of moisture. *Locke.*

For your lean cattle, fodder them with barley ffraw first, and the *oat* Araw laft. *Mortimer's Husbandry.*

His horse's allowance of *oats* and beans, was greater than the journey required. *Swift.*

**OA'TTHISTLE.** *n. f.* [*oat* and *thistle*.] An herb. *Ains.*

The definition of "Oats" (top) by Samuel Johnson in his Dictionary of 1755 exemplifies his prejudice against the Scots and shows his divergence from his source, Nathan Bailey (bottom), who interspersed idiomatic examples throughout his entries (1736).

**OARS,** [*oan*, Sax *aura* *Sa*] a boat for carrying passengers, with two men to row it; also instruments wherewith boats are row'd.

To have an OAR in ebery Man's Boat.

That is, to meddle with every man's concerns.

**OATS** [*of aten* or *etan*, Sax. *to eat*] a grain, food for horses.

To sow one's mind OATS.

That is to play one's youthful pranks.

**OAT** *Thistle*, an herb.

**OA'TEN**, of or pertaining to *oats*

**OATH** [*að*, Sax. *Ēð*, Dan and *Su.* *Ēðt*, *Da.* *Ēþ*, *G.*] a swearing, or confirming a thing by swearing.

**OATH** [in a legal sense] a solemn action, whereby God is called to witness the truth of an affirmation, given before one or more persons impowered to receive the fame.

**OAT-MEAL** [*of aten* and *mealepe*, Sax.] meal or flour made of oats.

New trends in dictionary making

"mean" sources marked a turning point in the history of lexicography. Even as late as 1835 the critic Richard Garnett said that "the only good English dictionary we possess is Dr. Jamieson's Scottish one." Another collector, James Jermy, showed by his publications between 1815 and 1848 that he had the largest body of quotations assembled before that of the *Oxford English Dictionary* (*OED*). Charles Richardson was also an industrious collector, presenting his dictionary, from 1818 on, distributed alphabetically throughout the *Encyclopaedia Metropolitana* (vol. 14 to 25) and then reissued as a separate work in 1835–37. Richardson was a disciple of the benighted John Horne Tooke, whose 18th-century theories long held back the development of philology in England. Richardson excoriated Noah Webster for ignoring "the learned elders of lexicography" such as John Minshew (whose *Guide into the Tongues* appeared in 1617), Gerhard Johannes Vossius (who published his *Etymologicum linguae Latinae* in 1662), and Franciscus Junius (*Etymologicum Anglicanum*, written before 1677). Richardson did collect a rich body of illustrative quotations, sometimes letting them show the meaning without a definition, but his work was largely a monument of misguided industry that met with the neglect it deserved.

Scholars more and more felt the need for a full historical dictionary that would display the English language in accordance with the most rigorous scientific principles of lexicography. The Philological Society, founded in 1842, established an "unregistered words committee," but, upon hearing two papers by Richard Chenevix Trench in 1857—*On Some Deficiencies in Our English Dictionaries*—the society changed its plan to the making of "A New English Dictionary." Forward steps were taken under two editors, Herbert Coleridge and Frederick James Furnivall, until, in 1879, James Augustus Henry Murray, a Scot known for his brilliance in philology, was engaged as editor. A small army of voluntary readers were inspired to contribute quotation slips, which reached the number of 5,000,000 in 1898, and no doubt 1,000,000 were added after that. Only 1,827,306 of them were used in print. The copy started going to the printer in 1882; Part I was finished in 1884. Later, three other editors were added, each editing independently with his own staff—Henry Bradley, from the north of England, in 1888, William Alexander Craigie, another Scot, in 1901, and Charles Talbot Onions, the only "Southerner," in 1914. So painstaking was the work that it was not finished until 1928, in over 15,500 pages with three long columns each. A supplement, presenting new material collected since the work began, was issued in 1933. An extraordinarily high standard was maintained throughout. As the name *New English Dictionary* proved to be inadequate, the work came to be called *The Oxford English Dictionary* (*OED*) after 1895.

In the United States, lexicographical activity has been unceasing since 1828. In the middle years of the 19th century, a "war of the dictionaries" was carried on between the supporters of Noah Webster and those of his rival, Joseph Emerson Worcester. To a large extent, this was a competition between publishers who wished to pre-empt the market in the lower schools, but literary people took sides on the basis of other issues. In particular, the contentious Noah Webster had gained a reputation as a reformer of spelling and a champion of American innovations, while the quiet Worcester followed traditions.

In 1846 Worcester brought out an important new work, *A Universal and Critical Dictionary of the English Language*, which included many neologisms of the time, and in the next year Webster's son-in-law, Chauncey Allen Goodrich, edited an improved *American Dictionary* of the deceased Webster. In this edition the Webster interests were taken over by an aggressive publishing firm, the G. & C. Merriam Co. Their agents were very active in the "war of the dictionaries" and sometimes secured an order, by decree of a state legislature, for their book to be placed in every schoolhouse of the state. Worcester's climactic edition of 1860, *A Dictionary of the English Language*, gave him the edge in the "war," and James

Russell Lowell declared: "From this long conflict Dr. Worcester has unquestionably come off victorious." The Merriams, however, brought out their answer in 1864, popularly called "the unabridged," with etymologies supplied by a famous German scholar, Karl August Friedrich Mahn. Thereafter, the Worcester series received no major re-editing, and its faltering publishers allowed it to pass into history.

One of the best English dictionaries ever compiled was issued in 24 parts from 1889 to 1891 as *The Century Dictionary*, edited by William Dwight Whitney. It contained much encyclopaedic material but bears comparison even with the *OED*. Isaac Kauffman Funk, in 1893, brought out *A Standard Dictionary of the English Language*, its chief innovation being the giving of definitions in the order of their importance, not the historical order. Thus, at the turn of the new century, the U.S. had four reputable dictionaries—Webster's, Worcester's (already becoming moribund), the *Century*, and Funk's *Standard*. England was also well served by many (the original dates given here)—John Ogilvie (1850), P. Austin Nuttall (1855), Robert Gordon Latham (1866, re-editing Todd's Johnson of 1818), Robert Hunter (1879), and Charles Annandale (1882).

#### KINDS OF DICTIONARIES

**General-purpose dictionaries.** Although one may speak of a "general-purpose" dictionary, it must be realized that every dictionary is compiled with a particular set of users in mind. In turn, the public has come to expect certain conventional features (see below *Features and problems*), and a publisher departs from the conventions at his peril. One of the chief demands is that a dictionary should be "authoritative," but the word authoritative is ambiguous. It can refer to the quality of scholarship, the employment of the soundest information available, or it can describe a prescriptive demand for compliance to particular standards. Many people ask for arbitrary decisions in usage choices, but most linguists feel that, when a dictionary goes beyond its function of recording accurate information on the state of the language, it becomes a bad dictionary.

Most people encounter dictionaries in the abridged sizes, commonly called "desk" or "college-size" dictionaries. Such handy abridgments go back to the 18th century; Dr. Johnson issued an octavo size in 1756. Their form had become stultified until, in the 1930s, Edward Lee Thorndike, drawing upon the principles of the psychology of learning, produced a series for schools (*Beginning, Junior, and Senior*). His dictionaries were not "museums" but tools that encouraged schoolchildren to learn about language. He drew upon his word counts and his "semantic counts" to determine inclusions. The new mode was carried on to the college level by Clarence L. Barnhart in *The American College Dictionary* (*ACD*), in 1947, and in the later college-size works that were revised to meet that competition—the Merriam-Webster *Seventh New Collegiate* (1963), the *Standard College Dictionary* (1963), and *Webster's New World Dictionary* (1953, and second edition 1970). An especially valuable addition was *The Random House Dictionary* (1966), edited by Jess Stein in a middle size called "the unabridged" and by Laurence Urdang in a smaller size (1968).

The Merriam-Webster *New International* of 1909 had a serene, uncluttered air that suited a simpler age. The second edition, completely re-edited, appeared in 1934, and it, in turn, was superseded in 1961 by the *Third New International*, edited by Philip Babcock Gove. Because its competitors of similar size have not been kept up to date, it stands alone among American dictionaries in giving a full report on the lexicon of present-day English. Unfortunately, the advance publicity, before publication, emphasized the quotations from ephemeral writers such as Polly Adler, Ethel Merman, and Mickey Spillane and the statement about "ain't" as "used orally in most parts of the U.S. by many cultivated speakers." Such reports aroused a storm of denunciation in newspapers and magazines by writers who, others asserted, revealed a shocking ignorance of the nature of language. The comments

*The  
Century  
Dictionary*

beginnings  
of the  
*OED*

*The Third  
New  
International*

were collected in a "casebook" entitled *Dictionaries and That Dictionary*, edited by James H. Sledd and Wilma R. Ebbitt (1962).

In 1969 came *The American Heritage Dictionary*, edited by William Morris, who was known for his valuable small dictionary *Words* (1947). The *American Heritage* was designed to take advantage of the reaction against the Merriam-Webster *Third*. A "usage panel" of 104 members, chosen mostly from the conservative "literary establishment," provided material for a set of "usage notes." Their pronouncements, found by scholars to be inconsistent, were supposed to provide "the essential dimension of guidance," as the editor put it, "in these permissive times." The etymological material was superior to that in comparable dictionaries.

In England, Henry Cecil Wyld produced his *Universal Dictionary of the English Language* (1932), admirable in every way except for its social class elitism. The smaller sized dictionaries of the Oxford University Press deserve their wide circulation.

Scholarly dictionaries. Beyond the dictionaries intended for practical use are the scholarly dictionaries, with the scientific goal of completeness and rigour in their chosen area. Probably the most scholarly dictionary in the world is the *Thesaurus Linguae Latinae*, being edited in Germany. Its main collections were made from 1883 to 1900, but by 1969 its publication had reached only the letter *O*. A number of countries have "national dictionaries" under way—projects that often take many decades. Two have already been mentioned—the Grimm dictionary for German (a new edition begun in 1965) and the Littré for French (re-edited 1956–58); but, in addition, there are the *Woordenboek der Nederlandsche taal* for Dutch, begun in 1882 and now very close to completion; the *Ordbok ofver svenska språket*, for Swedish, begun in 1882, reaching *S* in 1965; the *Slovar sovremennogo russkogo literaturnogo yazika* ("Dictionary of Modern Literary Russian," begun in 1950); the *Nynorsk ordbok* projected for Norwegian; and *Det Norske litterære ordbok* projected for Danish. Of outstanding scholarship are the *Dictionary of Sanskrit on Historical Principles* being prepared at Pune (Poona), India, and *The Historical Dictionary of the Hebrew Language*, now getting under way in Jerusalem. The most ambitious project of all is located at the Centre National in Nancy, France, directed by Paul Imbs, preparing for a *Trésor de la langue française*. In the decade following 1960, over 250,000,000 word examples were collected, the latest techniques of computerization being used. It remains to be seen how much of this can be printed. A laboratory at Besançon, under the direction of B. Quemada, for contemporary French, has extensive collections.

The *Oxford English Dictionary* remains as the supreme completed achievement in all lexicography. Its size makes its revision impractical and the decision was therefore made for supplementation rather than revision. In 1919 plans were pushed forward for a set of "period dictionaries." After the completion of the *OED* in 1928, the remaining quotations, both used and unused, were divided up for use in each project. The prime mover of this plan, Sir William Craigie, undertook *A Dictionary of the Older Scottish Tongue* himself, covering the period from the 14th to the 17th century in Scottish speech. Enough material was amassed under his direction so that editing could begin in 1925, and before his death in 1957 he arranged that it should be carried on at the University of Edinburgh. By 1971 it had reached the word "natural." The work on the older period spurred the establishment of a project on modern Scots, which got under way in 1925, called *The Scottish National Dictionary*, giving historical quotations after the year 1700. By 1971 the project had passed the word "stane."

For the mainstream of English, a period dictionary for Old English (before 1100) was planned for many decades by a dictionary committee of the Modern Language Association of America (Old English section), but only in the late 1960s did it get under way at the Centre for Medieval Studies at the University of Toronto. Plans are for the dictionary to be based on a combining of compu-

terized concordances of bodies of Old English literature. A *Middle English Dictionary* has fared much better, covering the period 1100 to 1475. Started in 1925, it had reached the middle L's by 1971, with an overwhelming fullness of detail. For the period 1475 to 1700, an *Early Modern English Dictionary* has not fared as well. It got under way in 1928 at the University of Michigan, and over 3,000,000 quotation slips were amassed, but the work could not be continued in the decade of the Great Depression, and only in the middle 1960s was it revived again. The *OED* supplement of 1933 is again being supplemented—this time in three large volumes, the first of which was published in 1972.

Craigie, in 1925, proposed a dictionary of American English. Support was found for the project, and he transferred from Oxford University to the University of Chicago in order to become its editor. The aim of the work, he wrote, was that of "exhibiting clearly those features by which the English of the American colonies and the United States is distinguished from that of England and the rest of the English-speaking world." Thus, not only specific Americanisms were dealt with but words that were important in the natural history and cultural history of the New World. After a 10-year period of collecting, publication began in 1936 under the title *A Dictionary of American English on Historical Principles*, and the 20 parts (four volumes) were completed in 1944. This was followed in 1951 by a work that limited itself to Americanisms only—*A Dictionary of Americanisms*, edited by Mitford M. Mathews.

The English language, as it has spread widely over the world, has come to consist of a group of coordinate branches, each expressing the needs of its speakers in communication; further scholarly dictionaries are needed to record the particular characteristics of each branch. Both Canada and Jamaica were treated in 1967—*A Dictionary of Canadianisms on Historical Principles*, Walter Spencer Avis, editor in chief, and *Dictionary of Jamaican English*, edited by Frederic G. Cassidy and R.B. LePage. A historical dictionary of South African English is under way at Rhodes University, Grahamstown, South Africa, edited by William Branford, and some day full dictionaries must be compiled for Australian English, New Zealand English, and so on. Such dictionaries are valuable in displaying the intimate interrelations of the language to the culture of which it is a part.

Specialized dictionaries. Specialized dictionaries are overwhelming in their variety and their diversity. Each area of lexical study, such as etymology, pronunciation, and usage, can have a dictionary of its own. The earliest important dictionary of etymology for English was Stephen Skinner's *Etymologicon Linguae Anglicanae* of 1671, in Latin, with a strong bias for finding a classical origin for every English word. In the 18th century, a number of dictionaries were published that traced most English words to Celtic sources, because the authors did not realize that the words had been borrowed into Celtic rather than the other way around. With the rise of a soundly based philology by the middle of the 19th century, a scientific etymological dictionary could be compiled, and this was provided in 1879 by Walter William Skeat. It has been kept in print in re-editions ever since but was superseded in 1966 by *The Oxford Dictionary of English Etymology*, by Charles Talbot Onions, who had worked many decades on it until his death. Valuable in its particular restricted area is J.F. Bense's *Dictionary of the Low-Dutch Element in the English Vocabulary* (1926–39).

Two works are especially useful in showing the relation between languages descended from the ancestral Indo-European language—Carl Darling Buck's *Dictionary of Selected Synonyms in the Principal Indo-European Languages* (1949) and Julius Pokorny's *Indogermanisches etymologisches Wörterbuch* (1959). The Indo-European roots are well displayed in the summary by Calvert Watkins, published as an appendix to *The American Heritage Dictionary* mentioned earlier. Interrelations are also dealt with by Eric Partridge in his *Origins* (1958).

the 18th century, is best known in the present day by two examples, one in England and one in America. That of Daniel Jones, *An English Pronouncing Dictionary*, represents what is "most usually heard in everyday speech in the families of Southern English persons whose men-folk have been educated at the great public boarding-schools." Although he called this the Received Pronunciation (RP), he had no intention of imposing it on the English-speaking world. It originally appeared in 1917 and was repeatedly revised during the author's long life. Also strictly descriptive was a similar U.S. work by John S. Kenyon and Thomas A. Knott, *A Pronouncing Dictionary of American English*, published in 1944 and never revised but still valuable for its record of the practices of its time.

The "conceptual dictionary," in which words are arranged in groups by their meaning, had its first important exponent in Bishop John Wilkins, whose *Essay towards a Real Character and a Philosophical Language* was published in 1668. A plan of this sort was carried out by Peter Marc Roget with his *Thesaurus*, published in 1852 and many times reprinted and re-edited. Although philosophically oriented, Roget's work has served the practical purpose of another genre, the dictionary of synonyms.

The dictionaries of usage record information about the choices that a speaker must make among rival forms. In origin, they developed from the lists of errors that were popular in the 18th century. Many of them are still strongly puristic in tendency, supporting the urge for "standardizing" the language. The work with the most loyal following is Henry Watson Fowler's *Dictionary of Modern English Usage* (1926), ably re-edited in 1965 by Sir Ernest Gowers. It represents the good taste of a sensitive, urbane litterateur. It has many devotees in the U.S. and also a number of competitors. Among the latter, the most competently done is *A Dictionary of Contemporary American Usage* (1957), by Bergen Evans and Cornelia Evans. Usually the dictionaries of usage have reflected the idiosyncrasies of the compilers; but, from the 1920s to the 1960s, a body of studies by scholars emphasized an objective survey of what is in actual use, and these were drawn upon by Margaret M. Bryant for her book *Current American Usage* (1962). A small corner of the field of usage is dealt with by Eric Partridge in *A Dictionary of Cliches* (1940).

The regional variation of language has yielded dialect dictionaries in all the major languages of the world. In England, after John Ray's issuance of his first glossary of dialect words in 1674, much collecting was done, especially in the 19th century under the auspices of the English Dialect Society. This collecting culminated in the splendid *English Dialect Dictionary* of Joseph Wright in six volumes (1898–1905). American regional speech was collected from 1774 onward; John Pickering first put a glossary of Americanisms into a separate book in 1816. The American Dialect Society, founded in 1889, made extensive collections, with plans for a dictionary, but this came to fruition only in 1965, when Frederic G. Cassidy embarked on *A Dictionary of American Regional English* (known as *DARE*).

The many "functional varieties" of English also have their dictionaries. Slang and cant in particular have been collected in England since 1565, but the first important work was published in 1785, by Capt. Francis Grose, *A Classical Dictionary of the Vulgar Tongue*, reflecting well the low life of the 18th century. In 1859 John Camden Hotten published the 19th-century material, but a full historical, scholarly survey was presented by John Stephen Farmer and W.E. Henley in their *Slang and Its Analogues*, in seven volumes, 1890–1904, with a revised first volume in 1909 (all reprinted in 1971). For the present century, the dictionaries of Eric Partridge are valuable. Slang in the United States is so rich and varied that collectors have as yet only scratched the surface, but the work by Harold Wentworth and Stuart B. Flexner, *Dictionary of American Slang* (1960), can be consulted. The argot of the underworld has been treated in many studies by David W. Maurer.

Of all specialized dictionaries, the bilingual group are the most serviceable and frequently used. With the rise of the vernacular languages during the Renaissance, translating to and from Latin had great importance. The Welshman in England was provided with a bilingual dictionary as early as 1547, by William Salesbury. Scholars in their analyses of language, as well as practical people for everyday needs, are anxious to have bilingual dictionaries. Even the most exotic and remote languages have been tackled, often by religious missionaries with the motive of translating the Bible. The finding of exact equivalents is more difficult than is commonly realized, because every language slices up the world in its own particular way.

Dictionaries dealing with special areas of vocabulary are so overwhelming in number that they can merely be alluded to here. In English, the earliest was a glossary of law terms published in 1527 by John Rastell. His purpose, he said, was "to expown certeyn obscure & derke termys concernynge the lawes of thys realme." The dictionaries of technical terms in many fields often have the purpose of standardizing the terminology; this normative aim is especially important in newly developing countries where the language has not yet become accommodated to modern technological needs. In some fields, such as philosophy, religion, or linguistics, the terminology is closely tied to a particular school of thought or the individual system of one writer, and, consequently, a lexicographer is obliged to say, "according to Kant," "in the usage of Christian Science," "as used by Bloomfield," and so on.

#### FEATURES AND PROBLEMS

**Establishment of the word list.** The goal of the big dictionaries is to make a complete inventory of a language, recording every word that can be found. The obsolete and archaic words must be included from the earlier stages of the language and even the words attested to only once (nonce words). In a language with a large literature, many "uncollected words" are likely to remain, lurking in out-of-the-way sources. The *OED* caught many personal coinages, but not "head-over-heelishness" (1882), "odditude" (1860), "pigstyosity" (1869), "white-chokerism" (1866), and other graceless jocularities. Also, the so-called latent words are a problem, when a lexicographer knows that a derivative word probably has been used, but he has no evidence for it. The *OED* had three quotations for "kindheartedness" but none for "kindheartedly," which any speaker of English would feel free to use. Some "ghost words" have arisen from the misreading of manuscripts and from misprints, and the lexicographer attempts to cast these out.

Various large blocks of words have a questionable status. Both geographic names and biographical entries are selectively included in some dictionaries but are really encyclopaedic. More than 2,000,000 insects have been identified and named by entomologists, while names of chemical compounds and drugs may be almost as numerous. Trade names and proprietary names may number in the hundreds of thousands. Vogue suffixes like "-ism," "-ology," "-scope," or "-wise" are used by some with the freedom of a grammatical construction. These millions are beyond what any dictionary can be expected to include.

For the smaller-sized dictionaries, the editors attempt to choose the words that are likely to be looked up. They comb the scholarly works carefully and supplement them from files that they may have collected. They may decide to put derivative words at the end of entries as "run-ons" or to have all words strictly as separate alphabetical entries. The size is ultimately decided by the commercial consideration of how much can be put into a work that can be sold for a reasonable price and held readily in the hand. (Bulk also influences the size of the word list for unabridged dictionaries.)

The establishment of a word list involves many difficult technical problems. Linguists tend to use the terms morpheme, free form, bound form, lexeme, and so on, inasmuch as "word" is a popular term not suited to technical

Bilingual  
diction-  
aries

Problems  
in selecting  
a word list

Diction-  
aries of  
usage

use. A safe compromise is to use "lexical unit." This term allows the inclusion of set phrases (established groups) and idioms. Words having different etymological sources must be considered as different words. Thus "calf" in the sense of the young of a bovine animal came from Common Germanic, whereas "calf" for the fleshy back of the lower part of the leg came from Old Norse, perhaps from a Celtic source. A more difficult problem is found when a word entered the language at different points—such as "cookie," from the Dutch *koekje* "little cake," recorded in Scottish in 1701 in the form *cuckie*, then independently taken from the Dutch of the Hudson Valley in the form *cockie* in 1703, and perhaps independently taken into South African English from Afrikaans in the mid-19th century.

**Spelling.** Dictionaries have probably played an important role in establishing the conventions of English spelling. Dr. Johnson has received much credit for this, though he differed very little from his predecessors. He used the spelling "smoak" in the early part of his dictionary, but when he came to the entry itself, he changed it to "smoke," and this has prevailed. Noah Webster introduced some simplifications that have become accepted in American English. American dictionaries usually label the distinctive British spellings, such as "centre" and its class, "honour" and its class, "connexion," "gaol," "kerb," "tyre," "waggon," and a few others.

The desire for uniformity is so great that popular variants are not welcomed; the very common "alright" is not yet approved, nor is the widespread "miniscule" for "minuscule." The *OED* is exceptional in listing the early variant spellings, showing that a common word like "good" has been spelled in 13 different ways, with seven more from Scottish usage. When the spelling reform movement was at its height, from the 1880s to about 1910, the dictionaries included the new forms, but in recent years these have been expunged. The graphic dress of the language is now so sacrosanct that dictionaries are used as authoritarian "style manuals" in matters of spelling, hyphenation, and syllabification.

**Pronunciation.** Dictionaries are more responsive to usage in the matter of pronunciation than they are in spelling. It is claimed that in the 19th century the Merriam-Webster dictionaries foisted a New England pronunciation on the United States, but in recent years many regional variations have been recorded. *Webster's Third New International* (1961) went to surprising lengths in its variants; perhaps its record is in giving 132 different ways of pronouncing "a fortiori."

The former practice of giving pronunciations as if the words were pronounced in isolation in a formal manner represented an artificiality that distorted language in use; recent dictionaries have marked pronunciation as it appears in continuous discourse. Furthermore, there has been a trend toward what has been called "democratization." In the word "government," for instance, it is recognized that many people do not pronounce an *n*, and some people actually say something like "gubb-munt." There is a constant battle between traditional spoken forms and spelling pronunciations.

Since the alphabet is notoriously inadequate for recording the sounds of English, dictionaries are forced to adopt additional symbols. A system of using numerals over vowels was handed down from the 18th century, but that gave way to the diacritic markings of the Merriam-Webster series. The rise of the International Phonetic Alphabet (IPA) has offered another possibility, but the general public as yet finds it abstruse. Even more detailed symbols are needed in linguistic atlases and phonetic research. With considerable courage, Clarence L. Barnhart introduced the symbol schwa (ə) into *The American College Dictionary* (1947) for the neutral mid-central vowel, as at the beginning and end of "America," and the symbol has now become widely accepted. Although some systems are clumsier than others, the key does not matter much if it is applied consistently.

**Etymology.** The supplying of etymologies involves such difficult decisions for a lexicographer as whether words should be carried back into prehistory by means

of reconstructed forms or the degree to which speculation should be permitted. A U.S. Romance scholar, Yakov Malkiel, has presented the notion that words follow "trajectories"—by finding certain points in the history of a word, one can link up the developments in form and meaning. The austere treatment of some words consists in saying "derivation unknown," and yet this sometimes causes interesting possibilities to be ignored.

A fundamental distinction is made in word history between the "native stock" and the "loanwords." There have been so many borrowings into English that the language has been called "hypertrophied." The traditional view is to regard the borrowings as a source of "richness." A historical dictionary does its best to ascertain the date at which a word was adopted from another language, but the word may have to go through a period of probation. Murray, the editor of the *OED*, listed four stages of the word "citizenship": the casual, the alien, the denizen, and the natural. The casuists may not be part of the language, as they appear only in travel writings and accounts of foreign countries, but a lexicographer must collect citations for them in order to record the early history of a word that may later become naturalized. Some words may remain, "denizens" for centuries, Murray pointed out, such as "phenomenon" treated as Greek, "genus" as Latin, and "aide-de-camp" as French. When a word is borrowed, its etymology may be traced through its descent in its original language.

Some early philosophies have assumed that there is a mystic relation between the present use of a word and its origin and that etymology is a search for the "true meaning." The recognition of continuous linguistic change establishes, however, that etymology is no more than early history, sometimes as reconstructed on the basis of relationships and known sound changes. Ingenuity in etymologizing is dangerous, and even plausibility can be misleading, but ascertained fact has overriding importance. It is curious that recent slang is often more uncertain in its origin than words of long history.

**Grammatical information.** Dictionaries are obliged to contain the two basic kinds of words of a language—the "function words" (those that perform the grammatical functions in a language, such as the articles, pronouns, prepositions, and conjunctions) and the "referential words" (those that symbolize entities outside the language system). Each kind must be treated in a suitable way. Dictionaries have been much criticized for not including a sufficiency of grammatical information. It is usual to mark the part of speech, but not the categories of mass noun and count noun. (A mass noun, such as "milk" or "oxygen," cannot ordinarily be used in the plural, while a count noun is any noun that can be pluralized.) Such information is given in some dictionaries designed for teaching, and the technique could well be adopted more generally. The irregular inflections must be given, showing that one says "goose," "geese," but not "moose," "meese." Or in the verbs one says "walk," "walked," but "ride," "rode." It is usual to treat the different parts of speech as separate lexical entries, as in "to walk" and "to take a walk," requiring a parallel list of senses, but Edward Lee Thorndike, in his school dictionaries, experimented with grouping the parts of speech together when they had a similar sense.

The relation of grammar to the vocabulary is the subject of considerable controversy among linguists. If one considers the analysis of language as one unified enterprise, then the grammar is central and the lexical units are inserted at some point in the analysis. Another view is that the division is into coordinate branches, such as phonology, syntax, and lexicon. Certainly lexicographers try to take advantage of all findings made by grammarians.

**Sense division and definition.** A language like English has so many complex developments in the senses—i.e., the particular meanings—of its words that the task of the lexicographer is difficult. It is generally accepted that "meaning" is a suffusing characteristic of all language by definition, and the attempt to slice meaning into "senses" must be done arbitrarily by the person analyzing the lan-

American  
spelling

Systems  
for  
indicating  
sounds

Grammar  
and  
vocabulary

guage. This is where collected contexts form the basis of the lexicographer's judgment. He sorts the quotations into piles on the basis of similarities and differences and he may have to discard "transitional" examples. Figurative developments, such as the "mouth" of a river or the "foot" of a hill, make complications in the relationships.

For the order in which the senses of words are given, the order of historical development has been chiefly used. For an old word like "earth," the information may be insufficient. The editors of the OED had to give up, because, they said, "Men's notions of the shape and position of the earth have so greatly changed since Old Teutonic times"; they were obliged to compromise with a logical order. Sometimes, but not always, a word seems to have a "core," or central, meaning from which other meanings develop. If the historical order is followed, the obsolete and archaic meanings may have to appear first; and, therefore, some popular dictionaries give the most important meaning first and work down to the rare and occasional meanings at the end. The so-called "semantic count," giving senses in order of frequency, has also been used.

There seems to be no one method that is best for defining all words. The lexicographer must use artistry in selecting the ways that will convey a sense accurately and succinctly. He attempts to find what is "criterial" in a particular meaning, but he can also give further detail until he runs into the area of the encyclopaedic.

In logical theory it would be ideal to have a "metalinguage" in which definitions could be stated, but nothing of the sort is available for popular use. A "defining vocabulary" can be established, and in school dictionaries the definitions use simple words. In the last analysis all definitions have to fall back on undefined terms (to be accepted like axioms) that symbolize first-order experience of life. In this connection the logician Willard Quine has argued that lexicography is basically concerned with synonymy.

Usage labels. Part of the information that a dictionary should give concerns the restrictions and constraints on the use of words, commonly called usage labelling. There is great variation in language use in many dimensions—temporal, geographical, and cultural. The people who make a two-part division into "correct" and "incorrect" show that they do not understand how language works. The valuation does not lie in the word itself but in the appropriateness of the context. Therefore, it is preferable to be sparing in the use of labels and to allow the tone to become apparent from the illustrative examples. An important distinction was put forward in 1948 by an American philologist, John S. Kenyon, when he discriminated between "cultural levels," which refer to the degree of education and cultivation of a person, and "functional varieties," which refer to the styles of speech suitable to particular situations. Thus a cultivated person rightly uses informal or colloquial language when at ease with friends.

A lexicographer is faced with the difficult task of selecting a suitable set of labels. In the temporal categories, labels such as obsolete, obsolescent, archaic, and old-fashioned are dangerous, because some speakers have long memories and might use old words very naturally. The national labels are problematical, because words move easily from one branch of the language to another. The word "blizzard," for instance, is no doubt an Americanism in origin, but, since the 1880s, it has been so well-known over the English-speaking world that a national label would be misleading. The label "dialect" or "regional," either for England or America, offers many problems, for alleged "boundaries" are permeable. The label "colloquial" was much misunderstood, and now "informal" is often used in its place. There may be a "poetic vocabulary" that needs labelling, and few people will agree on any definition of "slang."

It is revealing that in the Merriam-Webster *Third New International* under the word "cock-eyed," marked "slang," one of the quotations is by a careful stylist named Jacques Barzun; in order to use effective English, as he does, this cultivated writer is willing to draw upon

slang. Some would argue that in marking the use as "slang," the Merriam-Webster staff was not sufficiently "permissive."

Some dictionaries wisely include special paragraphs on the constraints of usage, sometimes as a "synonymy" and sometimes as a "usage note."

Illustrative quotations. Dictionaries of the past have copied shamelessly from one to another, but the collecting of a file of illustrative quotations makes possible a fresh, original treatment. Scholarly works like the OED and its supplementations follow the canon of always using the earliest quotation and the latest for an obsolete word; in between, the quotations are selected for revealing facets of usage or for "forcing" a meaning. The criterion of use by only the best writers does not hold for a truly historical dictionary, because a "low" source may be especially revealing. The giving of exact source citations is not a matter of pedantry but establishes the scientific basis by which others can check the evidence. A different set of quotations, accurately attested, might have led to a different treatment. Thus the phrase "illustrative quotation" is something of a misnomer, for the quotations are more than "illustrative"; they form the basic evidence from which conclusions are drawn. It is the work of the editor to decide when the collections are sufficient—"ripe," as it were—to move from the collecting stage to the editing stage.

A small-sized dictionary may advantageously use made-up sentences, because an aptly framed "forcing" context can tell more than a definition. In fact, the habitual collocations of a word (the surrounding words with which it usually appears) may be revealing of the nature of a word. "Dictionaries of collocations" may be a step forward in future lexicography.

Technological aids. The development of machine aids, such as the computer, has been heralded by some as ushering in a new era in lexicography. Although the computer can do well in many tasks of great drudgery—mechanical excerpting of texts, alphabetizing, and classifying by designated descriptors—it is limited to what a human being tells it to do. It is difficult for a computer to sort out homographs—separate words that are spelled alike; and, at the editing stage, the delicate decisions must be humanly made.

The computer can be used to good advantage in the compilation of concordances of individual authors or of limited texts, and then one type of dictionary could be made by a summation of concordances. Such a procedure, with a large body of literature like that of the Renaissance, would overwhelm an editor. More feasible, perhaps, is the establishment of a computerized archive that would never be published, but would serve as a storehouse from which, by advanced retrieval methods, the desired information could be called forth at will. The *Trésor de la langue française* of Nancy, already mentioned, is a step in this direction.

Attitudes of society. Without a doubt, dictionaries have been a conservative force for many hundreds of years, not only in countries that have had an official academy that has the national language as part of its province but also in the English-speaking countries, in which academies have been spurned. Well-entrenched popular attitudes account for this. A Neoplatonic outlook assumes that there exists an ideal form of language from which faltering human beings have departed and that dictionaries might bring people closer to the perfect language. Also, there is a widespread "yearning for certainty," a seeking for guidance amid the wilderness of possible forms. Thus, people welcome self-proclaimed "supreme authorities."

Americans have had additional reasons for their homage to the dictionary. In colonial times Americans felt themselves to be far from the centre of civilization and were willing to accept a book standard in order to learn what they thought prevailed in England. This linguistic colonialism lasted a long time and set the pattern of accepting the dictionary as a "lawgiver." In 1869, a cultural leader declared: "Upon the proper spelling, pronunciation, etymology, and definition of words, a dictionary

Citation of sources

Uses for computers

Variations  
in  
language  
use

might be made to which high and almost absolute authority might justly be awarded." In this vein teachers have taken pains to inculcate "the dictionary habit" in their pupils. Rather than observe the language around them, as Englishmen commonly do, Americans give up their autonomy and fly to a dictionary to settle questions on language. This call for dogmatic prescription has been a source of uneasiness to lexicographers, most of whom now argue that all they can do legitimately is to describe how the language has been used.

Social attitudes have affected the dictionaries also in the enforcement of certain taboos. Certain words commonly called obscene have been omitted, and, thus, irrational taboos have been strengthened. If the sex words were given in their alphabetical place, with suitable labels, the false attitudes in society would more readily be cleansed. A perennial problem in lexicography is the treatment of the terms of ethnic insult, such as "dago," "kike," and "wop." There is constant social pressure for leaving them cut, and some dictionaries have succumbed to it, but it may be that an enlightened attitude shows that the open discussion of prejudices is the best way of getting rid of them.

The greatest value of a dictionary is in giving access to the full resources of a language and as a source of information that will enhance free enjoyment of the mother tongue.

#### MAJOR DICTIONARIES

For the English language the important dictionaries have already been cited in the appropriate sections; but the supreme achievement represented by the *OED* should be emphasized again. The major dictionaries in some other languages may be mentioned here.

For the French language, the Académie's dictionary is now in its eighth edition (1931–35) and manifests conservative views about the vocabulary, but three other works are actually more serviceable—the *Petit Larousse: dictionnaire encyclopédique pour tous* (1959); a new edition of the famous Littré, *Dictionnaire de la langue française* (1956–58), seven volumes; and a splendid new work, Paul Robert, *Dictionnaire alphabétique et analogique de la langue française* (1960–64), six volumes. For French etymology alone, the standard work is Walther von Wartburg, *Französisches etymologisches Wörterbuch*, nearing completion in 1970 in volume 18, with a few gaps to be filled.

Among other Romance tongues, Italian has had many dictionaries. The Accademia della Crusca of Florence furnished its *Vocabolario* in a first edition in 1612, but the edition begun in 1863 bogged down at the letter *O* in 1923, and a successor work, begun in 1941, has not gone far. There is also the dictionary by G. Devoto and G.C. Oli, *Dizionario della lingua Italiana* (1971). Following the model of the *OED* is the still uncompleted *Grande dizionario della lingua italiana* (1961), edited by Salvatore Battaglia. Very serviceable to English speakers is the *Italian Dictionary* of Alfred Hoare (1915; second edition, 1925) and that of Barbara Reynolds, begun in 1962, and still under way. For Spanish, the Real Academia Española in Madrid has done well since its first edition in 1726–39. At present the 18th edition, from 1956, is available. Contributions from New World Spanish need further scholarly treatment.

For the German language, the great dictionary begun by the brothers Grimm, completed in 1960, is to be re-edited in a project that will take many years; but, meanwhile, a standard work is that of Hermann Paul, *Deutsches Wörterbuch*, which first appeared in 1897 but is now available in a sixth edition (1968). The national dictionaries in the Scandinavian countries were mentioned above, but a work done with special scholarly skill is noteworthy: Einar Haugen, editor in chief, *Norwegian English Dictionary* (Madison, Wisconsin [Oslo printed], 1965), dealing with the two official languages of Norway, Bokmål and Nynorsk. Another form of a Germanic language, Afrikaans, which developed from the Dutch transplanted to South Africa in the 17th century, has a big dictionary under way, *Woordeboek van die Afrikaan-*

*se taal*, begun at Pretoria in 1950 as a collaboration of the best scholars in South Africa. A full dictionary of Yiddish requires profound scholarship, and this was provided by Uriel Weinreich in *Modern English-Yiddish, Yiddish-English Dictionary* (1968).

Greek lexicography offers special difficulties because of the long range of illustrious literature that must be covered and the split in recent centuries between Katharevusa, the literary language, and Demotic, the language of everyday life. For the English-speaking world, the standard work for Ancient Greek is by Henry George Liddell and Robert Scott, *A Greek-English Lexicon*, published in a first edition in 1843, but now available in a ninth edition, 1925–40. A full dictionary of Demotic, edited by Demetrius Georgacas at the University of North Dakota, is still in the project stage. For Russian the Soviet Academy of Arts has produced a useful work in four volumes (1957–61), but a more detailed one has been in progress since 1950, reaching *F* in 1964. The Royal Irish Academy is at work on a definitive dictionary of Irish, but only "contributions" and certain parts are so far available. Many linguists have attempted to cover Arabic; probably the most useful work is that of Hans Wehr, as translated and edited by J. Milton Cowan, *A Dictionary of Modern Written Arabic* (1961). For Japanese, the standard source is the *Dai-jiten* ("Great Dictionary"), issued at Tokyo in 26 volumes (1934–36). The best known Chinese dictionary, *Tz'u hai*, was revised in 1969 and published in Taipei, Taiwan.

Titles of other works are to be found in the bibliographies listed below, especially in Constance Winchell's *Guide*.

**BIBLIOGRAPHY.** For the best list of dictionaries, see CONSTANCE M. WINCHELL, *Guide to Reference Books*, 8th ed., pp. 91–132 (1967; 1st suppl., 1965–1966, 1968; and 2nd suppl., 1967–1968, 1970). See also ROBERT L. COLLISON, *Dictionaries of Foreign Languages* (1957); A.J. WALFORD (ed.), *A Guide to Foreign Language Grammars and Dictionaries*, 2nd ed. (1967); WOLFRAM ZAUNMULLER, *Bibliographisches Handbuch der Sprachwörterbücher* (1958); GERT A. ZISCHKA, *Index Lexicorum* (1959); and *Foreign Language-English Dictionaries*, 2 vol. (Library of Congress, Reference Department, 1955). For dictionaries published in Communist countries, see DANUTA RYMŚA-ZALEWSKA (ed.), *Bibliography of Dictionaries* (1965). Dictionaries of Americanisms and of slang are well covered by W.J. BURKE, *The Literature of Slang*, pp. 2–11 (1939).

**History.** For the history of classical dictionaries, see JOHN EDWIN SANDYS, *A History of Classical Scholarship*, 3rd ed., vol. 1, pp. 295–407 (1921). An old standard survey is JAMES A.H. MURRAY, *The Evolution of English Lexicography* (1900). See also MITFORD M. MATHEWS, *A Survey of English Dictionaries* (1933, reprinted 1966); and JAMES ROOT HULBERT, *Dictionaries: British and American*, rev. ed. (1968). For excellent scholarly details in their areas, see DEWITT T. STARNES, *Renaissance Dictionaries: English-Latin and Latin-English* (1954); DEWITT T. STARNES and GERTRUDE E. NOYES, *The English Dictionary from Cawdrey to Johnson, 1604–1755* (1946); and JAMES H. SLEDD and GWYN J. KOLB, *Dr. Johnson's Dictionary: Essays in the Biography of a Book* (1955). For the history of the *Oxford English Dictionary*, see WILLIAM A. CRAIGIE, "Historical Introduction," in the *Supplement* (1933), transferred to vol. 1 in the re-issue of 1933; HANS AARSLEFF, "The Early History of the *Oxford English Dictionary*," *Bulletin of the New York Public Library*, 66:417–439 (1962), and *The Study of Language in England, 1780–1860* (1967), especially ch. 6. For American dictionaries, see JOSEPH HAROLD FRIEND, *The Development of American Lexicography, 1798–1864* (1967). The documents on the controversy over the Merriam-Webster *Third New International Dictionary* are collected by JAMES H. SLEDD and WILMAR E. EBBITT in *Dictionaries and That Dictionary* (1962). For discussions of the technical problems arising in lexicography, see FRED W. HOUSEHOLDER and SOL SAPORTA (eds.), *Problems in Lexicography*, 2nd ed. (1967), papers of a conference held in 1960—especially practical is the paper by CLARENCE L. BARNHART, "Problems in Editing Commercial Monolingual Dictionaries," pp. 161–181; LADISLAV ZGUSTA, *Manual of Lexicography* (1971); and ALLEN WALKER READ, "Approaches to Lexicography and Semantics," in THOMAS A. SEBEOK (ed.), *Current Trends in Linguistics*, vol. 10, pp. 145–205 (1972). An "International Conference on Lexicography in English" was held in New York City, June 5–7, 1972; its proceedings are published in the *Ann. N.Y. Acad. Sci.* (1973).

## Diderot, Denis

Man of letters and philosopher, Denis Diderot straddled the 18th century as the chief editor of the French *Encyclopédie*, the testament of the Age of the Enlightenment, and by virtue of the originality of his contributions in the fields of philosophy and ethics, dramatic and aesthetic theory, literary criticism, fiction, scientific speculation, and politics.

Diderot, oil painting by Louis-Michel van Loo, 1767. In the Louvre, Paris.

**Youth and marriage.** He was born at Langres on October 5, 1713, the son of a widely respected master cutler, whose worth he recognized in later life. He was tonsured in 1726, though he did not in fact enter the church, and was first educated by the Jesuits at Langres. From 1729 to 1732 he studied in Paris at the Collège d'Harcourt or at the Lycée Louis-le-Grand or possibly at both these institutions, and he was awarded the degree of master of arts in the University of Paris on September 2, 1732. He then studied law as an articled clerk in the office of Clément de Ris but was more interested in languages, literature, philosophy, and higher mathematics. Of the period 1734 to 1744 comparatively little is known. He dropped an early ambition to enter the theatre and, instead, taught for a living, led a penurious existence as a publisher's hack, and wrote sermons for missionaries at 50 *écus* each. At one time he seems to have entertained the idea of taking up an ecclesiastical career, but it is most unlikely that he entered a seminary. Yet his work testifies to his having gone through a religious crisis, and he progressed relatively slowly from faith to deism and to atheism. That he led a disordered existence is made clear in his posthumously published novel, *Le Neveu de Rameau* ("Rameau's Nephew"). He frequented the coffeehouses, particularly the *Régence* and the *Procope*, where he met the philosopher Jean-Jacques Rousseau in 1741 and established a friendship with him that was to last for 15 years, until it was broken by a quarrel.

In 1741 he also met Antoinette Champion, daughter of alinedraper, and on November 6, 1743, married her—secretly, because of his father's disapproval. The relationship, as surviving letters show, was based on romantic love, but the marriage was not a happy one owing to incompatible interests. The bond held, however, partly through a common affection for their daughter, Angélique, sole survivor of three children, who was born in 1753 and whom Diderot eventually married to Albert de Vandeul, a man of some standing at Langres. Diderot lavished care over her education, and she eventually wrote a short account of his life and classified his manuscripts. There is a bourgeois solidity about the pattern of his family life—he always kept himself informed of events at Langres, and he remained deeply attached to his sister Denise—which is in marked contrast with that of the aristocratic Voltaire and the plebeian Rousseau.

**Mature career.** In order to earn a living, he undertook translation work and in 1745 published a free translation of the *Inquiry concerning Virtue* by the 3rd Earl of Shaftesbury, whose fame and influence he spread in France. His *Pensées philosophiques* (1746; *Philosophic Thoughts*, 1916), an original work with new and explosive anti-Christian ideas couched in a vivid prose, contains many passages directly translated from or inspired by Shaftesbury. The proceeds of this publication, as of his allegedly indecent novel *Les Bijoux indiscrets*, were used to meet the demands of his mistress, Madeleine de Puisieux, with whom he broke a few years later during his detention at Vincennes. In 1755 he met "Sophie" Volland, with whom he formed an attachment that was to last over 20 years. The liaison was founded on common interests, natural sympathy, and a deepening friendship. His correspondence with Sophie, together with his other letters, forms one of the most fascinating documents on Diderot's personality, enthusiasms and ideas and on the intellectual society of Louise d'Épinay, F.M. Grimm, the Baron d'Holbach, Ferdinando Galiani, and other deistic writers and thinkers (Philosophes) with whom he felt most at home. Through Rousseau, Diderot met Condillac, the philosopher, and for a time the three friends dined together at the Panier Fleuri. Diderot set great store, in his personal life, by friendship as a basis for the establishment of moral values. This was brought out in his short story "Les Deux Amis de Bourbonne" ("The Two Friends of Bourbonne"), in which the Germans Goethe and Schiller were to become interested, and in the conclusion of "Ceci n'est pas un conte" ("This Is No Yarn").

**The Encyclopédie.** In 1745 the publisher André Le Breton approached Diderot with a view to bringing out a French translation of Ephraim Chambers' *Cyclopaedia*, after two other translators had withdrawn from the project. Diderot undertook the task with the distinguished mathematician Jean Le Rond d'Alembert as co-editor and profoundly changed the nature of the publication, broadening its scope and turning it into an important organ of radical and revolutionary opinion. He gathered around him a team of dedicated litterateurs, scientists, and even priests, many of whom, as yet unknown, were to make their mark in later life. All were fired with a common purpose: to further knowledge and, by so doing, strike a resounding blow against reactionary forces in church and state. As a *dictionnaire raisonné* ("rational dictionary"), the *Encyclopédie* was to bring out the essential principles and applications of every art and science. The underlying philosophy was rationalism and a qualified faith in the progress of the human mind. In 1749 he published the *Lettre sur les aveugles* (trans. c. 1750, *An Essay on Blindness*), remarkable for its proposal to teach the blind to read through the sense of touch, along lines that Louis Braille was to follow in the following century, and for the presentation of the first step in his evolutionary theory of survival by superior adaptation. This daring exposition of the doctrine of materialist atheism with its stress on human dependence on sense impression led to Diderot's arrest and incarceration in the prison of Vincennes for three months. His work on the *Encyclopédie*, however, was not interrupted for long, and in 1750 he published his *Prospectus*, which d'Alembert expanded into the momentous *Discours préliminaire* (1751). The history of the *Encyclopédie*, from the publication of the first volume in 1751 to the distribution of the final volumes of plates in 1772, was checkered, but ultimate success was never in doubt. A critical moment occurred in 1758 on the publication of the seventh volume when d'Alembert resigned on receiving warning of trouble and after reading Rousseau's attack on his article "Genève." Another serious blow came when the philosopher Helvétius' book *De l'esprit* ("On the Mind"), said to be a summary of the *Encyclopédie*, was condemned to be burned by the Parlement of Paris; the work itself was suppressed. Untempted by Voltaire's offer to have the publication continued outside France, Diderot held on in Paris with great tenacity. His heart was nearly broken, however, by the discovery in 1764 that Le Breton

Correspondence with "Sophie" Volland

Meeting with Rousseau

Arrest and incarceration in Vincennes

had secretly removed compromising material from the corrected proof sheets of about ten folio volumes. The censored passages, though of considerable interest, would not have made an appreciable difference on the impact of the work. To the 17 volumes of text and 11 volumes of plates (1751–72), Diderot contributed innumerable articles partly original, partly derived from varied sources, especially on the history of philosophy ("Eclectisme" ["Eclecticism"]), aesthetics ("Beau" ["The Beautiful"]), and the mechanical arts. He was an energetic general director and supervised the illustrations for 3,000 to 4,000 plates of exceptional quality, which are still prized by historians today. The completion of the *Encyclopédie* left Diderot without a source of income. To relieve him of financial worry, Catherine the Great of Russia first bought his library through an agent in Paris, requesting him to retain the books until she required them, and then appointed him librarian on an annual salary for the duration of his life. Diderot went to St. Petersburg in 1773 to thank her and was received with great honour and warmth. He wrote for her the *Plan d'une université pour le gouvernement de Russie* ("Plan of a University for the Government of Russia"). He stayed five months, long enough to become disillusioned with enlightened despotism as a solution to social ills and for his political ideas to harden, as evidenced in *Observations sur les instructions de Sa Majesté Impériale aux députés* ("Observations on Her Imperial Majesty's Instructions to Her Deputies"). It is now known that some of the most revolutionary passages in the writer and propagandist Guillaume Raynal's *Histoire des deux Indes* ("History of the Indies") actually came from Diderot's pen, as did arguments to legitimize revolution.

**Philosophical and scientific works.** In 1751 Diderot published *Lettre sur les sourds et muets* ("Letter on the Deaf and Dumb"), which studies the function of language and deals with points of aesthetics, and in 1754 he published the *Pensées sur l'interprétation de la nature* ("Thoughts on the Interpretation of Nature"), acclaimed as the method of philosophical inquiry of the 18th century; however, he published few other works in his lifetime. His writings, in manuscript form, were known only to his friends and the privileged correspondents of the *Correspondance littéraire*, a sort of private newspaper edited by Baron Grimm (1759–81) that was circulated in manuscript form. Among his philosophical works, special mention may be made of *L'Entretien entre d'Alembert et Diderot* ("Conversation Between d'Alembert and Diderot"), *Le Rêve de d'Alembert* ("D'Alembert's Dream"), and the *Eléments de physiologie*. In all these works, he developed his materialist philosophy, foreshadowing the evolutionary doctrine of Charles Darwin and evolving the first modern theory of the cellular structure of matter. Though his speculations in the field of science are of great interest, it is the dialectical brilliance of their presentation that is exceptional. His ideas, often propounded in the form of paradox, and invariably in dialogue, stem from a sense of reality and a profound understanding of the complexities and contradictions inherent in human nature. He developed a theory of dreams that was later to impress Freud.

**Essays, novels, and plays.** His essays, among them "Regrets sur ma vieille robe de chambre" ("Regrets over My Old Bathrobe") and "Entretien d'un père avec ses enfants" ("Conversation of a Father with His Children"), based on personal experience, have the qualities of form and style of his short stories and his novels: *La Religieuse* ("The Nun"), *Jacques le fataliste*, and *Le Neveu de Rameau*. *Jacques le fataliste* is in the tradition of the picaresque novel and of the "philosophical tale." In spite of his scientific determinism, Diderot's philosophical standpoint is ambivalent, as is his ethical standpoint in *Le Neveu de Rameau*, which contains a satire of contemporary society by offering a vigorous dramatic sketch of a parasite and an eccentric amoralist. In the *Supplément au voyage de Bougainville* ("Supplement to Bougainville's Voyage"), Diderot presented his idea of a free society based on tolerance and sexual liberty.

His major plays, *Le Fils naturel* (trans. 1767, Dorval;

or, *The Test of Virtue*) and *Le Phre de famille* ("The Father of the Family"), make tedious reading today. His theories on drama, expounded in *Entretiens sur le fils naturel* ("Discussion on the Natural Son") and *Discours sur la poésie dramatique* ("Discourse on Dramatic Poetry"), were to exercise a determining influence on the German dramatist Gotthold Lessing, whose famous *Hamburgische Dramaturgie* ("Dramatic Notes from Hamburg") appeared in 1767–69. Diderot sought greater realism on the stage through the presentation of a serious bourgeois drama and a greater moral and social impact on the spectator by showing characters in their professions and milieu. He urged modifications in stagecraft and décor and hoped to move audiences through *tableaux vivants*. In his *Paradoxe sur le comédien*, Diderot argued that great actors, like great poets, are insensitive and must remain fabulous puppets. Although he wrote literary criticism, it is as the first great art critic, covering the salons, or annual art exhibitions, for the *Correspondance littéraire*, that he is best remembered. His analysis of art, artists, and the technique of painting, together with the excellence of his taste and his style, have won him posthumous fame; his *Essai sur la peinture* ("Essay on Painting"), especially, was admired by Goethe and later by the 19th-century poet and critic Charles Baudelaire.

**Late life and works.** In 1774 Diderot, now old and ill, worked on a refutation of Helvétius' work *De l'homme* (1772; "On Man"), which was an amplification of the destroyed *De l'esprit*. He wrote *Entretien d'un philosophe avec la Maréchale* ("Conversation with the Maréchale") and published in 1778 *Essai sur les règnes de Claude et de Néron* ("Essay on the Reigns of Claudius and Nero"). Usually known as *Essai sur la vie de Sénèque* ("Essay on the Life of Seneca"), the work may be regarded as an apologia of the Roman satirist and philosopher. Diderot's intimate circle was dwindling. Mme d'Épinay and d'Alembert died before him; only Grimm and Baron d'Holbach remained. Slowly Diderot retired into the shell of his own personal and family life. The death of Sophie Volland in February 1784 was a great grief to him; he survived her by a few months, dying of coronary thrombosis on July 30, 1784, in the house in the rue de Richelieu that Catherine the Great had put at his disposal. Apocryphally, his last words were: "Le premier pas vers la philosophie, c'est l'incrédulité" ("The first step toward philosophy is incredulity"). Through the intervention of his son-in-law, he was buried in consecrated ground at Saint-Roch.

#### MAJOR WORKS

PHILOSOPHY AND SCHOLARSHIP: *Pensées philosophiques* (1746); *Lettre sur les aveugles* (1749); *Prospectus* (1750), to the *Encyclopédie*; *Lettre sur les sourds et muets* (1751); *Encyclopédie*, 17 vol. of text and 11 vol. of plates (1751–72), edited by Diderot and Jean d'Alembert and containing many articles by Diderot; *Pensées sur l'interprétation de la nature* (1754); *Le Rêve de d'Alembert* (written 1769, published 1830); *L'Entretien entre d'Alembert et Diderot* (written 1769, published 1830); *Eléments de physiologie* (1774–80).

LITERARY WORKS: (NOVELS): *Les Bijoux indiscrets* (1748); *La Religieuse* (written 1760, published 1796); *Jacques le fataliste* (written 1773, published 1796); *Le Neveu de Rameau* (written between 1761 and 1774, translated into German by Goethe 1805, French edition 1821, authentic text 1891); *Supplément au voyage de Bougainville* (written 1772, published 1796). (SHORT STORIES): "Les Deux Amis de Bourbonne" (1773); "Ceci n'est pas un conte" (written 1772, published 1798). (PLAYS): *Le Fils naturel* (published 1757; performed 1771); *Le Père de famille* (1758; performed 1761); *Est-il bon? Est-il méchant?* (performed 1781, published 1834).

(ESSAYS AND TREATISES): *L'Histoire et le secret de la peinture en cire* (1755); *Entretiens sur le fils naturel* (1757); *Discours sur la poésie dramatique* (1758); *Éloge de Richardson* (1761); *Essai sur la peinture* (written 1765, published 1796); *Réflexions sur Terence* (1762); "Regrets sur ma vieille robe de chambre" (1772); *Entretien d'un père avec ses enfants* (1773); *Paradoxe sur le comédien* (written 1773–78, published 1830); *Plan d'une université pour le gouvernement de Russie* (published 1813–14), written for Catherine the Great; *Observations sur les instructions de Sa Majesté Impériale aux députés* (1774); *Réfutation de l'ouvrage d'Helvétius intitulé l'homme* (published 1875); *Essai sur les règnes de Claude et de Néron* (1778), usually called the *Essai sur la vie de Sénèque*.

TRANSLATIONS: Translations into English of a number of Diderot's individual works have been published but most of them so long ago as to be difficult to obtain. More recent translations include the following: *Denis Diderot: Selections*, ed. with introduction by E. Herriot (1953); *The Paradox of Acting*, trans. by W.H. Pollock (1957); *Diderot, Interpreter of Nature: Selected Writings*, trans. by Jean Stewart and Jonathan Kemp, and ed. with introduction by Jonathan Kemp, 2nd ed. (1963); *The Wigmaker's Art in the 18th Century: A Translation of the Section on Wigmaking in the 3rd Edition (1776) of the Encyclopédie . . .*, ed. by J. Stevens Cox (1965); *Diderot's Selected Writings*, trans. by Derek Coltman, and ed. with introduction and notes by Lester G. Crocker (1966); *The Nun*, trans. by Marianne Sinclair, with introduction and afterword by Richard Griffiths (1966); *The Encyclopédie of Diderot and d'Alembert: Selected Articles*, ed. by J. Lough (1969).

**BIBLIOGRAPHY.** A.M. WILSON, *Diderot: The Testing Years, 1713-1759* (1957), is the standard and most scholarly biography for the years covered. LESTER G. CROCKER, *Diderot, the Embattled Philosopher*, rev. ed. (1966), provides both a biographical and critical general study. JOHN (LORD) MORLEY, *Diderot and the Encyclopaedists*, 2 vol. (1878, reprinted 1923), is still of value. In the absence of a new critical edition (in preparation), the *Oeuvres complètes de Denis Diderot*, ed. by J. ASSEZAT and M. TOMEUX, 20 vol. (1875-77); and the selected *Oeuvres* in five volumes in the "Classiques Garnier" are the best available.

(Ro.N.)

## Diesel, Rudolf

Though best known for his invention of the pressure-ignited heat engine that bears his name, Rudolf Diesel was also an eminent thermal engineer, a connoisseur of the arts, a linguist, and a social theorist. As a one-man creative community, Diesel epitomized the confluence of the fine arts, the sciences, both "pure" and "social," and the creative pragmatics of mechanical engineering and invention. He described his artistic self as *ein Glückspilz* ("a lucky mushroom"); his career as an inventor as "enslavement to despair and ecstasy"; his crusade for peace and labour reform as "stubborn proselytizing by a chronic victim of petty and prejudiced nationalisms." During the last two decades of his life his informed admirers and critics alike came to regard his many-sided creative skills and his no less amazing ambivalences as stage props for one of the most memorable mechanical inventions of the 19th century.

BY courtesy of the Deutsches Museum, Munich

Diesel. 1883.

**Inventions** Diesel's inventions, which ranged from the fantasy of a "universal sun motor" to the refinement of ice ready-frozen in restaurant table bottles, have three points in common: they relate to heat transference by natural physical processes or laws; they involve markedly creative mechanical design; and they were initially motivated

by the inventor's concept of sociological needs. Diesel originally conceived the diesel engine as a facility, readily adaptable in size and costs and utilizing locally available fuels, to enable independent craftsmen and artisans better to endure the powered competition of large industries that then virtually monopolized the predominant power source—the oversized, expensive, fuel-wasting steam engine. He envisaged making his rational heat engine, to adapt his own words, as big as a hut or as small as a hat, suitable for fuels from shale oils to coal or palm oils to surplus butter. He projected the engine principle as a solvency saver for all such small but useful producers as watchmakers, jewelers, dentists and dental technicians, cobblers, toy-makers, etc. His broader goal was socio-economic justice and balance, to save the engine user from being made its "tending wage slave."

**Childhood and education.** Diesel was born in Paris on March 18, 1858, the only son of Theodor, a Bavarian immigrant leather craftsman, and Elise Strobel Diesel, a German-born governess and language tutor. During his Paris childhood, despite his sensitivity and his being teased as a "pretty little German pig" by chauvinistic schoolmates, Rudolf won grammar school honours and, at 12, admission to the *École Primaire Supérieure*, then the most highly esteemed secondary school in Paris.

This triumph was negated by the outbreak of the Franco-Prussian War. By the French War Ministry's decree of August 28, 1870, the Diesels, as "undesirable aliens," were rounded up by police and shipped to neutral asylum in London. Rudolf was rescued from the ensuing upset and impoverishment by a teacher-cousin in Augsburg, his father's home town. The cousin, Christoph Barnickel, wrote to invite Rudolf to enter the Royal County Trade School, where Barnickel taught, as a "deserving refugee pupil and ward."

During the ensuing three years, Rudolf again suffered derision, this time as a "pretty French pig." Nevertheless, he led his class, set an all-time high scholastic record, and, despite being a "nonnational," won a scholarship to the Technische Hochschule of Munich. In his four years there he repeated his attainment of unprecedentedly high grades. With his own earnings as an undergraduate tutor and by making and selling second-degree geometrical surfaces (ellipsoids, hyperboloids, etc.), he managed to rent himself a piano, took piano and voice lessons, attended operas, concerts, art exhibitions, and lectures in Munich. He left the Hochschule as a special protégé of Carl von Linde, its most renowned professor and pioneer in mechanical refrigeration.

**Life in Paris.** After two years as a mechanic and parts designer at the Sulzer Machine Works of Winterthur, Switzerland, by then self-labelled as the steam engine capital of the world, Diesel returned to Paris as a thermal engineer, installer, and salesman for the Linde Refrigeration Enterprises, then operating in five countries. On the Left, or south, Bank he found friends among international artist groups and, in more sumptuous neighbourhoods, among more affluent professional men. With his exceptional personal charms, not to mention his talents as a drawing-room artiste, he became established both as a devotee of fine arts and an internationalist.

When his father, who had earlier abandoned his leather craft to open shop as a *Heilmagnetiseur*, or "Magnetic Health Builder," exhorted his son to act more like a real German, Rudolf replied that the Diesel forebears had never been real Germans. Rather, they were all Saale Valley Slavs, or Thuringians, a gentle, poetic clan who had adopted the name Diesel from earlier Slav names, including *Dossel* and *Tüssel*, on being converted as Lutherans. Since his 13th birthday, Rudolf had been a rather devout Lutheran and believed the denomination to be symbolic of international religious liberation.

At the age of 25, Diesel married Martha Flasche, a German-raised governess he had met in the home of Ernest Brandes, an international merchant friend. The following year (1884) Martha bore a son, Rudolf, who grew up to be an abstract artist and mystic; two years later a daughter, Hedy; and in 1889 a second son, Eugen, who became a writer on, and professor of, philosophy.

During 1885 the seeker of a "power provider for global justice" set up his first shop-laboratory in Paris and began his 13-year ordeal of creating his distinctive engine. A dedicated pacifist, Diesel also envisaged what he privately termed his "Black Mistress" as an implement for sustaining peace. In 1888, his second year of intensive work on the engine, the inventor barely escaped alive when ammonia gas, being tested as a fuel, exploded. Almost instantly he set out to exploit the near catastrophe as a war squelcher. He proposed to fill small, readily breakable glass vials with contact-explosive gas and supply the chemical fireworks to war ministries for use in lieu of lethal bombs and bullets. Thus, all battles could be made shams, entertaining at least to the "militant imbeciles who revel in competitive uproars." When the French Patent Office turned it down, Diesel offered his proposal to Count Georg Mdñster, then the imperial German consul general to Paris. The rarely smiling Count is said to have laughed aloud. By that time, however, Diesel's 30th year, his stature as a thermal engineer, inventor, and internationalist was above being the subject of derision. One cause was his extraordinary scholastic brilliance. After three gruelling and impoverishing years of preliminaries in Paris, however, Diesel was obliged to take temporary employment with the Linde Enterprises, this time in Berlin. From there, late in 1892, he gained a German development patent. On the strength of this and about a dozen trunkfuls of immaculate drawings and tabulations and on promise of eventual manufacturing rights, three sponsors, the Maschinenfabrik firm at Augsburg and the firms of Sulzer and Krupp, came to the inventor's support.

**Invention of the Diesel engine.** At Augsburg, on August 10, 1893, Diesel's prime model, a single ten-foot iron cylinder with a flywheel at its base, ran on its own power for the first time. The pressure needle promptly shot to 80 atmospheres, at the time the highest mechanically created pressure ever recorded. But at that point the indicator plate exploded. Again the smock-clad inventor dodged barely in time to save his head. Next, a carefully revised model ran on its own power for one minute on February 17, 1894. Expert onlookers termed that an epochal minute, a proof of momentous potentials of a still imperfect engine.

Diesel spent two more years at improvements and on the last day of 1896 demonstrated another model with the spectacular if theoretical mechanical efficiency of 75.6 percent, in contrast to the then prevailing efficiency of the steam engine — 10 percent or less. Although commercial manufacture was delayed another year and even then begun at snail's pace, by 1898 Diesel was a millionaire from franchise fees, in great part international.

By 1904, when Diesel first toured the United States as an elite lecturer, his appallingly bad financial management was returning him to respectable poverty. Publication of his two-volume work on social philosophy, *Solidarismus*, did not relieve his financial difficulties; it sold fewer than 200 copies. Diesel, however, was internationally recognized as the pre-eminent pioneer of the power age and a champion of the fine arts. His engines were powering pipelines, electric and water plants, automobiles and trucks, and marine craft and soon thereafter were used in mines, oil fields, factories, transoceanic shipping, and elsewhere. But by 1912, when he toured the United States, his health was worsening; he had contracted gout and was emotionally disturbed by the overtures of World War I. Even so, the oncoming year promised to be his best.

He returned to Munich to be greeted by his three grandchildren, a welcome deluge of new engine adaptations, a reopening of the Munich Opera, and a salon art exhibition that his wife had arranged in his honour. On September 27, 1913, he set out on a brief journey to London, where he would again be honoured by an engineers' convention. Two evenings later he boarded a ferry to England in company with a longtime engineer friend, with whom he dined jovially. Later that night, his stateroom and luggage still intact, Diesel disappeared at sea and presumably drowned in the English Channel.

**BIBLIOGRAPHY.** EUGEN DIESEL, *Diesel: Der Mensch, Das Werk, Das Schicksal* (1937), is a sensitive and revealing profile of the inventor-philosopher as recounted by his son. RUDOLF DIESEL, *Solidarismus*, 2 vol. (1903), is the inventor's own attempt to appraise his abstruse social and economic philosophy against a background of what he recognized as a paradoxical industrial society. W.R. NITSKE and C.M. WILSON, *Rudolf Diesel: Pioneer of the Age of Power* (1965), is a detailed, authoritative biography.

(C.M.W.)

## Diesel Engine

The diesel engine is an internal-combustion engine that differs from the older gasoline engine principally in that it relies on heat generated by compressing air in the cylinder to ignite the fuel, rather than on an electric spark. To generate the required heat the diesel must produce higher compression than the gasoline engine, making it bulkier, heavier, and more expensive; it also operates at slower speeds. But it can operate on cheaper, less highly refined fuel, which gives it an advantage in many transportation and construction-equipment applications: locomotives, trucks, tractors, buses, bulldozers, graders and other heavy-duty machines, and in marine propulsion.

### HISTORY

Though two English engineers had patented engines that did not depend on spark ignition, Rudolf Diesel of Germany conceived his invention as an improvement on the gasoline engine that fellow-German Nikolaus Otto had developed in 1876. Seeking to increase the efficiency of the Otto engine, it occurred to Diesel that he could do away with electrical ignition if he could compress air to so small a volume that the temperature would be above the ignition point of an appropriate fuel. The cycle of operations he conceived was set forth in his patents of 1892 and 1893 (see illustration): (1) air is drawn into the

The diesel cycle

Four-cycle diesel engine showing the sequence of cycle events.

cylinder as the piston moves away from the cylinder head (intake); (2) the air in the cylinder is compressed by the piston as it moves upward, toward the cylinder head (compression); (3) when the piston reaches the top of its stroke, the fuel charge is injected into the cylinder, where it is ignited by the high temperature of the compressed air. The fuel is injected at such a rate that the maximum cylinder pressure never exceeds the pressure attained by the compression of the air; after completion of the fuel injection, the piston continues to move away from the cylinder head in its downward or expansion stroke (power); (4) the burned fuel is forced from the cylinder by upward motion of the piston (exhaust). This is called four-cycle operation as four separate piston strokes are required; two up and two down.

In 1892–93 Diesel took out patents on an engine to operate on the cycle just described. Either powdered coal or liquid petroleum would be used as fuel. Powdered coal was included because of its ready availability as a waste material of the Saar coal mines. Diesel planned to use compressed air to introduce the coal dust into the engine cylinder but found it difficult to control the rate of injection so that the maximum pressure in the cylinder after ignition would not exceed a safe limit. After the

experimental engine was wrecked by an explosion in the cylinder, Diesel gave up the idea of using coal dust and devoted his efforts to the use of liquid petroleum. He continued, however, to use compressed air to introduce the liquid petroleum into the cylinder.

The first commercial engine built on Diesel's patents was installed in St. Louis, Missouri, by a brewer, **Adolphus Busch**, who had seen one on display at an exposition in Munich and had purchased a license from Diesel for the manufacture and sale of the engine in the U.S. and Canada. The engine operated successfully for many years and was the forerunner of the **Busch-Sulzer** engine that powered many submarines of the U.S. Navy in World War I. Another Diesel engine used for the same purpose was the **Nelsec**, built by the New London Ship and Engine Company in **Groton**, Connecticut.

The diesel engine became the major power plant for submarines during World War I. It was not only economical in the use of fuel but it proved itself reliable under wartime conditions. Diesel fuel, less volatile than gasoline, was more easily stored and handled.

At the end of the war many men who had operated diesels were looking for peacetime jobs. Manufacturers began to adapt diesels for the peacetime economy. One modification was the development of the so-called **semi-diesel** that operated on a two-stroke cycle at a lower compression pressure and made use of a hot bulb or tube to ignite the fuel charge. These changes resulted in an engine less expensive to build and maintain.

**Fuel injection developments.** One objectionable feature of the full diesel was the necessity of a high-pressure, injection air compressor. Not only did it require energy to drive it but the sudden expansion of the air compressed to 1,000 pounds per square inch when it entered the cylinder in which the pressure was only 500–600 pounds per square inch resulted in a refrigerating effect that delayed ignition. Diesel had needed high-pressure air in order to introduce powdered coal into the cylinder; when liquid petroleum replaced the powdered coal as fuel, a pump could be made to take the place of the high-pressure air compressor.

Common  
rail method

There were a number of ways in which a pump could be used. In England, the Vickers Company used what was called the common rail method in which a battery of pumps maintained the fuel under pressure in a pipe running the length of the engine with leads to each cylinder. From this rail (or pipe) fuel supply line, a series of injection valves admitted the fuel charge to each cylinder at the right point in its cycle. Another method employed cam-operated jerk, or plunger-type pumps, to deliver fuel under momentarily high pressure to the injection valve of each cylinder at the right time.

The elimination of the injection air compressor was a step in the right direction, but there was yet another problem to be solved: the engine exhaust contained an excessive amount of smoke, even at outputs well within the horsepower rating of the engine, and even though there was enough air in the cylinder to burn the fuel charge without leaving a discoloured exhaust that normally indicated overload. Engineers finally realized that the problem was that the momentarily high-pressure injection air exploding into the engine cylinder had diffused the fuel charge more efficiently than the substitute mechanical fuel nozzles were able to do, with the result that without the air compressor, the fuel had to search out the oxygen atoms to complete the combustion process, and since oxygen makes up only 20 percent of the air, each atom of fuel had only one chance in five of encountering an atom of oxygen. The result was improper burning of the fuel.

The usual design of a fuel injection nozzle introduced the fuel into the cylinder in the form of a cone spray, with the vapour radiating from the nozzle, rather than in a stream or jet. Very little could be done to diffuse the fuel more thoroughly. Improved mixing had to be accomplished by imparting additional motion to the air, most commonly by induction-produced air swirls or a radial movement of the air, called squish, or both, from

the outer edge of the piston toward the centre. Various methods have been employed to create this swirl and squish. Best results are apparently obtained when the air swirl bears a definite relation to the fuel injection rate. Efficient utilization of the air within the cylinder demands a rotational velocity that causes the entrapped air to move continuously from one spray to the next during the injection period, without extreme subsidence between cycles.

Swirl or  
squish

**Price's engine.** In 1914 a young engineer, William T. Price, began to experiment with an engine that would operate with a lower compression ratio than that of the diesel and at the same time would not require either hot bulbs or tubes. As soon as his experiments began to show promise, he applied for patents.

In Price's engine the selected compression pressure of 200 pounds per square inch did not provide a high enough temperature to ignite the fuel charge when starting. Ignition was accomplished by a fine wire coil in the combustion chamber. Nichrome wire was used for this because it could easily be heated to incandescence when an electric current was passed through it. The experimental engine had a single horizontal cylinder with a bore (cylinder diameter) of 17 inches and a stroke (maximum piston movement) of 19 inches and operated at 257 revolutions per minute. Because the nichrome wire required frequent replacement, the compression pressure was raised to 350 pounds per square inch, which did provide a temperature high enough for ignition when starting. Some of the fuel charge was injected before the end of the compression stroke in an effort to increase the cycle timing and to keep the nichrome wire glowing hot.

#### OPERATION

**Cycle efficiency.** The thermal efficiency of any engine cycle may be expressed by the following simple equation:

$$\text{Thermal Efficiency} = \frac{E_1 - E_2}{E_1}$$

in which  $E_1$  represents the heat energy released from the fuel during combustion and  $E_2$  represents the heat energy rejected during the cycle. This equation states that the thermal efficiency of an engine cycle is equal to the difference between the heat supplied by the fuel and the heat rejected during the cycle divided by the heat supplied.

In the meantime many engines of the two-stroke cycle, semidiesel type were being installed. Some were used to produce electricity for small municipalities. Some were installed in water pumping plants. Many provided power for tugs, fishing boats, trawlers, and workboats.

**Diesel-electric combinations.** In the early 1920s the General Electric Company suggested to the **Ingersoll-Rand Company**, for whom Price was working, that they cooperate in the building of a diesel-electric locomotive. At that time there were many gasoline engine driven locomotives in service. A diesel-electric locomotive with Price's engine was completed in 1924 and placed in service for switching purposes in New York City.

The success of this locomotive resulted in orders from railroads, factories, and open-pit mines. The engine used in most of these installations was a 6 cylinder, 10-inch bore, 12-inch stroke, rated 300 brake horsepower at 600 revolutions, and weighing 15,000 pounds.

**Marine applications.** Many diesel engines were purchased for marine propulsion. The diesels, however, normally rotated faster than was desirable for large ships' propellers because the high speeds of the huge propellers tended to create hollowed-out areas within the water around the propeller (cavitation), with resultant loss of thrust. The problem did not exist, however, with smaller propellers, and diesel engines proved especially suitable for yachts, in which speed is desired. The problem was solved by utilizing a diesel-electric installation in which the engines were connected to direct-current generators that furnished the electricity to drive an electric motor connected to the ship's propeller.

There were also many installations in which the diesel

was connected either directly or through gears, to the propeller. An unusual installation was a diesel-driven ferry that plied on the Hudson River between the towns of Hudson and Athens. In this installation the engine crankshaft was extended at both ends and coupled to shafting that carried a propeller at both ends of the ferry boat.

Emergency  
power

When diesel engines of larger horsepower and slower rotation speeds became available, they were installed in cargo and passenger carrying ships. Diesel engines were also installed in hospitals, telephone exchanges, airports, and other places to provide emergency power if regular electrical power was interrupted.

Dual fuel engines. The dual fuel engine is an internal combustion engine that can be operated as an oil diesel entirely on liquid petroleum or, without any mechanical alterations, can produce its horsepower rating on a combination of liquid fuel and natural, or artificially produced, gas. Liquid fuel is needed to perform the basic function of igniting the gas.

The gas diesel operates on gas as the primary fuel that is ignited by the introduction of a small pilot charge of liquid fuel into the cylinder shortly before the piston reaches top dead centre on its compression stroke. The amount of liquid fuel used in the gas diesel is never more than is needed for the ignition of the gas.

On April 30, 1901, the U.S. Patent Office issued to Rudolf Diesel patents that covered all the essential features of the dual fuel and gas diesel engines. In 1932 patents were issued to Victor Heidelberg that covered the advantages of the higher fuel economy made possible by the higher compression ratios that could be used.

Both patents lay unused until 1940, when the rising price of liquid fuel created a demand for natural gas that could be purchased at a very low rate on the basis of an interruptible contract. With such a contract the engine owner could switch from gas to oil and back again on short notice.

Diesel engine starting. A diesel engine is started by driving it from some external power source until conditions have been established under which the engine can run by its own power. The most positive starting method is by admitting air at 250 to 350 pounds per square inch to each of the cylinders in turn on their normal firing stroke. The compressed air becomes heated sufficiently to ignite the fuel. Other starting methods involve auxiliary equipment and include admitting blasts of compressed air to an air-activated motor geared to rotate the large engine's flywheel; supplying electric current to an electric starting motor, similarly geared to the engine flywheel; or by means of a small gasoline engine geared to the engine flywheel. The selection of the most suitable starting method depends upon the physical size of the engine to be started, the nature of the connected load, and whether or not the load can be disconnected during starting.

Fuel for diesels. Petroleum products normally used as fuel for diesel engines are distillates composed of heavy hydrocarbons, with at least 12 to 16 carbon atoms per molecule. These heavier distillates are taken from crude oil after the more volatile portions used in gasoline are removed. The boiling points of these heavier distillates range from 350° to 650° F. Thus, their evaporation temperature is much higher than that of gasoline that has fewer carbon atoms per molecule. Specifications for diesel fuels published in 1970 listed three grades: the first was a volatile distillate recommended for high-speed engines with frequent and wide variations in load and speed; the second, a distillate for high-speed engines in services with high loads and uniform speeds; and the third, a fuel for low- and medium-speed engines in services with sustained loads.

Water and  
sediment

Water and sediment in fuels can be harmful to engine operation; clean fuel is essential to efficient injection systems. Fuels with a high carbon residue can be handled best by engines of low-speed rotation. The same applies to those with high ash and sulfur content. The cetane number, which defines the ignition quality of a fuel, is

ascertained by adjusting a mixture of cetane and *alpha*-methyl-naphthalene until it has the same ignition quality as the fuel being tested. The percentage of cetane in this mixture is then the cetane number of the fuel under test. For the first two grades of diesel fuel described above, the minimum cetane number is 40; for the third grade, the minimum is 30, representing 30 percent cetane in the fuel.

Supercharging. The horsepower output of a diesel engine can be increased by compressing the air charge prior to its admission to the cylinder, thus increasing the weight of air available for combustion. This supercharging can be used either to increase horsepower output at sea level or to recover horsepower lost at higher altitudes due to thinner air. Supercharging can be accomplished in a number of ways: (1) by an engine-driven blower, (2) by an exhaust gas-driven compressor, or (3) by a tuned manifold that produces a phenomenon known as ramming.

In ramming, the cylinders of a multiple-pipe system are selectively connected to two or more exhaust pipes in such a way (tuned manifold) that no cylinder will be exhausted into the pipe at the same instant that another is being cleared of exhaust gases by forced fresh air. The advantage of such a precision grouping is the retention and utilization of the kinetic energy remaining within these exhaust gases and at a high level, for use as power generation when channelled to the turbine. Excessive back pressure is also prevented against the cylinder being scavenged.

#### THE DIESEL ENGINE TODAY

Since its success in World War II, in which it was the most prevalent power plant for armed forces equipment on the ground and at sea, the diesel engine became the conventional power source for most railroad locomotives, most heavy construction machinery, most high-powered farm tractors, and a large proportion of trucks and buses. Its weight makes it unsuitable for aircraft use, and it has had only limited (but growing) application in passenger automobiles. In general, it finds applications wherever its greater weight and cost and less smooth-running operation are offset by its lower cost of operation. An especially noteworthy application is in marine propulsion. While passenger-carrying vessels favour turbines that provide more speed and less vibration, cargo vessels, especially the largest sizes, profit from low-cost diesel power. Of 371 ships built in two recent years for the merchant fleet of the U.S.S.R., for example, 7 were propelled by steam turbines, 1 by a gas turbine, and 363 by diesel plants.

## Dietary Laws and Food Customs

Like all other biologically and physically necessary things and acts, food and eating are always surrounded by social regulations that prescribe what may or may not be

ingested under particular social conditions. These prescriptions and proscriptions are sometimes religious; often they are secular; frequently, they are both. This article surveys the variety of laws and customs pertaining to food materials and the art of eating in human societies from earliest times to the present. It will be seen that behaviour in respect to food—whether religious, secular, or both—is institutionalized behaviour and is not separate or apart from organizations of social relations.

By an institution is meant here a stable grouping of persons whose activities are designed to meet specific challenges or problems, whose behaviour is governed by implicit or explicit rules and expectations of each other and who regularly use special paraphernalia and symbols in these activities. Social institutions are the frames within which man spends every living moment. This survey explores the institutional contexts in which dietary laws and food customs are cast in different societies; the attempt will also be made to show that customs surrounding food are among the principal means by which human groups maintain their distinctiveness and help provide their members with a sense of identity.

Other points of view about food customs cover a wide range. What may be labelled an ecological approach suggests that food taboos among a group's members prevent over-utilization of particular foods to maintain a stable equilibrium in the habitat. Recently, investigators of such customs have been exploring the hypothesis that they provide an adaptive distribution of protein and other nutrients so that these may be evenly distributed in a group over a long period instead of being consumed at one time of the year. The ecological approach also suggests that many food taboos are directed against women to maintain a low population level; this seems to be an adaptive necessity in groups at the lowest technological levels, in which there is a precarious balance between population and available resources.

There are also psychological approaches to food customs. Psychoanalytic writers speculate that food symbolizes sexuality or identity because it is the first mode of contact between an infant and its mother. This point of view is most clearly exemplified in ideas that attitudes toward food, established early in life, tend to shape attitudes toward money and other forms of wealth and retentiveness or generosity. According to Claude Lévi-Strauss, a French anthropologist, the categories represented in food taboos enable people to order their perceptions of the world in accordance with the principle of polarities that govern the structure of the mind. Thus, they aid in maintaining such dichotomies as those between nature and culture or between man and animal.

#### NATURE AND SIGNIFICANCE IN WORLD CULTURES

There are no universal food customs or dietary laws. Nor are food customs and dietary laws confined to either preliterate ("primitive") or advanced cultures; such regulations are found at all stages of development. Nevertheless, different types of regulations in respect to food are characteristic of groups at different levels of cultural or socio-technological development.

Each society has attached symbolic value to different foods. These symbolizations define what may or may not be eaten and what is desirable to eat at different times and in different places. In most cases, such cultural values bear little relationship to nutritive factors. As a result, they often seem difficult to explain. Moreover, dietary customs and laws are resistant to rational argument and change. For example, experts from health and nutritional agencies find it difficult to persuade mothers to give cow's milk to children in societies in which it is looked upon as undesirable. Such customs and laws also prevent people from adopting alternative foods during periods of shortage. During and after World War II, some Indians refused to eat Western wheat and rioted and died rather than accept it.

**Food as a material expression of social relationships.** Cutting across dietary laws and customs is the more general association of food and drink with those social interactions that are considered important by the group. In

many societies the phrase "We eat together" is used by a man to describe his friendly relationship with another from a distant village, suggesting that even though they are not neighbours or kinsmen they trust one another and refrain from practicing sorcery against each other. Among the Nyakyusa of Tanzania, "for conversation to flow merrily and discussion to be profound, there must be . . . 'the wherewithal for good fellowship,' that is, food and drink—and very great stress is laid on sharing these." In Old Testament times, almost every pact, or covenant, was sealed with a common meal; eating together made the parties as though members of the same family or clan. Conversely, refusal to eat with someone was a mark of anger and a symbol of ruptured fellowship. Eating salt with one's companions meant that one was bound to them in loyalty; references to this are found in the New Testament.

Such sentiments, however, are not confined to tribal or ancient cultures. In Israeli kibbutzim (communal settlements), the communal dining room is a keystone institution, and commensality is one of the hallmarks of kibbutz life. The decline of communal eating and the increasing frequency of refrigerators, cooking paraphernalia, and private dining in kibbutz homes is regarded by some observers as a sign of the imminent demise of kibbutzim. In many U.S. communes there is a single facility for cooking and dining. Dinners must be taken communally; private dining is taken as a signal that one is ready to leave the group.

The provision of food and drink, if not actual feasting, is characteristic of rites of passage—i.e., rites marking events such as birth, initiation ceremonies, marriage, and death—in almost all traditional cultures and in some modern nontraditional groups as well. The reason for this is that these events are regarded as being of importance not only to the individual and his family but also to the group as a whole because each event bears in one way or other on the group's continuity.

Furthermore, food and drink are almost universally associated with hospitality. In most cultures, there are explicit or implicit rules that food or drink be offered to guests, and there are usually standards prescribing which foods and drinks are appropriate. Reciprocally, these sets of rules also assert that guests are obligated to accept proffered food and drink and that failure to do so is insulting. In many societies, there are prescribed ritual exchanges of food when friends meet. Food is thus one of the most widespread material expressions of social relationships in human society.

**Regulations about the quantity of food and drink consumed.** It is extraordinarily rare for cultures to condone gluttony, the conventional exaggerations of the eating behaviour of the ancient Roman elite notwithstanding. Most people cannot afford to be gluttons. There are more examples of the other extreme, asceticism, though these too are infrequent.

A clear-cut example of gastronomic asceticism is provided by Indians of the U.S. Northeast, such as the Micmac, Montagnais, and Ojibwa. It was an ideal among them to eat sparingly. Preparation for this attitude began in early childhood with short fasts of a day or two, culminating in the puberty fast; the latter lasted about ten days, during which time the child was isolated in a tiny wigwam without food or water. The puberty fast also had important religious significance. During the fast, the child had to supplicate the deities for a vision (easily induced under such conditions), which came in the form of a supernatural figure, usually in animal shape; this was to become his guardian spirit.

Rules pertaining to drink are even more varied. Tribal groups throughout the world (except in Oceania and most of North America) knew alcohol; in each case, this led to the adoption of rules concerning its use.

Although a high intake of alcohol always has physiological effects, people's comportment is determined more by what their society tells them is the way to behave when consuming alcohol than by its toxic effects. In many societies, drinking is an established part of the total round of social activities. Robert McC. Netting, a U.S. anthro-

The common meal

Alcoholic beverages

Theoretical approaches to food customs

pologist, observed that the Kofyar of northern Nigeria "make, drink, talk, and think about beer." All social relations among them are accompanied by its consumption, and fines are levied in beer payments. Ostracism takes the form of exclusion from beer drinking; they "certainly believe that man's way to god is with beer in hand." Their beer, however, is weak in alcoholic content and is quite nutritious, and they rarely consume European beer and never distilled liquor. Among Central and South American peasants, men are allowed or required to drink themselves into a state of stupefaction during religious celebrations (fiestas); though this drinking is frequent and heavy, it does not appear to result in addiction. Representative of the other extreme are the Hopi and other Indian tribes of the U.S. Southwest who have banned all alcoholic beverages (and almost all narcotics), asserting that these substances threaten their way of life.

Most cultures, however, prescribe moderation in drinking. In ancient Mesopotamia, beer played an important role in temple services and in the economy; but the code of Hammurabi—the monument of law named after the king of Babylon—strictly regulated tavern keepers and servants (these places were supposed to be avoided by the social elite). Similar patterns obtained in ancient Egypt. The ancient Greeks sought to attribute their intellectual and material culture to the introduction of vine and olive growing. The use of wine was quite general in biblical times; it belonged to the list of indispensable provisions listed in the Old Testament in the Book of Judges (chapter 13) and the First Book of Samuel (chapters 16 and 25). Wine was no less important in New Testament times; in Revelation to John (chapter 6) it is said that only wine and oil are to be protected from the apocalyptic famine. Wine is also frequently used in biblical imagery. In both Testaments, however, wine is both praised and condemned.

**Use of food in religion.** The most widespread symbolic use of food is in connection with religious behaviour. In fact, eating and drinking are minimal elements in most religious behaviour and experience, whether in eating, sacrifice, or communion. According to many anthropologists, there are essentially two reasons for this. First, religion is one of the systems of thought and action by which the members of a group express their cohesiveness and identity. Implicitly or explicitly, the members of every cultural group assert that its unity and distinctiveness derive from the deity or deities associated with it. Religion is a tie that binds. But no symbolic activity in human society stands alone and without material representation. Like all other symbolizations of institutional relationships, those of religion must also have substantial form. Food and drink—and their ingestion—are among the most important substances of religion.

The second reason, closely related to the foregoing, is that one element of dogma in every religion is the definition of polluting, or supernaturally dangerous, objects or personal states. Just as there is no objective or scientific connection between the nutritive qualities of different foods and the symbolic values attached to them, there is no objective relationship between an object or a personal state and its definition as polluting. Cultures vary in the objects and states that are defined as defiling, such as saliva, sneezing, menstruation, killing an enemy in warfare, a corpse, parturition, but cutting across these is the belief held in every religion that there are foods and drinks that are polluting or defiling.

As Mary Douglas, a British anthropologist, has suggested in *Purity and Danger*, her analysis of the religiously sanctioned food taboos in Leviticus (chapter 11) and Deuteronomy (chapter 14), concepts of pollution and defilement are among the means used by preliterate or tribal societies to maintain their separateness, boundedness, and exclusivity; thus, these concepts and rules contribute strongly to the sense of identity—the social badges—that people derive from participation in the institutions of their firmly bounded or encapsulated groups. More concretely, when a person proclaims his affiliation with and allegiance to a particular group that he regards as his self-contained universe and beyond whose margins he

sees danger, threat, and alienation, he simultaneously invokes—explicitly or implicitly—the many badges of his social identity; these include the totem (*i.e.*, the emblem of a family or clan) that he may not eat, the foods that are regarded as defiling, the drinks that he must avoid, the sacred meals in which he participates, and the other rituals associated with his exclusive group. He thereby asserts his separateness from people in all other groups—usually referred to in pejorative terms—and his identification with the members of his own group. Food customs are not always formalized, however; they are sometimes cast in terms of preference. Americans, for example, unless they are members of ethnic or religious groups that have their own dietary laws, often shun the "exotic" foods of alien cultures; but these avoidances are not phrased in religious or other institutional terms.

#### LAWS AND CUSTOMS AT DIFFERENT STAGES OF SOCIAL DEVELOPMENT

Although there are dietary laws and customs in all societies, groups differ in this regard in two important ways: in the range or extent of foods that are defined as polluting or tabooed and in conceptualizations of the consequences resulting from violations of these laws and customs. In comparing societies, however, it must be remembered that the range of variability among them is so great that it would be necessary to list hundreds of societies and their customs to get a complete and detailed picture of their food customs and laws. For purposes of both economy and conceptual coherence it is necessary to group societies into levels, or stages, of social and technological development and to compare these; in this approach, individual societies are regarded as special or particular exemplary cases of the general class of the level of development in which the groups are found or classed.

**Hunter-gatherers.** The earliest cultural level that anthropologists know about is generally referred to as hunting-gathering. Hunter-gatherers are always nomadic, and they live in a variety of environments. Some, as in sub-Saharan Africa and India, are beneficent environments; others, such as those of the Arctic or North American deserts, are harsh and dangerous. Encampments of hunter-gatherers are usually small (generally fewer than 60 persons) and are constantly splitting up and recombining. An important rule among almost all hunter-gatherers is that every person physically present in a camp is automatically entitled to an equal share of meat brought into the group whether or not he has participated in the hunt; this rule does not usually extend to vegetables or fruits and nuts.

It may be thought that hunter-gatherers who live in habitats of scarcity and in which hunting is dangerous would try to make maximum use of all potentially available food; they are, however, also characterized by customs and beliefs that proscribe certain foods or at least limit their consumption. Many Alaskan Eskimo groups, for instance, make a sharp distinction between land and sea products; the Eskimo believe that products of the two spheres should be kept separate, maintaining that land and sea animals are repulsive to each other and should not be brought together. Thus, for example, before hunting caribou (a spring activity), a man must clean his body of all the seal grease that has accumulated during the winter; similarly, before whaling in April, the individual's body must be washed to get rid of the scent of caribou. Weapons used for hunting caribou should not be used at sea; implements used at sea, however, may be used to hunt caribou. If these rules are violated, the hunter or whaler will be unsuccessful in his food quest; the consequences of this, of course, can be dire.

In addition, the Eskimo observe food taboos in connection with critical periods of the individual's life and development. Among the most outstanding of these are the food taboos that a woman is subject to for four or five days after giving birth. She may not eat raw meat or blood and is restricted to those foods that are believed to have beneficial effects on the child. For example, it is felt that she should eat ducks' wings to make her child a good runner or paddler. Because the Eskimo are often beset by

groups

food shortages, they sometimes have to eat forbidden foods. In such cases, there are several things that a person can do to neutralize the taboo. He first rubs the forbidden food over his body and then hangs the meat outside and allows it to drain. Another act that is regarded as particularly efficacious is to stuff a mitten into the collar of his parka with the hand side facing outward; it is believed that the harmful effects of the taboo food go into the mitten and travel away from him.

There are, of course, other food avoidances observed by the Eskimo, but these examples will suffice to illustrate the basic principles of dietary customs and laws among hunter-gatherers. First, the taboos are always thought to have magical consequences for the individual; observing them will assure health and strength, violating them will result in illness and weakness for the person or, in the case of a parturient mother, for her child. Second, food taboos are generally associated with critical periods during the life cycle, as in pregnancy, menses, illness, or dangerous hunts. Third—and this is true of almost all societies, not only those of hunter-gatherers—in every group's system of thought there are categories or types of foods that are regarded as dangerous, defiling, or undesirable. At first glance, these rules and customs seem arbitrary and capricious, but evidence is accumulating that there are rational elements in them. Although it would be difficult in the present stage of knowledge to apply this principle to every dietary taboo or custom in every society, it seems that prohibitions are placed on those foods that are the most difficult and dangerous to procure. Sometimes, however, these foods are also highly prized.

Corporate kin groups. With the development of corporate kin groups in social history, largely (but not exclusively) as an accompaniment of horticultural cultivation, a significant change occurred in the role of food in institutional life. Underlying the development of corporate kin groups was the development of the notion of exclusive rights to territory claimed by a group of kinsmen. This exclusive territoriality was probably designed, in large measure, to protect investments of time and effort in particular plots. The solidarity and sense of kin-group exclusiveness implicit in a corporate kin group grew out of kin-group ownership of the land and the individual's reliance on interhousehold cooperation in his productive activities. Such groups quickly evolve insignia, rules, and symbols that represent their ideals of exclusivity and inalienability of social relations; food plays an important role in this. Hence, taboos are thought to have consequences for the group as a whole rather than for the individual.

Another significant accompaniment of the development of corporate kin groups is the elaboration of initiatory rites, which mark an individual's transition from childhood to full membership in his community or kin group; they confer citizenship in the fullest sense of the term. Such events are celebrated by feasts, reciprocal exchanges of food, and food taboos, in addition to the ceremonial rituals themselves. Preparations for these feasts sometimes occupy the group for several months, especially when it is necessary to acquire from relatives and friends the animals that will be slaughtered and eaten, because it is rare for one family, or even one village, to own enough animals for a proper feast. They lay the groundwork for one of the basic rules of the group into which the individual is being initiated, namely, that the distribution of food and interhousehold cooperation in its acquisition is one of the most significant ways in which he and the members of the group are knit together.

Feasting is also an integral element of religious assemblages and ritual in these societies, as are offerings to deities, whether spirits or ancestors. Because one of the main purposes of religious activity is to symbolize the solidarity of the group, food is used as a material representation of this cohesiveness. Additionally, it is believed in almost all tribal societies, whether or not they are characterized by corporate groupings, that all plant and animal foodstuffs are made available to man through the beneficence of the gods. Man's relationship with the

deities in tribal societies is always, in part, an economic one involving the deities' provision of food. A gift from the gods must be balanced by a reciprocal gift to them from their adherents. In prayer, men thank their deities for these gifts; in sacrifice and offerings, they offer gifts to their deities.

Chiefdoms. The next major social and political developments in human history are the appearance of institutions in which political and economic power is exercised by a single person (or group) over many communities. Often referred to as chiefdoms by anthropologists, this development signalled a process evident today throughout the world, namely, the steady growth of centralized power and authority at the expense of local and autonomous groupings.

Political authority in chiefdoms is inseparable from economic power, including the right by rulers to exact tribute and taxation. One of the principal economic activities of the heads of chiefdoms is to stimulate the production of economic surpluses, which they then redistribute among their subjects on different types of occasions, as during feasts in the celebration of religious ceremonies, rites of passage of members of chiefly families, and periods of famine. The accumulation of these surpluses requires conservation policies. Because techniques of food preservation were poorly developed in preliterate chiefdoms, the heads of chiefdoms often adopted the policy of placing taboos—often phrased in religious terms—on different crops or resource areas, forbidding their consumption until the prohibitions were lifted. These taboos, however, were not exclusively for conservation purposes; they were also occasionally designed to underwrite higher standards of living for the chiefs themselves. For instance, in some Polynesian societies, as in Samoa, fishermen were required to obey a taboo that a portion of their catch must be given to the chief. The penalties for violating such taboos were supernaturally produced illness or other misfortunes.

Complex societies. As societies became increasingly complex, heterogeneous, and divided along lines of caste, class, and ethnic affiliation, their dietary customs became correspondingly less uniform because they mirrored these divisions and inequalities. Although these distinctive customs are almost always placed in the context of religious belief and practice, according to many anthropologists, the dietary observances in everyday behaviour are primarily shaped by economic and social considerations; moreover, observances at the village level rarely correspond directly to formal prescriptions and proscriptions.

The dietary laws and customs of complex nations and of the world's major religions, which developed as institutional parts of complex nations, are always based on the prior assumption of social stratification, traditional privilege, and social, familial, and moral lines that cannot be crossed. Taboos and other regulations in connection with food are incompatible with the idea of an open society. Nevertheless, complex nations were characterized by caste organizations that, in almost all cases, religion helped to legitimate. Caste systems, in addition to their other characteristics, are supported by deeply felt fears of pollution or contamination as a result of unguarded contact of the more "pure" with those who are less "pure."

Although there is no doubt that the development of caste is linked to some form of occupational separation in a society, which, in turn, leads to the development of ideas concerning the separation of unclean persons from the ordinary or of the ordinary from the superpure, there is considerable controversy over the origins of caste systems. Regardless of the origins, however, the separation of castes is always mirrored in rules for eating that, when breached, represent a threat to the social order and to the individual's sense of identity. There is also a question among scholars whether or not caste is unique to India. Nevertheless, in Japan as well as India, eating together implies social and ritual equality, as it does in the United States, where, unlike Japan and India, food-related caste behaviour has not been institutionalized in religion. In

Economic powers of the chief

Social stratification as basis for food customs

Territorial rights and initiatory rites

India and Japan, a person who cooks for another and serves his food must be equal or superior in rank to the recipient of the food; only in this way can the latter avoid pollution. In the caste system of the United States, a Negro may cook and serve but not eat with the whites (though this is changing in many sectors). Before the U.S. civil-rights movement, violation of these eating taboos constituted defiance of caste; observance of the etiquette was evidence of the acceptance of caste. It seems that dietary rules of caste relationships were never incorporated into U.S. religion because the society as a whole was governed by an ideology—though not a reality—of free and open social mobility.

#### RULES AND CUSTOMS IN WORLD RELIGIONS

**Judaism.** Perhaps the best known illustration of the idea that the dietary laws and customs of a complex nation and its religion are based on the prior assumption of social stratification or, at least, of a sense of separateness, is provided by Judaism as spelled out in the Mosaic Law in the Old Testament books of Leviticus (chapter 11) and Deuteronomy (chapter 14). Prohibited foods may not be consumed in any form: all animals—and their products—that do not chew the cud and do not have cloven hoofs (e.g., pig and horse); fish without fins and scales; blood; seafood (e.g., clams, oysters, shrimp, crabs) and all other living creatures that creep; and those fowl enumerated in the Bible. All foods outside these categories may be eaten.

Interpretation of Jewish laws. Mary Douglas has offered probably the most cogent and widely accepted interpretation of these laws in her book *Purity and Danger*. She suggests that these notions of defilement are rules of separation; they symbolize and help maintain the biblical notion of the separateness of the Hebrews from other societies. A central element in her interpretation is that each of the injunctions is prefaced by the command to be holy and that it is the distinction between holiness and abomination that enables these restrictions to make sense. "Holiness means keeping distinct the categories of creation. It therefore involves correct definition, discrimination, and order." The Mosaic dietary laws exemplify holiness in this sense. The ancient Hebrews were pastoralists, and cloven-hoofed and cud-chewing hoofed animals are proper food for such people; hence, Douglas maintains, they became part of the social order and were domesticated as slaves. Pigs and camels do not meet the criteria of animals that are fit for pastoralists. As a result, they are excluded from the realm of propriety. Douglas notes that there is remarkable consistency in Mosaic dietary laws. The Bible "allots to each element its proper kind of animal life. In the firmament two-legged fowls fly with wings. In the water scaly fish swim with fins. On the earth four-legged animals hop, jump, or walk. Any class of creatures which is not equipped for the right kind of locomotion in its element is contrary to holiness." People who eat food that is "out of place," as it were, such as four-footed creatures that fly, are themselves unclean and are prohibited from approaching the Temple.

There is, however, another dimension to Old Testament food customs. In addition to expressing their separateness as a nation—membership in which was ascribed by birthright—Israelite food customs also mirrored their internal divisions, which were castelike and were inherited. Though the rules of separation referred primarily to the priests, they also affected the rest of the population. The priest's inherent separateness from ordinary men was symbolized by the prescription that he must avoid uncleanness more than anyone else. He must not drink wine or strong drink, and he must wash his hands and feet before the Temple service. Explicit in Old Testament prescriptions is that an offering sanctifies anyone who touches it; therefore, often the priests alone were permitted to consume it.

These rules symbolizing the priestly group's castelike separateness also validated a system of taxation benefiting them, couched in terms of offerings, sacrifice, first-fruit ceremonies, and tithes. The religious rationalization of taxation is illustrated in the Old Testament by the first-fruits ceremony. Fruit trees were said to live their own

life, and they were to remain untrimmed for three years after they were planted. But their fruits could not be enjoyed immediately: God must be given his share in the first-fruit ceremonies. These first fruits represent the whole, and the entire power of the harvest—which is God's—is concentrated in them. Sacrifice is centred around the idea of the first-fruits offering. Its rationalization was that everything belonged to God; the central point in the sacrifice is the sanctification of the offering, surrendering it to God. Its most immediate purpose was to serve as a form of taxation to the priests; only they were considered holy enough to take possession of it.

Elaboration of the Jewish laws. After the exile of the Jews from Palestine following the conquest by Rome in the 1st century AD, a remarkable elaboration in their dietary laws occurred, probably as a result of the Jews' attempts to maintain their separateness from nations into whose midst they were thrust. Many customs evolved that have taken on the force of law for those Jews who have sought to maintain a traditional way of life. For example, the Bible does not prescribe ritual slaughter of animals, yet this practice has taken on the same compulsion as the taboo on pigs and camels; a permitted food (e.g., cattle, chicken) that has not been ritually slaughtered is now regarded to be as defiling as pork. Similarly, one of the hallmarks of the Passover holiday in Judaism is the eschewal of all foods containing leaven, the consumption only of foods that have been designated as "kosher for Passover," and the use of special sets of utensils that have not been used during the rest of the year. But these, too, are postbiblical customs that have been given the force of law; the Bible prescribes nothing more than eating unleavened bread during the Passover season.

Further elaborations on the Mosaic Law in regard to food can be observed in the dietary customs of certain groups of modern Jews in their daily lives. In the pre-World War II eastern European Jewish community (or *shtetl*), behaviour in regard to food not only included the biblical prescriptions and proscriptions but, in many ways, resembled the behaviour of people in the corporate communities of tribal societies. The major life crises were celebrated by feasts or other uses of food. Wine and other foods were integral parts of circumcision ceremonies and of a boys' attainment of ritual majority (*Bar Mitzwa*). Weddings were also celebrated with huge feasts that required weeks, if not months, of preparation, and guests were seated at the wedding feast according to their social rank. Following the wedding celebration, grain was sprinkled on the couple's heads, apparently to promote fertility. Those who visited mourners were to eat hard-boiled eggs or other circular food because roundness symbolizes mourning.

Aside from the daily requirements of following the Mosaic dietary laws, which apply to everyone, the heaviest burden for maintaining these observances falls on the women; their ritual and secular statuses are always inferior to the men's. It is the task of the housewife to be sure that meat and dairy foods are not mixed, that ritually slaughtered meat is not blemished, and that cooking equipment and dishes and utensils for meat and dairy are rigidly separated. The only personal states of ritual pollution relating to food in *shtetl* culture also refer only to women. For instance, a woman who has not been ritually cleansed after her menses must not make or touch pickles, wine, or beet soup. If she violates this customary rule, it is believed that these foods will spoil.

A further illustration of the idea that dietary rules and customs are inextricably associated with the maintenance of group separateness is provided by one sect of Jews in the United States, those who refer to themselves as *Hasidim* (Pious Ones). These people live in self-contained enclaves; most of them are immigrants from the *shtetl*. In addition to preserving their distinctiveness from surrounding non-Jewish communities, they are equally devoted to preserving their distinctiveness vis-à-vis other Jews; no matter what their degrees of piety, the latter are regarded by *Hasidim* as nonreligious.

This is clearly reflected in their behaviour in regard to

Prohibited  
foods

*Shtetl*  
commu-  
nities

"Hasidic"  
Jews

food. The Hasidim assert that the larger Jewish community (and its rabbis) do not meet Hasidic standards and qualifications in the manufacture, preparation, handling, and sale of food; even non-Hasidic ritual slaughterers are classed with assimilated Jews who do not observe dietary laws at all. Hence, their food products are regarded as forbidden, and Hasidim consider only their own products as permissible for consumption. Even neutral foods, such as vegetables, are defined as nonkosher if handled by a non-Hasid since there is always the suspicion that it may come into contact with nonkosher—and thus contaminating—matter. Thus, for instance, only milk that they designate as "Jewish" can be used; only noodles prepared by someone from the Hasidic community may be consumed because there is the suspicion that eggs with a drop of blood (which are forbidden) may have been used in the noodles' preparation; only approved sugar may be used; and even paper bags that hold food come under these restrictions because only a member of the community is above the suspicion that forbidden matter has been included in the glue that is used in manufacturing the bags.

The extremity of Hasidic strictures with regard to food has to be viewed in the context of their setting in the United States and not only in the light of their Jewish sources. The Hasidim regard the growing secularization of U.S. life as the greatest threat to the perpetuation of the ancient tradition of Judaism; their extremism is the wall they have erected to stave off this danger of threatened assimilation.

**Black Muslim movement.** Until relatively recently, the separatism of U.S. Negroes was underwritten by an intricate combination of law and custom. The attempt of the United States government to achieve an integration of blacks and whites in daily social, economic, and political life was viewed by some Negroes as a threat to their social identity. Ideologies designed to legitimate the maintenance of their social identity began to develop, especially after the desegregation decision of the Supreme Court in 1954, the most notable of which is known as the Nation of Islam (the Black Muslims). In their attempt to separate themselves from the larger aggregate of U.S. Negroes, as well as from the rest of U.S. society, the Black Muslims sought to develop a separate social identity by adopting a set of symbols to which they attached particular meanings. A person's membership in the group not only depended on assuming a Muslim name but also on eating certain foods and avoiding others, including alcohol and tobacco. Forbidden foods include meats and fish proscribed by the Bible and Qurʾān and also more than a dozen vegetables that were staples in the slave diet.

**Islām.** Islāmīc dietary laws—as spelled out in the Qurʾān—also illustrate their relationship to the establishment of a sense of social identity and separateness. Muhammad, the founder of Islam, was among other things a political leader who welded a nation out of the mutually warring tribes of Arabia. His religious ideology legitimated the unification of these autonomous tribes and his own paramount rule over them. The main religious tenets of Islām were derived from Judaism and early Christianity, and it is clear from the Qurʾān that Islām was intended to encompass all aspects of life.

Muhammad apparently knew more about Judaism than about Christianity, and many of his strictures in the Qurʾān were explicit in establishing distinctions between Arabs and Jews. This is evident in his dietary regulations, which borrow heavily from Mosaic Law. Specifically, Muhammad proscribed for Muslims the flesh of animals that are found dead, blood, swine's flesh, and food that had been offered or sacrificed to idols. The most radical departure of Qurʾānic from Mosaic dietary laws was in connection with intoxicating beverages. Though Jews frowned upon alcoholic beverages, they do not forbid them, and wine is an important element in many rituals and feasts; Muhammad, however, absolutely forbade any such beverages.

Specific departures from Mosaic and Christian dietary rules notwithstanding, Islam represents a more fundamental removal from all other major religions: what is polluting, forbidden, and enjoined for one person in Islām

applies equally to all. Islām's sharpest contrast in this regard is to the religions of India. This difference is highlighted by the fact that Muslims of all social statuses in an Indian village eat freely with each other, worship in the same mosques, and participate in ceremonies together.

**Christianity.** Christianity did not develop elaborate dietary rules and customs. This probably grew out of the controversy between the Judaizing and Hellenizing branches of the church during the earliest years of Christianity over whether or not to observe Mosaic food laws. The Council of Jerusalem settled on the formula that meat offered to idols, blood, and things strangled must be abstained from, thus freeing the Gentiles in all other respects from the law. The apostle Paul's position on the matter, however, was that "nothing is unclean in itself"; and it was thus that the New Testament repudiated the entire body of laws of purity, especially those pertaining to food. Jesus is said to have declared that defilement could not be caused by any external agent. The apostle Peter's vision of the sheet lowered from heaven and containing all types of animals that the divine voice pronounced clean and fit for food provided the church with a mandate to abandon the Old Testament food laws.

Food, however, in terms of the Last Supper and the Eucharist, plays an important role in Christianity. As told by the early Christians, Jesus foresaw his death and performed a simple ceremony during a last meal to bring home the significance of his death to the Twelve: he broke a loaf into pieces and gave it to them saying, "Take this, it is my body." After they had eaten, he took the cup of wine and said, "This is my blood."

During the 1st century AD, Christian communities developed into self-contained units with an organized life of their own. When they were beginning to see themselves as a church, they held two separate kinds of services: (1) meetings on the model of the synagogue that were open to inquirers and believers and consisted of readings from the Jewish scriptures and (2) agapē, or "love feasts," for believers only. The latter was an evening meal in which the participants shared and during which a brief ceremony, recalling the Last Supper, commemorated the Crucifixion. This was also a thanksgiving ceremony; the Greek name for it was eucharist, meaning "the giving of thanks." This common meal gradually became impracticable as the Christian communities grew larger, and the Lord's Supper was thereafter observed at the conclusion of the public portion of the scripture service; the unbaptized withdrew so that the baptized could celebrate together.

Thus, from the very inception of Christianity, food and beverage has symbolized that religious experience is not purely personal but also communal. Moreover, differences in interpretation of the Lord's Supper have provided some of the contrasts among the major Christian churches. The opposing views of Roman Catholics and Protestants over whether the Eucharist bread is changed in substance or is a symbol of the flesh of Christ is an example of the role of food as a representation of religious differences within Christianity.

The rituals of the Eucharist provide the clearest examples in the Christian churches or confessions of the relationship between social stratification and food behaviour. Christianity, unlike Judaism or Hinduism and other Asian religions, was never tied to a caste system; correspondingly, it repudiated the entire body of purity-pollution laws of the Old Testament. Christianity was, however, part of the early European social system that was based on clear-cut separations of social classes. Religious food customs in Christianity, most notably in the Eucharist, reflects this.

The first Christian churches developed alongside the most rigid social stratification in European history, with elaborate notions of class authority and superiority and subordination. The separation of those in authority from the masses of ordinary people is mirrored in the Roman eucharistic ritual in which the sacrament's celebrant—the officiating priest—partook of the bread and wine first and then served only the bread to those of the faithful who wished it.

Relation-  
ship with  
Judaism  
and Chris-  
tianity

With the Reformation during the 16th century, which was (among other things) an overthrow of the traditional social order, a slight but important change in the eucharistic ritual was introduced, reflecting the **weakening**—but not the abandonment—of stratification and its attendant hierarchies of authority. In many Protestant confessions the officiating minister also partook of the bread and wine first, then served it to the congregation. In the Presbyterian ritual, the minister partook first and then served it to the elders who then served the people. Although this continued to reflect a system of stratification, it was a radical departure from the Roman rule that only the officiating priest could serve everyone. These rules for both Roman Catholics and Protestants are gradually changing in the 20th century.

Fast and  
abstinence

Until relatively recently, the most notable dietary law in Christianity was the Roman Catholic prescription to abstain from eating meat on Friday. This ban was lifted as part of the modernization of Roman Catholicism that was begun during the reign of Pope John XXIII. In Roman Catholic abstinence meat is forbidden, but there is no restriction on the amount of food eaten; fasting means that the quantity of food is also restricted. Historically, there have been several categories of fasts. The 40 days of Lent have traditionally been a period of mortification, including practices of fast and abstinence; the rules, however, have been greatly modified in recent years. Ember Days—a Wednesday, Friday, and Saturday at each of the four seasons—seem to be survivals of full weekly fasts formerly practiced four times a year. Vigils are single fast days that have been observed before certain feast days and other festivals. Rogation Days are the three days before Ascension Day and are marked by a fast preparatory to that festival; they seem to have been introduced after an earthquake about 470 as penitential rogations, or processions, for supplication.

Also important in the Christian complex of fasting is that associated with monastic life. Mortification is seen as essential to the practice of asceticism, and, in many rules of monastic life, fasting is regarded as one of the most efficient exercises of mortification.

**Religions of India.** It is in the religions of India that one can most clearly observe the principles outlined above concerning the relationship between dietary laws and customs and the existence of social stratification, traditional privilege, and social, familial, and moral lines that cannot be crossed. Hinduism provides the best example, although the same principles also obtain in the religions of Jainism and Sikhism.

Relation-  
ship  
between  
dietary  
customs  
and caste  
systems

Food observances help to define caste ranking: Brahmins are the highest caste because they eat only those foods prepared in the finest manner (*pakkā*); everyone else takes inferior (*kaccā*) food. *Pakkā* food is the only kind that can be offered in feasts to gods, to guests of high status, and to persons who provide honorific services. Food is regarded as *pakkā* if it contains ghee (clarified butter), which is a very costly fat and which is believed to promote health and virility. *Kaccā* is defined as inferior because it contains no ghee; it is used as ordinary family fare or as daily payment for servants and artisans. When food serves as payment for services (e.g., barbering), the quality of the food depends on the relative ranks of the parties to the transaction; the person making the payment gives inferior food, such as coarser bread, to a lower ranking person performing the service. Performance of a service denotes that a person is ready to accept some kind of food, and giving food denotes an expectation that a service will be performed. Members of subordinate castes pick up the dirty plates of members of superior castes, as at village feasts. Food left on plates after eating is defined as garbage (*jūthā*); it is felt to have been polluted by the eater's saliva. This garbage may be handled in the family by a person whose status is lower than the eater's, such as a wife. Such food may be fed to domestic animals; among humans outside the family it can only be given to members of the lowest castes, such as sweepers. The highest Brahmins do not accept any cooked food from members of any other caste, but uncooked food may be received from or handled by mem-

bers of any caste. Nor will such Brahmins accept water across caste lines. Cow's milk is ritually pure and cannot be defiled, but a Brahmin will not accept milk from an untouchable—a member of the lowest caste groups—lest it has been diluted with water.

Water is easily defiled, but, if it is running in a stream or standing in a reservoir, it is not polluted even by an untouchable in it. Water in a well or container, however, is defiled by direct or indirect contact with a person of low caste. Thus, a ritually observant Brahmin will not allow a low-caste person to draw water from his well, although this rule is lapsing, possibly because of the introduction of plumbing and the removal of water from the list of scarce resources.

In the general Hindu system of purity–pollution, meats are graded as to their relative amount of pollution. Eggs are the least and beef the most defiling; but the highest caste Brahmins avoid all meat products **absolutely**. Also, certain strong foods (e.g., onions and garlic) are thought to be inappropriate to Brahminical status. Alcohol too is prohibited; it is not considered polluting in itself, but the prohibition seems related to the Brahminical value of self-control. Alcohol's manufacture and trade is confined to members of lower castes.

People who eat at each other's feasts hold equal rank. People who eat at every house in a village occupy a very low status, and refusal to take food from another constitutes a claim to higher caste rank. More generally, givers of food outrank receivers. This, however, is a definition of collective, not of individual, rank. If a member of one caste gives food to a member of a second, all members of the first caste are regarded as higher than a third, even if there is no direct transaction between the first and third castes. Thus, the behaviour of every person in a village has consequences for the entire village.

In actual practice, however, there is not an automatic enactment of these formal rules in village life; instead, they vary considerably according to local conditions. For instance, one of the formal rules of Hindu religious caste organization is that vegetarians outrank meat eaters, because contact with killed animals is regarded as polluting. Nevertheless, McKim Marriott, a U.S. anthropologist who has investigated village caste relationships, has found instances in which meat eaters outrank vegetarians. He concludes from his observations that it is caste rank—mostly in terms of the kinds of work that people in different castes do—that determines purity and pollution. In daily social relations this sometimes means that a caste of sufficiently high status may not be demeaned by receiving food from a lower caste if the latter is not too far below and if the proper food and vessels are used.

Status is rarely immutable over long stretches of time. In most societies, people who occupy low status try to exploit every opportunity to improve their position, and, Marriott found, Indian villagers are no exception. Because food in this culture is one of the principal indices of rank, it is used as a pawn in manoeuvres for social mobility. Specifically, members of a low caste will try to gain dominance over persons in another by feeding them, although the latter cannot be too far above the upwardly mobile group. There is no direct way of forcing a higher group to accept food; one of the techniques most often used is for the lower caste to threaten to withhold services unless a heretofore slightly higher caste receives food from the former. Such mobility, as noted earlier, affects not only the two castes concerned but also all other groups in the village, and the manoeuvring involves everyone in the community.

Marriott's emphasis on occupation (and, therefore, rank) as the determinant of food customs has not been accepted by all students of Indian society. He continues to leave some aspects of caste behaviour unexplained, such as the extreme statuses of Brahmins and untouchables, to say nothing of the existence of the total caste system itself and the mechanisms by which it is maintained. These problems have yet to be worked out. In any case, there can be no doubt that concepts of pollution and purity in regard to food in India, as everywhere else, are governed by a systematic set of rules analogous to a lan-

Local  
variability  
of dietary  
restrictions

guage's grammar and that applications of the rules are logical and consistent within the grammatical framework. Observations of daily village life do not contradict this concept of the codification of food rules; they only suggest that earlier "grammars" may have been too narrowly conceived.

Lack of  
unity in  
Buddhism

Buddhism. Buddhism is, perhaps, the most difficult religion to discuss in terms of dietary laws and customs because it does not have any unity; its tradition has a complex history, and individual believers are characterized by varied faiths. Though Buddhism originated in India, it also diffused to—and had a great impact on—Ceylon, Tibet, China, and Japan. In each case, it was reshaped to conform with local conditions, especially those of social stratification. For example, most of the countries of Southeast Asia have caste systems in which there are outcastes or untouchables; Buddhism has been important in supporting such systems. Specifically, untouchability and the occupation of butchering animals tend to go together both in Buddhism and in many of the countries of Southeast Asia. But Burma, where Buddhism is the dominant religion, is an exception; having no caste system, Burmese society has not made butchering a basis of untouchability.

Buddhism developed its own class distinctions, most notably between the monastic elite and the lay devotees. The social and political ethic of the laity was based on a merit-making ethic that was geared primarily to the urban mercantile and artisan classes. Thus, Buddhism claimed from its inception to be a Middle View (*Mādhymika*), opposed equally to the extremes of sensuousness and indulgence and of self-mortification. This Middle View was exemplified in the "five precepts": no killing, stealing, lying, adultery, or drinking of alcoholic beverages. These precepts were translated into an ethic of moderation in diet. A person must allay his hunger so that he may practice the religious life. Buddhism holds that man is weak and helpless by himself; thus it sees the purpose of religious action as bringing a return from the deities. Deriving from this is the practice of holding ritual vegetarian feasts for large numbers of monks, a noble patron, or for the benefit of a departed soul to promote health and longevity. Another Buddhist custom is the issuing of a prohibition against killing animals to end a drought or to speed the recovery of a sick emperor. According to the Vedic treatise the *Satapatha Brāhmaṇa*, food, when enclosed in the body, is linked to the body by means of the vital airs. The essence of food is invisible. Food is the highest of all things that can be swallowed, and food and breath are both gods.

The prohibition of killing animals is more stringent in Buddhism than the injunction against eating them. Buddhism allows pure flesh to be eaten if it has not been procured for eating purposes or if the eater has not supposed it to be. The sin is upon the slayer, not the eater. This notion has been used in India and Japan to justify the outcasting or untouchability of butchers.

Religions of China. China is an example of the proposition offered above that religion alone does not give rise to eating rules; instead, religion serves to legitimate customary patterns of behaviour and social relations that emerge out of economic (especially occupational) and political relationships. Although China was under strong Buddhist influence, the Chinese never developed the institution of untouchability or outcaste. Indeed, Buddhism did not really penetrate China until after the beginning of the 2nd century AD; during the previous century, Buddhism was confined to foreigners in the northern commercial cities.

Chinese  
culture  
before the  
Han  
dynasty

Before 200 BC (the approximate beginning of the Han dynasty), Chinese culture was based on a rather elaborate system of social stratification in which mobility was rare and difficult. It was, in other words, a relatively closed social system, if not feudal. During this time, there were restrictions on the consumption of food: beef, mutton, and pork were to be eaten by an emperor; beef by feudal lords; mutton by high-ranking state ministers; pork by lower ministers; fish by generals; and vegetables by commoners (who probably could not afford meat or fish any-

way). Officials, in fact, were known as "meat eaters," and it was generally only the aged commoners who were allowed to eat meat.

During this time, military affairs and sacrifices were considered the two most important things in the state. Sacrifice was inseparable from veneration of the ancestors, and almost no ceremonies were conducted without sacrifice and offerings. These ceremonies were integral features of daily life and, as a result, foodstuffs became associated with the moral code that was based on maintaining fixed social and political relationships. God and ancestors were often referred to as those "who are sacrificed to," and disobedience to them was believed to result automatically in catastrophe. Ceremonies marking important personal transitions (*e.g.*, initiation to adulthood and marriage) were held in the ancestral temple and were accompanied by feasts and sacrifices to the ancestors.

Ancestral veneration and the ethos of religiously validated legitimate authority remained as integral features of Chinese culture until the most recent years. Religious belief and observance notwithstanding, however, Chinese culture underwent a drastic change with the establishment of the Han dynasty. Most notably, the social class system was opened up—at least ideally—by the adoption of the principle of recruitment for public office; in later dynasties, this was expanded into the well-known system of written examinations, of grading officeholders by merit, and other features of the famous Chinese civil service. Correlated with the removal of the barriers to social mobility and establishment of the principle of ideally open recruitment to the civil service, the pre-Han food restrictions disappeared. This was also the time of Buddhism's greatest thrusts into Chinese thought and life.

Food continued to occupy an important social and religious place in villages, at least until the establishment of the People's Republic of China. For instance, marriage ceremonies traditionally last four days; the highlight of each day's celebration is a feast or sacrifice to the ancestors, sometimes both. Feasts and sacrifices are also important features of funerals, some of which are marked by two feasts in one day. These ceremonial occasions often work considerable economic hardship on families, forcing many of them into debt.

Religions of Japan and Korea. Japan and Korea exhibit many of the same characteristics with respect to food customs as India, though with much less elaboration, and thereby the same relationships to Buddhism, though in an opposite direction. These relationships to Buddhism are also highlighted by contrasting Japan and Korea with China. Whereas post-Han China placed emphasis on achieved status and on personal superiority rather than on considerations of race or blood as a basis of social position, Japan and Korea (and also Tibet) established and continued a system of hereditary status and outcasting. As in India, therefore, the Japanese and Koreans considered pollution to be a hereditary taint; Buddhism played a major role in the legitimization of this ideology.

Outcastes in Japan are often referred to pejoratively as *Eta* (*eta* meaning "very dirty" or "defiling"). The accepted usage among students of Japanese society for outcastes is *burakumin*, meaning "people of a special village." They are crudely discriminated against in employment and intermarriage, live rurally or in slum conditions, have the lowest educational levels in the nation, and often suffer from malnutrition. They are required to wear special clothing, slippers, and hair styles; to stay away from other households; to remain in their own hovels at night; and to prostrate themselves before higher-caste people.

Outcaste  
groups

The history of the Japanese caste system in respect to food customs gives important clues to its origin. Among the ancient Japanese, meat was included in the diet, and the flesh of animals, fishes, and birds was offered to the gods as sacrifice. The flesh of ox, horse, dog, monkey, and fowl was prohibited, but deer, rabbit, and pig were not. During the 8th century AD, the Japanese began to depend

mostly upon plant rather than animal foods. In Japan's limited territory, it is understandable that cattle were raised for plowing and other agricultural work rather than for meat and milk. In 741 a law was passed forbidding the killing of cattle and horses, the latter being necessary for military as well as productive purposes. This provided a conducive atmosphere for Buddhist influences in the 6th and 7th centuries (primarily from China and Korea) that stressed the abhorrence and ritual impurity of blood and death.

## Shintō

Buddhism, however, was only one of several sources of outcasting slaughterers and butchers. During the 8th century, *Shintō*—the only indigenous religion of Japan—began to stress concepts of uncleanness as things that are displeasing to the gods: wounds, disease, death, menstruation, and childbirth; and this too contributed strongly to the development of *Eta* status. It was apparently about this time that the belief developed in Japan that a person's association with blood and death changed his nature; this contamination not only carried over to a man's descendants but was thought to be communicable. It was apparently also at this time that Japanese cuisine began to favour fish (especially raw fish) as a staple source of protein.

Important in this connection is that occupational specialization began to flourish in Japan during the 9th and 10th centuries; by this time, Buddhism was widespread in Japan. Traditional occupational roles became spheres of monopoly; in the face of competition from economically specialized groups who forced them out, people dealing with slaughtering, butchering, and tanning began to form guilds. This was rationalized by Buddhist and *Shintō* ideas that occupations associated with animal slaughter and processing (confined to *Eta*) should be separated from the general body of commoner and slave occupations.

During the Heian period (794–1185), communities whose members were engaged in occupations related to death and animal products were forced outside the normal society, and they thus came to form the main body of outcasts in Japan. Increasingly, the latter were outcasted and considered untouchable, a pattern that reached its heights in the Tokugawa period (1603–1867). By the 17th century, the idea developed—supported by *Shintō* and Buddhism—that eating the flesh of all animals caused pollution for 100 days.

Outcasting dies slowly. Though the egalitarian ideologies of modern industrialization are incompatible with caste, outcasting tends to remain in Japan and, alongside it, many of the food customs associated with the caste system. As in India, eating together (along with marriage and social visiting) between untouchables and members of normal society is disdained. In many parts of Japan, especially in traditional villages, the diet tends to be largely vegetarian, though fish (and occasionally chicken) accompany banquets. Pigs are raised for sale to *Eta*, and pork is eaten in cities. Horses and cows are still used only as beasts of burden. Milk continues to be considered dirty and tends to be drunk only on a doctor's prescription. Also, as in all traditionalist groups, corporate groups of households (*kumi*), especially in villages, periodically hold festivals at their village shrines; each household takes a turn in providing food and beverage. The core of the festivity lies in drinking sake, an alcoholic beverage, and eating a grand meal.

## Differential Equations

Differential equations are equations that relate a function  $f$  to its derivatives. This type of equation finds widespread application in science and technology because it can be used to express natural laws that describe the behaviour of rates of change of quantities. A well-known example in physics concerns radioactivity. A radioactive element changes spontaneously into a stable element, a process that is known as radioactive decay or disintegration. The law describing this behaviour states that the rate of decay with time—that is, the amount of a substance changing per second, say—is proportional to the amount of substance present. Initially, when the material is a pure radioactive element, this rate of decay is high. As the radioactive element changes into a stable element, however, the rate of change falls because there is less radioactive material. Therefore, the rate of decay decreases continuously with time.

In this process the quantity of interest is the amount of substance ( $n$ ) remaining after a given time; *i.e.*, the number of atoms or the mass. Clearly this quantity will depend in some way on the time that has elapsed; in other words, it is a mathematical function of time and can be denoted by  $n(t)$ .

A formulation of the law is that  $\frac{dn}{dt}$  equals the product of  $-\lambda$  and  $n$  (see Box, law 1). In this case  $n$  represents the amount of radioactive material.  $\lambda$  is a constant, and  $\frac{dn}{dt}$  is a notation for the rate at which  $n$  increases with time. The minus sign is required because  $n$  is decreasing with time and not increasing.  $\frac{dn}{dt}$  is known as the derivative of  $n$  with respect to  $t$ . An idea of the nature of a derivative can be obtained by considering the behaviour of a specific function of  $x$ , say  $x^2$ . If  $x$  has the value  $a$  (a real number) this function has the value  $a^2$ . If this value now changes to  $(a + h)$ , the value of the function becomes  $(a + h)^2$ . The change in the value of the function is  $(a + h)^2 - a^2$ , and this change has occurred as a result of  $x$  changing by  $h$ . Thus the rate at which  $x^2$  has

changed with respect to the change in  $x$  is given by the quotient:  $\frac{(a+h)^2 - a^2}{h}$ . This gives an average rate of change over the value  $h$ . If  $h$  now becomes smaller, and tends to zero, the quotient tends to the value  $2a$ , because when the  $(a+h)^2$ -term is expanded and the  $a^2$ -term subtracted from it, the division yields  $2a + h$  (see 2).  $2a$  is the rate of change of  $x^2$  with  $x$  at the point  $a$  and is known as the derivative of the function. If  $a$  is allowed to vary—i.e., to take any values—a new function  $2x$  is obtained that for a given value of  $x$  expresses the rate of growth of  $x^2$  with  $x$  at that value. In general a function of a single real variable  $x$  can be denoted by  $u(x)$  and its derivative by  $\frac{du(x)}{dx}$  or by  $u'(x)$ .

This process can be repeated: the derivative of  $u'(x)$  can be formed and denoted by  $u''(x)$  or by  $\frac{d^2u(x)}{dx^2}$ , and similarly for higher derivatives  $u^{(n)}(x)$ , when the independent variable is time and the dependent variable distance, the first derivative is velocity, the rate at which distance changes with time. The second derivative is acceleration, the rate at which velocity changes.

Returning to the example of radioactive decay, the equation involves a derivative and is one example of a differential equation. The solution of this differential equation is the function  $n(t)$ , which shows how  $n$  depends on  $t$ . The problem of solving it is that of finding the function of  $t$  the derivative of which is  $-\lambda n(t)$ .

A common example of a differential equation that involves a second derivative is the equation describing the motion of a simple pendulum under the influence of gravity. The second derivative of the angular displacement from the vertical  $\theta$  is proportional to the sine of the angular displacement (see 3). The equation involves the length  $a$  of the pendulum and  $g$ , the acceleration of a falling body under the influence of gravity, called the acceleration of free fall. The equation may be expressed in words as follows: the rate of increase with time of the rate of increase of angular displacement with time (the

angular acceleration) is directed toward the vertical position and is inversely proportional to the length of the pendulum and directly proportional to the sine of the angular displacement. This rather complicated verbalization illustrates the economy and precision of the mathematical formulation.

Most physical situations are too complicated to be expressed simply by one variable depending on another. For example, the position of a body in a vertical plane is given by two coordinates  $x$  and  $y$ , indicating the distances from a vertical and horizontal axis respectively. The motion of a body moving in this plane can be expressed by an equation involving these two coordinates  $(x, y)$ , each of which depends on the time  $t$ .

In particular, if air resistance is neglected, a particle moving under the influence of gravity is described by a pair of differential equations expressed in terms of second derivatives (see 4), in which  $g$  denotes the acceleration caused by gravity. There is no acceleration in the horizontal direction because there is no force in this direction.

A further example is provided by geometry. It is shown in calculus that the curvature  $k$  of a curve—the equation of which in Cartesian coordinates is  $y = y(x)$  is defined in terms of the second derivative of  $y$  (see 5). A curve with the property that the rate of change with respect to  $x$  of its curvature is a prescribed function  $\psi(x)$  therefore has an equation that satisfies the equation  $dk/dx = \psi(x)$ , which is equivalent to an equation involving a third derivative (see 6). By using the alternative notation of primes denoting differentiation (see 7), it is also possible to write this equation in a more simple form (see 8). For example, a circle has constant curvature so that it has  $\psi(x) \equiv 0$ ; hence, all circles are symbolized by the same differential equation with the term involving  $\psi(x)$  set equal to zero (see 9).

The preceding examples are all equations that involve functions of a single variable. Derivatives of such functions are called ordinary derivatives, and, therefore, equations of this type are called ordinary differential equations. The pair of equations involve simultaneously the derivatives of two independent variables  $x$  and  $y$  and are an example of a pair of ordinary simultaneous differential equations.

The transverse displacement of a vibrating string is determined by an equation of a totally different kind. If the string is at rest stretched to a tension  $T$  between points  $x = 0$  and  $x = a$  of the  $x$ -axis, then if the string is set vibrating the displacement,  $y$ , of a point that originally had a coordinate  $x$  will depend not only on  $x$  but also on the time  $t$ . In other words,  $y$  is a function of two independent variables,  $x$  and  $t$ . Its variation is governed by the fact that the second partial derivative with respect to  $x$  is proportional to the second partial derivative with respect to  $t$  (see 10), the proportionality constant  $c = \sqrt{T/\sigma}$ ,  $\sigma$  being the mass per unit length of the string. The derivatives in this equation are partial derivatives, and the equation is an example of a partial differential equation. The theory of such equations is markedly different from that of ordinary differential equations and is considered later.

This article is divided into the following sections:

#### Ordinary differential equations

- Historical background
- Types of problems solvable with this discipline
- Types of solutions
- Existence and uniqueness of solutions

### Ordinary differential equations

Equations of the first order and first degree

An ordinary differential equation is a relation connecting the function  $y$  of an independent variable  $x$  and its derivatives  $y', y'', \dots, y^{(n)}$  (see 11). If the derivative of the highest order occurring in the equation is  $y^{(n)} \equiv d^n y/dx^n$ , the equation is said to be of order  $n$ . For example, equation (1) is a first-order equation, and equations (3) and (4) have an order of two. The power to which the highest derivative occurs is called the degree of the equation. Equations (1), (3), and (4) are of the first degree; a second-order differential equation involving  $(y'')^2$  and no higher of  $y'$  (see 12), however, is of the second degree because the highest derivative occurs to the power 2. If the equation is of a form (see 13) in which the function  $y$  and its derivatives occur linearly and in which the coefficients  $a_n(x), \dots, a_1(x), a_0(x)$  depend only on  $x$  and not on  $y$  or any of its derivatives, the equation is said to be linear. If  $\psi(x) \equiv 0$  (equal for all values of  $x$ ), the equation is said to be homogeneous; and if  $\psi(x)$  is not equal to zero for all values of  $x$ , it is said to be non-homogeneous. Equation (1) is linear and homogeneous, but equation (3) is nonlinear.

#### HISTORICAL BACKGROUND

The study of differential equations is almost as old as that of the calculus itself. Sir Isaac Newton discovered a method of infinite series and the calculus in 1665–66. In 1671 he wrote an account of his theory of "fluxions," a fluxion being a derivative of a "fluent," the name Newton gave to his dependent variables. Newton discussed "fluxional equations," or as they are now called, differential equations. These he divided into three categories. In modern notation, the first category is that in which  $dy/dx$  is a function of  $x$  alone or of  $y$  alone; the second consists of ordinary differential equations of the first order of the form  $dy/dx = f(x, y)$ ; and the third is made up of partial differential equations of the first order. Newton derived solutions of differential equations by a method using power series with indeterminate coefficients, which he claimed to be universally effective. Though written in 1671 in Latin, his work, entitled *The Method of Fluxions and Infinite Series*, was not published until 1736. As a result it had little or no influence on the development of the theory of differential equations.

A greater impact was made by the work of the German mathematician Gottfried Wilhelm Leibniz. Although his investigations were not begun until 1673, Leibniz became known through the publication of his results in 1684 in the *Acta Eruditorum* ("Deeds of Distinguished Men"), a scientific journal that had been established only two years earlier.

Foremost among the devoted followers of Leibniz were the Swiss mathematicians, the brothers Jakob and Johann Bernoulli. With others of their family, they played a notable part in the development of the theory of differential equations and of the use of such equations in the solution of physical problems.

In May 1690, in a paper in the *Acta Eruditorum* Jakob Bernoulli showed that the problem of determining the isochrone—i.e., the curve in a vertical plane such that a particle will slide from any point to the bottom in exactly the same time, no matter what the starting point—is equivalent to that of solving a first-order nonlinear differential equation (see 14). He then solved the equation by what is now called the method of separation of variables; the general method was enunciated by Leibniz in the following year. Jakob Bernoulli's paper of 1690

is a milestone in the history of calculus, for in it the term integral occurs in the literature for the first time.

In 1692 Leibniz discovered the method of solving first-order equations of homogeneous type and still later that of solving linear equations of the first order. The problem of finding the general solution of what is now called Bernoulli's equation was proposed by Bernoulli in 1695 and solved by Leibniz and Johann Bernoulli by different methods. Thus within a few years of the birth of the infinitesimal calculus, most of the known methods of solving first-order ordinary differential equations had been developed.

Numerous applications of the use of differential equations in deriving the solutions of geometrical problems were made before 1720. Among these may be mentioned the problem of determining a plane curve the curvature of which is a prescribed function of position and that of finding the orthogonal trajectories of a given family of plane curves. Some of the differential equations formulated in this way were of the second or higher order. Second-order equations of the form  $F(y, y', y'') = 0$ , in which the independent variable  $x$  does not appear explicitly, were discussed as early as 1712 by an Italian mathematician, Iacopo Francesco Riccati, who gave his name to Riccati's equation (see below) although, in fact, Jakob Bernoulli had earlier studied the special case  $y' = x^2 + y^2$ . Some of the younger members of the Bernoulli family, particularly Daniel, contributed to studies of Riccati's equation. Important work on first-order equations of exact type (see below) and of first-order equations of degree higher than the first was done in the 1730s by Alexis-Claude Clairaut, a Frenchman who was one of the most precocious mathematicians of all time.

Early applications

$$(11) \quad f(x, y, y', \dots, y^{(n)}) = 0$$

$$(12) \quad (y'')^2 + (y')^3 + y^4 = 0$$

$$(13) \quad a_n(x)y^{(n)} + \dots + a_1(x)y' + a_0(x)y = \psi(x)$$

$$(14) \quad (b^2y - a^3)^{1/2} y' = a$$

$$(15) \quad (1 - x^4)^{1/2} y' + (1 - y^4)^{1/2} = 0$$

The second period in the history of differential equations was dominated by the Swiss mathematician Leonhard Euler, who made many contributions to the theory, starting in 1728. He introduced several methods of lowering the order of an equation, the concept of an integrating factor, the theory of linear equations of arbitrary order, the development of the use of series solutions, and the discovery that a first-order nonlinear differential equation with square roots of quartics as coefficients (see 15) has an algebraic solution. This last result, which is a special case of Abel's theorem, led to the theory of elliptic functions created in the 1820s by Niels Henrik Abel of Norway and Karl Gustav Jacob Jacobi of Germany.

Much of the early work on differential equations was concerned with the discussion of basic questions concerning what is meant by a function or by the solution of a differential equation. Such questions continued to be raised because the answers found satisfactory by one generation of mathematicians were challenged by their successors. The first attempt to establish a rigorous theory of functions was made by Abel and the French mathematician Augustin-Louis Cauchy, in the 1820s. Cauchy's work in real analysis gave an entirely new direction to the theory of ordinary differential equations, steering it away from the investigating of techniques of solution into the asking of general questions about the existence and uniqueness of solutions. Cauchy himself proved the first existence theorem and gave methods of

deriving solutions through limiting processes. The theory of analytic functions, also due to Cauchy, led to the creation of the theory of differential equations in the complex domain and, in turn, to the study of functions of several complex variables.

Much recent work in ordinary differential equations is of a basic nature, concerned with the conditions that guarantee the existence of a solution of a given equation; the theory is more concerned with establishing that a solution exists than with trying to derive a closed form for it. Such an attitude is essential when many of the practical problems involving differential equations are solved by the use of electronic computers; the validity of numerical processes must be thoroughly investigated. The study of differential equations continues to contribute to the solution of practical problems in control theory, in orbital mechanics, and in many other branches of science and technology, and also to ask challenging questions of pure mathematicians working in such apparently abstract subjects as functional analysis and the theory of differentiable manifolds.

#### TYPES OF PROBLEMS SOLVABLE WITH THIS DISCIPLINE

Some simple examples of how differential equations may arise in the analysis of problems in physics and geometry have already been given. In such problems the unknown quantity has to satisfy not only a differential equation but also some other conditions. For example, the quantity  $n(t)$  may have to satisfy the condition that at  $t=0$  it takes a prescribed value  $N$ . Some other problems that can be solved with the help of differential equations are listed below.

**Problems in mechanics.** The catenary. If a cable of uniformly distributed mass  $m$  per unit length is suspended between two points A and B, the curve formed by the cable is called a catenary. If a coordinate system is chosen with an origin vertically below the lowest point of the curve, and with a  $y$ -axis that is vertically upward, the shape of the curve is determined by a second-order non-linear differential equation (see 16), involving a constant  $a$  (with the dimensions of length). The constant is expressed in terms of  $T$ , the vertical tension acting on the cable at its lowest point, and  $g$ , the acceleration caused by gravity, by the formula  $a = T/(mg)$ . If the distance of the origin below the lowest point of the cable is taken to be  $a$ , the required solution must satisfy the conditions  $y(0) = a$ ,  $y'(0) = 0$ .

**Motion in a line under known forces.** The motion of a particle of mass  $m$  projected vertically upward in a straight line with velocity  $v$  is described by a differential equation relating the time derivative of  $mv$  to  $g$  (see 17) and the resistance of the medium  $R(v)$ , the function  $R$  being known. If the mass  $m$  is constant, the left side of the equation reduces to the time derivative of the velocity (see 18). If  $m$  is a prescribed function of  $v$ , the left side can be attacked by the rule for differentiating a product (see 19).

**Escape velocity from the Earth.** If the acceleration caused by gravity at the Earth's surface is  $g$ , then, at time  $t$ , the distance  $r$  from the Earth's centre of a particle moving vertically upward is determined by a differential equation which states that the second derivative of  $v$  is proportional to  $(R/r)^2$  (see 20), in which  $R$  is the radius of the Earth. If the initial velocity of projection is  $V$ , then the initial conditions are the position and velocity at  $t=0$  (see 21).

The motion at any point in the upward trajectory is determined by the solution of this initial value problem. If the particle is to escape from the Earth's gravitational field,  $(dr/dt)^2$  must exceed zero for all values of  $r$ . It turns out that this condition is satisfied only if  $V^2$  is greater than or equal to  $2gR$ . For this reason  $\sqrt{2gR}$  is called the escape velocity from the Earth.

**Vertical motion of a rocket.** A problem of interest is that of a rocket ascending in a straight line under the influence of gravity with a thrust that is constant both in magnitude and direction.

The thrust of the rocket is produced by the ejection of mass at a constant rate  $f$  with exhaust velocity  $V_e$ , which

when measured relative to the rocket is constant. The height  $x$  above the Earth's surface at a time  $t$  while the rocket is still firing is determined by the non-linear differential equation (see 22) relating the second derivative of  $x$  to an expression of the form  $(1 + x/R)^2$  and involving  $g$ , the acceleration caused by gravity at the Earth's surface;  $R$ , the radius of the Earth; and  $m_0$ , the initial mass of the rocket. The initial conditions in this case are that  $x=0$ ,  $dx/dt=V$  when  $t=0$ .

**Motion of a planet under an inverse square law.** If a planet is moving in a plane under an inverse square law, then its motion can be described by the plane polar coordinates  $r, \theta$ , the origin of which is situated at the centre of force.

The inverse square law relates the radial force on the planet to the inverse of the square of the distance from the origin. The motion is described by a pair of second-order differential equations derived from Newton's second law (see 23) involving a constant  $c$ .

$$(16) \quad a \frac{d^2y}{dx^2} = \left[ 1 + \left( \frac{dy}{dx} \right)^2 \right]^{1/2}$$

$$(17) \quad \frac{1}{m} \frac{d}{dt}(mv) = -g - R(v)$$

$$(18) \quad \frac{dv}{dt} = -g - R(v)$$

$$(19) \quad \left[ 1 + \frac{vm'(v)}{m(v)} \right] \frac{dv}{dt} = -g - R(v)$$

$$(20) \quad \frac{d^2r}{dt^2} = -g \left( \frac{R}{r} \right)^2$$

$$(21) \quad r=R, \quad \frac{dr}{dt}=V, \quad \text{when } t=0$$

$$(22) \quad \frac{d^2x}{dt^2} + g \left( 1 + \frac{x}{R} \right)^{-2} = \frac{V_e f}{m_0 - ft}$$

$$(23) \quad \begin{cases} \frac{d^2\rho}{dt^2} - \rho \left( \frac{d\phi}{dt} \right)^2 = -c\rho^2 \\ \frac{d}{dt} \left( \rho^2 \frac{d\phi}{dt} \right) = 0 \end{cases}$$

$$(24) \quad \begin{cases} L \frac{dx}{dt} + Rx + \frac{q}{C} = E(t) \\ L \frac{d^2q}{dt^2} + R \frac{dq}{dt} + \frac{q}{C} = E(t) \end{cases}$$

$$(25) \quad \begin{cases} L_1 \frac{dx}{dt} + R_1 x + \frac{q}{C} + M \frac{dy}{dt} = E(t) \\ M \frac{dx}{dt} + L_2 \frac{dy}{dt} + R_2 y = 0, \quad \text{with } x = dq/dt \end{cases}$$

Problems in other areas of physics. **Electrical circuits.** The electrical current  $x$  in a simple circuit containing a resistance  $R$ , a self-inductance  $L$ , and a capacitance  $C$  when a voltage  $E(t)$  is applied is determined by a simple differential equation (cf. Figure 1A). The drops in voltage across the ends of the resistance and the inductance are, respectively,  $Rx$  and  $L(dx/dt)$ . The drop across the capacitance is  $q/C$ , in which  $q$  is the charge on the condenser. The current is given by  $x = dq/dt$ , and the voltage  $E(t)$  must equal the sum of the voltage drops. The charge is therefore determined by the differential equation obtained by substituting  $x = dq/dt$  (see 24).

Figure 1: Electrical circuits. (A) Simple circuit containing a resistance  $R$ , a self-inductance  $L$ , and a capacitance  $C$ . (B) Coupled circuits in which the currents  $x$  and  $y$  are determined by a set of differential equations.

Similarly, for the coupled circuits shown in Figure 1B, the currents  $x$  and  $y$  are determined by a pair of similar linear second-order differential equations (see 25).

**Self-oscillatory problems.** Certain electrical circuits, such as feedback circuits controlled by thermionic valves, have the property that a source of power increases with the amplitude of the oscillation. To exhibit the main features of the behaviour of such systems, the 20th-century Dutch mathematician Balthasar van der Pol took as his mathematical model a second-order equation (see 26), which is now called van der Pol's equation. This equation is typical of the models describing a series of self-oscillatory problems. For example, the equation for the oscillations of a valve generator with a cubic valve characteristic can be reduced to van der Pol's equation; van der Pol himself used this equation in the theory of the oscillations in a symmetric multivibrator, in which there is an inductance.

**Potential theory.** In many branches of physics, such as electrostatics, magnetostatics, irrotational motion of perfect fluids, and others, an equation of interest is the partial differential equation named after Pierre-Simon Laplace, an 18th-century French mathematician. This equation (see 27) relates second partial derivatives of the potential  $u$ . The equation can be expressed in cylindrical coordinates  $(\rho, \phi, z)$  (see 28). If there are solutions of this equation in the form of a product of  $\exp\{-\xi z\}$ ,  $\cos(\nu\phi)$  and some function of  $\rho$ ,  $R(\rho)$  (see 29), then  $R$  must be a solution of a second-order linear ordinary differential equation with variable coefficients so that  $R(\rho) = \omega(\xi\rho)$  in which  $\omega(t)$  is a solution of a second-order linear equation with variable coefficients (see 30) known as Bessel's equation of order  $\nu$ , so named after Friedrich Wilhelm Bessel, a 19th-century German mathematician.

Similarly, Laplace's equation can be expressed in spherical coordinates (see 31). For axisymmetric solutions of the form  $v(r, \theta) = r^n \Theta(\theta)$ —i.e., solutions that do not depend on the azimuthal angle  $\phi$ — $\Theta$  must be a solution of another linear ordinary differential equation with variable coefficients (see 32). Changing the independent variable in this equation from  $\theta$  to  $\mu = \cos \theta$  gives solutions of the desired form if  $\Theta(\theta) = w(\cos \theta)$ , in which  $w(\mu)$  is any solution of the ordinary differential equation (see 32) called Legendre's equation of order  $n$ , named after Adrien-Marie Legendre, an 18th–19th-century French mathematician.

**Stellar structure.** An interesting ordinary differential equation arises in the discussion of the theory of stellar structure. If the gravitational equilibrium of a mass of gas is considered it is found that its pressure  $p$  varies with the distance  $r$  from the centre of the mass according to a second-order differential equation involving  $G$ , the gravitational constant, and  $\rho$ , the density (see 33). The density is related to the pressure through the physical law  $\log p = \log k + (1 + 1/\mu) \log \rho$  in which  $K$  and  $\mu$  are constants. If  $\log p = \log \rho_c + \mu \log \theta$ , in which  $\rho_c$  is the central density, and a new independent variable  $\xi = kr$  is introduced, in which  $k$  is defined in terms of  $\rho_c$  and constants (see 34), the Lane-Emden equation and initial conditions for it are obtained (see 35). Unless  $\mu$  is 0 or 1, the equation is nonlinear.

The harmonic oscillator in wave mechanics. One problem in wave mechanics is that of determining the wave function  $\psi$  of a particle of mass  $m$  moving on the  $x$ -axis under the action of a force  $-kx$ . The wave function  $\psi$  for a particle has the physical significance that  $|\psi(x, y, z)|^2 d\tau$  is the probability of finding the particle in a small element of volume  $d\tau$  centred at the point with coordinates  $(x, y, z)$ . In this problem the equation describing the particle is a particular case of a more general second-order differential equation named after a 20th-century Austrian physicist, Erwin Schrodinger (see 36), involving  $E$ , the total energy of the particle, and  $h$ , Planck's constant. The problem here is not so much to solve this ordinary differential equation as to find the possible values of  $E$  that ensure  $|\psi| \rightarrow 0$  as  $|x| \rightarrow \infty$ . (For an understanding of convergence to the real number "infinity," see ANALYSIS, REAL.) If the variables are changed to  $x = (h^2/4\pi^2 mk)^{1/2} z$ ,  $a = 1/4$ , and  $\lambda = (4\pi E/h)(m/k)^{1/2}$ ,

an equation relating  $\frac{d^2\psi}{dz^2}$  and  $(\lambda - z^2)\psi$  (see 37) is obtained. The problem is to find the set of allowed values of  $\lambda$  ensuring the existence of solutions such that  $|\psi| \rightarrow 0$  as  $|z| \rightarrow \infty$ . Such a problem is called a Sturm-Liouville problem (named after the 19th-century French mathematicians Charles-François Sturm and Joseph Liouville).

$$(26) \quad \frac{d^2x}{dt^2} - \mu(1-x^2) \frac{dx}{dt} + w^2x = 0$$

$$(27) \quad \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

$$(28) \quad \frac{\partial^2 u}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial u}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 u}{\partial \phi^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

$$(29) \quad u(\rho, \phi, z) = e^{-\xi z} \cos(\nu\phi) R(\rho)$$

$$(30) \quad \begin{cases} \frac{d^2 R}{d\rho^2} + \frac{1}{\rho} \frac{dR}{d\rho} + \left( \xi^2 - \frac{\nu^2}{\rho^2} \right) R = 0 \\ \frac{d^2 w}{dt^2} + \frac{1}{t} \frac{dw}{dt} + \left( 1 - \frac{\nu^2}{t^2} \right) w = 0 \end{cases}$$

$$(31) \quad \frac{\partial^2 v}{\partial r^2} + \frac{2}{r} \frac{\partial v}{\partial r} + \frac{1}{r^2 \sin \theta} \frac{\partial}{\partial \theta} \left( \sin \theta \frac{\partial v}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 v}{\partial \phi^2} = 0$$

$$(32) \quad \begin{cases} \frac{1}{\sin \theta} \left[ \frac{d}{d\theta} \sin \theta \frac{d\Theta}{d\theta} \right] + n(n+1)\Theta = 0 \\ (1-\mu^2) \frac{d^2 w}{d\mu^2} - 2\mu \frac{dw}{d\mu} + n(n+1)w = 0 \end{cases}$$

$$(33) \quad \frac{1}{r^2} \frac{d}{dr} r^2 \frac{dp}{dr} + 4\pi G \rho = 0$$

$$(34) \quad k^2 = 4\pi G \rho_c^{1-1/\mu} [K(1+\mu)]$$

$$(35) \quad \begin{cases} \frac{d^2 \theta}{d\xi^2} + \frac{2}{\xi} \frac{d\theta}{d\xi} + \theta^\mu = 0 \\ \theta = 1, \quad \frac{d\theta}{d\xi} = 0, \quad \xi = 0 \end{cases}$$

$$(36) \quad \frac{d^2 \psi}{dx^2} + \frac{8\pi^2 m}{h^2} (E - \frac{1}{2} kx^2) \psi = 0$$

$$(38) \quad m \frac{d^2 x}{dt^2} = f$$

Control theory. A different kind of problem involving differential equations arises in optimal control theory. In control theory attention is first of all focussed on a process; that is, some action changing with time and usually described by a differential equation or a system of differential equations. In parallel with the concept of process, controls are considered for influencing the particular process being discussed, and the objective is the result achieved by the process through a properly applied control strategy. If with respect to some criterion of performance, the strategy that is best is sought, the problem is called an optimal control problem.

A simple problem of this kind is that of driving a railroad locomotive from one station to another on the assumption that the same force is available for both starting and stopping; *e.g.*, two rocket motors pointed in opposite directions and each capable of a maximum thrust  $P$ . If the locomotive is treated as a particle of mass  $m$  and the decreases in  $m$  caused by loss of fuel and all resistance phenomena are neglected, the product of  $m$  and the second derivative of  $x$  equals  $f$  (see 38), in which  $x$  is the distance travelled by the locomotive from its starting point and  $f$  is the force applied by the rocket motors. The control is defined by the inequality  $|f| \leq P$ . As an objective, one of the following conditions could be taken:

(i) The journey must be accomplished in the minimum time.

(ii) To avoid excessive wear on components the journey must be accomplished with the minimum expenditure of energy.

(iii) The amount of rocket fuel used should be kept to a minimum.

Once one of these criteria has been decided upon, the optimal control problem consists of designing a scheme for applying  $f$  in such a way as to achieve the desired result; *i.e.*, of selecting from the set of solutions of the differential equations corresponding to all permissible forms of the one that is best.

Chemical kinetics. Simple chemical reactions can be described by first-order ordinary differential equations. A simple first-order reaction such as the decomposition of nitrogen pentoxide may be considered first. If  $c$  is the concentration of nitrogen pentoxide at time  $t$ , then the derivative of  $c$  is equal to the product of a constant  $k$ , which is called the rate constant for the reaction, and  $-c$  (see 39).

Similarly, in a second-order reaction of the type  $A + B \rightarrow A' + B'$  in which  $a$  and  $b$  are the initial concentrations of  $A$  and  $B$ , respectively, and  $x$  is the fraction of the concentration of the reaction that has been consumed at time  $t$ , the derivative of  $x$  is proportional to the product of  $(a - x)$  and  $(b - x)$  (see 40).

Reversible reactions can also be described by differential equations. For example, consider a simple reaction

of the type  $A \xrightleftharpoons[k_2]{k_1} B$ , such as the interconversion between  $\alpha$ -D-glucose and  $\beta$ -D-glucose in which  $a$  and  $b$  are the initial concentrations of  $A$  and  $B$  and  $a - x$  and  $a + x$  their values at time  $t$ . (If  $\frac{dx}{dt} = 0$  the reaction is at equilibrium.) The derivative of  $x$  is proportional to the difference of  $k_1(a - x)$  and  $k_2(b + x)$ , in which  $k_1$  and  $k_2$  are constants (see 41).

A catalytic reaction is one in which some substance, known as a catalyst, changes the reaction rate without itself suffering any permanent change. In an autocatalytic reaction a substance  $A$  is transformed to another substance  $B$ , which then acts as a catalyst for the reaction. If  $x$  is the concentration of  $B$  at time  $t$  and  $N$  is its final value, then such a process can be described by a differential equation in which  $dx/dt$  is proportional to the product of  $x$  and  $(N - x)$  (see 42).

Growth of populations. To illustrate how ordinary differential equations arise in biology, an equation arising in a simple study of the growth of populations is considered.  $p(t)$  denotes the number of inhabitants of a given area at time  $t$ , and it is assumed that in the time interval  $t$  to  $t + h$

$$(39) \quad \frac{dc}{dt} = -kc$$

$$(40) \quad \frac{dx}{dt} = k(a - x)(b - x)$$

$$(41) \quad \frac{dx}{dt} = k_1(a - x) - k_2(b + x)$$

$$(42) \quad \frac{dx}{dt} = kx(N - x)$$

$$(43) \quad \frac{dp}{dt} = (N - M)p + (I - E)$$

$$(44) \quad \frac{dp}{dt} = \epsilon p - kp^2 + (I - E)$$

$$(45) \quad \frac{dp}{dt} = p(\epsilon - kp)$$

$$(46) \quad \begin{cases} \frac{dC_A}{dt} = \frac{1}{V_A} [a_1 C_T - a_2 C_A - a_3 + \\ + (b_1 C_T - b_2)(C_T - C_A)] \\ \frac{dC_T}{dt} = \frac{1}{V_T} [R - a_1 C_T + a_2 C_A + a_3] \end{cases}$$

$$(47) \quad \begin{cases} \frac{dQ_1}{dt} = k_2 Q_2 - (k_1 + k_3) Q_1 \\ \frac{dQ_2}{dt} = k_1 Q_1 - k_2 Q_2 \end{cases}$$

$$(48) \quad f\{x, \phi(x), \phi'(x), \dots, \phi^{(n)}(x)\} = 0, \quad a \leq x \leq b$$

(i) the number of individuals born is  $Nph$ ,  
(ii) the number of individuals dying is  $Mph$ ,  
(iii) the number of individuals entering the area is  $Ih$ ,  
(iv) the number of individuals leaving the area is  $Eh$ ,  
in which  $N$ ,  $M$ ,  $I$ , and  $E$  will, in general, be functions of both  $p$  and  $t$ . The function  $p(t)$  is then determined by the fact that its first derivative is proportional to the obvious combination of these quantities (see 43).

In one population model it is assumed that  $I$  and  $E$  are constants and that  $N = n - vp$ ,  $M = m + pp$  in which  $m$ ,  $n$ ,  $\mu$ , and  $v$  are constants. If these forms are substituted into the above population equation and  $n - m = \epsilon$  and  $\mu + v = k$ , a nonlinear differential equation known as Verhulst's equation is obtained (see 44), the constant  $\epsilon$  being called the coefficient of increase and  $k$  being called the limiting coefficient.

If the population is isolated (*i.e.*, if there is neither immigration nor emigration),  $I = E = 0$ , and the equation reduces to a simpler form in which  $dp/dt$  equals the product of  $p$  and  $\epsilon - kp$  (see 45).

Physiology. Regulation of carbon dioxide in the body. An example of the occurrence of a pair of ordinary simultaneous equations in physiology is provided by a simple model of the regulation of carbon dioxide ( $\text{CO}_2$ ) in the human body. In this model it is assumed that the carbon dioxide is distributed between two compartments corresponding to the lungs and the remaining tissue and that respiration is a function of  $\text{CO}_2$  only. With further simplifying assumptions it can be shown that during respiration  $C_A$ , the alveolar (lung)  $\text{CO}_2$  concentration, and  $C_T$ , the concentration of  $\text{CO}_2$  in the tissue, are determined by the pair of simultaneous equations that relate  $\frac{dC_A}{dt}$  and  $\frac{dC_T}{dt}$  each to  $C_A$  and  $C_T$  (see 46), in which  $V_A$  and  $V_T$  are the respective volumes of the alveolar

$$(49) \quad \begin{cases} x^3 + y^3 + 3xy = 1 \\ (x + y^2)y' + x^2 + y = 0 \end{cases}$$

$$(50) \quad (y')^2 + xy' - y = 0$$

$$(51) \quad y = cx + c^2$$

$$(52) \quad y = x + 1$$

$$(53) \quad y(x) = -\frac{1}{4}x^2$$

$$(54) \quad 2(y')^3 = 3y$$

$$(55) \quad 9y^2 = 4(x - c)^3$$

$$(56) \quad \frac{d^2y}{dx^2} + \omega^2 y = 0$$

$$(57) \quad y(x) = c_1 \cos(\omega x) + c_2 \sin(\omega x)$$

$$(58) \quad y(a) = y_0, \quad y'(a) = v_0$$

and tissue compartments;  $C_I$  is the concentration of inspired carbon dioxide;  $a_1, a_2, a_3, b_1, b_2$ , are constants; and  $R$  is the rate at which carbon dioxide is formed by metabolism.

**Distribution of creatinine in the human body.** Another example taken from physiology arises in the analysis of a two-compartment model for the distribution of creatinine in the human body. The first compartment is the blood plasma; the second is not clearly identified, but there is evidence that such a compartment exists. If  $Q_1, Q_2$  denote, respectively, the quantities of creatinine in the first and second compartments, their variation is determined by a pair of linear first-order differential equations relating  $dQ_1/dt$  and  $dQ_2/dt$  to  $Q_1$  and  $Q_2$  (see 47), with rate constants  $k_1, k_2$ , and  $k_3$ .

#### TYPES OF SOLUTIONS

A relation  $y = \phi(x)$  is said to be a solution or integral of the differential equation  $f(x, y, y', \dots, y^{(n)}) = 0$  in the range  $a \leq x \leq b$  if, when substituted into the equation, it gives a result that is identically zero in that range (see 48). It is frequently difficult or undesirable to express a solution  $y$  explicitly as a function of  $x$ , but instead to have an implicit relation  $F(x, y) = 0$  between the solution  $y$  and the independent variable  $x$ . Such a relation is a solution if, when solved explicitly for  $y$  in terms of  $x$ , it yields a solution in the way described above. For example, if both sides of a polynomial equation in  $x$  and  $y$  are differentiated with respect to  $x$ , then the function  $y(x)$  determined by this implicit relation will be a solution of the differential equation thereby obtained (see 49). The simplest of all ordinary differential equations is  $y' = g(x)$ , in which  $g$  is an elementary function. An example is if  $g(x) = 2x$ . The problem of solving this differential equation is equivalent to finding a function  $y(x)$  the derivative of which is  $2x$ ; this leads to the solution  $y = x^2 + c$  in which  $c$  is an arbitrary constant. The process of integration has led to the occurrence of an arbitrary constant in the solution. It can be intuitively seen (and it can be proved rigorously) that finding the solution of a differential equation of the  $n$ th order will somehow be equivalent to performing  $n$  integrations and that the final solution  $y(x)$  will contain  $n$  arbitrary constants of integration.

Any solution of an  $n$ th order equation of the form  $y = \phi(x, c_1, c_2, \dots, c_n)$  in which  $c_1, \dots, c_n$  are arbitrary constants is called a general solution of the equation. Any solution that may be obtained from the general solution of an equation by assigning particular values to the constants is called a particular solution of that

equation. It sometimes happens that a nonlinear differential equation has a solution that cannot be obtained by assigning specific values to the arbitrary constants in the general solution. Such a solution is called a singular solution of the differential equation.

For example, a particular nonlinear differential equation (see 50) has a general solution that is linear in the independent variable (see 51) with an arbitrary constant  $c$ . A particular solution may be obtained from (51) by taking  $c = 1$  (see 52). On the other hand, a function proportional to  $x^2$  (see 53) also satisfies the differential equation. Because this solution cannot be obtained from the general solution by assigning a particular value to  $c$ , it is a singular solution of the differential equation (50). In this instance the graphs of the functions defined by (51) are straight lines and the graph of the function defined by (53) is a parabola that is the envelope of that family of straight lines (cf. Figure 2).

Similarly, a nonlinear equation with the cube of the derivative proportional to  $y$  (see 54) has a general solution with  $y^2$  proportional to  $(x - c)^3$  (see 55), and the singular solution  $y = 0$ . Here the general solution is represented by a family of semicubical parabolas, and the singular solution is the line that passes through the cusp of each member of the family (cf. Figure 3). Such a line is called a cusp locus.

Figure 2: Graphs of functions defined by straight lines and a parabola that is the envelope of that family of straight lines (see text).

It has been pointed out above that the solution of problems in physics or engineering is equivalent to that of finding solutions of differential equations satisfying certain additional conditions. To illustrate the kind of problem arising in this way, the following equation may be considered: with the product of a constant,  $w^2$ , and the function  $y$  being added to the second derivative of  $y$  to give a result of zero (see 56). Its general solution is found to be the product of a constant,  $c_1$ , and a cosine, added to the product of another constant,  $c_2$ , and a sine (see 57). The solution corresponds to the conditions of  $y$  and its derivative at some point  $a$  being set equal to  $y_0$  and  $v_0$ , respectively (see 58), in which  $a, y_0, v_0$  are prescribed real numbers, is obtained by choosing  $c_1$  and  $c_2$  to satisfy the linear algebraic equations obtained by setting the general solution at  $a$  equal to  $y_0$  while its derivative is set

Boundary-value problems

Use of arbitrary constants

Figure 3: A family of semicubical parabolas, representing a general solution, and a singular solution, which is the line that passes through the cusp of each member of the family (see text).

equal to  $v_0$  (see 59). The solution corresponding to the conditions of  $y$  at two different points  $a$  and  $b$  being set equal to constants  $y_0$  and  $y_1$ , respectively (see 60), is obtained by choosing  $c_1$  and  $c_2$  to satisfy the linear equations obtained by setting the general solution at  $a$  and  $b$  equal to  $y_0$  and  $y_1$ , respectively (see 61).

Problems of this kind are called boundary value problems; the problem posed by equations (56) and (58) is called a one-point boundary value problem or an initial value problem, while that posed by equations (56) and (60) is called a two-point boundary value problem.

Another kind of problem can be exemplified by reference to equation (56). It may be stated as a question: Do there exist real values of  $\omega$  such that the equation (56) has nonzero solutions satisfying the boundary conditions  $y(0) = y_0$  ( $\neq 0$ )? That there are real values of  $\omega$  follows immediately from the fact that, if  $n$  is an integer, then the function  $y = \sin(n\pi x/a)$  satisfies these boundary conditions and the differential equation considered above, with  $\omega = n\pi/a$  (see 62). Hence,  $\pm n\pi/a$ ,  $n = 1, 2, 3, \dots$ , are possible values of  $\omega$ . A problem of this kind is called an eigenvalue problem or a Sturm-Liouville problem.

#### EXISTENCE AND UNIQUENESS OF SOLUTIONS

From the geometrical interpretation of the derivative of a function, it is tempting to assume that the initial value problem consisting of a differential equation and the value  $y_0$  of the function  $y$  at some point  $a$  (see 63) has a unique solution through each point  $(a, y_0)$  of the  $xy$ -plane. It is a simple matter, however, to construct differential equations that do not have a solution at all at a specific point and others that have more than one solution—often an infinite number—at a point. For this reason it is necessary to study sufficient conditions for the existence and uniqueness of solutions of the initial value problem (see 63). The proof of the classic theorem in this area depends on the fact that any solution of the initial value problem (63) satisfies the integral equation given by formally integrating both sides of the differential equation, the constant of integration being  $y_0$  (see 64). Conversely, any solution of this integral equation is a solution of the initial value problem (63).

To state the fundamental result, the following concept is required: a function  $f(x, y)$  is said to satisfy a Lipschitz condition with respect to  $y$  in a region  $D$  of the  $xy$ -plane if there exists a constant  $K$  such that the magnitude of the difference between  $f(x, y_1)$  and  $f(x, y_2)$  is less than or equal to  $K$  times the magnitude of the difference between  $y_1$  and  $y_2$  (see 65), for every pair of points  $(x, y_1)$ ,  $(x, y_2)$  belonging to  $D$ . The condition is named after a 19th-century German mathematician, Rudolf Lipschitz.

The basic theorem states: If  $f(x, y)$  is continuous and satisfies a Lipschitz condition with respect to  $y$  in some region  $D$  of the  $xy$ -plane and if  $(a, y_0)$  is any point in this region, then the initial value problem (63) has a unique solution.

It turns out that continuity of  $f$  is sufficient to guarantee existence and that it is the Lipschitz condition on  $f$  that ensures uniqueness.

By generalizing the Lipschitz condition (see 65) to the case in which both  $f$  and  $y$  are  $n$ -vectors and  $D$  is a region of the  $xy$ -space (of dimension  $n + 1$ ), the theorem can be established for a vector differential equation (see 63). Now any differential equation of order  $n$  can be written as a first-order equation for an  $n$ -vector. For example, the initial value problem posed by equations (56)

The Lipschitz condition

$$(59) \quad \begin{cases} c_1 \cos(\omega a) + c_2 \sin(\omega a) = b \\ -c_1 \sin(\omega a) + c_2 \cos(\omega a) = v_0 \end{cases}$$

$$(60) \quad y(a) = y_0, \quad y(b) = y_1$$

$$(61) \quad \begin{cases} c_1 \cos(\omega a) + c_2 \sin(\omega a) = y_0 \\ c_1 \cos(\omega b) + c_2 \sin(\omega b) = y_1 \end{cases}$$

$$(62) \quad \frac{d^2 y}{dx^2} + \frac{n^2 \pi^2}{a^2} y = 0$$

$$(63) \quad \frac{dy}{dx} = f(x, y), \quad y(a) = y_0$$

$$(64) \quad y(x) = y_0 + \int_a^x f\{t, y(t)\} dt$$

$$(65) \quad |f(x, y_1) - f(x, y_2)| \leq K |y_1 - y_2|$$

$$(66) \quad \frac{dz}{dx} = Az, \quad z(a) = z_0$$

$$(67) \quad z = \begin{bmatrix} y \\ y' \end{bmatrix}, \quad A = \begin{bmatrix} 0 & 1 \\ -\omega^2 & 0 \end{bmatrix}, \quad z_0 = \begin{bmatrix} y_0 \\ v_0 \end{bmatrix}$$

$$(68) \quad n = n_0 e^{-\lambda t}$$

$$(69) \quad x = c_1 + c_2 t, \quad y = c_3 + c_4 t - \frac{1}{2} g t^2$$

$$(70) \quad y = a \cosh(x/a)$$

$$(71) \quad \sum_{r=0}^{\infty} \frac{(-1)^r (\frac{1}{2}x)^{2r+\nu}}{r!(\nu+1)_r}$$

$$(72) \quad \sum_{r=0}^{\infty} \frac{(\frac{1}{2}n + \frac{1}{2})_r (\frac{1}{2}n + 1)_r}{r!(n + \frac{3}{2})_r} x^{-2r-n-1}$$

$$(73) \quad \sum_{r=0}^{\lfloor \frac{1}{2}n \rfloor} \frac{(\frac{1}{2} - \frac{1}{2}n)_r (-\frac{1}{2}n)_r}{r!(\frac{1}{2} - n)_r} x^{n-2r}$$

$$(74) \quad \sum_{r=0}^{\infty} \frac{(-n)_r (n+1)_r}{r!r!} \left(\frac{1-x}{2}\right)^r$$

and (58) can be written in the form of an initial value problem for a first-order equation (see 66), but in this case  $z$ ,  $A$ ,  $z_0$  denote matrices (see 67). The existence theorem for an  $n$ th-order equation can therefore be deduced from that for a first-order equation in which the independent variable is an  $n$ -vector.

#### FORMS OF SOLUTIONS

**Closed form solutions.** In many cases it is possible to express the solution of a differential equation by a simple formula. For example, if the derivative of  $n$  is proportional to  $-n$ , then the general solution is an arbitrary

constant  $n_0$  times a negative exponential (see 68). The pair of equations describing motion in a gravitational field has as the general solution for  $x$  a linear function and for  $y$  a quadratic (see 69), with arbitrary constants  $c_1$ ,  $c_2$ ,  $c_3$ , and  $c_4$ . Similarly, the solution of the equation for a catenary satisfying the initial conditions  $y = a$ ,  $dy/dx = 0$  at  $x = 0$  is a hyperbolic cosine (see 70).

**Series solutions.** Often when it is not possible to find a closed form solution, it is a simple matter to find a solution in the form of an infinite series. This form of solution is particularly appropriate to the solution of second-order linear equations. For example, Bessel's equation has a series solution in powers of  $x/2$  (see 71), in which the symbol  $(\nu + 1)_r$  denotes the product  $(\nu + 1)(\nu + 2) \dots (\nu + r)$ . Similarly, Legendre's equation has a solution in the form of descending powers of  $x$  that is valid only if  $|x| > 1$  (see 72). The same equation has a power series solution valid if  $|x| < 1$  (see 73), and a series

Power  
series

solution in powers of  $\frac{1-x}{2}$  that is valid for  $-1 < x < 3$  (see 74). It will be noted that in the case in which  $n$  is a positive integer, each of the last two series reduces to a polynomial of degree  $n$  in  $x$ .

**Integral forms.** In a similar way, the solution of a differential equation can be expressed in the form of an integral that cannot be expressed in terms of elementary functions. For example, the solution of equation (3) satisfying the initial conditions  $\theta = \alpha$ ,  $d\theta/dt = 0$  when  $t = 0$  may be expressed by an equation involving an integral of a linear combination of a cosine to the  $-1/2$  power (see 75). The integral on the left side of this equation cannot be expressed in terms of elementary functions. Similarly, Bessel's equation of order 0 has the solution as the integral of an expression involving exponential and square roots (see 76).

**Approximations.** In many cases it is not possible to derive the solution of a differential equation in any of the above forms and recourse has to be made to approximate methods.

**Iteration method.** In dealing with initial value problems one of the simplest ways of obtaining an approximate solution is to solve the integral equation discussed earlier (see 64) by iteration; i.e., to construct a sequence of approximations  $y_1(x)$ ,  $y_2(x)$ ,  $\dots$ ,  $y_n(x)$  by the scheme of substituting an approximation for  $y$  into the integral equation and obtaining as the result a better approximation and repeating the process (see 77). It can be proved that, if the conditions of the existence-uniqueness theorem are satisfied, this sequence will converge to the correct solution. By taking the  $n$ th iterate, an approximate solution of the initial value problem is obtained.

For example, for the initial value problem for a certain first-order nonlinear differential equation (see 78), a sequence of approximations that are partial sums of a power series (see 79) are given.

**Taylor series method.** In theory this method is applicable to an equation of any order. As an example, the initial value problem for a second-order differential equation (see 80) is considered. First of all  $y''(a) = f(a, y_0, y_1)$  is calculated. The given equation is differentiated with respect to  $x$  (see 81). This is evaluated at  $a$  to yield the value of  $y'''(a)$ . By successive differentiation  $y^{(n)}(a)$  can be found for  $n = 3, 4, 5, \dots$  and an approximation to the value of  $y(a + h)$  can be found from the truncated Taylor series (see 82). The process is then repeated at the point  $x = a + h$ , and so on.

**The Runge-Kutta methods.** To indicate the methods due to the German mathematicians Carl David Tolmé Runge (1895) and William Martin Kutta (1901), the initial value problem (63) is considered. In these methods the Taylor expansion is used indirectly:  $y(a + h)$  is calculated (see 83) in terms of  $y(a)$ , the function  $f(x, y)$ , and constants  $a_0, \dots, a_p$ ,  $b_0, \dots, b_p$ ,  $c_0, \dots, c_p$ , which are chosen in such a way that, when the expression is expanded for  $y(a + h)$  in ascending powers of  $h$ , the coefficients agree with those of the Taylor expansion for  $y(a + h)$ .

For example, if  $p = 1$  is taken, a formula involving two values of  $f(x, y)$  is obtained (see 84). In this formula

$$(75) \quad \int_{\theta}^{\alpha} \frac{d\phi}{\sqrt{(\cos\phi - \cos\alpha)}} = \frac{2g}{a} t$$

$$(76) \quad \int_1^{\infty} \frac{e^{-zt} dt}{\sqrt{(t^2 - 1)}}$$

$$(77) \quad y_{r+1}(x) = y_0 + \int_a^x f\{t, y_r(t)\} dt, \quad y_0(x) = y_0$$

$$(78) \quad \frac{dy}{dx} = 1 + x^2 y^2, \quad y(0) = 0$$

$$(79) \quad x, \quad x + \frac{1}{5}x^5, \quad x + \frac{1}{5}x^5 + \frac{2}{45}x^9 + \frac{1}{325}x^{13}, \dots$$

$$(80) \quad y'' = f(x, y, y'), \quad y(a) = y_0, \quad y'(a) = y_1$$

$$(81) \quad y''' = \frac{\partial f}{\partial x} + \frac{\partial f}{\partial y} y' + \frac{\partial f}{\partial y'} y''$$

$$(82) \quad y(a+h) = y_0 + y_1 + \frac{1}{2}y''(a)h + \dots + \frac{1}{n!}y^{(n)}(a)h^n$$

$$(83) \quad y(a+h) = y(a) + h \sum_{k=0}^p a_k f(a + b_k h, y_0 + c_k h)$$

$$(84) \quad y(a+h) = y(a) + (1-c)hf(a, y_0) + \\ + chf\left(a + \frac{h}{2c}, y_0 + \frac{k_0}{2c}\right)$$

$$(85) \quad y_{r+1} = y_r + (1-c)k_r + cm_r$$

$$(86) \quad \frac{dy}{dx} = f(x, y)$$

$$(87) \quad \frac{dy}{dx} = f(x)g(y)$$

$$(88) \quad y \frac{dy}{dx} = xy + x$$

$$(89) \quad \int \frac{dy}{g(y)} = \int f(x) dx + c$$

$$(90) \quad \int \frac{y dy}{y+1} = \int x dx + c$$

$$(91) \quad \frac{dy}{dx} = g\left(\frac{y}{x}\right)$$

$$(92) \quad x \frac{dv}{dx} + v = g(v)$$

$k_0 = hf(a, y_0)$ , and  $c$  is any nonzero real number. The numerical solution of the initial value problem (63) can be generated by repeated applications of this relationship. If  $x_r = a + rh$ ,  $y_r = y(a + rh)$ ,  $k_r = hf(x_r, y_r)$ , and  $m_r = hf(x_r + h/2c, y_r + k_r/2c)$ , ( $c \neq 0$ ), then  $y_{r+1}$  can be calculated from  $y_r$ ,  $k_r$ ,  $m_r$ , and  $c$  (see 85). This is known as the Runge-Kutta second-order process. More elaborate schemes can, of course, be derived by taking a higher value of  $p$ .

#### FIRST-ORDER EQUATIONS

When first-order equations of the first degree are solved for the derivative, they are of a form in which the derivative  $y'$  equals  $f(x, y)$ , an explicit function of  $x$  and  $y$  (see 86). There are certain distinguishable types of such equations that may be easily solved and that are now discussed briefly.

**Equations with separable variables.** If the derivative can be expressed as the product of  $f(x)$  and  $g(y)$  (see 87), in which  $f(x)$  is a function of  $x$  alone and  $g(y)$  is a function of  $y$  alone, it is said to have its variables separable. For example, the nonlinear equation in which the product of  $y$  and its derivative equals the sum of  $xy$  and  $x$  (see 88) has its variables separable. The general solution of such an equation is obtained by moving the expressions involving  $x$  to one side of the equation and those involving  $y$  to the other, and then integrating both sides (see 89), involving  $c$ , as arbitrary constant. For example, the equation just considered (see 88) has general solution in terms of an integral of  $y$  divided by  $y + 1$  and an integral of  $x$  (see 90).

These integrals can be evaluated, giving the result that  $y - \log(y + 1) = x^2/2 + c$ .

**Homogeneous equations.** A differential equation in which the derivative  $dy/dx$  equals  $g(y/x)$ , in which  $g$  is a function of  $y/x$  alone (see 91), is said to be homogeneous. Such an equation is reduced to separable form (see 92) by the substitution  $y = xu$ . For example, the equation in which  $dy/dx$  equals  $2y^2 + x^2$  divided by  $xy$  (see 93) is homogeneous; the substitution  $y = xv$  reduces it to the separable form as a differential equation with  $v$  as the dependent variable (see 94). It is possible to obtain the solution of this differential equation by certain integrations (see 95), in which  $k$  is an arbitrary constant. Performing the integrations, the general solution is obtained in terms of logarithms (see 96), in which  $c$  is an arbitrary constant; ( $2k = \log c$ )—i.e., the sum of  $v^2$  and one equals  $cx^2$  (see 97). Returning to the original variables, the sum of  $x^2$  and  $y^2$  equals  $cx^4$  (see 98), which is the general solution of equation (93).

**Exact equations.** If there exists a function  $\psi(x, y)$  such that the partial derivative of  $\psi$  with respect to  $x$  equals  $P(x, y)$ , and the partial derivative of  $\psi$  with respect to  $y$  equals  $Q(x, y)$  (see 99), the differential equation formed by the sum of  $P(x, y)$  and the product of  $Q(x, y)$  and  $y'$  being equal to zero (see 100) is said to be exact. The reason for this is that the function  $y(x)$  defined by  $\psi(x, y)$  being equal to an arbitrary constant  $c$  (see 101) has a derivative  $y'$  that satisfies the equation obtained by differentiating  $\psi(x, y)$  with respect to  $x$  by the chain rule (see 102).

Hence, because of these relations (see 99), the differential equation (100) follows. It is obvious from equations (99) that a necessary condition for the equation (100) to be exact is that the partial derivative of  $P(x, y)$  with respect to  $y$  equals the partial derivative  $Q(x, y)$  with respect to  $x$  (see 103); it can also be shown that this condition is sufficient. For example, a nonlinear differential equation with exponential coefficients (see 104) is exact because the partial derivative with respect to  $x$  of the coefficient of  $y'$  equals the partial derivative with respect to  $y$  of the rest of the equation (see 105). It has the general solution in implicit form with an arbitrary constant (see 106). Instead of saying that the equation (100) is exact,  $P(x, y)dx + Q(x, y)dy$  is sometimes termed an exact differential.

**Integrating factors.** Although a differential equation may not be exact in the form in which it is encountered, it has been proved that it may be made exact by multipli-

$$(93) \quad \frac{dy}{dx} = \frac{2y^2 + x^2}{xy} = \frac{2(y/x)^2 + 1}{(y/x)}$$

$$(94) \quad x \frac{dv}{dx} + v = \frac{2v^2 + 1}{v}$$

$$(95) \quad \int \frac{v dv}{v^2 + 1} = \int \frac{dx}{x} + k$$

$$(96) \quad \log(v^2 + 1) = 2 \log x + \log c$$

$$(97) \quad v^2 + 1 = cx^2$$

$$(98) \quad x^2 + y^2 = cx^4$$

$$(99) \quad \frac{\partial \psi}{\partial x} = P(x, y), \quad \frac{\partial \psi}{\partial y} = Q(x, y)$$

$$(100) \quad P(x, y) + Q(x, y)y' = 0$$

$$(101) \quad \psi(x, y) = c$$

$$(102) \quad \frac{\partial \psi}{\partial x} + \frac{\partial \psi}{\partial y} y' = 0$$

$$(103) \quad \frac{\partial P}{\partial y} = \frac{\partial Q}{\partial x}$$

$$(104) \quad 2e^x y y' + y^2 e^x - 1 = 0$$

$$(105) \quad \frac{\partial}{\partial y} (y^2 e^x - 1) = \frac{\partial}{\partial x} (2e^x y)$$

$$(106) \quad y^2 e^x - x = c$$

$$(107) \quad 2xy' + 3y = 0$$

$$(108) \quad 2yy'x^3 + y^2 \cdot 3x^2 = 0$$

$$(109) \quad \frac{\partial}{\partial y} (\mu P) = \frac{\partial}{\partial x} (\mu Q)$$

$$(110) \quad \frac{1}{Q} \left( \frac{\partial P}{\partial v} - \frac{\partial Q}{\partial x} \right) = g(x)$$

$$(111) \quad \frac{\mu'(x)}{\mu(x)} = g(x)$$

$$(112) \quad \mu(x) = \exp \left\{ \int g(x) dx \right\}$$

$$(113) \quad y' + a(x)y = b(x)$$

$$(114) \quad \mu(x) = \exp \left\{ \int a(x) dx \right\}$$

$$(115) \quad \begin{cases} xy' + (x^2 + 1)y = x \\ a(x) = x + x^{-1} \end{cases}$$

$$(116) \quad \begin{cases} \mu = \exp \left[ \int (x + x^{-1}) dx \right] \\ = \exp \left[ \frac{1}{2} x^2 + \log x \right] = x e^{\frac{1}{2} x^2} \end{cases}$$

$$(117) \quad \frac{d}{dx} [x e^{\frac{1}{2} x^2} y] = x e^{\frac{1}{2} x^2}$$

$$(118) \quad y = x^{-1} + c x^{-1} e^{-\frac{1}{2} x^2}$$

$$(119) \quad y' + a(x)y = b(x)y^n$$

$$(120) \quad z' - (n-1)a(x)z = -(n-1)b(x)$$

$$(121) \quad z = y^{1-n}$$

$$(122) \quad y' = a(x)y^2 + b(x)y + c(x)$$

$$(123) \quad z' + (2af + b)z + a = 0$$

$$(124) \quad y = c + \int \frac{pdp}{(1+p^2)^{\frac{3}{2}}} = c - (1+p^2)^{-\frac{1}{2}}$$

$$(125) \quad x^2 + (y-c)^2 = 1$$

$$(126) \quad y = xy' + f(y')$$

$$(127) \quad [x + f'(p)] \frac{dp}{dx} = 0$$

$$(128) \quad y = cx + f(c)$$

$$(129) \quad x = -f'(p), \quad y = f(p) - pf'(p)$$

$$(130) \quad P_n(x)y^{(n)} + P_{n-1}(x)y^{(n-1)} + \cdots + P_1(x)y' + P_0(x)y = f(x)$$

$$(131) \quad P_n(x)D^n + P_{n-1}(x)D^{n-1} + \cdots + P_1(x)D + P_0(x)$$

$$(132) \quad a_1 y_1(x) + a_2 y_2(x) + \cdots + a_n y_n(x) = 0$$

$$(133) \quad y(x) = c_1 y_1(x) + \cdots + c_n y_n(x) + Y(x)$$

$$(134) \quad W(y_1, \dots, y_n) = \begin{vmatrix} y_1(x) & \cdots & y_n(x) \\ y_1'(x) & \cdots & y_n'(x) \\ \vdots & & \vdots \\ y_1^{(n-1)}(x) & \cdots & y_n^{(n-1)}(x) \end{vmatrix}$$

$$(135) \quad \Pi_n(D)y = f(x)$$

$$(136) \quad \Pi_n(t) = p_n t^n + p_{n-1} t^{n-1} + \cdots + p_1 t + p_0, \quad (p_n \neq 0)$$

$$(137) \quad c_1 e^{\lambda_1 x} + c_2 e^{\lambda_2 x} + \cdots + c_n e^{\lambda_n x}$$

cation by a suitable factor. Such a multiplier is called an integrating factor. For example, the equation formed by the sum of  $2xy'$  and  $3y$  being equal to zero (see 107) is not exact, but multiplying throughout by  $x^2y$  gives an equation (see 108) that is exact and has general solution  $y^2x^3 = c$ .

If both sides of equation (100) are multiplied by  $\mu(x, y)$  and the exactness condition (103) is used, then  $\mu$  will be an integrating factor of the equation if, and only if, it satisfies the condition that the partial derivative of  $\mu P$  with respect to  $y$  equals the partial derivative of  $\mu Q$  with respect to  $x$  (see 109). For example, the general first-order differential equation being considered (100) will possess an integrating factor  $\mu(x)$  if, and only if, the difference of the partial derivative of  $P$  with respect to  $y$  and that of  $Q$  with respect to  $x$ , divided by  $Q$ , equals  $g(x)$ , a function of  $x$  alone (see 110), and then  $\mu$  may be taken to be any solution of the equation given by  $g(x)$  being equal to  $\mu'(x)$  divided by  $\mu(x)$  (see 111); i.e.,  $\mu(x)$  is an exponential (see 112).

**Linear equations.** If the above procedure is applied to the linear first-order equation with the coefficient of  $y$  being  $a(x)$  and the inhomogeneous term being  $b(x)$  (see

113), it is found to have an integrating factor  $\mu(x)$  equal to an exponential with the integral of  $a(x)$  in the exponent (see 114).

For example, if the sum of  $xy'$  and  $(x^2 + 1)y$  equals  $x$  (see 115), then  $\mu(x)$  is equal to the product of  $x$  and an exponential with exponent  $x^2/2$  (see 116). The equation can be written as the derivative of the product of  $\mu(x)$  and  $y$  being equal to  $\mu(x)$  (see 117). Integrating and dividing by  $xe^{x^2/2}$  yields the general solution in terms of  $x^{-1}$ , an exponential, and an arbitrary constant  $c$  (see 118).

**Bernoulli's equation.** Bernoulli's equation, in which the sum of  $y'$  and  $a(x)y$  equals  $b(x)y^n$  (see 119), may be reduced to a linear equation with variable coefficients (see 120) in the new independent variable  $z$ . This independent variable,  $z$ , is defined as being equal to  $y$  to the  $(1-n)$  power (see 121).

**Riccati's equation.** If any solution  $f(x)$  can be found for Riccati's equation, in which  $y'$  equals a quadratic function of  $y$ , with coefficients  $a(x)$ ,  $b(x)$ , and  $c(x)$  of the quadratic, linear, and constant terms, respectively (see 122), then by the substitution  $y = f(x) + z^{-1}$  the problem of finding the general solution of Riccati's equation can be reduced to that of finding the general solution of the first-order linear equation with the coefficient of  $z$  being  $2af + b$  and the constant term being  $a$  (see 123). This applies no matter how trivial  $f(x)$  is.

**Equations of higher degree.** So far the treatment has been limited to equations that are of the first order as well as the first degree. If  $p$  is written for  $y'$ , the general first-order equation will be of the form  $F(x, y, p) = 0$  in which  $F$  is not linear in  $p$ . When an equation of either of the forms  $F(x, p) = 0$  or  $G(y, p) = 0$  is solvable for  $p$ ,  $p = f(x)$  or  $p = g(y)$ , integration is immediate.

On the other hand, if  $x = \phi(p)$ ,  $y$  can be found by the formula  $y = c + \int p dx = c + \int p \phi'(p) dp$ ; and the general solution may be obtained by eliminating  $p$  from this last equation and  $x = \phi(p)$ . A similar procedure also holds if  $Y = \psi(p)$ .

For example, if  $x^2 = p^2(1 - x^2)$ , then  $x = ap(1 + p^2)^{-1/2}$  so that  $y$  can be written as the sum of an arbitrary constant  $c$  and the integral of a function of  $p$  (see 124). Eliminating  $p$  from these two relations gives the general solution, in which the sum of  $x^2$  and  $0, -c^2$  equals 1 (see 125).

**Clairaut's equation.** The differential equation in which  $y$  equals the sum of the product of  $x$  and  $y'$  and  $f(y')$  (see 126), in which  $f$  is a prescribed function of  $y'$  alone, is called Clairaut's equation. Writing  $p = y'$  and differentiating both sides of this equation with respect to  $x$  leads to the product of  $dp/dx$  and  $x + f'(p)$  being equal to zero (see 127), so that either  $dp/dx = 0$  or else  $x + f'(p) = 0$ .

The first alternative yields the general solution (see 128) in which  $y$  is a linear function of  $x$ , and the second alternative yields the solution obtained by eliminating  $p$  from a pair of equations (see 129); if  $f(p)$  is not a linear function of  $p$ , the result will be a singular solution of the given differential equation.

#### LINEAR DIFFERENTIAL EQUATIONS

**Equations of  $n$ th order.** A linear differential equation of order  $n$  is an equation involving  $y$  and its derivatives linearly, the coefficient of  $y'$  being  $P$ , and the inhomogeneous term being  $f(x)$  (see 130), in which  $P, \dots, P_0, f$  are given functions of  $x$ , and  $P_n(x)$  does not vanish identically. The linear differential equation obtained from equation (130) by replacing  $f(x)$  by 0 is called the homogeneous equation corresponding to the nonhomogeneous equation (130). For example, Bessel's equation and Legendre's equation are linear equations of the second order and of homogeneous type.

If the differential operator  $d/dx$  is denoted by  $D$  and if  $L$  is written for the operator formed by the sum of terms of the form  $P_i D^i$  (see 131), then equation (130) may be written in the form  $Ly = f(x)$  and the corresponding homogeneous equation in the form  $Ly = 0$ .

Functions  $y_1(x), \dots, y_n(x)$  are said to be linearly independent solutions of the homogeneous equation  $Ly = 0$  if  $Ly_r(x) = 0, r = 1, 2, \dots, n$ , and if the functions are

Homogeneous and nonhomogeneous equations

such that there does not exist a set of constants  $a_1, a_2, \dots, a_n$ , not all of which are zero, such that, for all values of  $x$ , the sum of the terms  $a_j y_j(x)$  is equal to zero (see 132).

The basic result in the theory of linear differential equations is that if  $y_1, y_2, \dots, y_n$  are  $n$  linearly independent solutions of  $Ly = 0$  and if  $Y(x)$  is any solution of equation (130), then the general solution of (130) is  $Y(x)$  added to a sum of terms of the form  $c_j y_j(x)$  (see 133), in which  $c_1, \dots, c_n$  are arbitrary constants.

The general solution of a linear differential equation is therefore the sum of two parts:  $c_1 y_1(x) + \dots + c_n y_n(x)$ , which is called the complementary function, and  $Y(x)$ , which is called a particular integral. To determine whether or not a set of functions is linearly independent, the following criterion is used: a necessary and sufficient condition that  $y_1(x), \dots, y_n(x)$  are linearly independent is that the Wronskian  $W$ , defined as the determinant of the matrix formed by the  $n$  linearly independent solutions and their first  $n - 1$  derivatives (see 134), is not identically zero.

**Equations with constant coefficients.** There is a simple theory of linear equations of the type (130) in which  $P_r(x) = p_r$ , a constant, ( $r = 0, 1, \dots, n$ ). Such equations can be written in the form of an expression  $\Pi_n(D)y$  set equal to  $f(x)$  (see 135), in which  $\Pi_n(t)$  denotes the polynomial defined as the sum of terms of the form  $p_j t^j$  (see 136).

The form of the complementary function depends on the zeros of the polynomial  $\Pi_n$ . If  $\Pi_n(t)$  has  $n$  distinct zeros  $\lambda_1, \lambda_2, \dots, \lambda_n$ , the complementary function of the equation (135) is in the form of a sum of terms  $c_j \exp(\lambda_j x)$  (see 137) in which, as before,  $c_1, c_2, \dots, c_n$  denote arbitrary constants. Some of the zeros may, of course, be complex; but, if the coefficients  $p_1, \dots, p_n$  are real, then complex zeros when they do occur will occur in complex pairs.

For example, if  $\lambda_1 = \mu_1 + i\omega_1$ , then there will be another zero, which may be labelled  $\lambda_2$ , of the form  $\lambda_2 = \mu_1 - i\omega_1$ ; the linearly independent solutions  $\exp(\lambda_1 x)$ ,  $\exp(\lambda_2 x)$  may be replaced by  $\exp(\mu_1 x) \cos(\omega_1 x)$ ,  $\exp(\mu_1 x) \sin(\omega_1 x)$ . Putting this another way, it can be said that, if  $\Pi_n(t)$  contains the simple quadratic factor  $(t - \mu_1)^2 + \omega_1^2$ , then the complementary function contains the corresponding terms that are products of the exponential  $\exp(\mu_1 x)$  and a linear combination of the sine and cosine of  $\omega_1 x$  (see 138).

On the other hand, if  $\lambda_1$  is a multiple root, of order  $m$ , say—i.e., if  $\Pi_n(t)$  has a factor  $(t - A)^m$ —the complementary function contains the terms  $(c_1 x + c_2 x^2 + \dots + c_m x^{m-1}) \exp(\lambda_1 x)$ . Similarly, if  $\Pi_n(t)$  has a factor of the form  $[(t - \mu_1)^2 + \omega_1^2]^m$ , there are  $2m$  terms of the analogous form involving  $\exp(\mu_1 x) \cos(\omega_1 x)$  and  $\exp(\mu_1 x) \sin(\omega_1 x)$  (see 139) in the complementary function.

In many practical cases it is possible to obtain a particular integral  $Y(x)$  by inspection. When this cannot be done, the Laplace transform is used. Because for  $Y(x)$  any solution (see 135) may be taken, it is only necessary to find the solution  $Y(x)$  of that equation satisfying the conditions of  $Y(x)$  and its first  $n - 1$  derivatives at  $x = 0$  being equal to zero (see 140). If a function  $\phi(x)$  is defined for all positive real values of  $x$ , its Laplace transform is defined as the result of multiplying the function by  $e^{-px}$  and integrating from  $x = 0$  to infinity (see 141). When  $\mathfrak{L}[\phi(p)]$  is the Laplace transform of  $\phi(x)$ ,  $\phi(x)$  is said to be the inverse Laplace transform of  $\mathfrak{L}[\phi(p)]$  and  $\phi(x) = \mathfrak{L}^{-1}[\phi(p); x]$ .

To apply the Laplace transform to the solution of equations of the type (135), a formula is used expressing the Laplace transform of the derivative of a function in terms of the Laplace transform of the function itself. If the function  $Y(x)$  satisfies the conditions (140), it is found that if  $m = 1, 2, \dots, n$  and  $\mathfrak{L}[Y(p)]$  denotes the Laplace transform of  $Y(x)$ , then the Laplace transform of the  $m$ th derivative of  $Y(x)$  is the product of  $p^m$  and  $\mathfrak{L}[Y(p)]$  (see 142). Taking the Laplace transform of both sides of equation (135), it is found that  $\mathfrak{L}[Y(p)]$  satisfies the simple algebraic equation  $\Pi_n(p)\mathfrak{L}[Y(p)] = \mathfrak{L}[f(p)]$  in which  $\mathfrak{L}[f(p)]$  denotes the Laplace transform of  $f(x)$ .

For the particular integral, this equation may be solved for  $Y(p)$  and the inverse Laplace transform (see 143) taken.

**Linear equations of the second order.** The general theory of linear differential equations will be illustrated by examples of equations of the second order  $Ly = f(x)$ , in which  $L$  denotes the operator  $p(x)D^2 + q(x)D + r(x)$ .

A homogeneous equation  $L_y = 0$  is said to be exact if it can be written in the form  $DM = 0$  in which  $M$  is a first-order linear differential operator of the form  $p(x)D + s(x)$ . The equation  $L_y = 0$  can be integrated once to give a first-order linear equation in which  $M_y$  is equal to an arbitrary constant  $c_1$  (see 144), which can in turn be integrated by the method described above for the solution of equation (113); this will, of course, involve a second arbitrary constant  $c_2$ . This equation (144) is called a first integral of the original second-order equation. The equation  $py'' + qy' + ry = 0$  is exact if, and only if,  $p'' - q' + r = 0$  for all values of  $x$ , in which case  $s(x) = q(x) - p'(x)$ .

If the equation  $L_y = 0$  is not exact, but there exists a function  $z(x)$  such that  $zLy = 0$  is exact,  $z$  is said to be an integrating factor of  $L_y = 0$ . From the condition for a second-order equation to be exact it is easily deduced that  $z$  is an integrating factor if it is a solution of the equation  $L^*z = 0$  in which the operator  $L^*$  is defined in terms of differentiation (see 145) and is called the adjoint of  $L$ . If  $L^* = L$ , the operator  $L$  is said to be self-adjoint; the condition for this is that  $q(x) = p'(x)$ .

The two standard methods of solving a second-order equation are based on writing the solution in the form  $y = uv$  in which  $u$  is a prescribed function of  $x$  and  $v$  is the new dependent variable.

If  $u$  is chosen to be any solution of the first-order equation  $2pu' + qu = 0$ , the resulting equation for  $v$  is of the form  $v'' + P(x)v = 0$ , and the general solution of this equation may be known. This procedure is known as reducing the equation to normal form, or as removing the first derivative.

The two standard methods of solution

$$(138) \quad e^{\mu_1 x} (c_1 \cos \omega_1 x + c_2 \sin \omega_1 x)$$

$$(139) \quad (c_1 + \dots + c_m x^{m-1}) e^{\mu_1 x} \cos(\omega_1 x) + (c_{m+1} + \dots + c_{2m} x^{m-1}) e^{\mu_1 x} \sin(\omega_1 x)$$

$$(140) \quad Y(0) = Y'(0) = \dots = Y^{(n-1)}(0) = 0$$

$$(141) \quad \overline{\phi}(p) \equiv \mathfrak{L}[\phi(x); p] = \int_0^\infty \phi(x) e^{-px} dx$$

$$(142) \quad \mathfrak{L}[Y^{(m)}(x); p] = p^m \overline{Y}(p)$$

$$(143) \quad Y(x) = \mathfrak{L}^{-1} \left[ \frac{\overline{f}(p)}{\Pi_n(p)}; x \right]$$

$$(144) \quad p(x)y' + s(x)y = c_1$$

$$(145) \quad L^*z = (pz)'' - (qz)' + r$$

$$(146) \quad y_2(x) = y_1(x) \int_a^x \frac{dt}{p(t)[y_1(t)]^2}$$

$$(147) \quad \sum_{r=0}^{\infty} a_r x^{r+\rho}, \quad a_n \neq 0$$

$$(148) \quad y''(x) + k^2 \sin v = 0$$

$$(149) \quad y'' + ay + by^2 = 0$$

$$(150) \quad y'' - \varepsilon(1 - y^2)y' + y = 0$$

Use of the  
Laplace  
transform

$$(151) \quad y'(x) = g(x, c_1)$$

$$(152) \quad \int \frac{dp}{\sqrt{(1+p^2)}} = \int \frac{dx}{a} + c_1$$

$$(153) \quad y = a \cosh\left(\frac{x}{a} + c_1\right) + c_2$$

$$(154) \quad \int \frac{dy}{h(y, c_1)} = x + c_2$$

$$(155) \quad p^2 + ay^2 + \frac{2}{3}by^3 = c_1$$

$$(156) \quad p^2 - 2k^2 \cos y = c_1$$

$$(157) \quad \frac{d}{dx} H(x, y, y') = 0$$

$$(158) \quad \begin{cases} xyy'' + 2yy' + xy'^2 = 0 \\ \frac{d}{dx} (2xyy' + y^2) = 0 \end{cases}$$

$$(159) \quad \left[ \frac{d}{dx} + p(x) \right] M(x, y, y') = 0$$

$$(160) \quad M(x, y, y') = c_1 \exp[-\int p(x) dx]$$

$$(161) \quad y'' + \alpha(x)y' + \beta(x)y = f(x), \quad a < x < b$$

$$(162) \quad y(x) = c_1 y_1(x) + c_2 y_2(x) + Y(x)$$

$$(163) \quad \begin{cases} c_1 y_1(a) + c_2 y_2(a) = y_0 - Y(a) \\ c_1 y_1'(a) + c_2 y_2'(a) = y_1 - Y'(a) \end{cases}$$

$$(164) \quad c_1 = \frac{y_0 y_2'(a) - y_1 y_2(a)}{W(y_1, y_2; a)}, \quad c_2 = \frac{y_1 y_1(a) - y_0 y_1'(a)}{W(y_1, y_2; a)}$$

$$(165) \quad \begin{cases} \frac{\partial^2 G}{\partial x^2} + \alpha(x) \frac{\partial G}{\partial x} + \beta(x)G = 0, & G(a, \xi) = 0 \\ \frac{\partial G(a, \xi)}{\partial x} = 0, & G(\xi, \xi) = 0, & \frac{\partial G(\xi, \xi)}{\partial x} = 1 \\ Y(x) = \int_a^x G(x, \xi) f(\xi) d\xi \end{cases}$$

The second method consists in finding a particular solution of the equation by inspection and taking this solution to be  $u$ . The resulting second-order equation for  $v$  is, in effect, a first-order linear equation for  $w = v'$ . This can easily be solved and  $v$  obtained by a further integration. This method is particularly useful in the case of a self-adjoint equation  $(py')' + ry = 0$ ; if  $y_1(x)$  is any solution of this equation the general solution is  $c_1 y_1(x) + c_2 y_2(x)$  in which  $y_2(x)$  is defined in terms of  $y_1(x)$  and an integral (see 146), the lower limit of integration  $a$  being chosen to ensure that the integral exists.

Another useful method of solving a linear second-order equation is to derive a solution in the form of a power series (see 147), by substituting a series in the equation. If the coefficient of the lowest power of  $x$  is equated to zero, a quadratic equation is obtained; either of the roots of this quadratic equation gives a possible value of  $p$ . If the coefficient of  $x$  to the power  $r + p$  is equated to zero, a recurrence relation is obtained for the coefficients  $a_r$  of this series.

#### NONLINEAR DIFFERENTIAL EQUATIONS

Some examples of nonlinear differential equations. Nonlinear equations of the second order may now be considered.

One of the simplest nonlinear second-order differential

equations has the sum of  $y''$  and  $k^2 \sin y$  equal to zero (see 148). It describes the motion of a simple pendulum, and also the deflection of a thin strut.

The equation (see 16) defining the catenary is a nonlinear equation.

The motion of an undamped mass-spring system in which the spring control takes the asymmetrical form  $ay + by^2$  may be described by the nonlinear equation in which the sum of  $y''$  and the spring control term equals zero (see 149). If there is damping, the motion is described by the slightly more complicated equation  $y'' + ky' + ay + by^2 = 0, k > 0$ .

Further, as was noted above, certain properties of thermionic tubes can be predicted from considerations of a differential equation involving an expression of the form  $(1 - y^2)y'$  (see 150).

Methods of solution of nonlinear differential equations. It is much more difficult to derive the solutions of nonlinear equations than those of linear equations. When a given differential equation is one of a simple type, however, its solution can be determined by elementary means.

Equations not containing  $y$  explicitly. A nonlinear second-order equation of the type  $y'' = f(x, y')$  can be regarded as a first-order equation  $p' = f(x, p)$  for the derivative  $p = y'$ . When the solution  $p(x) = g(x, c_1)$  of this equation has been found, the solution of the original equation is found by integrating the resulting equation (see 151). The catenary equation is of this form and so has a first integral (see 152), which is equivalent to  $\sinh^{-1}(p) = x/a + c_1$ ; i.e., to  $p = \sinh(x/a + c_1)$ . Integration of this equation in turn leads to the general solution in terms of a hyperbolic cosine (see 153).

Equations not containing  $x$  explicitly. In a similar way a nonlinear second-order equation of the type  $y'' = f(y, y')$  can be reduced to the first-order form  $p(dp/dy) = f(y, p)$  because if  $p = y'$ , then  $y'' = p(dp/dy)$ . If the solution of this first-order equation is  $p(y) = h(y, c_1)$ , the solution of the original equation is obtained by an integration (see 154).

For example, the undamped mass-spring equation (149) has a first integral involving  $p^2$  and  $y^3$  (see 155); and the pendulum equation (148) has a first integral involving  $p^2$  and  $\cos y$  (see 156).

Exact equations. If a nonlinear equation  $F(x, y, y', y'') = 0$  can be written as the derivative of some function  $H(x, y, y')$  being equal to zero (see 157), it has the first integral  $H(x, y, y') = c_1$  and hence can be solved by the methods available for the solution of first-order equations.

For example, a second-order equation involving  $x, y, y', (y')^2$ , and  $y''$  can be written in the equivalent form in which the derivative of an expression involving a first derivative of  $y$  equals zero (see 158), and therefore it can be solved by this method.

A slight generalization of this method arises when the equation can be factorized in the form of the derivative of an expression involving  $x, y$ , and  $y'$  added to the product of that expression and a function of  $x$  being equal to zero (see 159), which can be integrated to give a first-order equation involving an exponential (see 160).

#### BOUNDARY VALUE PROBLEMS

When differential equations occur in the discussion of a physical problem, it usually happens that the solution of interest is not the general solution but the particular solution that satisfies certain additional conditions. For instance, to solve the problem of the catenary does not require the general solution of the second-order differential equation (16) but the particular solution,  $y(x)$ , that satisfies the additional geometrical conditions  $y(0) = a, y'(0) = 0$ .

To illustrate the ideas involved, equations of the second order will be discussed; they are easily generalized to equations of the  $n$ th order.

Initial value problems. The problem of finding a function  $y(x)$  in the interval  $a \leq x \leq b$  satisfying a second-order differential equation  $F(x, y, y', y'') = 0$  and the conditions  $y(a) = y_0, y'(a) = y_1$ , in which  $y_0, y_1$  are pre-

scribed real numbers, is called the initial value problem for the differential equation. The values  $y_0, y_1$  are called the initial values of the required solution. The adjective initial is appropriate because in a dynamical problem (as in the problem of determining the escape velocity from the Earth, discussed above) the conditions of this type specify the initial state and initial rate of change of the system the subsequent history of which is described by the differential equation itself. Initial value problems are also known as one-point boundary value problems.

Linear equations. The linear second-order differential equation with  $x$  between  $a$  and  $b$ , in which  $\alpha(x)$ , the coefficient of  $y'$ ,  $\beta(x)$ , the coefficient of  $y$ , and  $f(x)$ , the inhomogeneous term, are prescribed functions (see 161), may now be considered with the initial values prescribed as above.

If  $y_1(x)$  and  $y_2(x)$  are linearly dependent solutions of the homogeneous form of the equation and  $Y(x)$  is a particular solution of the nonhomogeneous equation (161), then the solution of the initial value problem for the differential equation is the sum of  $Y(x)$  and a linear combination, with constants  $c_1$  and  $c_2$ , of  $y_1(x)$  and  $y_2(x)$  (see 162).

The constants  $c_1$  and  $c_2$  are chosen to satisfy the simultaneous linear equation arising from setting the solution and its derivative equal to  $y_0$  and  $y_1$ , respectively (see 163). If the particular solution  $Y(x)$  is chosen in such a way that  $Y(a) = Y'(a) = 0$ , the equations for  $c_1$  and  $c_2$  reduce to a simple pair the solution of which can be found by Cramer's rule (see 164). This solution involves  $W(y_1, y_2; a)$ , the Wronskian  $y_1(a)y_2'(a) - y_2(a)y_1'(a)$ , which is nonzero because the solutions  $y_1$  and  $y_2$  are linearly independent. The solution of the initial value problem is given by equations (162) and (164).

The Green's function for a linear initial value problem. There is a simple formula for the determination of the particular integral  $Y(x)$  of the linear differential equation of second order (see 161) satisfying the initial condition  $Y(a) = Y'(a) = 0$ . If  $G(x, \xi)$  is a function of the two variables  $x$  and  $\xi$  such that  $G$  and its partial derivatives with respect to  $x$  satisfy the homogeneous equation, conditions at  $x = \xi$  and at  $x = a$ , then  $Y(x)$  can be expressed as an integral of the product  $G(x, \xi)f(\xi)$  (see 165). The function  $G(x, \xi)$  is called the Green's function of the problem (named after George Green, a 19th-century English mathematician). It can be shown that the Green's function can be expressed in terms of  $y_1, y_2$ , and the Wronskian  $W(y_1, y_2; \xi)$  (see 166) in which  $y_1(x)$  and  $y_2(x)$  have the same meanings as before.

For example, for the initial value problem in which the sum of the second derivative  $y''$  and  $\omega^2 y$  equals  $f(x)$  with  $y$  and its first derivative equalling  $y_0$  and  $y_1$ , respectively, at  $x = 0$  (see 167), the functions  $y_1(x) = \cos(\omega x)$  and  $y_2(x) = \sin(\omega x)$  may be taken to obtain the formula  $G(x, \xi) = \omega^{-1} \sin\{\omega(x - \xi)\}$  from equation (166). Therefore, it is possible to express the solution as the sum of a linear combination of  $\cos(\omega x)$  and  $\sin(\omega x)$  and the integral of the product of  $f(\xi)$  and the Green's function (see 168).

Nonlinear equations. The solution of the initial value problem for a nonlinear equation is a much more difficult problem except in those rare cases in which it is possible to find a general solution of the differential equation. The particular values of the arbitrary constants  $c_1$  and  $c_2$  are then found by fitting the values of  $y(a)$  and  $y'(a)$ .

For equations of the type  $y'' = g(x, y, y')$ , a solution can be generated in the following manner. Differentiation of both sides of the equation by the chain rule produces an expression for the third derivative  $y'''$  (see 169), and it is possible to obtain higher derivatives by repeated differentiation.

Substitution of the initial values, the expressions for  $y''(a), y'''(a)$ , and higher derivatives at  $x = a$  (see 170) in the Taylor expansion about  $x = a$  (see 171) leads to a series expansion for the solution of the initial value problem.

Two-point boundary value problems. The problem of finding a function  $y(x)$  in the interval  $a < x < b$  satisfying a second-order differential equation  $F(x, y, y', y'') = 0$

and the conditions  $y(a) = y_0, y(b) = y_1$  in which  $y_0, y_1$  are prescribed real numbers is called the two-point boundary value problem for the differential equation. This problem can be generalized to cover the boundary conditions expressed by setting linear combinations of  $y$  and  $y'$  at each point equal to prescribed constants (see 172); only the simple case is treated here.

Linear equations. The two-point boundary value problem for a second-order linear equation (see 161) is con-

$$(166) \quad G(x, \xi) = \frac{y_1(\xi)y_2(x) - y_1(x)y_2(\xi)}{W(y_1, y_2; \xi)}$$

$$(167) \quad \begin{cases} \frac{d^2 y}{dx^2} + \omega^2 y = f(x), & x > 0 \\ y(0) = y_0, & y'(0) = y_1 \end{cases}$$

$$(168) \quad y_0(x) = y_0 \cos(\omega x) + \frac{y_1}{\omega} \sin(\omega x) + \frac{1}{\omega} \int_0^x f(\xi) \sin\{\omega(x - \xi)\} d\xi$$

$$(169) \quad y''' = \frac{\partial g(x, y, y')}{\partial x} + \frac{\partial g(x, y, y')}{\partial y} y' + \frac{\partial g(x, y, y')}{\partial y'} y''$$

$$(170) \quad \begin{cases} y(a) = y_0, & y'(a) = y_1, & y''(a) = g(a, y_0, y_1) \\ y'''(a) = g_x(a, y_0, y_1) + y_1 g_y(a, y_0, y_1) + \\ & + g(a, y_0, y_1) g_{y'}(a, y_0, y_1) \end{cases}$$

$$(171) \quad y(x) = y(a) + \frac{(x-a)}{1!} y'(a) + \frac{(x-a)^2}{2!} y''(a) + \frac{(x-a)^3}{3!} y'''(a) + \dots$$

$$(172) \quad \lambda_1 y(a) + \mu_1 y'(a) = y_0, \quad \lambda_2 y(b) + \mu_2 y'(b) = y_1$$

$$(173) \quad y(x) = y_0 \frac{y_2(x)}{y_2(a)} + y_1 \frac{y_1(x)}{y_1(b)} + \eta(x)$$

$$(174) \quad \eta(x) = y_2(x) \int_a^x \frac{y_1(\xi) f(\xi) d\xi}{W(y_1, y_2; \xi)} + y_1(x) \int_x^b \frac{y_2(\xi) f(\xi) d\xi}{W(y_1, y_2; \xi)}, \quad a < x < b$$

$$(175) \quad G(x, \xi) = \begin{cases} \frac{y_1(\xi)y_2(x)}{W(y_1, y_2; \xi)}, & a < \xi < x \\ \frac{y_1(x)y_2(\xi)}{W(y_1, y_2; \xi)}, & x < \xi < b \end{cases}$$

$$(176) \quad y(x) = \frac{y_0 y_2(x)}{y_2(a)} + \frac{y_1 y_1(x)}{y_1(b)} + \int_a^b G(x, \xi) f(\xi) d\xi$$

$$(177) \quad y_1(a) = 0, \quad y_2(b) = 0$$

$$(178) \quad \begin{cases} \dot{x} = a_{11}x + a_{12}y \\ \dot{y} = a_{21}x + a_{22}y \end{cases}$$

$$(179) \quad \begin{cases} (a_{11} - A)A + a_{12}B = 0 \\ a_{21}A + (a_{22} - A)B = 0 \end{cases}$$

$$(180) \quad \begin{vmatrix} a_{11} - \lambda & a_{12} \\ a_{21} & a_{22} - \lambda \end{vmatrix} = 0$$

sidered:  $y_1(x)$  and  $y_2(x)$  are taken to be linearly independent solutions satisfying the conditions  $y_1(a) = 0$ ,  $y_2(b) = 0$ , and  $\eta(x)$  is taken as the particular solution of the equation (161) satisfying the conditions  $\eta(a) = \eta(b) = 0$ . The solution of the two-point boundary value problem is then the sum of a linear combination of  $y_1(x)$  and  $y_2(x)$  and a function  $\eta(x)$  (see 173).

The Green's function for a linear two-point boundary value problem. It can be shown that the function  $\eta(x)$  can be expressed in terms of  $y_1x$ ,  $y_2x$ , and integrals involving  $f(\xi)$  (see 174), which gives the required particular integral. The function  $G(x, \xi)$  defined in terms of the functions and their Wronskian (see 175) is called the Green's function of the two-point boundary value problem. In terms of it the solution of the problem may be written as the sum of an integral of  $G(x, \xi)f(\xi)$  and a linear combination of  $y_1(x)$  and  $y_2(x)$  (see 176). In the use of this formula it is necessary to remember that  $y_1(x)$ ,  $y_2(x)$  are not completely arbitrary linearly independent solutions of the homogeneous form of (161) but must satisfy the boundary conditions (see 177).

Nonlinear equations. When the general solution of a second-order nonlinear equation is not known, the solution of a two-point boundary value problem is obtained by solving the initial value problem for  $y(a) = y_0$ ,  $y'(a) = y_0$ , and (usually by a method of trial and error) to find the value of  $y$  that leads to a solution for which  $y(b) = y_1$ .

#### SYSTEMS OF DIFFERENTIAL EQUATIONS

**Two simultaneous differential equations in two variables.** Two simultaneous equations in two variables will now be considered. They can be solved if they are linear and of first order.

Linear systems. A pair of homogeneous linear equations of the first order with dependent variables  $x$  and  $y$  and independent variable  $t$  can be solved for  $dx/dt$  and  $dy/dt$  formally written as dotted letters. In other words, the system is reduced to a pair of equations expressing the derivative with respect to  $t$  each in terms of a linear combination of  $x$  and  $y$  (see 178). The functions  $x(t) = Ae^{\lambda t}$ ,  $y(t) = Be^{\lambda t}$  satisfy these equations if the linear algebraic equations obtained by substituting these expressions for  $x(t)$  and  $y(t)$  into the original system are satisfied (see 179).

Regarded as equations for  $A$  and  $B$ , these equations have a nontrivial solution only if  $\lambda$  is a root of the equation that arises from the requirement that the determinant of the matrix of a system of homogeneous linear algebraic equations be zero (see 180), in which case  $A$  and  $B$  may be expressed in terms of an arbitrary constant  $c$  (see 181).

If the roots  $\lambda_1$ ,  $\lambda_2$  of the quadratic equation (180) are distinct, there are two linearly independent solutions, and the general solution of the pair of equations (178) may be written as linear combinations of these two solutions involving the  $a_{ij}$  and two arbitrary constants,  $c_1$  and  $c_2$  (see 182). For example, if the sum of the derivative of  $x$  with respect to  $t$ ,  $ax$ , and  $y$  equals zero and the derivative of  $y$  with respect to  $t$  equals the sum of  $6x$  and  $y$ , then  $\lambda_1$  must equal  $-1$ ,  $\lambda_2$  must equal  $-2$ , and the  $a_{ij}$  are determined (see 183) so that the general solution is a linear combination of  $e^{-t}$  and  $e^{-2t}$  involving arbitrary constants  $c_1$  and  $c_2$  (see 184). In order to obtain the solution for which  $x(0) = x_0$ ,  $y(0) = y_0$ , it is necessary to choose the constants  $c_1$  and  $c_2$  in such a way that the solution satisfies these conditions at  $t = 0$  (see 185). These equations are solved for  $c_1$  and  $c_2$  to give the particular solution desired (see 186).

Use of the Laplace transform. To obtain the solution of the pair of first-order linear differential equations (178), the formulas expressing the result of using the Laplace transform (often formally written as a bar over the expression transformed) on a derivative (see 187) are used to obtain simultaneous linear algebraic equations (see 188) for the Laplace transforms  $\mathfrak{L}[x(p)]$ ,  $\mathfrak{L}[y(p)]$  of the unknown functions  $x(t)$ ,  $y(t)$ . For instance, the pair (183) considered above can be attacked in this way (see 189) with the solution giving the Laplace transforms

$$(181) \quad A = a_{12}c, \quad B = (\lambda - a_{11})c$$

$$(182) \quad \begin{cases} x(t) = a_{12}c_1e^{\lambda_1 t} + a_{12}c_2e^{\lambda_2 t} \\ y(t) = (\lambda_1 - a_{11})c_1e^{\lambda_1 t} + (\lambda_2 - a_{11})c_2e^{\lambda_2 t} \end{cases}$$

$$(183) \quad \begin{cases} \dot{x} + 4x + y = 0, & y - 6x - y = 0 \\ a_{11} = -4, & a_{12} = -1, & a_{21} = 6 \\ a_{22} = 1, & \lambda_1 = -1, & \lambda_2 = -2 \end{cases}$$

$$(184) \quad x(t) = -c_1e^{-t} - c_2e^{-2t}, \quad y(t) = 3c_1e^{-t} + 2c_2e^{-2t}$$

$$(185) \quad -c_1 - c_2 = x_0, \quad 3c_1 + 2c_2 = y_0$$

$$(186) \quad \begin{cases} x(t) = (3e^{-2t} - 2e^{-t})x_0 + (e^{-2t} - e^{-t})y_0 \\ y(t) = 6(e^{-t} - e^{-2t})x_0 + (3e^{-t} - 2e^{-2t})y_0 \end{cases}$$

$$(187) \quad \mathfrak{L}[\dot{x}(t); p] = p\bar{x}(p) - x_0, \quad \mathfrak{L}[\dot{y}(t); p] = p\bar{y}(p) - y_0$$

$$(188) \quad \begin{cases} (a_{11} - p)\bar{x}(p) + a_{12}\bar{y}(p) + x_0 = 0 \\ a_{21}\bar{x}(p) + (a_{22} - p)\bar{y}(p) + y_0 = 0 \end{cases}$$

$$(189) \quad (p + 4)\bar{x}(p) + \bar{y}(p) = x_0, \quad -6\bar{x}(p) + (p - 1)\bar{y}(p) = y_0$$

$$(190) \quad \bar{x}(p) = \frac{(p - 1)x_0 - y_0}{(p + 1)(p + 2)}, \quad \bar{y}(p) = \frac{6x_0 + (p + 4)y_0}{(p + 1)(p + 2)}$$

$$(191) \quad \begin{cases} \bar{x}(p) = \frac{3x_0 + y_0}{p + 2} - \frac{2x_0 + y_0}{p + 1} \\ \bar{y}(p) = \frac{6x_0 + 3y_0}{p + 1} - \frac{6x_0 + 2y_0}{p + 2} \end{cases}$$

$$(192) \quad \begin{bmatrix} \dot{x} \\ \dot{y} \end{bmatrix} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix} \begin{bmatrix} x \\ y \end{bmatrix}$$

$$(193) \quad \mathbf{z} = \begin{bmatrix} x \\ y \end{bmatrix}, \quad \mathbf{A} = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}$$

$$(194) \quad \dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$$

$$(195) \quad \frac{d^2x}{dt^2} + p(t)\frac{dx}{dt} + q(t)x = f(t)$$

$$(196) \quad \frac{dx}{dt} - y = 0, \quad \frac{dy}{dt} + p(t)y + q(t)x = f(t)$$

$$(197) \quad \mathbf{z} = \begin{bmatrix} x \\ y \end{bmatrix}, \quad \mathbf{A}(t) = \begin{bmatrix} 0 & -1 \\ q(t) & p(t) \end{bmatrix}, \quad \boldsymbol{\phi} = \begin{bmatrix} 0 \\ f(t) \end{bmatrix}$$

$$(198) \quad \dot{\mathbf{z}} + \mathbf{A}(t)\mathbf{z} = \boldsymbol{\phi}(t)$$

$$(199) \quad \begin{cases} \dot{x}_1 = a_{11}x_1 + a_{12}x_2 + \cdots + a_{1n}x_n \\ \dot{x}_2 = a_{21}x_1 + a_{22}x_2 + \cdots + a_{2n}x_n \\ \vdots \\ \dot{x}_n = a_{n1}x_1 + a_{n2}x_2 + \cdots + a_{nn}x_n \end{cases}$$

$$(200) \quad \dot{\mathbf{z}} = \mathbf{A}\mathbf{z}$$

$\mathfrak{L}[x(p)]$  and  $\mathfrak{L}[y(p)]$  in terms of  $p$ ,  $x_0$ , and  $y_0$  (see 190). If these equations are appropriately rewritten (see 191) and the Laplace transforms are inverted, the solution (186) is obtained.

Matrix form of the pair of equations. The pair of equations (178) may be written in matrix form (see 192) if matrices  $z$ , with elements  $x$  and  $y$ , and  $A$ , with elements  $a_{11}$ ,  $a_{12}$ ,  $a_{21}$ , and  $a_{22}$  (see 193), are introduced. This last equation can be written in a matrix form similar to the form of a single first-order equation (see 194).

Second-order equations. The general second-order linear differential equation (see 195) can be written as a pair of simultaneous equations by defining a new variable  $y$  as equal to the first derivative  $dx/dt$  (see 196). In terms of matrices (see 197) similar to those in the previous example, this pair can, in turn, be written in matrix form (see 198).

A system of  $n$ -simultaneous equations in  $n$  variables. The system (178) can be generalized to the set of linear differential equations in  $n$  variables (see 199), which can be written in matrix form by writing the derivative of  $z$  with respect to  $t$  as equal to the matrix product  $Az$  (see 200), in which  $z$  is an  $n$ -component column vector and  $A$  is an  $n \times n$  matrix of coefficients (see 201). If  $z$  equals a constant vector  $c$  times an exponential  $e^{\lambda t}$  (see 202), and if  $I$  is the unit  $n \times n$  matrix, then the matrix product  $Ac$  must equal  $\lambda Ic$  (see 203) for  $z$  to be a solution of the system.

In order for  $c$  to be a non-null vector, it is necessary that  $\det(A - \lambda I) = 0$ ; i.e., the vector (202) is a solution of equation (200) only if  $\lambda$  is an **eigenvalue** (see ALGEBRA, LINEAR AND MULTILINEAR) of the matrix  $A$ . This is illustrated by equation (180) in the case  $n = 2$ .

The main result is that the general solution of the system of equations (200) is the product of a constant vector  $z_0$  and an exponential  $e^{\lambda t}$  (see 204), the exponential with matrix exponent being defined by the Maclaurin series expansion of the exponential (see 205).

#### PERTURBATIONS

Because it is difficult to obtain exact solutions of nonlinear differential equations, recourse is often taken to approximate methods, foremost among which are perturbation methods that are applicable to equations containing a small parameter  $\epsilon$ . A typical such equation is one in which  $y''$ ,  $\omega^2 y$  and an additional term  $\epsilon f(y, y')$  all sum to zero (see 206); for example, van der Pol's equation (150) is of this form.

The two principal perturbation methods are the **Lindstedt-Poincaré** method and the **Krylov-Bogolyubov** method, which are discussed below.

**Lindstedt-Poincaré** method. The method used extensively by the 19th–20th-century Swedish mathematician Anders Lindstedt and the French mathematician Henri Poincaré for the solution of differential equations in celestial mechanics consists in assuming a solution that can be expanded in powers of  $\epsilon$ , the coefficients of the expansion being  $y_0(x)$ ,  $y_1(x)$ ,  $y_2(x)$ , . . . (see 207), when it is assumed that  $0 < \epsilon < 1$ , and that  $\omega^2$  has an expansion in powers of  $\epsilon$  (see 208), the coefficients of which  $\alpha_0$ ,  $\alpha_1$ ,  $\alpha_2$ , . . . are constants the values of which have to be determined.

For example, in order to find periodic solutions of the equation considered above (see 206) in a special case (see 209), a solution of the form given by the expansion (207) is substituted in the differential equation, and the coefficients of the powers of  $\epsilon$  are equated to zero. This leads to a sequence of linear second-order equations with constant coefficients (see 210), which are easily solved; the unknown constants  $\alpha_0$ ,  $\alpha_1$ ,  $\alpha_2$ , . . . are determined by the fact that each of the functions  $y_r(x)$  must be periodic, with the same period.

**Krylov-Bogolyubov** method. If  $\epsilon$  is zero, the equation being considered (206) clearly has the solution  $y = A \sin(ax + \phi)$ , in which  $A$  and  $\phi$  are constants. The Krylov-Bogolyubov method consists in allowing  $A$  and  $\phi$  to become slowly varying functions of  $x$  when  $\epsilon$  is small but not zero.

An approximate solution is  $y = A(x) \sin[ax + \phi(x)]$ ; this approximation is then substituted into the differential equation. And, because  $A$  and  $\phi$  are slowly varying, it is thus possible to determine from the integrals first  $A$  and then  $\phi$  (see 211).

#### STABILITY

There are very few differential equations the general solution of which can be derived, and so the study of the qualitative properties of solutions of differential equations without solving the equations explicitly has developed. One qualitative phenomenon of great practical interest is the concept of stability of a certain solution of a system of differential equations.

Suppose that a physical system is represented by a differential equation in which the derivative of an  $n$ -vector  $x$  equals a function of  $x$  and  $t$ ,  $\mathbf{f}(x, t)$ , which is also an  $n$ -vector (see 212), and that  $x = u(t)$  is a special solution of this equation describing a special regime of the system. Any physical system will be subject to small disturbances so that the regime  $u(t)$  will not maintain itself, and a disturbed motion  $x = w(t)$  results. As time goes on, either  $w(t) \rightarrow u(t)$ , in which case stability occurs, or  $w(t)$  deviates from  $u(t)$  and instability results.

$$(201) \quad z = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}, \quad A = \begin{bmatrix} a_{11} & a_{12} & \cdots & a_{1n} \\ a_{21} & a_{22} & \cdots & a_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ a_{n1} & a_{n2} & \cdots & a_{nn} \end{bmatrix}$$

$$(202) \quad z = ce^{\lambda t}$$

$$(203) \quad (A - \lambda I)c = 0$$

$$(204) \quad z(t) = e^{tA} z_0$$

$$(205) \quad e^{tA} = 1 + \frac{tA}{1!} + \frac{t^2 A^2}{2!} + \cdots + \frac{t^n A^n}{n!} + \cdots$$

$$(206) \quad y'' + \epsilon f(y, y') + \omega^2 y = 0$$

$$(207) \quad y(x) = y_0(x) + \epsilon y_1(x) + \epsilon^2 y_2(x) + \cdots$$

$$(208) \quad \omega^2 = \alpha_0 + \epsilon \alpha_1 + \epsilon^2 \alpha_2 + \cdots$$

$$(209) \quad f(y, y') = -\epsilon(1 - y^2)y', \quad y(0) = 0, \quad y'(0) = \omega_0 A$$

$$(210) \quad \begin{cases} y_0'' + \alpha_0 y_0 = 0, & y_0(0) = 0, & y_0'(0) = \omega_0 A \\ y_1'' + \alpha_0 y_1 = -\alpha_1 y_0 + y_0'(1 - y_0^2) \\ y_1(0) = y_1'(0) = 0 \\ y_2'' + \alpha_0 y_2 = -(\alpha_2 y_0 + \alpha_1 y_1) + y_1'(1 - y_0^2) - 2y_0 y_0' y_1 \\ y_2(0) = y_2'(0) = 0 \end{cases}$$

$$(211) \quad \begin{cases} \frac{dA}{dx} = -\frac{\epsilon}{2\pi\omega} \int_0^{2\pi} f(A \sin t, A\omega \cos t) \cos t \, dt \\ \frac{d\phi}{dx} = \frac{\epsilon}{2\pi\omega} \int_0^{2\pi} f(A \sin t, A\omega \cos t) \sin t \, dt \end{cases}$$

$$(212) \quad \dot{x} = \mathbf{f}(x, t)$$

$$(213) \quad \dot{z} = \mathbf{g}(z, t)$$

Putting  $w(t) = u(t) + z(t)$  a 19th–20th-century-Soviet mathematician, Aleksandr Lyapunov, obtained an equation in which  $z$  and  $\mathbf{g}$  are  $n$ -vectors, the derivative of  $z$  with respect to  $t$  equals  $\mathbf{g}(z, t)$  (see 213), and  $\mathbf{g}(0, t) = 0$  for  $t > 0$ . To the regime  $u(t)$  of the first equation (see 212) there corresponds the regime  $z = 0$  of the second equation (see 213). The origin  $z = 0$  is now considered as the basic motion and a solution  $z(t)$  of (213) is thought of as a disturbed motion. The terms stability of the **undis-**

turbed motion or simply the stability of the origin are used in this case.

The property  $\mathbf{g}(0, t) = \mathbf{0}$  for a suitable range of  $t$  characterizes the origin as a critical point of (213). It is assumed that this critical point is isolated and also that  $\mathbf{g}$  is continuous and satisfies conditions for the uniqueness of solutions of Lyapunov's equation (213) in a certain region  $\Omega$  specified by  $\|\mathbf{x}\| < A, t > 0$ , in which  $\|\mathbf{x}\|$  denotes the length of the vector  $\mathbf{x}$  and  $A$  denotes a positive constant. Stability is characterized by Lyapunov as follows: if for any prescribed  $\varepsilon, 0 < \varepsilon < A$ , there exists  $\delta > 0$  such that every trajectory originating within the sphere  $\|\mathbf{x}\| = \delta$  always remains within the sphere  $\|\mathbf{x}\| = \varepsilon$ , the origin is stable (cf. Figure 4 in which these spheres are denoted by  $S(\delta)$  and  $S(\varepsilon)$  respectively). If every trajectory originating within  $S(\delta)$  tends to  $\mathbf{0}$  the origin is said to be asymptotically stable. If, however, no matter what  $\delta$  is chosen, some trajectory originating from a point within  $S(\delta)$  eventually reaches  $S(\varepsilon)$ , the origin is unstable.

Figure 4: Three types of trajectories, stable as represented by  $\Gamma_1$ , asymptotically stable as represented by  $\Gamma_2$ , and unstable, drawn in relation to an origin and two spheres denoted by  $S(\delta)$  and  $S(\varepsilon)$ .

Lyapunov attacked the stability problem by two distinct methods. The first, applicable only to some analytical systems, consists essentially in finding explicit series solutions convergent near the origin and considering the behaviour of this series as  $t \rightarrow \infty$ . The second method does not require the construction of explicit solutions, and for this reason that method has a greater range of validity than the first; it rests on the construction of a scalar function  $V(\mathbf{x}, t)$ .

For example, Lyapunov's stability states that if there can be found a positive definite function  $V(\mathbf{x}, t)$  the time derivative of which taken along all the trajectories in  $\Omega$  is negative or zero, then the origin is stable. Of four such theorems of Lyapunov, two refer to stability and two to instability; the latter may be replaced by a more comprehensive theorem of Četaev.

### Partial differential equations

In most physical problems any dependent variable is likely to be a function of more than one independent variable. The example of a vibrating string has already been given. Another example is in the study of thermal effects in a solid body in which the temperature  $u$  may vary from point to point in the solid as well as from time to time. As a consequence, the function  $u(x, y, z, t)$  is written to denote that  $u$  depends on  $(x, y, z)$ , the coordinates of a typical point, and on the time  $t$ .

If for such a function, the difference quotient, the difference between  $u(a + h, b, c, \tau)$  and  $u(a, b, c, \tau)$ , divided by  $h$  (see 214), tends to a finite number as  $h$  tends to zero, that number is denoted by  $u_x(a, b, c, \tau)$ , or by  $\frac{\partial u(a, b, c, \tau)}{\partial x}$ , and is called the partial derivative with respect to  $x$  of the function  $u(x, y, z, t)$  at the point  $(a, b, c, \tau)$ . It measures the rate of change at that point of the

function  $u$  with respect to  $x$ , the other variables remaining fixed. As the point  $(a, b, c, \tau)$  varies, a new function  $u_x(x, y, z, t)$  or  $\partial u / \partial x$  is generated that expresses the rate of growth with  $x$  of the function  $u$ . The process can be repeated: the partial derivative of  $\partial u / \partial x$  with respect to  $x$  is denoted by  $\partial^2 u / \partial x^2$ . Similarly the consideration of the variation of  $u$  with respect to the other variables leads to the definition of the other partial derivatives, the partial derivatives with respect to  $y, z$ , and  $t$  (see 215); and the partial derivatives with respect to  $x$  of these yield in turn the mixed derivatives of the second order in which  $u$  is differentiated twice, once with respect to each of two different variables (see 216).

When the laws of physics are applied to a situation involving a function of this kind, a relation involving the function  $u$  and its partial derivatives is often obtained. Such a relation is called a partial differential equation. For example, if  $u(x, y, z, t)$  were the temperature at time  $t$  at the point  $(x, y, z)$  in a homogeneous isotropic solid, the variation of  $u$  is specified by the heat conduction equation, in which the sum of the second partial derivatives with respect to  $x, y$ , and  $z$  is proportional to the first partial derivative with respect to  $t$  (see 217). The expression on the left side of this equation arises so frequently that it is given a special name and a special symbol; it is called the Laplacian of  $u$  and is now denoted by  $\Delta u$ .

As in the theory of ordinary differential equations, the order of a partial differential equation is defined to be the order of the derivative of highest order occurring in the equation. For example, the heat equation (see 217) is a second-order equation in four variables, an equation stating that the sum of the cube of the partial derivative of  $u$  with respect to  $x$  and the partial derivative of  $u$  with respect to  $y$  equals zero (see 218) is a first-order equation in two variables while an equation involving first partial derivatives with respect to  $x, y$ , and  $t$  with variable coefficients (see 219) is a first-order equation in three variables.

The study of partial differential equations began with

$$(214) \quad \frac{u(a+h, b, c, \tau) - u(a, b, c, \tau)}{h}$$

$$(215) \quad \frac{\partial u}{\partial y}, \frac{\partial u}{\partial z}, \frac{\partial u}{\partial t}$$

$$(216) \quad \frac{\partial^2 u}{\partial x \partial y}, \frac{\partial^2 u}{\partial x \partial z}, \frac{\partial^2 u}{\partial x \partial t}$$

$$(217) \quad \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} + \frac{\partial^2 u}{\partial z^2} = \frac{1}{\kappa} \frac{\partial u}{\partial t}$$

$$(218) \quad \left( \frac{\partial u}{\partial x} \right)^3 + \frac{\partial u}{\partial y} = 0$$

$$(219) \quad x \frac{\partial u}{\partial x} + y \frac{\partial u}{\partial y} + \frac{\partial u}{\partial t} = 0$$

$$(220) \quad \frac{\partial u}{\partial \xi} = 0$$

$$(221) \quad u = f(\eta)$$

$$(222) \quad \frac{\partial^2 u}{\partial \xi \partial \eta} = 0$$

$$(223) \quad u = f(\xi) + g(\eta)$$

$$(224) \quad \frac{\partial E_x}{\partial x} + \frac{\partial E_y}{\partial y} + \frac{\partial E_z}{\partial z} = 4\pi\sigma(x, y, z)$$

Early work on partial differential equations

the study of continuum mechanics and physics. Although there were some earlier investigations, the first proper studies of these types of equations began in the 18th century with the studies of Leonhard Euler (Swiss) and Jean Le Rond d'Alembert (French) on wave motion, Pierre-Simon Laplace (French) on potential theory, Jean-Baptiste-Joseph Fourier (French) on the conduction of heat, and Carl Friedrich Gauss (German) on potential theory and electromagnetic theory. The theory of partial differential equations has always gone hand-in-hand with developments in mathematical physics and has drawn much of its strength from the association, as is seen even in the more theoretical works of pure mathematicians of distinction such as Augustin-Louis Cauchy (French), Bernhard Riemann (German), and Sofya Kovalevskaya (Russian). The growth of abstract analysis has had important repercussions on the theory of partial differential equations, and this influence has in turn suggested fruitful problems to workers in both abstract and numerical analysis.

Probably the simplest partial differential equation involving a function  $u(\xi, \eta)$  of two independent variables is the one that may be verbalized as follows: the first partial derivative with respect to one of the variables equals zero (see 220), which may readily be seen to have the general solution of an arbitrary function  $f(y)$  of the other variable only (see 221). A comparison with the case of ordinary differential equations in which the equation  $u'(x) = 0$  has solution  $u(x) = c$  illustrates the point that the role played by arbitrary constants in the theory of ordinary differential equations is taken over by arbitrary functions in the theory of partial differential equations.

Similarly, if the second mixed partial derivative of  $u$  with respect to  $\xi$  and  $\eta$  equals zero (see 222), then the general solution is the sum of  $f(\xi)$  and  $g(\eta)$ , in which the functions  $f$  and  $g$  are arbitrary and are each functions of only one variable (see 223).

This statement can be extended to a general partial differential equation of order  $n$  for a function of  $k$  independent variables. Subject to a variety of restrictions that must be imposed, the general solution of such an equation depends on  $n$  arbitrary functions of  $k - 1$  independent variables.

#### PARTIAL DIFFERENTIAL EQUATIONS OF SPECIAL INTEREST

Some partial differential equations have arisen so frequently in the study of physics that they have been studied intensively. Collectively, they are known as the equations of mathematical physics, and have throughout the development of the theory of partial differential equations provided the motivation for many studies of theoretical, as well as practical, interest.

**Poisson's equation.** A simple linear partial differential equation of the second order is named after a 19th-century French physicist, Siméon-Denis Poisson. It arises in the mathematical treatment of electrostatics. Gauss's law of electrostatics states that the flux of the electric vector ( $E_x, E_y, E_z$ ) out of a surface is equal to  $4\pi$  times the charge contained within that surface; this leads to the relation that the sum of  $\partial E_x / \partial x$ ,  $\partial E_y / \partial y$ , and  $\partial E_z / \partial z$  is proportional to  $\sigma(x, y, z)$  (see 224), in which  $\sigma$ , the density of electric charge, is assumed to be known. It is also known physically that the electrostatic field is characterized by the fact that the electric vector can be derived from a potential function  $u$ ; i.e., that there exists a function  $u$  such that each component of the electric vector equals minus the partial derivative of  $u$  with respect to that variable (see 225). The insertion of these expressions into the previous equation leads to the relation that the sum of  $\Delta_3 u$  and  $4\pi\sigma(x, y, z)$  equals zero (see 226), in which  $\Delta_3$  is the Laplacian operator introduced above. Poisson's equation arises also in the theory of the gravitational potential.

**Laplace's equation.** In the absence of electric charges the function  $\sigma$  of equation (226) reduces to the simpler form in which the Laplacian of  $u$  equals zero (see 227). This is called Laplace's equation. It arises also in the analysis of the irrotational motion of a perfect fluid and

in the steady-state conduction of heat (see below *The diffusion equation*).

In the cylindrical coordinates  $(\rho, \phi, z)$  Laplace's equation assumes a form that can be derived by the chain rule (see 228) in which it is more suitable for the discussion of problems involving regions bounded by cylinders. In a similar manner, in spherical polar coordinates  $(r, \theta, \phi)$ , which are used in the analysis of problems concerning regions that are bounded by spheres or cones, Laplace's equation is transformed to an expression involving partial derivatives with respect to these variables (see 229).

**The wave equation.** Sound waves in space. If, because of the passage of a sound wave, the gas at a point  $(x, y, z)$  at time  $t$  has velocity  $(u, v, w)$  and pressure  $p$  and

$$(225) \quad E_x = -\frac{\partial u}{\partial x}, \quad E_y = -\frac{\partial u}{\partial y}, \quad E_z = -\frac{\partial u}{\partial z}$$

$$(226) \quad \Delta_3 u + 4\pi\sigma(x, y, z) = 0$$

$$(227) \quad \Delta_3 u = 0$$

$$(228) \quad \frac{\partial^2 u}{\partial \rho^2} + \frac{1}{\rho} \frac{\partial u}{\partial \rho} + \frac{1}{\rho^2} \frac{\partial^2 u}{\partial \phi^2} + \frac{\partial^2 u}{\partial z^2} = 0$$

$$(229) \quad \frac{\partial^2 u}{\partial r^2} + \frac{2}{r} \frac{\partial u}{\partial r} + \frac{1}{r^2 \sin \theta} \left( \frac{\partial}{\partial \theta} \sin \theta \frac{\partial u}{\partial \theta} \right) + \frac{1}{r^2 \sin^2 \theta} \frac{\partial^2 u}{\partial \phi^2} = 0$$

$$(230) \quad \frac{\partial u}{\partial t} = -c^2 \frac{\partial s}{\partial x}, \quad \frac{\partial v}{\partial t} = -c^2 \frac{\partial s}{\partial y}, \quad \frac{\partial w}{\partial t} = -c^2 \frac{\partial s}{\partial z}$$

$$(231) \quad \frac{\partial s}{\partial t} + \frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} + \frac{\partial w}{\partial z} = 0$$

$$(232) \quad u = -\frac{\partial \psi}{\partial x}, \quad v = -\frac{\partial \psi}{\partial y}, \quad w = -\frac{\partial \psi}{\partial z}$$

$$(233) \quad \begin{cases} \frac{\partial}{\partial x} \left( \frac{\partial \psi}{\partial t} - c^2 s \right) = 0, & \frac{\partial}{\partial y} \left( \frac{\partial \psi}{\partial t} - c^2 s \right) = 0 \\ \frac{\partial}{\partial z} \left( \frac{\partial \psi}{\partial t} - c^2 s \right) = 0 \end{cases}$$

$$(234) \quad \frac{\partial s}{\partial t} = \Delta_3 \psi$$

$$(235) \quad \frac{1}{c^2} \frac{\partial^2 \psi}{\partial t^2} = \Delta_3 \psi$$

$$(236) \quad \Delta_2 u = \frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2}$$

$$(237) \quad \Delta_2 u = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}$$

$$(238) \quad \frac{\partial^2 u}{\partial x^2} = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}$$

$$(239) \quad c_x = -\kappa \frac{\partial u}{\partial x}, \quad c_y = -\kappa \frac{\partial u}{\partial y}, \quad c_z = -\kappa \frac{\partial u}{\partial z}$$

$$(240) \quad \frac{\partial u}{\partial t} + \frac{\partial c_x}{\partial x} + \frac{\partial c_y}{\partial y} + \frac{\partial c_z}{\partial z} = 0$$

$$(241) \quad \frac{\partial u}{\partial t} = \frac{\partial}{\partial x} \left( \kappa \frac{\partial u}{\partial x} \right) + \frac{\partial}{\partial y} \left( \kappa \frac{\partial u}{\partial y} \right) + \frac{\partial}{\partial z} \left( \kappa \frac{\partial u}{\partial z} \right)$$

density  $\rho$ , then for small oscillations  $p = \rho_0(1 + s)$ ,  $p = p_0 + c^2 \rho_0 s$ , in which  $s$  is the condensation of the gas and  $c^2 = (dp/d\rho)_0$ , and  $\rho_0$ ,  $p_0$  are the equilibrium values of  $p$  and  $\rho$ . The equations of (small) motions are that the partial derivative of each component of the velocity with respect to time equals the product of  $c^2$  and the appropriate partial derivative of  $s$  (see 230); and the equation of continuity is to the same approximation that the sum of  $\partial u/\partial x$ ,  $\partial v/\partial y$ ,  $\partial w/\partial z$ , and  $\partial s/\partial t$  equals zero (see 231). For irrotational motion there exists a function  $\psi$  with the property that each component of the velocity equals minus the appropriate partial derivative of  $\psi$  (see 232).

The above equations (see 230 and 232) are therefore equivalent to the equation that the partial derivative of  $\partial\psi/\partial t - c^2 s$  with respect to each of  $x$ ,  $y$ , and  $z$  is zero (see 233). The equation of continuity (231) is equivalent to the restriction that the partial derivative of  $s$  with respect to  $t$  equals the Laplacian of  $\psi$  (see 234) so that the function  $\psi$  satisfies the relation that the second partial derivative of  $\psi$  with respect to  $t$  is proportional to the Laplacian of  $\psi$  (see 235). This equation is called the three-dimensional wave equation.

It can also be shown that in the absences of charges or currents the scalar potential and each component of the vector potential of an electromagnetic field satisfy the three-dimensional wave equation with  $c$  the velocity of light.

**Transverse vibrations of a membrane.** If a thin elastic membrane of uniform areal density  $a$  is stretched to a uniform tension  $T$  and if, in the equilibrium position, the membrane coincides with the  $xy$ -plane, then the small transverse vibration  $u(x, y, t)$  of the point  $(x, y)$  of the membrane satisfies an equation in which the two-dimensional Laplacian of  $u$  (see 236) is proportional to the second partial derivative with respect to  $t$  (see 237), and the wave velocity  $c$  is defined by the equation  $c^2 = T/a$ . Equation (237) is called the two-dimensional wave equation.

**Transverse vibrations of a string.** If a string of uniform linear density  $\sigma$  is stretched to a uniform tension  $T$ , and if, in the equilibrium position, the string coincides with the  $x$ -axis, then when the string is disturbed slightly from its equilibrium position, the transverse displacement  $u(x, t)$  satisfies an equation in which the second partial derivative of  $u$  with respect to  $x$  is proportional to the second partial derivative with respect to  $t$  (see 238), with constant of proportionality  $c^2 = T/\sigma$ . This equation is known as the one-dimensional wave equation.

**The diffusion equation.** Another interesting partial differential equation arises in the analysis of the diffusion process in physical chemistry. This is a process leading to the equalization of concentrations within a single phase, and it is governed by laws relating the rate of flow of the diffusing substance with the concentration gradient causing the flow. If  $u$  is the concentration of the diffusing substance, then the diffusion current vector  $(c_x, c_y, c_z)$  is defined by the equations in which each component of the diffusion current vector equals a quantity  $-\kappa$  times the appropriate first partial derivative of  $u$  (see 239). This is known as Fick's law, named after a 19th-century German physiologist, Adolf Fick, in which  $\kappa$  is the diffusion coefficient for the substance under consideration.

The continuity for the diffusion substance takes a form (see 240) that is similar to the usual continuity equation so that the concentration  $u(x, y, z, t)$  satisfies the diffusion equation (see 241) obtained by substituting Fick's law into the equation of continuity. In the most general case, the quantity  $\kappa$  is a function of  $x$ ,  $y$ ,  $z$  and of the concentration  $u$ , but if  $\kappa$  does happen to be a constant, the diffusion equation (241) reduces to the form of the heat conduction equation (217).

The diffusion equation (241) is satisfied also by the temperature  $u$  in a solid conducting heat; for that reason this equation is sometimes known as the heat conduction equation. In the steady-state case in which  $\kappa$  is constant, it follows from equation (217) with  $\partial u/\partial t \equiv 0$  that  $u$  satisfies Laplace's equation (227).

The form (217) of the diffusion equation is also satisfied by the vorticity in a viscous fluid started into motion from rest and by the electric field vector in the propagation of long waves in a good conductor.

If  $u$  depends only on one space coordinate  $x$  and the time  $t$ , the heat conduction equation (217) reduces to a form in which the second partial derivative of  $u$  with respect to  $x$  is proportional to the first partial derivative of  $u$  with respect to  $t$  (see 242); this is called the one-dimensional diffusion equation.

**The Fokker-Planck equation.** An equation very similar to the diffusion equation (242) is the Fokker-Planck equation linearly relating a quantity  $P$  and its first and second derivatives with respect to  $x$  with its first derivative with respect to  $t$  (see 243), which reduces in the case that the coefficient  $D$  of the second derivative is equal to zero to a first-order equation with a variable coefficient of  $\partial P/\partial x$  (see 244). The physical interpretation is that  $P$  is the probability that a random variable has the value  $x$  at time  $t$ . For instance,  $P$  might be the probability distribution of the deflection  $x$  of an electrical noise trace at time  $t$ .

**Birth-and-death equations.** Equations similar to the Fokker-Planck equation arises in the theory of birth and

$$(242) \quad \frac{\partial^2 u}{\partial x^2} = \frac{1}{\kappa} \frac{\partial u}{\partial t}$$

$$(243) \quad \frac{\partial P}{\partial t} = \beta \frac{\partial}{\partial x} (xP) + D \frac{\partial^2 P}{\partial x^2}$$

$$(244) \quad \frac{\partial P}{\partial t} = \beta P + \beta x \frac{\partial P}{\partial x}$$

$$(245) \quad u(z, t) = \sum_{n=0}^{\infty} P_n(t) z^n$$

$$(246) \quad \frac{\partial u}{\partial t} = (z-1)(\lambda z - \mu) \frac{\partial u}{\partial z}$$

$$(247) \quad \frac{\partial E}{\partial x} + Ri + L \frac{\partial i}{\partial t} = 0, \quad \frac{\partial i}{\partial x} + GE + C \frac{\partial E}{\partial t} = 0$$

$$(248) \quad \frac{\partial^2 u}{\partial x^2} = LC \frac{\partial^2 u}{\partial t^2} + (RC + LG) \frac{\partial u}{\partial t} + RG u$$

$$(249) \quad \Delta_3 \psi + \frac{8\pi^2 m}{h^2} (W - V) \psi = 0$$

$$(250) \quad \frac{\partial \sigma_{xx}}{\partial x} + \frac{\partial \sigma_{xy}}{\partial y} = 0, \quad \frac{\partial \sigma_{xy}}{\partial x} + \frac{\partial \sigma_{yy}}{\partial y} = 0$$

$$(251) \quad \sigma_{xx} = \frac{\partial^2 \psi}{\partial y^2}, \quad \sigma_{xy} = -\frac{\partial^2 \psi}{\partial x \partial y}, \quad \sigma_{yy} = \frac{\partial^2 \psi}{\partial x^2}$$

$$(252) \quad \frac{\partial^2}{\partial y^2} \{ \sigma_{xx} - \eta(\sigma_{xx} + \sigma_{yy}) \} + \frac{\partial^2}{\partial x^2} \{ \sigma_{yy} - \eta(\sigma_{xx} + \sigma_{yy}) \} = 2 \frac{\partial^2 \sigma_{xy}}{\partial x \partial y}$$

$$(253) \quad \frac{\partial^4 \psi}{\partial x^4} + 2 \frac{\partial^4 \psi}{\partial x^2 \partial y^2} + \frac{\partial^4 \psi}{\partial y^4} = 0$$

$$(254) \quad (\frac{1}{2} \sigma_{xx} - \frac{1}{2} \sigma_{yy})^2 + \sigma_{xy}^2 = k^2$$

$$(255) \quad \left( \frac{\partial^2 \psi}{\partial x^2} - \frac{\partial^2 \psi}{\partial y^2} \right)^2 + 4 \frac{\partial^4 \psi}{\partial x^2 \partial y^2} = 4k^2$$

death processes in bacterial populations. If it is assumed that the probability of the birth or death of a bacterium is proportional to the number present, and if  $P_n(t)$  is the probability of there being  $n$  bacteria in the population at time  $t$ , the probability generating function  $u(z, t)$  defined by a power series in  $z$  with the  $n$ th term having coefficient  $P_n(t)$  (see 245) satisfies a partial differential equation in which  $\partial u / \partial t$  equals a quadratic in  $z$ , with constants  $\lambda$  and  $\mu$ , times  $\partial u / \partial z$  (see 246).

Similar equations arise in birth-and-death problems in which different physical assumptions are made and in discussions of the probability distribution of telephone conversations carried on over a certain number of telephone lines.

**Poincaré's telegraphy equation.** An interesting second-order equation was derived by Poincaré in his study of the one-dimensional flow of electricity in a long insulated cable. The current  $i(x, t)$  and the voltage  $E(x, t)$  then satisfy the pair of differential equations involving (see 247)  $R, L, C$ , and  $G$ , which denote, respectively, the series resistance, the inductance, capacitance, and conductance per unit length. It can then be shown that both  $E$  and  $i$  satisfy a second-order partial differential equation linearly relating  $u$ , its second partial derivative with respect of  $x$ , and its first and second partial derivatives with respect to  $t$  (see 248), which is known as the telegraphy equation.

If the leakage to ground is small, so that  $G$  and  $L$  may be taken to be small, the telegraphy equation reduces to the one-dimensional diffusion equation with  $\kappa = (RC)^{-1}$ . On the other hand, if the emphasis is on high-frequency phenomena on a cable, the terms involving the time derivatives predominate. Equations (247) show that this is equivalent to taking  $G$  and  $R$  to be zero, and hence that the telegraphy equation (248) reduces to the one-dimensional wave equation (238) with  $c = (LC)^{-1/2}$ . (In this context, the equation is sometimes referred to as the radio equation.)

**Schrodinger's equation.** In wave mechanics the wave function  $\psi$  of a single particle such as an electron has the physical interpretation that  $|\psi(x, y, z)|^2 d\tau$  is the probability that the electron will be found in a small element of volume  $d\tau$  the centre of which is at the point with coordinates  $(x, y, z)$ . In the steady-state case the variation of  $\psi$  throughout a field the potential energy of which is  $V(x, y, z)$  is described by Schrodinger's equation involving  $m$ , the mass of the particle,  $h$ , Planck's constant, and  $E$ , the total energy of the particle and linearly relating the Laplacian of  $\psi$  and the quantity  $(E - V)\psi$  (see 249).

**Higher-order equations in physics.** The above equations are—with the exception of one or two first-order equations—all of the second order. It is therefore important to notice that not all physical problems can be formulated in terms of partial differential equations of the second order.

For instance, a state of plane strain in a two-dimensional solid free from body forces can be specified by three stress components  $\sigma_{xx}$ ,  $\sigma_{xy}$ , and  $\sigma_{yy}$  that satisfy equilibrium conditions that can be stated as first-order linear partial differential equations (see 250). If  $\sigma_{xx}$ ,  $\sigma_{xy}$ , and  $\sigma_{yy}$  are equal to the appropriate second partial derivatives of any arbitrary function  $\psi$ , then they (see 251) satisfy the equilibrium conditions, and  $\psi$  is called an Airy stress function.

If the body is elastic, the components of stress satisfy compatibility equations involving the second partial derivatives of  $u$ ,  $\sigma_{xy}$ , and  $\sigma_{yy}$  (see 252), from which it follows that  $\psi(x, y)$  satisfies a fourth-order linear equation that can be written  $\Delta^2 \Delta^2 \psi = 0$  and is called the two-dimensional biharmonic equation (see 253). (The reason for this is that Laplace's equation is sometimes referred to as the harmonic equation.)

If, instead of being elastic, the body is perfectly plastic, then the stress components satisfy the quadratic condition; this quadratic condition is known as the Hercky-Mises condition (see 254). Hence, the Airy stress function satisfies a fourth-order nonlinear partial differential equation (see 255).

## CLASSIFICATION OF PARTIAL DIFFERENTIAL EQUATIONS

A partial differential equation governing a dependent variable  $u$  is said to be linear if  $u$  and its partial derivatives occur only to the first power. For example, if second-order equations in two independent variables  $x$  and  $y$  are considered, then a linear equation involves a sum of  $u$  and its first and second derivatives, with coefficients  $a, b, c, f, g, h$ , and  $k$  that are functions of  $x$  and  $y$  only (see 256).

The solution of a nonlinear equation is considerably more difficult to obtain than the solution of a linear equation; general methods of solution have been devised, however, for two special types of nonlinearity. A nonlinear equation in which the partial derivatives of  $u$  occur linearly—but in which  $u$  itself does not do so (see 257)—is said to be quasi-linear, whereas an equation that is linear in only the highest order derivatives (see 258) is said to be semilinear.

$$(256) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} + f \frac{\partial u}{\partial x} + g \frac{\partial u}{\partial y} + hu = k$$

$$(257) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} + f \frac{\partial u}{\partial x} + g \frac{\partial u}{\partial y} = h(x, y, u)$$

$$(258) \quad a \frac{\partial^2 u}{\partial x^2} + 2b \frac{\partial^2 u}{\partial x \partial y} + c \frac{\partial^2 u}{\partial y^2} = f\left(x, y, u, \frac{\partial u}{\partial x}, \frac{\partial u}{\partial y}\right)$$

$$(259) \quad a \frac{\partial u}{\partial x} + b \frac{\partial u}{\partial y} = c$$

$$(260) \quad \frac{dx}{a} - \frac{dy}{b} - \frac{du}{c}$$

$$(261) \quad \frac{dx}{x^2} = \frac{dy}{y^2} = \frac{du}{(x+y)u}$$

$$(262) \quad x^2 \frac{\partial u}{\partial x} + y^2 \frac{\partial u}{\partial y} = (x+y)u$$

$$(263) \quad u^2(1 + u_x^2 + u_y^2) = 1$$

$$(264) \quad \begin{cases} F(D, D')z = f(x, y) \\ F(D, D') = \sum_r \sum_s c_{rs} D^r D'^s \end{cases}$$

$$(265) \quad \sum_{s=1}^n x^{s-1} \phi_s(ax-y) e^{-bx}$$

$$(266) \quad F(D, D') e^{ax+by} = F(a, b) e^{ax+by}$$

$$(267) \quad \sum_{n=0}^{\infty} c_n \cos(nx + \epsilon_n) e^{-\kappa n^2 t}$$

**First-order equations.** There is a particular kind of non-linear equation of the first order in which the product  $a$  and  $\partial u / \partial x$  is added to the product of  $b$  and  $\partial u / \partial y$  to yield  $c$  (see 259), in which  $a, b$ , and  $c$  are functions not only of  $x$  and  $y$  but of  $u$  also. This type of equation has been investigated by the 18th-century French mathematician Joseph-Louis Lagrange.

The general solution of this equation is  $F(\xi, \eta) = 0$ , in which  $F$  is an arbitrary function of two variables and  $\xi(x, y, u) = C_1$  and  $\eta(x, y, u) = C_2$  form a solution of the simultaneous ordinary differential equations expressed by equating the ratios of  $dx$  to  $a$ ,  $dy$  to  $b$ , and  $du$  to  $c$  (see 260). For example, because a system of equations of this form with  $x^2$  for  $a$ ,  $y^2$  for  $b$ , and  $(x+y)u$  for  $c$  (see 261) have solution  $xy/u = c_1$ ,  $(x-y)/u = c_2$ , it follows that the general solution of the equation with these terms for

a, b, and c (see 262) is  $F(xy/u, (x-y)/u) = 0$ , in which the function  $F$  is arbitrary.

The problem of solving a general nonlinear equation of the first order  $f(x, y, u, u_x, u_y) = 0$  in which the function  $f$  is not linear in  $u_x$  and  $u_y$  is more difficult. It turns out that there are three classes of integrals of an equation of this type:

- (1) Two-parameter systems of surfaces  $F(x, y, u, a, b) = 0$ ; such an integral is called a complete integral.
- (2) If any one-parameter subsystem  $F(x, y, u, a, \phi(a)) = 0$  is taken and its envelope is formed (by eliminating  $a$  from the equations  $F = 0, F_a = 0$ ), a general integral is obtained.
- (3) If the envelope of the complete integral in (1) (obtained by eliminating  $a, b$  from the equations  $F = 0, F_a = 0, F_b = 0$ ) exists, a singular integral of the equation is obtained.

For example, there is the equation in which the sum of  $1, u_x^2$ , and  $u_y^2$ , that, when multiplied by  $u^2$  (see 263), has the complete integral  $(x-a)^2 + (y-b)^2 + u^2 = 1$ . If  $b = a$  and if the envelope of the resulting subsystem of spheres is written, then the general integral  $(x-y)^2 + 2u^2 = 2$  is obtained; moreover, because the envelope of the complete integral consists of the planes  $u = \pm 1$ , then it follows that  $u = 1$  and  $u = -1$  are both singular integrals of the equation.

Solutions of nonlinear first-order equations are usually obtained by a method known as Charpit's method, which is too complicated to be described here. The solutions of some special types are, however, easily derived.

If the equation is of the type  $f(u_x, u_y) = 0$ —i.e., if it involves only the derivatives  $u_x, u_y$ —the complete integral is  $u = ax + Q(a)y + b$ , in which  $a$  and  $b$  are arbitrary constants and  $q = Q(a)$  is the solution of the algebraic equation  $f(a, q) = 0$ .

If the equation is of the type  $f(u, u_x, u_y) = 0$ ,  $u_x$  and  $u_y$  are found by solving the equations  $f(u, u_x, u_y) = 0, u_x = au$ , and then determining  $u(x, y)$  from the equation  $du = u_x dx + u_y dy$ .

A separable equation  $f(x, u_x) = g(y, u_y)$  is solved by determining  $u_x$  and  $u_{xy}$  from the equations  $f(x, u_x) = a$  and  $g(y, u_y) = a$ , respectively, and finding  $u$  as in the last case.

And, finally, there are Clairaut equations,  $u = xu + yu + f(u_x, u_y)$ , which have complete integrals  $u = ax + by + f(a, b)$ .

**Linear equations with constant coefficients.** Linear partial differentials with constant coefficients can be solved simply. Such an equation can be written in the form of an equality between a linear combination of derivatives  $F(D, D')z$  and  $f(x, y)$ , a function of  $x$  and  $y$  (see 264). Any solution of the equation is called a particular integral and the most general solution of the corresponding homogeneous equation  $F(D, D')z = 0$  is called the complementary function of the equation; if  $z_1$  is a particular integral and  $u$  is the complementary function, the general solution is  $u + z_1$ . It follows from the linearity of the operator  $F$  that if  $u_1, u_2, \dots, u_n$  are solutions of  $Fz = 0$ , then  $\sum_{r=1}^n c_r u_r$ , in which the  $c$ 's are arbitrary constants, is also a solution.

The operators  $F(D, D')$  are classified into two main types:  $F(D, D')$  is reducible if it can be written as the product of linear factors of the form  $D + aD' + b$  with  $a, b$  constants; if it cannot be written in such a form, then  $F(D, D')$  is said to be irreducible.

The form of the complementary function in the reducible case follows from the fact that if  $(D + aD' + b)^n$  is a factor of  $(D, D')$  and if the functions  $\phi_1, \phi_2, \dots, \phi_n$  are arbitrary, then a sum involving these functions and an exponential (see 265) is a solution of  $F(D, D') = 0$ . When  $F$  is irreducible it is not always possible to find a solution with the full number of arbitrary functions, but it is possible to construct solutions that contain as many arbitrary constants as are required. The method of deriving such solutions depends on the result of differentiating an exponential (see 266) so that  $e^{ax+by}$  is a solution of  $F(D, D') = 0$ , provided that  $a$  and  $b$  are con-

nected through the equation  $F(a, b) = 0$ . In this way it is possible to construct a solution of the homogeneous equation that contains as many arbitrary constants as may be required.

For example, the one-dimensional diffusion equation (see 242) has a solution  $\exp(ax + bt)$  only if  $b = a^2\kappa$ , and this relation is satisfied if  $a = \pm i\eta$  and  $b = -\kappa\eta^2$  are taken. In this way solutions of the diffusion equation can be constructed as the sum of terms each of which is the product of a cosine and an exponential and involving constants  $c_n$  and  $\varepsilon_n$  (see 267).

**Semilinear equations of the second order with variable coefficients.** Next in order of complexity to an equation with constant coefficients is a semilinear second-order equation (see 258). This equation is reduced to canonical form by changing the independent variables from  $x, y$  to  $\xi, \eta$ . The choice of  $\xi$  and  $\eta$  is dictated by the nature of the roots  $\lambda_1(x, y), \lambda_2(x, y)$  of the quadratic equation  $a\lambda^2 + 2b\lambda + c = 0$ . There are three cases to be considered depending on the sign of the discriminant  $A$  defined by the equation  $A = b^2 - ac$ .

(i)  $A > 0$ : If for every  $(x, y)$  in a region  $\Omega$  of the  $xy$ -plane,  $A > 0$ , the roots  $\lambda_1, \lambda_2$  are real and distinct. If  $\xi$  and  $\eta$  are now chosen to be such that  $\xi(x, y) = c_1$  and  $\eta(x, y) = c_2$  are, respectively, the integral curves of the ordinary differential equations  $y' + \lambda_1(x, y) = 0$  and  $y' + \lambda_2(x, y) = 0$ , the equation is transformed to the canonical form in which the second mixed partial derivative equals some function of  $\xi, \eta, u$  and the first partial derivatives of  $u$  (see 268). In this case the equation is said to be hyperbolic in the region  $\Omega$ . The curves  $\xi(x, y) = c_1, \eta(x, y) = c_2$  are called the characteristic curves of the equation, or, more simply, the characteristics of the equation. An equation that is hyperbolic in a region  $\Omega$ , therefore, has two families of characteristics in that region.

For example, an equation in which the coefficient of  $\partial u / \partial x$  is  $1/x$  and the coefficient of  $\partial^2 u / \partial y^2$  is  $x^2$  (see 269) is hyperbolic at all points in the  $xy$ -plane, has the two families of characteristics  $x^2/2 + y = \text{constant}$  and canonical form with the second mixed partial equal to zero (see 270). From past equations, it is apparent that this equation has the general solution  $u = f(\xi) + g(\eta)$ , and thus the original equation has the general solution  $u = f(x^2/2 + y) + g(x^2/2 - y)$ , in which the functions  $f$  and  $g$  are arbitrary.

(ii)  $A = 0$ : The function  $\xi$  is defined in precisely the same way as in case (i) and  $\eta$  is taken to be any function of  $x$  and  $y$  that is independent of  $\xi$ . The canonical form of the equation in this case has the second partial derivative with respect to  $\eta$  equal to a function of  $\xi, \eta, u$  and the first partial derivatives of  $u$  (see 271). An equation of this type is said to be parabolic.

For example, an equation in which twice the second mixed partial derivatives is added to the other two second partial derivatives to give a result of zero (see 272) is parabolic. If  $\xi = x - y$  and  $\eta = x + y$ , it is found that it reduces to the canonical form in which the second partial derivative with respect to  $\eta$  equals zero (see 273), with solution  $u = \eta f(\xi) + g(\xi)$ , in which  $f$  and  $g$  are arbitrary functions. The solution of the original equation is therefore obtained by substituting the appropriate quantities for  $\eta$  and  $\xi$  in this expression (see 274).

(iii)  $A < 0$ : In this case the roots  $\lambda_1$  and  $\lambda_2$  are complex conjugates so that if  $\xi$  and  $\eta$  are chosen as in case (i) they will be complex-valued functions of the real variables  $x$  and  $y$ . In terms of this pair of functions  $\xi, \eta$  another pair  $\alpha, \beta$  are defined as a linear combination of  $\xi$  and  $\eta$  involving complex numbers (see 275). When transformed to the new independent variables, the equation takes the canonical form in which the second partial derivative with respect to  $\alpha$ , when added to the second partial derivative with respect to  $\beta$ , equals some function of  $\alpha, \beta, u$ , and the first partial derivatives of  $u$  (see 276). Such an equation is said to be of elliptic type.

For example, an equation in which the second partial derivative with respect to  $x$ , when added to the product of  $x^2$  and the second partial derivative with respect to  $y$ ,

The three  
types of  
semilinear  
second-  
order  
equations

gives zero (see 277) is elliptic throughout the whole  $xy$ -plane. If the method in (i) is used, then it is found that  $\xi = x^2/2 + iy$  and  $\eta = x^2/2 - iy$  may be taken, and hence  $\alpha = x^2/2$ ,  $\beta = y$ . Transforming to these new variables, the equation has the canonical form with the function being the product of  $-1/(2\alpha)$  and the first partial derivative with respect to  $\alpha$  (see 278).

#### INITIAL VALUE AND BOUNDARY VALUE PROBLEMS

In applications of partial differential equations, the concern is not so much with determining the general solution of an equation as with finding the solution that satisfies some other prescribed conditions. Problems involving the solution of a partial differential equation and the fulfillment of additional conditions have been classified into the following types. Only second-order equations in two independent variables will be considered.

$$(268) \quad \frac{\partial^2 u}{\partial \xi \partial \eta} = h\left(\xi, \eta, u, \frac{\partial u}{\partial \xi}, \frac{\partial u}{\partial \eta}\right)$$

$$(269) \quad \frac{\partial^2 u}{\partial x^2} - \frac{1}{x} \frac{\partial u}{\partial x} = x^2 \frac{\partial^2 u}{\partial y^2}$$

$$(270) \quad \frac{\partial^2 u}{\partial \xi \partial \eta} = 0$$

$$(271) \quad \frac{\partial^2 u}{\partial \eta^2} = h\left(\xi, \eta, u, \frac{\partial u}{\partial \xi}, \frac{\partial u}{\partial \eta}\right)$$

$$(272) \quad \frac{\partial^2 u}{\partial x^2} + 2 \frac{\partial^2 u}{\partial x \partial y} + \frac{\partial^2 u}{\partial y^2} = 0$$

$$(273) \quad \frac{\partial^2 u}{\partial \eta^2} = 0$$

$$(274) \quad u = (x + y)f(x - y) + g(x - y)$$

$$(275) \quad \alpha = \frac{1}{2}(\xi + \eta), \quad \beta = \frac{1}{2}i(\eta - \xi)$$

$$(276) \quad \frac{\partial^2 u}{\partial \alpha^2} + \frac{\partial^2 u}{\partial \beta^2} = k\left(\alpha, \beta, u, \frac{\partial u}{\partial \alpha}, \frac{\partial u}{\partial \beta}\right)$$

$$(277) \quad \frac{\partial^2 u}{\partial x^2} + x^2 \frac{\partial^2 u}{\partial y^2} = 0$$

$$(278) \quad \frac{\partial^2 u}{\partial \alpha^2} + \frac{\partial^2 u}{\partial \beta^2} + \frac{1}{2\alpha} \frac{\partial u}{\partial \alpha} = 0$$

$$(279) \quad u(0, t) = 0, \quad u(a, t) = 0, \quad t > 0$$

$$(280) \quad u(x, 0) = f(x), \quad u_t(x, 0) = g(x), \quad 0 < x < a$$

$$(281) \quad u_{xy} = f(x, y, u, u_x, u_y)$$

**Initial value problems.** The classic case of an initial value problem arises in the discussion of the transverse oscillations of a stretched string. The transverse displacement  $u(x, t)$  satisfies the partial differential equation (238) for  $0 < x < a$ ,  $t > 0$ , in which  $a$  denotes the length of the string. Because the string is assumed to be fixed at its ends,  $u(0, t)$  and  $u(a, t)$  must both equal zero for all positive values of  $t$  (see 279), and if the problem is that of determining the subsequent shape of the string when its initial shape and velocity are prescribed, the function  $u$  must satisfy equations in which  $u(x, 0)$  and  $u_t(x, 0)$  equal prescribed functions  $f(x)$  and  $g(x)$  (see 280).

These particular equations—that is, (238), (279), and (280)—describe a problem that is analogous to an initial value problem in the theory of differential equations.

Arguing from this fact and also from physical intuition, one would expect to realize the existence of a unique solution  $u(x, t)$ . Because  $u$  satisfies the boundary conditions (279) as well as the initial conditions (280), the present problem is said to be a mixed initial and boundary value problem.

A different example is provided by solutions of the heat conduction equation (see 242). Here, on physical grounds, it would be expected that a unique function  $u(x, t)$  would be determined by the boundary conditions (see 279) and the single initial condition  $u(x) = f(x)$ ,  $0 < x < a$ .

**Cauchy problems.** A generalization of the initial value problems considered above is Cauchy's problem. This is best described for a hyperbolic equation in canonical form with independent variables  $x$  and  $y$  (see 281). The Cauchy problem for this equation consists of finding a solution  $u$  with the property that prescribed values  $u = u(s)$ ,  $u_x = p(s)$ ,  $u_y = q(s)$  are assumed along a given curve with parametric equations  $x = x(s)$ ,  $y = y(s)$ . Because  $u$ ,  $p$ ,  $q$  must satisfy the compatibility equation found by the chain rule (see 282),  $p$  and  $q$  cannot be assigned independently. The values of  $u$  and its normal derivative on the curve  $\partial u / \partial n$  are in fact sufficient for the specification of  $u$ ,  $p$ , and  $q$ . These quantities are referred to as the Cauchy data.

**Dirichlet problems.** The first boundary value problem, also called the Dirichlet problem, consists of finding a solution  $u(x, y)$  of an elliptic equation in a region  $\Omega$  of the  $xy$ -plane that takes on prescribed values on the boundary of  $\Omega$ .

**Neumann problems.** The second boundary value problem for an elliptic partial differential equation in a region  $\Omega$  consists in finding a solution that possesses a prescribed normal derivative  $\partial u / \partial n = f$  on the boundary  $B$  of  $\Omega$ . It is often called a Neumann problem. It turns out the Neumann problem cannot be solved for Laplace's equation  $u_{xx} + u_{yy} = 0$  unless the prescribed function  $f$  satisfies the condition that the integral of  $f$  around the boundary equal zero (see 283).

**Robin problems.** The third boundary value problem, or Robin's problem, for an elliptic partial differential equation in a region  $\Omega$  consists of finding a solution  $u$  of the equation satisfying the condition that the sum of  $\alpha u$  and the normal derivative of  $u$  equal  $f$  (see 284) at all points of the boundary of  $\Omega$ ,  $\alpha$  and  $f$  being prescribed.

#### SYSTEMS OF PARTIAL DIFFERENTIAL EQUATIONS

In many applications it is necessary to consider a pair of first-order equations each involving one partial derivative with respect to  $x$  and two partial derivatives with respect to  $y$  (see 285) with coefficients of the partial derivatives with respect to  $y$  being  $a_{11}$ ,  $a_{12}$ ,  $a_{21}$ ,  $a_{22}$ , which are functions of  $x$  and  $y$  and  $b_1$ ,  $b_2$  are functions of  $x$ ,  $y$ ,  $u$ . The first stage in solving equations of this type is to transform the system into one in which each equation involves differentiations in one direction only.

If a certain quadratic equation in  $\lambda$  formed from  $a_{11}$ ,  $a_{22}$ ,  $a_{12}$ , and  $a_{21}$  (see 286) has two real distinct roots  $\lambda_1(x, y)$ ,  $\lambda_2(x, y)$ , the system can be transformed to a pair of equations, each involving only one differentiation operator  $D_j$  (see 287), in which  $D_j$  is the operator of differentiation consisting of differentiation with respect to  $x$  added to the product of  $\lambda_j$  and differentiation with respect to  $y$  (see 288) in the direction defined by an ordinary differential equation in which the derivative of  $y$  equals  $\lambda_j$  (see 289). It should be emphasized that this reduction is possible if, and only if, the equation (286) has two distinct real roots. When this is the case, the system is said to be of hyperbolic type. On the other hand, if the roots of (286) are complex, the system is of elliptic type. The two families of curves in the  $xy$ -plane defined by the ordinary differential equations (289) are called the characteristics of the system.

If the column vector  $U$ , with elements  $u$  and  $v$ , the column vector  $B$ , with elements  $b_1$  and  $b_2$ , and the square matrix  $A$ , with elements  $a_{11}$ ,  $a_{12}$ ,  $a_{21}$ , and  $a_{22}$  (see 290), are introduced, the system may be written as a matrix equation relating the partial derivatives  $U_x$  and  $U_y$  (see 291)

and the equation in  $\lambda$  (see 286) as an equation stating that the determinant of  $A - \lambda I$  is zero (see 292). It is now an easy matter to generalize the system being considered (see 291) by taking  $U$ ,  $B$  to be column vectors with  $m$  components and  $A$  is a matrix with  $m$  rows and  $m$  columns. The determinant equation (292) now has  $m$  roots. If these roots are real and distinct the system can be transformed to  $m$  equations, each involving only one differentiation operator  $D$ , (see 293). The only change in the interpretation is that the equations defining  $D_j$  (288 and 289) now hold for  $j = 1, 2, \dots, m$ . Again the system (291) is hyperbolic.

A quasi-linear second-order partial differential equation can be replaced by a system of the type in which the partial derivative of  $U$  with respect to  $x$  equals the matrix product of  $A$  and the partial derivative of  $U$  with respect to  $y$  (see 294), in which  $U$  has 8 components and  $A$  is an  $8 \times 8$  matrix.

#### TECHNIQUES OF SOLUTION OF PARTIAL DIFFERENTIAL EQUATIONS

**Separation of variables.** One of the oldest techniques for the solution of a linear partial differential equation for a function  $u$  of the independent variables  $x, y, \dots, t$  is to assume a solution that is a product of  $X(x)$ ,  $Y(y)$ ,  $\dots$ ,  $T(t)$  of functions of one variable (see 295) and by substituting in the original equation to obtain ordinary differential equations for the functions  $X, Y, \dots, T$ .

For example, if  $u$  satisfies the one-dimensional wave equation (see 238), the equation has solutions of the type  $u(x, t) = X(x)T(t)$  if  $X$  and  $T$  can be chosen such that the ratio of  $X''(x)$  to  $X(x)$  is proportional to the ratio of  $T''(t)$  to  $T(t)$  (see 296). Because the left side of this equation is a function of  $x$  alone and the right side is a function of  $t$  alone, the two can be equal for all values of  $x$  and  $t$  if, and only if, each is equal to a constant  $-\lambda c^2$ , say; i.e., it is necessary that  $X$  and  $T$  satisfy second-order linear differential equations with constant coefficients (see 297).

The value of  $\lambda$  is determined by the boundary conditions. For example, if the boundary conditions are that  $u(0, t) = u(a, t) = 0$  for all values of  $t > 0$ , they are satisfied if  $X(0) = X(a) = 0$ . This is possible only if  $\lambda = n^2\pi^2/a^2$ ,  $n = 1, 2, \dots$ , when  $X(x) = (\sin n\pi x/a)$ . If in addition  $u_t(x, 0) = 0$ , then  $T'(0) = 0$  also; i.e.,  $T(t) = \cos(n\pi ct/a)$ ; thus a solution of the equation (238) in the form of a function  $u_n(x, t)$  equalling the product of a cosine and a sine, involving  $t$  and  $x$  respectively (see 298), is obtained. This technique is called separation of variables.

Quite complicated solutions can be constructed by combining this method with the principle of linear superposition. For example, an infinite linear combination of the  $u_n(x, t)$ , with coefficients  $c_n$  (see 299) with  $u_n$  given above (see 298), will be a solution of the wave equation (see 238) for  $0 \leq x \leq a$ ,  $t \geq 0$ , satisfying the boundary conditions  $u(0, t) = u(a, t) = 0$  and the initial conditions  $u(x, 0) = f(x)$ ,  $u_t(x, 0) = 0$  if an infinite sequence of constants  $c_1, c_2, \dots$  can be found such that  $f(x)$  can be written as an infinite series with terms  $c_n \sin(n\pi x/a)$  (see 300). This leads to a consideration of the theory of Fourier series (see ANALYSIS, FOURIER). It should also be observed that the values  $\lambda_n = n^2\pi^2/a^2$ ,  $n = 1, 2, \dots$ , are called the eigenvalues of the stated problem.

**Integral transform solutions.** Closely related to the method of separation of variables is the method of integral transforms. To illustrate the method, the solution of Laplace's equation in two dimensions (see 301) is considered in the semi-infinite strip  $x > 0$ ,  $0 < y < a$ , when  $u$  satisfies the boundary conditions  $u(0, y) = 0$ ,  $u(x, y) \rightarrow 0$  as  $x \rightarrow \infty$ ,  $0 \leq y \leq a$  and  $u(x, 0) = 0$ ,  $u(x, a) = f(x)$ .

The method of separation of variables then gives a solution of the form  $\sin(\xi x) \sinh(\xi y)$ , in which  $\xi$  is any constant. By the superposition principle such a solution, when multiplied by  $F(\xi)/\sinh(a)$  and integrated from zero to infinity (see 302), will be the required solution if a function  $F$  can be found with the property that for all  $x > 0$ ,  $f(x)$  equals the integral from zero to infinity of  $F(\xi) \sin(\xi x)$  (see 303). This leads to a consideration of the theory of Fourier integrals. The Fourier sine transform of  $f(x)$  is  $F(\xi)$ .

Probably the best known example of an integral transform is the Laplace transform, which was considered earlier. To illustrate its use, the solution of the one-dimensional diffusion equation (see 242) is considered in the range  $x \geq 0$ ,  $t \geq 0$ , and satisfying the conditions  $u(x, 0) = 0$ ,  $u(0, t) = f(t)$ ,  $u(x, t) \rightarrow 0$  as  $x \rightarrow \infty$ . If the Laplace transforms  $\mathfrak{L}[u(x, p)]$  of  $u(x, t)$  and  $\mathfrak{L}[f(p)]$  of  $f(t)$  (see 304) are introduced, then it is easily shown that  $\mathfrak{L}[u(x, p)] = \mathfrak{L}[f(p)] \exp[-x\sqrt{p/\kappa}]$ ; thus the required solution is the function the Laplace transform of which is  $\mathfrak{L}[f(p)] \exp[-x\sqrt{p/\kappa}]$ . The solution can be found by means of the inversion theorem, which gives a method of finding a function the Laplace transform of which is prescribed.

**Variational methods.** Approximate solutions of partial differential equations can often be obtained by using the fact that the function  $u$  that makes a certain integral an extremum satisfies a partial differential equation.

To illustrate the procedure, the function  $u(x, y, z)$  is considered that makes the volume integral  $I(u)$  of a function  $F(x, y, z, u, u_x, u_y, u_z)$  of the coordinates,  $u$ , and its first partial derivatives (see 305), an extremum with respect to twice-differentiable functions that assume prescribed values at all points of the boundary  $S$  of  $V$ . This

$$(282) \quad \frac{du}{ds} = p(s) \frac{dx}{ds} + q(s) \frac{dy}{ds}$$

$$(283) \quad \int_B f ds = 0$$

$$(284) \quad \frac{\partial u}{\partial n} + \alpha u = f$$

$$(285) \quad \begin{cases} \frac{\partial u}{\partial x} + a_{11} \frac{\partial u}{\partial y} + a_{12} \frac{\partial v}{\partial y} = b_1 \\ \frac{\partial v}{\partial x} + a_{21} \frac{\partial u}{\partial y} + a_{22} \frac{\partial v}{\partial y} = b_2 \end{cases}$$

$$(286) \quad (a_{11} - \lambda)(a_{22} - \lambda) - a_{21}a_{12} = 0$$

$$(287) \quad \begin{cases} D_1 u + (\lambda_1 - a_{11}) D_1 v = b_1 + (\lambda_1 - a_{11}) b_2 \\ D_2 u + (\lambda_2 - a_{11}) D_2 v = b_1 + (\lambda_2 - a_{11}) b_2 \end{cases}$$

$$(288) \quad D_j = \frac{\partial}{\partial x} + \lambda_j \frac{\partial}{\partial y}, \quad j = 1, 2$$

$$(289) \quad \frac{dy}{dx} = \lambda_j(x, y), \quad j = 1, 2$$

$$(290) \quad U = \begin{bmatrix} u \\ v \end{bmatrix}, \quad A = \begin{bmatrix} a_{11} & a_{12} \\ a_{21} & a_{22} \end{bmatrix}, \quad B = \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}$$

$$(291) \quad U_x + A U_y = B$$

$$(292) \quad \det(A - \lambda I) = 0$$

$$(293) \quad \sum_{k=1}^m c_{jk} D_j U_k + \sum_{k=1}^m c_{jk} b_k = 0, \quad j = 1, 2, \dots, m$$

$$(294) \quad U_x = A U_y$$

$$(295) \quad u(x, y, \dots, t) = X(x)Y(y) \dots T(t)$$

$$(296) \quad c^2 X''(x)/X(x) = T''(t)/T(t)$$

$$(297) \quad X''(x) + \lambda X(x) = 0, \quad T''(t) + c^2 \lambda T(t) = 0$$

must satisfy the Euler-Lagrange equation (see 306). Hence, the solution of the Dirichlet problem for the Euler-Lagrange equation (306) is the function  $u$  that takes prescribed values on  $S$  and makes  $I(u)$  an extremum. The value of this observation lies in the fact that in certain cases direct methods may produce a solution of the extremal problem.

Dirichlet's  
principle

For example, from among the functions that have continuous second derivatives in  $V$  and on  $S$  and take on the prescribed values  $f$  on  $S$ , that function which makes the integral of the squares of the first derivatives (see 307) an extremum is the solution of the Dirichlet problem for Laplace's equation (see 308). This is known as Dirichlet's principle.

**Perturbation methods.** Perturbation theory was created by a British physicist Lord Rayleigh in the 19th century. He gave a formula for computing the natural frequencies and modes of a vibrating system the physical characteristics of which differ slightly from those of a simpler system the behaviour of which is completely known. In terms of the method of separation of variables, a differential equation of the form  $[L(\epsilon) + \lambda]X = 0$  has to be solved, subject to certain boundary conditions,  $L(\epsilon)$  being a differential operator containing a small numerical parameter  $\epsilon$ , when the eigenvalues and eigenfunctions of  $[L(0) + \lambda]X = 0$  with the same boundary conditions, are known.

For example, the method of separation of variables applied to the one-dimensional wave equation with an additional term of the product of  $\epsilon$  and the fourth partial derivative of  $u$  with respect to  $x$  (see 309) leads to the perturbed form of the first of the separated equations (297), a fourth-order linear ordinary differential equation (see 310).

The perturbation method consists essentially in expanding  $L(\epsilon)$  in powers of  $\epsilon$  with coefficients  $L^1, L^2, \dots$ , which are differential operators (see 311) and assuming that  $X_n$  and  $\lambda_n$  can also be expanded in powers of  $\epsilon$ , in which  $X_n^{(0)}(x)$  is the eigenfunction corresponding to the eigenvalue  $\lambda_n^{(0)}$  of the unperturbed problem (see 312).

**Approximate solutions.** One of the most frequently used methods of obtaining approximate solutions of partial differential equations is the method of finite differences, which consists essentially in replacing each partial derivative by a difference quotient. To be specific, the case of a function  $u(x, t)$  of two independent variables  $x$  and  $t$  is considered. If the value of  $u$  were known at each point  $(rh, sk)$  in which  $r$  and  $s$  are integers and  $h$  and  $k$  are small positive quantities, an approximation could be made to the partial derivative  $\partial u / \partial x$  at the point  $(rh, sk)$  by the difference quotient formed by taking the difference between  $u_{r+1,s}$  and  $u_{r,s}$  and dividing by  $h$  (see 313) in which  $u_{r,s} \equiv u(rh, sk)$ , and the second derivative  $\partial^2 u / \partial x^2$  by applying the process again to the difference quotient just obtained (see 314). Suitable approximations for  $\partial u / \partial t$  and  $\partial^2 u / \partial t^2$  can be found by the same process (see 315).

One possible finite-difference approximation to the one-dimensional diffusion equation (see 242) is therefore found by replacing the derivatives by the appropriate difference quotients (see 316), and the equation can be solved for  $u_{r,s+1}$ , with  $\rho = k/h^2$ . This gives a formula by means of which the unknown  $u_{r,s+1}$  might be determined at the  $(r, s+1)$  mesh point in terms of the known functions along the  $s$ th row. In this way the unknown values of  $u$  can be calculated along the first row,  $t = k$ , in terms of known boundary values along  $t = 0$ . The values along the second row,  $t = 2k$ , can be obtained in terms of the calculated values along the first, and the process is repeated to obtain the values along successive rows in terms of previously calculated values.

If  $u$  is the exact solution of the one-dimensional diffusion equation (see 242) and  $U$  the exact solution of the difference equation (see 316), then if  $U \rightarrow u$  as both  $h$  and  $k$  tend to zero, the finite difference equations are said to be convergent. At first sight it appears as though the mesh lengths  $h$  and  $k$  can be chosen arbitrarily, but this is not always so; for example, for the particular case of the difference equation (see 316) convergence only oc-

$$(298) \quad u_n(x, t) = \cos\left(\frac{n\pi ct}{a}\right) \sin\left(\frac{n\pi x}{a}\right)$$

$$(299) \quad u(x, t) = \sum_{n=1}^{\infty} c_n u_n(x, t)$$

$$(300) \quad f(x) = \sum_{n=1}^{\infty} c_n \sin\left(\frac{n\pi x}{a}\right)$$

$$(301) \quad u_{xx} + u_{yy} = 0$$

$$(302) \quad u(x, y) = \int_0^{\infty} F(\xi) \frac{\sinh(\xi y)}{\sinh(\xi a)} \sin(\xi x) d\xi$$

$$(303) \quad f(x) = \int_0^{\infty} F(\xi) \sin(\xi x) d\xi$$

$$(304) \quad \begin{cases} \mathcal{L}[u(x, p)] = \int_0^{\infty} u(x, t) e^{-pt} dt \\ \mathcal{L}[f(p)] = \int_0^{\infty} f(t) e^{-pt} dt \end{cases}$$

$$(305) \quad I(u) = \int_V F(x, y, z, u, u_x, u_y, u_z) d\tau$$

$$(306) \quad \frac{\partial F}{\partial u} = \frac{\partial}{\partial x} \left( \frac{\partial F}{\partial u_x} \right) + \frac{\partial}{\partial y} \left( \frac{\partial F}{\partial u_y} \right) + \frac{\partial}{\partial z} \left( \frac{\partial F}{\partial u_z} \right)$$

$$(307) \quad I(u) = \int_V [u_x^2 + u_y^2 + u_z^2] d\tau$$

$$(308) \quad \begin{cases} u_{xx} + u_{yy} + u_{zz} = 0 & \text{within } V \\ u = f, & \text{on } S \end{cases}$$

$$(309) \quad \frac{\partial^2 u}{\partial x^2} - \epsilon \frac{\partial^4 u}{\partial x^4} = \frac{1}{c^2} \frac{\partial^2 u}{\partial t^2}$$

$$(310) \quad X''(x) - \epsilon X^{(iv)}(x) + \lambda X(x) = 0$$

$$(311) \quad L(\epsilon) = L(0) + \epsilon L^{(1)} + \epsilon^2 L^{(2)} + \dots$$

$$(312) \quad \begin{cases} X_n = X_n^{(0)}(x) + \epsilon X_n^{(1)}(x) + \epsilon^2 X_n^{(2)}(x) + \dots \\ \lambda_n = \lambda_n^{(0)} + \epsilon \lambda_n^{(1)} + \epsilon^2 \lambda_n^{(2)} + \dots \end{cases}$$

curs if  $\rho \leq \frac{1}{2}$ . In the case of hyperbolic equations, it is possible to combine the use of characteristics with that of finite differences to obtain numerical solutions with a high degree of accuracy.

To obtain approximate solutions of boundary value problems for elliptic equations, it is sometimes possible to reformulate the problem as an integral equation and then to obtain approximate solutions of it.

#### EXISTENCE AND UNIQUENESS OF SOLUTIONS TO PARTIAL DIFFERENTIAL EQUATIONS

The basic existence and uniqueness theorem of the theory of partial differential equations is the Cauchy-Kovalevskaya theorem, which in its simplest form relates to a system in two independent variables  $x, y$  in which  $u_x$  equals the product of  $A(u)$  and  $u_y, u(0, y)$  being equal to  $h(y)$  (see 317),  $u$  and  $h$  being column vectors with  $m$  components, the vector  $h$  being prescribed, and  $A$  is an  $m \times m$  matrix.

To state the result it is necessary to use the fact that a function is said to be analytic at a point if it has a Taylor expansion at that point.

The Cauchy-Kovalevskaya theorem then states that about any point at which the components of the given matrix  $A$  and of the given vector  $h$  are analytic, a neighbourhood can be found in which there exists a unique

The  
Cauchy-  
Kovalev-  
skaya  
theorem

vector  $u$ , with analytic coefficients, which is a solution of the initial value problem (see 317).

Although it has the appearance of great generality, this theorem has the great limitation that it is restricted to problems involving only analytic functions. What it does show is that within the class of analytic solutions of equations with analytic coefficients, the number of arbitrary functions required for a general solution is equal to the order of the equation. When  $k$  independent variables are involved, a generalization of the theorem shows that each such arbitrary function is a function of  $k - 1$  variables.

#### GENERALIZED THEORY OF PARTIAL DIFFERENTIAL EQUATIONS

The generalized theory of partial differential equations depends on generalizing the concept of a derivative. In order to do this it is necessary to introduce the idea of a test function.

$$(313) \quad \frac{u_{r+1,s} - u_{r,s}}{h}$$

$$(314) \quad \frac{u_{r+1,s} - 2u_{r,s} + u_{r-1,s}}{h^2}$$

$$(315) \quad \begin{cases} \frac{u_{r,s+1} - u_{r,s}}{k} \\ \frac{u_{r,s+1} - 2u_{r,s} + u_{r,s-1}}{k^2} \end{cases}$$

$$(316) \quad \begin{cases} \frac{u_{r,s+1} - u_{r,s}}{k} = \kappa \frac{u_{r+1,s} - 2u_{r,s} + u_{r-1,s}}{h^2} \\ u_{r,s+1} = u_{r,s} + \kappa \rho (u_{r-1,s} - 2u_{r,s} + u_{r+1,s}) \end{cases}$$

$$(317) \quad u_x = A(u)u_y \quad u(0, y) = h(y)$$

$$(318) \quad \int_{\Phi} f(x, y) \frac{\partial^{r+s} \phi}{\partial x^r \partial y^s} dx dy \\ = (-1)^{r+s} \int_{\Phi} g(x, y) \phi(x, y) dx dy$$

$$(319) \quad \begin{cases} u_{xx} + u_{yy} = f(x, y) \text{ in } \Omega \\ u = g(x, y) \text{ on } \partial\Omega \end{cases}$$

$$(320) \quad \begin{cases} B(\phi, u) = - \int_{\Omega} (D_{1,0} \phi D_{1,0} u + D_{0,1} \phi D_{0,1} u) dx dy \\ B(\phi, u) = \int_{\Omega} \phi f dx dy \end{cases}$$

$$(321) \quad \int_{\Omega} \phi (u_{xx} + u_{yy}) dx dy = - \int_{\Omega} (\phi_x u_x + \phi_y u_y) dx dy$$

Again the treatment is restricted to two dimensions. The function  $\phi(x, y)$  is said to be a test function if it vanishes outside a bounded region  $\Phi$  of the  $xy$ -plane and if it is infinitely differentiable in that region. If  $f$  is locally integrable in a region  $\Omega$  and if there exists a locally integrable function  $g$  such that for all test functions  $\phi$ , the integral of  $f(x, y) \frac{\partial^{r+s} \phi}{\partial x^r \partial y^s}$  over  $\Phi$  equals the integral of  $(-1)^{r+s} g(x, y) \phi(x, y)$  over  $\Phi$  (see 318)  $g$  is called a generalized derivative of  $f$  and  $g = D_{r,s} f$  is written.

Now the Dirichlet problem for Laplace's equation in two dimensions may be considered (see 319); in this instance,  $\partial\Omega$  denotes the boundary of  $\Omega$ . A generalized solution of the Dirichlet problem is defined by introducing a bilinear function  $B(\phi, u)$ , and  $B(\phi, u)$  is defined for all test functions  $\phi$  (see 320).

A function  $u$  is said to be a generalized solution of the stated Dirichlet problem if, and only if,  $u = g$  on  $\partial\Omega$  and if for every test function  $\phi$ ,  $B(\phi, u)$  equals the integral of  $\phi f$  over  $\Omega$  (see 320). On the other hand, a classical solution is a twice-differentiable function that assumes the correct boundary values; therefore, from Green's theorem (see 321), it follows that, if a classical solution to the stated Dirichlet problem exists, then it is also a generalized solution.

The theory of generalized solutions of partial differential equations forms what is known as the abstract theory of partial differential equations. (I.N.S.)

#### Special functions

Certain special functions are often used in mathematics and in physics, chemistry, engineering, and other branches of science and technology. It is possible to classify these into elementary functions and higher transcendental functions. The elementary functions include the exponential, logarithmic, trigonometric, and related functions. Frequently the term special functions is only applied to high transcendental functions. Some of the more important ones arising in differential equations will now be described.

The gamma and beta functions. The gamma function arose from attempts to extend the factorial function,  $n! \equiv n(n-1)(n-2) \dots 1$ , to non-integral values of  $n$ . This function is defined by  $\Gamma(x)$  being equal to the integral from  $t=0$  to infinity of  $e^{-t} t^{x-1}$  (see 322), for values of  $x$  greater than zero. The function has the property that  $\Gamma(x+1)$  equals the product of  $x$  and  $\Gamma(x)$ .

It follows that, if  $n$  is a positive integer, then  $\Gamma(n+1)$  equals  $n!$ . Furthermore,  $\Gamma(1/2)$  equals the square root of  $\pi$  (see 323).

The function was first defined by Euler and is widely used in mathematics, physics, engineering, and especially in probability theory and statistics. It arises in the series solutions of many differential equations.

Some useful related functions are:

(i) The *Incomplete* Gamma functions, which are defined by letting the upper or the lower limit of integration be a variable (see 324).

(ii) The Beta function  $\beta(p, q)$ , which is defined as being equal to the integral from zero to one of the product of  $t^{p-1}$  and  $(1-t)^{q-1}$  (see 325) for positive values of  $p$  and  $q$ . It is related to the gamma function because  $\beta(p, q)$  equals the product of  $\Gamma(p)$  and  $\Gamma(q)$  divided by  $\Gamma(p+q)$  (see 326).

Hypergeometric function. The hypergeometric function is the function  $F(a, b; c; x)$  defined by the so-called hypergeometric series (see 327). It was known to Euler and gets its name from the fact that it is a generalization of the geometric series  $(1+x+x^2+\dots)$  and reduces to this series when  $a=1$  and  $b=c$ . It satisfies the hypergeometric equation, a second-order linear differential equation with variable coefficients (see 328). Twenty-four solutions of this equation can be expressed in terms of hypergeometric equations.

The hypergeometric equation occurs in problems in fluid flow and other branches of physics and engineering. The hypergeometric function is important in mathematics because many other special functions are related to it.

**Legendre polynomials.** Legendre polynomials arise as particular solutions of Laplace's equation:  $\Delta u = 0$ . If  $R$  is the distance between a point with Cartesian coordinates  $(x, y, z)$  and the point  $(0, 0, 1)$ , then the reciprocal distance,  $\frac{1}{R}$ , is a solution of Laplace's equation.

If spherical polar coordinates are used for the point  $(r, \theta, \phi)$ , this solution is  $1 - 2r \cos \theta + r^2$  to the  $-1/2$  power. It is axisymmetric because it is independent of  $\phi$ , the azimuthal angle.

If  $\cos \theta$  is replaced by  $\mu$  the solution is  $(1 - 2r\mu + r^2)^{-1/2}$ , and it can be expanded to give a power series in  $r$  with the coefficients being polynomials in  $\mu$ . Thus it can be written in the form of an infinite series with terms of the form  $r^n P_n(\mu)$  for  $r$  less than one (see 329).

The coefficients  $P_n$  are called the Legendre polynomials of degree  $n$ .

The polynomials are solutions of Legendre's equation (see 228), a particular case of Laplace's equation expressed in spherical polar coordinates for axisymmetric solutions. They can be produced from the generating function  $(1 - 2rp - r^2)^{-1/2}$  and are explicitly given by Rodrigues' formula (see 330), which is named after a 19th-century French mathematician, Olinde Rodrigues.

**Associated Legendre functions.** These are functions satisfying the associated Legendre differential equation, a second-order linear equation with variable coefficients (see 331). This reduces to Legendre's equation when  $m = 0$ . Its solutions are associated Legendre functions (or polynomials). They are denoted by  $P_n^m$  and can be expressed in terms of the Legendre polynomials (see 332).

**Spherical harmonics.** The Legendre polynomials and associated Legendre functions are particular solutions of Laplace's equation. In general, functions satisfying this equation are known as harmonic functions and solutions that are homogeneous in  $x$ ,  $y$ , and  $z$  are called spherical (solid) harmonics. If spherical polar coordinates  $(r, \theta, \phi)$  are used, a spherical (solid) harmonic of degree  $n$ , denoted  $R_n$ , can be written as the product of  $r^n$  and  $S_n(\theta, \phi)$  (see 333), a function of  $\theta$  and  $\phi$  satisfying a second-order linear partial differential equation, which is found substituting  $\mathfrak{L}$  into Laplace's equation and applying the method of separation of variables (see 334). It is called a spherical surface harmonic. If  $R_n(x, y, z)$  is a polynomial of degree  $n$  and  $n$  is a positive integer, then  $S_n$  is a polynomial in  $\cos \theta$ ,  $\sin \theta$ ,  $\cos \phi$ , and  $\sin \phi$ .

**Zonal, sectoral, and tesseral harmonics.** A polynomial spherical harmonic of degree  $n$  can be represented uniquely by the product  $C_n r^{2n+1}$ , in which  $C_n$  is a constant, times  $n$  differentiations  $\partial/\partial h_1, \partial/\partial h_2, \dots, \partial/\partial h_n$  of  $1/r$ , in which (see 335)  $h_1, h_2, \dots, h_n$  are  $n$  directions in space, and  $\frac{\partial}{\partial h}$  denotes differentiation in a direction  $h$ .

If the  $n$  directions coincide, then, on a unit sphere about the origin, there are  $n$  circles of latitude on which the spherical surface (or solid) harmonic vanishes. These divide the sphere into zones, and the spherical harmonic is known as a zonal harmonic. The curves on the unit sphere on which the surface harmonic vanishes are called nodal lines. If the  $n$  directions are situated on a plane and are at angles of  $\frac{\pi}{n}$  to each other, the nodal lines are  $n$  circles of longitude. These divide the sphere into sectors, the spherical harmonic being known as a sectoral harmonic. If  $(n - m)$  directions coincide in one particular direction and the remaining  $m$  directions lie in a plane at right angles to this direction and are at angles  $\frac{\pi}{m}$ , then there are  $m$  circles of longitude and  $(n - m)$  circles of latitude. These divide the unit sphere into rectangles, the spherical harmonic being a tesseral harmonic.

It can be proved that spherical surface harmonics can be represented by the product  $S_n^m(\theta, \phi)$  of the associated Legendre function  $P_n^m(\cos \theta)$  and the complex exponential  $\exp[i m \phi]$  (see 336). Laplace's equation is satisfied by a linear combination of terms  $R_n^m(x, y, z)$ , which are products of  $r^n$ ,  $\exp[i m \phi]$ , and  $P_n^m(\cos \theta)$  (see 337).

$P_n^m(\cos \theta)$  is an associated Legendre polynomial. If  $m = n$ , the harmonic is a sectoral harmonic. If  $1 \leq m \leq n - 1$ , it is a tesseral harmonic. If  $m = 0$ , it is a zonal harmonic; the Legendre polynomial  $P_n(\cos \theta)$  is a zonal harmonic of degree  $n$ .

Spherical harmonics and surface harmonics arise in a variety of physical applications of Laplace's equation. Surface harmonics also arise in connection with Poisson's equation (see 226), the wave equation (see 235), the diffusion equation (see 241), Schrödinger's equation (see 249), and other partial differential equations.

**Bessel functions.** Just as the Laplace equations expressed in spherical polar coordinates lead to the Legendre equation and Legendre polynomials, its expression in cylindrical polar coordinates leads to the equation known as Bessel's equation. Bessel's equation of order  $\nu$  is a second-order differential equation with variable

coefficients (see 338) and is satisfied by the Bessel function (or Bessel function of the first kind), which can be expressed as a power series in power of  $t/2$  (see 339).  $J_\nu(t)$  is the Bessel function of order  $\nu$ . Such functions were used by the German astronomer Friedrich Wilhelm Bessel in the 19th century in problems in astronomy, although they had been used earlier by Bernoulli and Euler.

A second solution of the equation, if  $\nu$  is not an integer, is  $J_{-\nu}(t)$  leading to the general solution  $AJ_\nu(t) + BJ_{-\nu}(t)$ ,  $A$  and  $B$  being constants.

If  $\nu$  is an integer,  $p$ , the second solution is denoted by  $Y_p(t)$ , and a general solution is  $AJ_p(t) + BY_p(t)$ . For non-integer and zero values of  $\nu$ ,  $Y_\nu(t)$  can be expressed as the difference of  $J_\nu(t) \cos(\nu\pi)$  and  $J_{-\nu}(t)$ , divided by  $\sin(\nu\pi)$  (see 340), and is called a Bessel function of the second kind. It can be shown that if  $\nu$  tends to an integer  $p$  (or to zero) in the limit, the expression gives  $Y_p(t)$  (or

$$(322) \quad \Gamma(x) = \int_0^\infty e^{-t} t^{x-1} dt$$

$$(323) \quad \begin{cases} \Gamma(x+1) = x\Gamma(x) \\ \Gamma(n+1) = n! \\ \Gamma(\frac{1}{2}) = \sqrt{\pi} \end{cases}$$

$$(324) \quad \begin{cases} \gamma(x, z) = \int_0^z e^{-t} t^{x-1} dt \\ \Gamma(x, z) = \int_z^\infty e^{-t} t^{x-1} dt \end{cases}$$

$$(325) \quad \beta(p, q) = \int_0^1 t^{p-1} (1-t)^{q-1} dt$$

$$(326) \quad \beta(p, q) = \frac{\Gamma(p)\Gamma(q)}{\Gamma(p+q)}$$

$$(327) \quad \begin{cases} 1 + \frac{abx}{c+1} + \frac{a(a+1)b(b+1)x^2}{c(c+1)2!} + \\ + \frac{a(a+1)(a+2)b(b+1)(b+2)x^3}{c(c+1)(c+2)3!} + \dots \end{cases}$$

$$(328) \quad x(1-x) \frac{d^2 y}{dx^2} + [c - (a+b+1)x] \frac{dy}{dx} - aby = 0$$

$$(329) \quad \begin{cases} \frac{1}{\sqrt{1-2r \cos \theta + r^2}} = 1 + r\mu + \frac{1}{2}r^2(3\mu^2 + 1) + \dots \\ = \sum_0^\infty r^n P_n(\mu) \end{cases}$$

$$(330) \quad P_n(\mu) = \frac{1}{2^n n!} \frac{d^n}{d\mu^n} (\mu^2 - 1)^n$$

$$(331) \quad (1 - \mu^2) \frac{d^2 \omega}{d\mu^2} - 2\mu \frac{d\omega}{d\mu} + \left\{ (n+1) - \frac{m^2}{1 - \mu^2} \right\} \omega = 0$$

$$(332) \quad P_n^m(\mu) = (-1)^m (1 - \mu^2)^{\frac{m}{2}} \frac{d^m}{d\mu^m} P_n(\mu)$$

$$(333) \quad R_n(x, y, z) = r^n S_n(\theta, \phi)$$

$$(334) \quad \frac{\partial^2 S}{\partial \theta^2} + \cot \theta \frac{\partial S}{\partial \theta} + \csc^3 \theta \frac{\partial^2 S}{\partial \phi^2} + n(n+1)S = 0$$

$$(335) \quad c_n \frac{r^{2n+1} \partial^n}{\partial h_1 \partial h_2 \dots \partial h_n r}$$

$Y_\nu(t)$ ; see 341). Thus  $AI_\nu(t) + BY_\nu(t)$  is a general solution for all values of  $\nu$ . Bessel functions of the second kind are sometimes called Neumann functions. The functions  $H_\nu^1(t)$ , defined as the sum of  $J_\nu(t)$  and  $iY_\nu(t)$ , and  $H_\nu^2(t)$ , defined as their difference (see 342) are called **Hankel** functions, or Bessel functions of the third kind.

If  $t$  is replaced by  $it$  (in which  $i = \sqrt{-1}$ ), the differential equation is the modified Bessel equation and its solutions are modified Bessel functions (of the first and second kind) of which  $I_\nu(t)$ , the modified Bessel function of the first kind, is the product of  $(i)^{-\nu}$  and  $J_\nu(it)$ , and  $K_\nu(t)$ ,

$$(336) \quad S_n^m(\theta, \phi) = e^{im\phi} P_n^m(\cos \theta)$$

$$(337) \quad R_n^m(x, y, z) = r^n e^{im\phi} P_n^m(\cos \theta)$$

$$(338) \quad \frac{d^2\omega}{dt^2} \frac{1}{t} \frac{d\omega}{dt} + \left(1 - \frac{\nu^2}{t^2}\right) \omega = 0$$

$$(339) \quad J_\nu(t) = \sum_{n=0}^{\infty} \frac{(-1)^n}{n! \Gamma(\nu + n + 1)} \left(\frac{t}{2}\right)^{\nu + 2n}$$

$$(340) \quad Y_\nu = \frac{J_\nu(t) \cos(\nu\pi) - J_{-\nu}(t)}{\sin(\nu\pi)}$$

$$(341) \quad Y_\nu(t) = \lim_{\nu \rightarrow p} \frac{J_\nu(t) \cos(\nu\pi) - J_{-\nu}(t)}{\sin(\nu\pi)}$$

$$(342) \quad \begin{cases} H_\nu^{(1)}(t) = J_\nu(t) + iY_\nu(t) \\ H_\nu^{(2)}(t) = J_\nu(t) - iY_\nu(t) \end{cases}$$

$$(343) \quad \begin{cases} I_\nu(t) = (i)^{-\nu} J_\nu(it) \\ K_\nu(t) = \frac{1}{2}\pi(\sin \nu\pi)^{-1} [I_{-\nu}(t) - I_\nu(t)] \end{cases}$$

$$(344) \quad H_n(x) = (-1)^n e^{x^2} \frac{d^n e^{-x^2}}{dx^n}$$

$$(345) \quad \frac{d^2y}{dx^2} - 2x \frac{dy}{dx} + 2ny = 0$$

$$(346) \quad \int_a^b P_n(x) P_m(x) W(x) dx = 0, \quad m \neq n$$

$$(347) \quad \int_a^b [P_n(x)]^2 W(x) dx = 1$$

$$(348) \quad L_n(x) = e^x \frac{d^n}{dx^n} (x^n e^{-x})$$

$$(349) \quad x \frac{d^2y}{dx^2} + (1-x) \frac{dy}{dx} + ny = 0$$

the modified Bessel function of the second kind, is defined in terms of  $I_\nu(t)$  and  $(\sin \nu\pi)^{-1}$  (see 343). If  $\nu$  is an integer  $p$ ,  $K_p(t)$  is the limit of the expression.

Bessel functions are widely used in physics, especially in problems in potential theory and diffusion. They frequently arise in problems involving cylindrical boundaries and are sometimes called cylinder functions.

**Hermite** polynomials. **Hermite** polynomials are defined in terms of the derivatives of  $\exp(-x^2)$  for non-negative integers  $n$  (see 344). They are solutions of **Hermite's** equation, named after the 19th-century mathematician Charles **Hermite**. This is a reduced form of Schrodinger's equations and is used in wave mechanics, especially in the theory of wavefunctions of the harmonic oscillator. Hermite's equation, also, is a second-order differential equation, with the coefficient of the first derivative being  $-2x$  (see 345).

**Orthogonal polynomials.** **Hermite** polynomials are examples of orthogonal polynomials. A system of polynomials  $P_n$  is orthogonal on the interval  $(a, b)$  with respect to a weight function  $w(x)$  if the integral over the interval of the product of two elements of the system,  $P_n(x)$  and  $P_m(x)$ , and the weight  $w(x)$ , equals zero whenever  $m$  and  $n$  are not equal (see 346). The system is **orthonormal** if it is orthogonal and normalized by the integral over the interval of the product of the square of  $P_n(x)$  and  $w(x)$  being equal to unity (see 347).

**Hermite** polynomials are orthogonal on the interval  $(-\infty, \infty)$  with a weighting function of  $\exp(-x^2)$ . Other systems of orthogonal polynomials exist. For example, **Legendre** polynomials are orthogonal in the interval  $(-1, 1)$  with a weighting factor of 1. The **Laguerre** polynomials, the  $n$ th of which is defined as the product of  $e^x$  and the  $n$ th derivative of  $x^n e^{-x}$  (see 348), are orthogonal over the interval  $(0, \infty)$  with a weighting factor of  $e^{-x}$  (sometimes more general functions with a weighting factor of  $x^a e^{-x}$  are called **Laguerre** polynomials). They are solutions of **Laguerre's** equation (see 349). This, like **Hermite's** equation, is used in wave mechanics. The associated **Laguerre** polynomials  $L_n^m(x)$  are defined by  $L_n^m(x)$  being equal to the  $m$ th derivative of the  $n$ th **Laguerre** polynomial (see 350). They satisfy the associated **Laguerre** equation (see 351). (Ed.)

### Dynamical systems on manifolds

A dynamical system is a way of describing the passage in time of all points of a given space  $\mathfrak{S}$ .  $\mathfrak{S}$  can be thought of, for example, as the space of states of some physical system. Then if  $x$  is in  $\mathfrak{S}$ , one unit in time later  $x$  will have moved to a point denoted by  $x_1$ . At time zero  $x$  is at  $x$  or  $x_0$ . Two units after time zero  $x$  will have moved to  $x_2$ . One unit before time zero  $x$  was at  $x_{-1}$ . If this procedure is extrapolated to fill up the real numbers  $\mathbb{R}$ , the trajectory  $x_t$  is obtained, for all time  $t$ , a real number. Thus for each  $x$ ,  $x_t$  is a curve in  $\mathfrak{S}$  and represents the life history of  $x$  as  $t$  goes from  $-\infty$  to  $\infty$ . If  $x_t$  is also assumed to be differentiable in  $(t, x)$ , then  $x \rightarrow x_t$  can be regarded as a transformation, or diffeomorphism, from  $\mathfrak{S}$  onto  $\mathfrak{S}$  for each  $t$ . In this case  $(\mathfrak{S}, x_t)$  define a dynamical system.

In applications of dynamical systems to fields outside of mathematics, the first goal is to explicate the manifold of states  $\mathfrak{S}$ . A state of a system is information characterizing the situation at a given moment. The first step in this explication process is to define the state in the most obvious unrestricted way. This will give a space that is possibly too large, and natural constraints on physical laws will cut down the unrestricted states to a subset of attainable or physical states. A physical state is one that has an actual possibility of occurring. These physical states form the final manifold of states. A number of examples in the following section will explain the process given in the previous sentences.

### EXAMPLES OF STATE SPACES

**Example from economics.** In the pure exchange economy of theoretical economics, a model is used with  $n$  different commodities, each measured in quantity by a positive real number (fixing a unit of measurement). Thus commodity space  $P$  will be the set of points of real Cartesian space  $\mathbb{R}^n$  with each coordinate positive. A point of  $P$  represents a bundle of commodities possessed, for example, by a certain consumer in the economy.

It is assumed that there are a finite number of consumers, say  $m$ , with the possessions of the  $i$ th consumer denoted by  $x_i$  in  $P$ . An unrestricted state of the economy is a point  $x = (x_1, \dots, x_m)$  in which each  $x_i$  is in  $P$ . The space of all these states is denoted by  $P^m$ , the Cartesian product of  $P$  with itself  $m$  times. Thus an unrestricted state of the economy simply gives the possessions of the consumers of that economy.

Now, it is supposed that the total resources in this economic model are fixed, say, at a point  $w$  in  $P$ . Thus the space of attainable states is a subset  $W$  of  $P^m$  described by the condition  $(x_1, \dots, x_m)$  is in  $W$  if the sum of the  $x_i$  is  $w$ .

Definition  
of a state  
of a  
system

**Examples from classical mechanics.** Particle in Euclidean space  $E^3$ . Ordinary 3-dimensional Euclidean space is denoted by  $E^3$ . A particle in  $E^3$  has its state characterized by its position  $\mathbf{x}$ , a point in  $E^3$ , and its velocity  $\mathbf{v}$ , a vector (or point) in  $E^3$ . Thus  $\mathbf{v}$  gives the direction in which the particle is moving together with its speed, the length of  $\mathbf{v}$ . The vector  $\mathbf{v}$  can be thought of as being based at  $\mathbf{x}$ . The states of this system are then all pairs  $(\mathbf{x}, \mathbf{v})$ ,  $\mathbf{x}, \mathbf{v}$  each in  $E^3$ . This space is denoted by  $E^3 \times E^3$ , the Cartesian product of  $E^3$  with  $E^3$ .

Particle on a *sphere*.  $D^3$  is a unit ball in  $E^3$ , so that  $D^3$  consists of all points the distance of which from the origin is less than or equal to one. The 2-sphere  $S^2$  is its boundary, or points of unit distance, from the origin of  $E^3$ . The space of states for the physical system of a particle on  $S^2$  will then be a certain subset of  $E^3 \times E^3$  of the first example.

There are two constraints: the first is that  $\mathbf{x}$  must be in  $S^2$ , and the second is that  $\mathbf{v}$  must be perpendicular to  $\mathbf{x}$ . The first constraint follows by definition, and the second constraint follows because if the velocity were not perpendicular to  $\mathbf{x}$ , then  $\mathbf{x}$  would have to leave the 2-sphere. The set of points  $(\mathbf{x}, \mathbf{v})$  that satisfies these two constraints is the state space  $\mathcal{S}$  for this problem.  $\mathcal{S}$  can also be thought of in the following way. If  $T_{\mathbf{x}}(S^2)$  is the tangent space to  $S^2$  at  $\mathbf{x}$ , so  $T_{\mathbf{x}}(S^2)$  is the set of all vectors  $\mathbf{v}$  in  $E^3$  based at  $\mathbf{x}$  with  $\mathbf{v}$  tangent to the surface  $S^2$  (or perpendicular to  $\mathbf{x}$ ), then  $\mathcal{S}$  is the union of all these  $T_{\mathbf{x}}(S^2)$  as  $\mathbf{x}$  varies over  $S^2$ . In other words,  $\mathcal{S}$  is the tangent bundle of  $S^2$ ,  $T(S^2)$  or the set of all  $(\mathbf{x}, \mathbf{v})$  in  $S^2 \times E^3$  in which  $\mathbf{v}$  is in  $T_{\mathbf{x}}(S^2)$ .

Particle on any surface in  $E^3$ . The previous example extends immediately to the case of a particle constrained to move on any (smooth) surface  $M$  in Euclidean space  $E^3$ . The sphere  $S^2$  is replaced by  $M$  everywhere in the discussion. Thus, for example, the space  $\mathcal{S}$  of all states for this system is  $T(M)$  or the set of  $(\mathbf{x}, \mathbf{v})$  in  $M \times E^3$  in which  $\mathbf{v}$  is tangent to  $M$  at  $\mathbf{x}$ .  $T(M)$  is called the tangent bundle of  $M$  and may be represented as the union of all the fibres  $T_{\mathbf{x}}(M)$  as  $\mathbf{x}$  ranges over the points of  $M$ .  $T_{\mathbf{x}}(M)$  in the space of all of the possible velocities for the particle at  $\mathbf{x}$ .

Plane rigid body. A point  $\mathbf{x}_0$  and a directed line  $\mathbf{n}_0$  are fixed in  $B$  through  $\mathbf{x}_0$ . Then the position of  $B$  in the plane  $E^2$  is characterized by the position of  $\mathbf{x}_0$  in  $E^2$  and the angle between  $\mathbf{n}_0$  and a fixed directed reference line  $\mathbf{n}$  in  $E^2$ . (For simplicity it is assumed that  $B$  has only one possibility for its orientation in  $F$ .) Therefore, the space of positions or configurations of  $B$  is a three-dimensional space or manifold, the Cartesian product of  $E^2$  and the circle  $S^1$ ,  $E^2 \times S^1$ . In this instance, the fact that there is a correspondence between angles and points on the circle is used.  $M = E^2 \times S^1$  is sometimes called the space of generalized coordinates for the configuration of  $B$ . If  $(\mathbf{x}, \theta)$  is in  $E^2 \times S^1$ , then  $(\mathbf{x}, \theta)$  stands for the configuration of  $B$ , in which  $\mathbf{x}_0$  is located at  $\mathbf{x}$  and  $\theta$  is the angle between  $\mathbf{n}_0$  and  $\mathbf{n}$ .

The possible velocities for  $B$  at  $(\mathbf{x}, \theta)$  are vectors  $(\mathbf{v}_1, \mathbf{v}_2)$  in  $E^2 \times \mathcal{R}$  (or  $E^3$ ), in which  $\mathbf{v}_1$  is the ordinary velocity of  $\mathbf{x}$  in  $E^2$  and  $\mathbf{v}_2$  is angular velocity. Therefore, for this mechanical system, the state space  $\mathcal{S}$  is the product  $(E^2 \times S^1) \times (E^2 \times \mathcal{R})$  of configuration and velocity space.

**A circuit with three electrical components.** A series connection between a resistor, an inductance, and a capacitor, wired to form a closed loop, may now be considered. To form the space of states, each of these three components is oriented. A state of the circuit consists of the current through each component and the voltage across each component. If  $i_p, v_p$  stand for the current and voltage, respectively, in the resistor, then  $i_\lambda, v_\lambda$  stand for current and voltage in the inductance and  $i_c, v_c$  for current and voltage in the capacitor. For historical reasons the capacitor is conventionally oriented in the opposite direction from the other two components. The Kirchhoff laws imply the following relations on the currents and voltages. The Kirchhoff current law (KCL) asserts that  $i_\lambda = i_p = -i_c$ , or that the current that flows into a junction between two components equals that flowing out.

The Kirchhoff voltage law (KVL) asserts that  $v_\lambda + v_p = -v_c$ , or that the voltages around a loop of components sum to zero.

The set of states in  $\mathcal{R}^6$  satisfying these Kirchhoff laws forms a three-dimensional linear subspace  $K$  of  $\mathcal{R}^6$ . Any physical state has to lie in  $K$ . To obtain the precise set of physical states, another step is needed, in order to bring in the implications of the resistors on  $(i_p, v_p)$ .

The most common type of resistor is linear in that it obeys Ohm's law; i.e.,  $v_p = R i_p$ , in which  $R$ , is some positive constant. For a physical state, Ohm's law must be satisfied as well as Kirchhoff's laws. This cuts down the space of physical states to a two-dimensional linear subspace  $\mathcal{S}$  for  $\mathcal{R}^6$ .

More generally, any resistor, linear or nonlinear, is defined by its characteristic  $A_p$ , which is a curve in the two-dimensional  $(i_p, v_p)$ -plane. Then a generalized version of Ohm's law stipulates that for a physical state in  $\mathcal{R}^6$ , the components  $(i_p, v_p)$  lie in  $A_p$ . It can be proved in the general case that these constraints force the physical states to lie in a two-dimensional manifold  $\Sigma$  of  $\mathcal{R}^6$ .

Suppose, for example, that the resistor is current controlled so that the characteristic  $A_p$  is the graph in  $\mathcal{R}^2$  of some smooth real function  $f$ . Thus  $v_p = f(i_p)$ . In this case it is convenient to take as a representation of  $\Sigma$ , the Cartesian  $(i_\lambda, v_\lambda)$ -plane  $\mathcal{R}^2$  identifying  $\mathcal{R}^2$  and  $\Sigma$  under the diffeomorphism  $\mathcal{R}^2 \rightarrow \Sigma \subset \mathcal{R}^6$ , which sends  $(i_\lambda, v_\lambda)$  into a state in  $\mathcal{R}^6$  that is completely determined by  $i_\lambda$  and  $v_\lambda$  (see 352). Then the space of states for this circuit is equivalent to  $\mathcal{R}^2$  or  $(i_\lambda, 0)$ -space.

**Simple electrical circuits.** This example just given can be generalized to what could be called simple electrical circuits. A simple electrical circuit consists of components and nodes. The components are circuit elements that are either resistors, inductances, or capacitors, each with two terminals. In the circuit, groups of terminals meet at the different nodes. It is assumed that the components have a given orientation so that the current flowing in one direction is given by a positive real number, and the current flowing is given by a negative number if it flows in the opposite direction.

The unrestricted states of the circuit have as components the currents through each component and the voltages across each component. So if there are  $N$  components, the space of unrestricted states  $\mathcal{S}$  is  $2N$ -dimensional Cartesian space  $\mathcal{R}^{2N}$ .

The laws of physics impose constraints on these states. First of all, Kirchhoff laws assert that a physical state must be in a linear subspace  $K$  of  $\mathcal{R}^{2N}$  with dimension  $K$  equal  $N$ . In formal terms Kirchhoff's current law says that for each node, the sum of the currents entering the node equals the sum of the currents issuing from the node. Kirchhoff's voltage law then requires that the voltages across each component of a closed cycle add to zero. It follows that the set of states in  $\mathcal{R}^{2N}$  satisfying Kirchhoff's current law and Kirchhoff's voltage law forms a linear subspace of dimension  $N$ .

The final physical constraint is given by a generalization of Ohm's law. A resistor component  $p$  is allowed to have as characteristic any non-singular curve—i.e., one-dimensional submanifold— $A_p$  in the  $(i_p, 0)$ -plane. This means that a physical state in  $K$  must have  $i_p, v_p$  components satisfying the condition that  $(i_p, v_p)$  is in  $A_p$ . If the  $p$ th resistor is linear, then  $A_p$  is a line through the origin with positive slope. Thus the physical states finally satisfy these further conditions, one for each resistor. The final subspace  $\Sigma$  of  $\mathcal{S}$  defined by these conditions and Kirchhoff conditions will be a submanifold in the general case the dimension of which is equal to the number of inductor components plus the number of capacitor components.

**Miscellaneous examples.** The 19th–20th-century Italian mathematician Vito Volterra has studied the growth and decline of two interacting species; for example, rabbits and foxes. The population of each species can be represented by a real positive number, subject to a slight approximation. Then the corresponding state space is the full positive quadrant in the plane—i.e., the set of pairs  $(r, f)$  of positive real numbers  $r$  and  $f$ .

In Turing's models in biology, the states appear as the concentrations of a number of chemicals (or **morphogens**) in each cell of some structure. Sometimes, as in hydrodynamics, the space of states appears as an  $\infty$ -dimensional space (a manifold or linear space).

#### MANIFOLDS

In each case of the examples, the state space is a manifold. A manifold can often be thought of as a domain (or open set) in Euclidean space of some dimension. More generally a manifold is defined by glueing together such open sets; thus, for example, while the 2-sphere is a 2-dimensional manifold, it is not equivalent to an open set of the plane. It can be obtained though as the union of two, 2-dimensional disks that overlap in a ring. Every  $k$ -dimensional manifold can be represented by a  $k$ -dimensional surface in Euclidean space of some higher dimension. It is most reasonable to take a **manifold**—i.e., differentiable manifold—as the basic space of a dynamical system.

If  $U$  is an open set in Euclidean space  $E$  and  $x$  is in  $U$ , then a **tangent vector** of  $U$  at  $x$  is simply a vector in  $E$ , which can be thought of as being based at  $x$ . The tangent bundle  $T(U)$  is the product  $U \times E$ , and a point  $(x, v)$  in  $U \times E$  consists of base point  $x$ , vector  $v$ .

More generally if  $x$  is a point in a manifold  $M$ , in which  $M$  is represented as a  $k$ -dimensional surface in some Euclidean space  $E$ , then a tangent vector of  $M$  at  $x$  is simply a vector in  $E$  based at  $x$  and tangent to  $M$ . The space of all tangent vectors to  $M$  at  $x$  is the tangent space  $T_x(M)$  of  $M$  at  $x$ . Then  $T(M)$ , the tangent bundle of  $M$ , is the (disjoint) union of all these  $T_x(M)$  as  $x$  varies over  $M$ , and is a manifold itself in a natural way.

In all the examples of mechanical systems, the initial step was to take the manifold  $M$  of positions or configurations. Then the space of states was the tangent bundle  $T(M)$  of  $M$ . A state in all of these examples consists of a configuration together with a (generalized) velocity based at that configuration. This persists in much more general examples of mechanical systems.

#### DYNAMICAL SYSTEMS AS VECTOR FIELDS ON MANIFOLDS

On manifolds (e.g., open sets of Euclidean space) differentiation makes sense, and a differentiable map (i.e., transformation) from a manifold to itself with a differentiable inverse is called a **diffeomorphism**. In these terms the definition of a dynamical system can be restated as assigning to each time  $t$  (a real number), a diffeomorphism  $\phi_t: M \rightarrow M$  with  $\phi_0$  the identity,  $\phi_{t+s} = \phi_t \circ \phi_s$ , and so that  $\phi_t(x)$  is differentiable in  $(t, x)$ . Thus for each  $x$  in the manifold, the trajectory  $\phi_t(x) = x_t$  is a curve through  $x$ . The derivative of this curve  $t \rightarrow \phi_t(x)$  at  $t=0$  can be taken, letting  $X(x)$  be the derivative of  $\phi_t(x)$  (see 353) to obtain the velocity or the tangent vector of the curve at  $x$ . Thus  $X(x)$  is in the tangent space  $T_x(M)$ . The association  $x \rightarrow X(x)$  is a vector field on  $M$  (or tangent vector field on  $M$ ). More generally, a vector field on  $M$  is any differentiable map  $X: M \rightarrow T(M)$  with  $X(x)$  in  $T_x(M)$ . For example, if  $M$  is an open set in Euclidean space  $E$ , then  $T(M) = M \times E$  and a vector field  $Y: M \rightarrow M \times E$  must be of the form  $Y(x) = (x, X(x))$  for some map  $X: M \rightarrow E$ . In this case by a slight abuse of language,  $X$  is called a vector field, so that a vector field can be thought of as assigning to each point  $x$ , in  $M$ , a vector in  $E$  based at  $x$ .

The notion of vector field on a manifold is of basic importance because among other things a dynamical system is characterized by its associated vector field. A converse to this statement is roughly true, and the converse could be regarded as the fundamental theorem of ordinary differential equations. More precisely, if  $x \rightarrow X(x)$  is a vector field on a manifold  $M$ , the ordinary differential equation can be considered for  $\phi_t(x)$ , given by the derivative of  $\phi_t(x)$  being equal to  $X(x)$  (see 354).

This equation has a solution, at least for all  $t$  satisfying  $t^-(x) < t < t^+(x)$  in which  $t^-$ ,  $t^+$  are real functions on  $M$  defining some (perhaps maximal) open set  $Q$  in  $R \times M$  containing  $0 \times M$ . This solution  $\phi_t(x)$ , defined for  $(t, x)$  in  $Q$ , then has the properties of a dynamical system ex-

$$(350) \quad L_n^m(x) = \frac{d^m}{dx^m} L_n(x)$$

$$(351) \quad x \frac{d^2 y}{dx^2} + (m+1-x) \frac{dy}{dx} + (n-m)y = 0$$

$$(352) \quad (i_\lambda, i_\lambda, -i_\lambda, f(i_\lambda), v_\gamma - f(i_\lambda), v_\gamma) = (i_\rho, i_\lambda, i_\gamma, v_\rho, v_\lambda, v_\gamma)$$

$$(353) \quad \left. \frac{d\phi_t(x)}{dt} \right|_{t=0} = X(x)$$

$$(354) \quad \frac{d}{dt} \phi_t(x) = X(x)$$

cept that it may not be defined for all  $t$  going to  $\pm\infty$ . This system of trajectories is still called a dynamical system (or flow), and in this sense vector fields on manifolds are equivalent to dynamical systems.

#### EXAMPLES OF DYNAMICAL SYSTEMS

**Particle in  $E^3$  in a force field.** Consider the example of a particle in three-dimensional Euclidean space. It is supposed now that there is a certain vector field, a force field defined on  $E^3$ , say  $x \rightarrow F(x)$ ,  $E^3 \rightarrow E^3$ . Thus if the particle is at  $x$  in  $E^3$ , the force exerted on it is  $F(x)$ , and Newton's law reads  $m\ddot{x} = F(x)$ . Here  $m$  is a constant positive real number, the mass of the particle, and  $\ddot{x} = x''(t)$  (or the second derivative of  $x$  with respect to  $t$ ) is the acceleration with  $t \rightarrow x(t)$  a curve in  $E^3$  that represents the passage of the particle in time. For an actual or physical path, Newton's equation is satisfied, or  $m\ddot{x}(t) = F(x(t))$  for all  $t$ .

Newton's equation is seen to be equivalent to the pair of equations (see 355) relating the derivatives of position and velocity to the velocity and the force, respectively. In this last form, the map  $(x, v) \rightarrow (v, F(x)/m)$  is a vector field on the state space for this mechanical system  $T(E^3)$ . This is the form of a vector field on the state space determining the passage in time of the space. The initial conditions are  $(x, v)$ , the position and velocity of the particle.

The force field  $x \rightarrow F(x)$  is called **conservative** if it is of the form  $F(x) = -\text{grad } V(x)$  in which  $V$  is some real function on  $E^3$ .  $\text{Grad } V(x)$  is defined as the vector in which the  $i$ th component is  $\partial v_i / \partial x_i$ , for  $i = 1, 2, 3$  (see 356), in terms of Cartesian coordinates.  $V$  is called the potential for the system. The classical example of a force field is that of gravitational force. If the source of this force is the point located at the centre of  $E^3$ , then (see 357) the force is inversely proportional to the square of the distance, involving the Euclidean norm on  $E^3$  (see 358) in Cartesian coordinates. In this case,  $F(x)$  is a conservative force field because a potential can be chosen (see 359) that is inversely proportional to the distance. This gives what is sometimes called the Kepler problem because the solution curves lead to the (Kepler) elliptical orbits of the Earth about the Sun. Strictly speaking, in the Kepler problem configuration space is  $E^3 - 0$ , because the vector field describing the dynamics is not defined at 0.

**Van der Pol equation.** The particular example of an electrical circuit given earlier is now considered. Physical laws of the inductor and capacitor give directly the differential equations for motion in terms of the representation of the state space found there. More precisely (see 360) the derivative of  $i_\lambda$  is proportional to  $v_\lambda$  and the derivative of  $v_\gamma$  is proportional to  $i_\gamma$  (see 360), in which  $L$ , the inductance, and  $C$ , the capacitance, are constants of proportionality. For simplicity,  $L$  and  $C$  are taken as constants equal to unity. Here  $v_\lambda = v_\gamma - f(i_\lambda)$  and  $i_\gamma = -i_\lambda$  by Kirchhoff's laws and the resistor characteristic. The differential equations then become appropriately changed (see 361). The corresponding vector field on  $\mathfrak{R}^2$  at the point  $(i_\lambda, v_\gamma)$  is  $(v_\gamma - f(i_\lambda), -i_\lambda)$ .

Diffeo-  
morphisms

tive force  
fields

Steady-state  
attractors

In the case in which  $f$  is linear, of the form  $v_p = R_p i_p$ ,  $R_p > 0$ , then it can be deduced that all solution curves of this dynamical system tend toward the origin. The origin is a steady state and an attractor. This means that a solution at the origin stays at the origin for all time or that the vector field is zero at the origin (steady state). That the origin is an attractor means that nearby solutions tend to the origin as  $t \rightarrow \infty$ . Steady-state attractors play a central role in applications of dynamical systems.

On the other hand, if a highly nonlinear characteristic is considered, say the derivative  $f'(0) < 0$ , then the unique zero  $(0, f(0))$  of the vector field can be shown to be a source. This means that orbits tend to  $(0, f(0))$  as  $t \rightarrow -\infty$ . If the characteristic  $(i_\lambda, f(i_\lambda))$  stays well inside the first and third quadrants for large  $|i_\lambda|$  (a natural assumption even for nonlinear resistors), then as  $t \rightarrow \infty$  all orbits tend toward some bounded region in  $\mathbb{R}^2$ . This follows from a general energy theorem. From these facts, the Poincaré-Bendixon theorem implies the existence of a periodic orbit, and one will be an attractor in the general case. A periodic orbit, period  $w > 0$  is an orbit where  $\phi_{t+w}(x) = \phi_t(x)$  for all  $t$ . This amounts to an oscillatory behaviour of the physical variables. That it is an attractor means that all nearby solutions tend toward it and thus will also oscillate, at least to a high degree of approximation. Periodic attractors are of basic importance in applications of dynamical systems.

The characteristic defined (see 362) by  $f(i_\lambda)$  being equal to  $\mu(i_\lambda^3 - i_\lambda)$  satisfies the conditions of the previous paragraph. Here there is a unique periodic attractor; the differential equation is called van der Pol's equation.

Volterra-Lotka equations. The equations describing how the populations of rabbits and foxes vary in time are called the Volterra-Lotka equations and are (see 363) a pair of coupled first-order equations with positive constants  $\alpha, \beta, h, \mu$ . For example,  $dr/dt = \alpha r$  governs how the number of rabbits increases eating grass, without taking into account the foxes that eat them. The Volterra-Lotka equation can be interpreted as giving a vector field on the positive quadrant in  $\mathbb{R}^2$ ; its solution curves are in fact periodic so that the populations are expected to change in cycles under these conditions.

#### GRADIENT DYNAMICAL SYSTEMS

Systems on  $E^3$ . A gradient dynamical system in  $E^3$  is considered. For a classical description, it is supposed  $f: E^3 \rightarrow \mathbb{R}$  is a differentiable function and  $E^3$  is provided with Cartesian coordinates  $(x_1, x_2, x_3) = x$ . Then  $X(x) = \text{grad } f(x)$  is the vector field on  $E^3$  that associates to the point  $x$  in  $E^3$  the vector  $\text{grad } f(x)$ , defined in terms of the partial derivatives of  $f$  (see 364). Thus  $\text{grad } f(x)$  can be thought of as a vector in  $E^3$  based at  $x$ , and it will be perpendicular to the level surface  $f^{-1}(c)$  at  $x$ ,  $f(\sim) = c$ . As a particular example, take  $f(x)$  equal to the sum of three terms  $a_i x_i^2$  (see 365), in which each  $a_i$  is a negative constant. Then the differential equation  $dx/dt = \text{grad } f(x)$  can be solved directly to see that each trajectory tends to the steady-state attractor  $(0, 0, 0) = 0$  in  $E^3$ .

Open sets on  $E^n$ . The last example can be generalized in several steps to gradient dynamical systems on abstract manifolds. A further step is to the case of a real differentiable function  $f: U \rightarrow \mathbb{R}$  with  $U$  an open set of  $n$ -dimensional Euclidean space  $E$ . Given Cartesian coordinates for  $E$  (see 366),  $\text{grad } f(x)$  can be defined as before by assigning to each  $x$  in  $U$ , the vector in  $E$  the  $i$ th component of which is the partial derivative of  $f$  with respect to  $x_i$  (see 367). Thus  $\text{grad } f$  is obtained as a map; i.e.  $\text{grad } f: U \rightarrow E$ .

It is convenient to give a second equivalent description of  $\text{grad } f$  that extends to manifolds that leads to a modern exposition of Hamiltonian mechanics.

This requires a precise definition of what is meant by Euclidean space. Euclidean space is a finite-dimensional real vector space  $E$  together with an inner product, say  $B$ .  $B$  is first of all a bilinear form on  $E$  so that  $B$  is a map  $B: E \times E \rightarrow \mathbb{R}$  satisfying conditions of linearity (see 368) for  $x, y, z$  in  $E$  and  $\lambda$  real. Moreover,  $B$  is symmetric so that  $B(x, y) = B(y, x)$ . Finally,  $B$  is positive definite so that  $B(x, x) \geq 0$  and  $B(x, x) = 0$  if, and only

The  
Poincaré-  
Bendixon  
theorem

Euclidean  
space

if,  $x = 0$ . From  $B$  a norm can be defined,  $\|x\| = B(x, x)$  and distance from  $x$  to  $y$  as  $\|x - y\|$ . A Cartesian coordinate system on  $E$  can be found (see 369) so that  $B(x, y)$  is a sum of terms of the form  $x_i y_i$ .

The derivative of  $f: U \rightarrow \mathbb{R}$  at  $x$  in  $U$  is now considered. This derivative of  $f$  at  $x$  is most naturally considered to be a linear map  $Df(x): E \rightarrow \mathbb{R}$  with the property that  $B(\text{grad } f(x), w) = Df(x)(w)$  for all  $w$  in  $E$ . Depending on the approach, this could be the defining property for  $Df(x)$  or for  $\text{grad } f(x)$ . In modern treatments of calculus, however, the definition of derivative is given as a linear transformation, so that the above property can be used to define  $\text{grad } f$ . In more detail, the linear space of maps from  $E$  to  $\mathbb{R}$  is denoted by  $E^*$  (the dual of  $E$ ). Then the derivative of  $f$  is a map  $Df: U \rightarrow E^*$ . A bilinear form  $B$  on  $E$  defines a natural induced map  $\phi_B: E \rightarrow E^*$  by  $\phi_B(x)(y) = B(x, y)$  for  $x, y$  in  $E$ . For the inner product this map  $\phi_B$  is seen to be an isomorphism, or in other words,  $B$  is nondegenerate. In these terms the definition is,  $\text{grad } f(x) = \phi_B^{-1} Df(x)$ . These arguments form the basis for the modern approach to gradient dynamical systems and Hamiltonian systems.

Two important properties of  $\text{grad } f$  follow. First  $\text{grad } f(x) = 0$  if, and only if, the derivative  $Df(x)$  of  $f$  at  $x$  is 0 (or  $x$  is a critical point for  $f$ ). So  $x$  is a steady state for the dynamical system  $\text{grad } f$  if, and only if,  $x$  is a critical point for the function  $f$ . Second, along a trajectory  $\phi_t(x)$  of  $\text{grad } f$ ,  $f$  is nondecreasing and in fact increases if  $x$  is not a critical point (see 370).

Thus, following a trajectory of  $\text{grad } f(x)$ , the function is maximized if possible, and in this way gradient systems are used in maximization problems.

Surfaces. Next a surface  $M$  in  $E^3$  is considered and a differentiable function  $f: M^2 \rightarrow \mathbb{R}$ . If  $x$  is in  $M$ , the inner product  $B$  on  $E^3$  restricts to give an inner product  $B_x$

$$(355) \quad \dot{x} = v, \quad \dot{v} = \frac{1}{m} F \quad \text{on} \quad E^3 \times E^3 = T(E^3)$$

$$(369) \quad B(x, y) = \sum_{i=1}^n x_i y_i$$

$$(370) \quad \left. \frac{d}{dt} \phi_t(x) \right|_{t=0} = Df(x)(\text{grad } f(x)) \\ = B(\text{grad } f(x), \text{grad } f(x)) \geq 0$$

$$(371) \quad J(x, \bar{x}) = x_1 \mathcal{L}(x_1) - x_2 \mathcal{L}(x_2)$$

$$(372) \quad P(i_\lambda, v_\gamma) = -i_\lambda v_\gamma + \int_0^\lambda f(u) du$$

$$(373) \quad \frac{di_\lambda}{dt} = -\frac{\partial P}{\partial i_\lambda}, \quad \frac{dv_\gamma}{dt} = \frac{\partial P}{\partial v_\gamma}$$

$$(374) \quad \frac{dx}{dt} = \text{grad}_J P(x)$$

$$(375) \quad B(x, \mathcal{L}[x]) = \sum_{i=1}^n x_i \mathcal{L}(x_i)$$

$$(376) \quad \Omega(x, \mathcal{L}[x]) = \sum_{i=1}^n x_i \mathcal{L}(x_{i+n}) - \sum_{i=1}^n x_{i+n} \mathcal{L}(x_i)$$

Riemannian  
structures

on the tangent space  $T_x(M)$ . The assignment  $x \rightarrow B_x$  is called a Riemannian structure on  $M$ . With this structure, the constructions of the previous section carry over. Thus for each  $x$ ,  $Df(x)$  is an element of the dual space  $T_x^*(M)$  (or  $T_x^*(M)$ ). This map  $x \rightarrow Df(x)$  [or  $df(x)$  oftentimes] is an example of a 1-form on  $M$ . Then an isomorphism  $\phi_{B_x}: T_x(M) \rightarrow T_x^*(M)$  is defined for each  $x$  via  $B_x$  just as  $\phi_B$  before. The inverse image of  $Df(x)$  under  $\phi_{B_x}$  is then  $\text{grad } f(x)$  for each  $x$ , and the previous properties of gradients follow in the same way.

A special case is the unit sphere  $S^2$  in  $E^3$  given as the set of  $x$  such that  $B(x, x) = 1$ . Then if  $f: S \rightarrow \mathbb{R}$  is the projection on some line—for example, the height or  $z$ -coordinate in an  $(x, y, z)$ -coordinate system on  $E^3$ —then  $f$  has two critical points, a maximum and a minimum. It can be shown that except for these two points all the other points of  $S^2$  under the gradient flow go from the minimum to the maximum.

**Riemannian manifolds.** The construction of gradient in the previous section extends verbatim to any  $k$ -dimensional surface  $M$  in  $E^n$  (or submanifold of  $E^n$ ).

Finally it should be remarked that all of this can be done abstractly on Riemannian manifolds by the same construction. A Riemannian manifold is a manifold  $M$  together with an inner product  $B_x$  on  $T_x(M)$  for each  $x$  differentiable in  $x$ . This inner product defines an isomorphism  $T_x(M) \rightarrow T_x^*(M)$  for each  $x$ , or putting this information for all  $x$  together,  $T(M) \rightarrow T^*(M)$ . Here  $T^*(M)$  is the disjoint union of  $T_x^*(M)$  over all  $x$  in  $M$  and is the cotangent bundle of  $M$ . This isomorphism converts 1-forms to vector fields. Thus, given any function  $f: M \rightarrow \mathbb{R}$ , then  $f \rightarrow Df \rightarrow \text{grad } f$ .

Other extensions. Finally, some extensions of gradients are discussed. In the example of a pure exchange economy, not one function on the state space is maximized but several. These are the utility functions of the  $m$  consumers. In this case the notion of gradient leads to versions of what is called Pareto Optima.

In a different direction, instead of a (positive definite)

inner product, an indefinite symmetric form on Euclidean space can be considered. For example, if  $J$  is the bilinear form on  $\mathbb{R}^2$  defined by being equal to the difference of  $x_1 \mathcal{L}(x_1)$  and  $x_2 \mathcal{L}(x_2)$  (see 371), then  $J$  is symmetric and nondegenerate; and if a real differentiable  $P$  is given on  $E^2$  a vector field  $\text{grad}_J P$  is obtained replacing  $B$  by  $J$  in the definition. It turns out that the equations of electrical circuit theory can be expressed in this form. For example, if for  $P$  on  $W^2$ , the function is taken to be  $-i_\lambda v_\gamma$  added to the integral from 0 to  $\lambda$  of  $f(u)$  (see 372), then the equations of the circuit discussed earlier have the form of the derivatives of  $i_\lambda$  and  $v_\gamma$  being proportional to appropriate partial derivatives of  $P$  (see 373). These equations may be expressed in terms of  $\text{grad}_J P(x)$  (see 374) in which  $x = (i_\lambda, v_\gamma)$ .

#### HAMILTONIAN MECHANICS

Hamiltonian mechanics as developed on manifolds has the virtue of including quite general mechanical systems and shows basic principles most simply. To define gradients, the inner product on Euclidean space  $E$  was of central importance. Hamiltonians are developed similarly with the bilinear form  $B$ , or inner product, replaced by a symplectic bilinear form  $\Omega$  on  $E$ .  $B(x, \mathcal{L}[x])$  is a sum of terms  $x_i \mathcal{L}(x_i)$  (see 375) for Cartesian coordinates  $(x_1, \dots, x_n) = x$  on  $E$ .  $E$  is taken to have even dimension  $2n$  and a bilinear form  $\Omega$  on  $E$  is defined (see 376). Not only is it seen that  $\Omega$  is bilinear, but it also is clearly antisymmetric,  $\Omega(x, \mathcal{L}[x]) = -\Omega(x, \mathcal{L}[x])$ . It can also be seen that  $\Omega$  is nondegenerate or that the map  $\phi_\Omega: E \rightarrow E^*$  is an isomorphism with  $\phi_\Omega(x)(\mathcal{L}[x]) = \Omega(x, \mathcal{L}[x])$ . In fact, any nondegenerate, antisymmetric bilinear form  $\Omega$  can be used in the following, and such an  $\Omega$  is called a symplectic structure on  $E$ .  $\Omega$  can be used to define Hamiltonian dynamical systems.

Open sets of  $E^{2n}$ . If  $U$  is an open set of  $E$  in which  $E$  has a symplectic structure (and so has even dimension) and  $H: U \rightarrow \mathbb{R}$  is any differentiable function, called a Hamiltonian in this context, then the derivative  $DH: U \rightarrow E^*$  is a 1-form on  $U$ , and  $X_H = \phi_\Omega^{-1} DH$  is a vector field (or ordinary differential equation) on  $U$ . Thus  $X_H$  is a map from  $U$  to  $E$ , and  $\Omega(X_H(x), Y)$  equals  $DH(x)(Y)$  for all  $x$  in  $U$  and  $Y$  in  $E$ . Note that  $X_H$  is defined as  $\text{grad } H$  except that  $B$  has been replaced by  $\Omega$ .

In terms of the Cartesian coordinates on  $E$  in which  $\Omega(x, \mathcal{L}[x])$  has a specific form (see 377),  $X_H$  has for its first  $n$  coordinates  $\partial H / \partial x_{n+i}$  and for its second  $n$  coordinates  $-\partial H / \partial x_i$  (see 377). If  $y_i = x_{n+i}$ ,  $i = 1, \dots, n$  the ordinary differential equations represented by  $X_H$  are the classical Hamilton's equations in which the derivative of  $x_i$  equals  $\partial H / \partial y_i$  and the derivative of  $y_i$  equals  $-\partial H / \partial x_i$  (see 378).

Particle in  $E^3$ . A special case of the foregoing is the earlier mechanical system of a particle of mass  $m$  moving in 3-space under a conservative force field  $F(x) = -\text{grad } V(x)$  with  $V: E^3 \rightarrow \mathbb{R}$ , (potential) function. Then on the state space  $E^1 \times E^3$  coordinates are chosen  $(x_1, x_2, x_3)$  for the configuration and  $y_i$  is proportional to  $v_i$  (see 379) for the second factor (or momentum coordinates). If  $\Omega$  is taken as above and  $H: E^3 \times E^3 \rightarrow \mathbb{R}$  defined in terms of a sum of the  $y_i^2$  and  $V(x)$  (see 380), then Hamilton's equations coincide with Newton's equations (see 381). The term (see 382) involving the  $y_i^2$  is called the kinetic energy, and  $V$  is the potential energy of this mechanical system; the sum  $K + V$  is the total energy or simply energy.

Manifolds. The concept of symplectic structure can be generalized easily to manifolds. If  $W$  is an even-dimensional manifold and  $x$  is a point of  $W$ , then a symplectic structure  $\Omega$  at  $x$  is simply a nondegenerate, antisymmetric bilinear form  $\Omega_x$  on the tangent space  $T_x(W)$ . A manifold  $W$  with such  $\Omega_x$  given for each  $x$ ,  $\Omega_x$  varying differentially with  $x$ , is called a symplectic manifold. As before, for each  $x$ ,  $\phi_{\Omega_x}: T_x(W) \rightarrow T_x^*(W)$  is an isomorphism from the tangent space to its dual, the cotangent space at  $x$ . Given a Hamiltonian  $H: W \rightarrow \mathbb{R}$ , then for each  $x$ , the derivative  $DH(x)$  is in  $T_x^*(W)$ , and the above isomorphism converts the 1-form  $DH$  to a vector field  $X_H$  (see 383). The vector field  $X_H$  is then the Hamiltonian

$$(377) \quad \begin{cases} \Omega(x, \mathfrak{L}[x]) = \sum_{i=1}^n x_i \mathfrak{L}(x_{i+n}) - \sum_{i=1}^n x_{n+i} \mathfrak{L}(x_i) \\ X_H = \left( \frac{\partial H}{\partial x_{n+1}}, \dots, \frac{\partial H}{\partial x_{2n}}, -\frac{\partial H}{\partial x_1}, \dots, -\frac{\partial H}{\partial x_n} \right) \end{cases}$$

$$(378) \quad \frac{dx}{dt} = \frac{\partial H}{\partial y_i}, \quad \frac{dy_i}{dt} = -\frac{\partial H}{\partial x_i}, \quad i = 1, \dots, n$$

$$(379) \quad (y_1, y_2, y_3), y_i = mv_i$$

$$(380) \quad H(x, y) = \frac{1}{2m} \sum y_i^2 + V(x)$$

$$(381) \quad \frac{dx_i}{dt} = v_i, \quad \frac{mdv_i}{dt} = -\frac{\partial V}{\partial x_i}$$

$$(382) \quad \frac{1}{2m} \sum y_i^2, \quad \frac{1}{2} m \sum v_i^2$$

$$(383) \quad X_H(x) = \phi_{\Omega_x}^{-1} DH(x)$$

$$(384) \quad (DH(x))(X_H(x)) = \Omega_x(X_H(x), X_H(x))$$

vector field (or ordinary differential equation) corresponding to the Hamiltonian  $H$ . As a Riemannian manifold is required to define gradient vector fields, a symplectic manifold is required in order to define Hamiltonian vector fields.

**Conservation laws.** Various physical principles can be derived in this setting. For example, conservation of energy amounts to the function  $H$  being constant on trajectories of  $X_H$ . This is the same thing as the assertion that for each  $x$ ,  $DH(x)$  evaluated at  $X_H(x)$  is zero. But another condition holds (see 384) from the definition of  $X_H$ , and the last is zero since  $\Omega_x$  is antisymmetric.

Liouville's theorem asserts that Hamiltonian systems preserve volume. In this context, that volume on the abstract manifold  $W$  is the  $n$ -fold wedge product of  $\Omega$  with itself. Without pursuing the technical definition of wedge product, it can be said that if  $\Omega$  is defined as above on  $E$  in coordinate, then the Liouville volume is just ordinary volume on  $E$ . It can be first checked that  $\Omega$  itself is invariant under a Hamiltonian flow  $X_H$ , and then it naturally follows that the wedge product, the Liouville volume is preserved. This can be contrasted with the gradient case. For example, neighbourhoods of a local maximum of a gradient flow are shrunk into smaller subsets by the dynamics. Volume is strictly decreased.

**Simple mechanical systems.** A simple mechanical system  $(M, K, V)$  has a manifold  $M$  that is the configuration space of the system.  $V: M \rightarrow \mathfrak{R}$  is a function, the potential energy, and kinetic energy  $K$  is considered to be given by some Riemannian metric on  $M$ . Thus for each  $x$  in  $M$  there is an inner product  $K_x$  on  $T_x(M)$  and  $K(v) = K_x(v, v)$  for  $v$  in  $T_x(M)$ . This can be compared with the earlier mechanical system of a particle constrained to move on the 2-sphere in  $E^3$ . In this case,  $K_x$  on  $T_x(S^2)$  is the restriction of inner product on  $E^3$  times half the mass. Together these sum to give the energy  $E: T(M) \rightarrow \mathfrak{R}$  as a real function on the tangent bundle of  $M$  as defined by  $E(v) = K(v) + V(x)$  for  $v$  in  $T_x(M)$ .

To put this into the symplectic perspective, it is convenient to consider the cotangent bundle  $T^*(M)$ . There is a canonically defined symplectic structure  $\Omega$  defined on  $T^*(M)$ , which extends the earlier example of  $\Omega$  on  $E^3 \times E^3$ . Furthermore, the energy  $E$  can be transferred to  $T^*(M)$  by a map called the Legendre transformation  $L: T(M) \rightarrow T^*(M)$ . More precisely, if  $v \in T_x(M)$ , then  $L(v) = \phi_{K_x}(v)$  in which  $\phi_{K_x}$  is the usual linear map induced by a bilinear form. Then the Hamiltonian  $H: T^*(M) \rightarrow \mathfrak{R}$  is defined by  $H = E \circ L^{-1}$ . The corresponding Hamiltonian vector field  $X_H$  on  $T^*(M) = W$

gives the dynamics for this mechanical system. The inverse of the Legendre transformation takes trajectories of  $X_H$  back to solutions of the Euler-Lagrange equations on  $T(M)$ . (S.Sm.)

**BIBLIOGRAPHY.** A good elementary introduction to the theory of ordinary differential equations is WALTER LEIGHTON, *Ordinary Differential Equations* (1963). Methods of solution are listed together with the solutions of many particular equations in ERICH KAMKE, *Differentialgleichungen, Lösungsmethoden und Lösungen*, 6th ed. (1959). The best accounts of the classical theory are contained in EARL A. CODDINGTON and NORMAN LEVINSON, *Theory of Ordinary Differential Equations* (1955); PHILIP HARTMAN, *Ordinary Differential Equations* (1964); and EINAR HILLE, *Lectures on Ordinary Differential Equations* (1968). The qualitative theory is discussed in V.V. NEMYTSKII and V.V. STEPANOV, *Qualitative Theory of Differential Equations* (1960). The theory of differential equations in Banach spaces is treated in HENRI CARTAN, *Calcul différentiel* (1967; Eng. trans., *Differential Calculus*, 1971).

Elementary accounts of partial differential equations, especially of the equations of mathematical physics, and of techniques of solving them may be found in A.J.W. SOMMERFELD, *Partielle Differentialgleichungen der Physik* (1943; Eng. trans., *Partial Differential Equations in Physics*, 1949); and IAN N. SNEDDON, *Elements of Partial Differential Equations* (1957). The classical theory is treated fully in IVAN G. PETROVSKY, *Lectures on Partial Differential Equations* (1954; orig. pub. in Russian, 1950); BERNARD EPSTEIN, *Partial Differential Equations: An Introduction* (1962); PAUL R. GARABEDIAN, *Partial Differential Equations* (1964). Finite-difference methods of obtaining approximate solutions are contained in GEORGE E. FORSYTHE and WOLFGANG R. WASOW, *Finite-Difference Methods for Partial Differential Equations* (1960). DOROTHY BERNSTEIN, *Existence Theorems in Partial Differential Equations* (1950), gives a complete account of existence and uniqueness theorems. For an introduction to the abstract theory, see AVNER FRIEDMAN, *Partial Differential Equations* (1969); and ROBERT W. CARROLL, *Abstract Methods in Partial Differential Equations* (1969).

Many works on various aspects of analysis contain discussions of special functions. In addition to these, there are also many works devoted entirely to special functions. MILTON ABRAMOWITZ and IRENE A. STEGUN (eds.), *Handbook of Mathematical Functions* (1964), is a large handbook covering many special functions with numerical tables, statements of mathematical properties, bibliographies, and other information. A very extensive treatise is ARTHUR ERDELYI et al., *Higher Transcendental Functions*, 3 vol. (1953–55). EDMUND T. WHITTAKER and GEORGE N. WATSON, *A Course of Modern Analysis*, 4th ed. (1928, reprinted 1958), contains a good treatment of special functions, as does IAN N. SNEDDON, *Special Functions of Mathematical Physics and Chemistry* (1956). For spherical harmonics, see THOMAS M. MACROBERT, *Spherical Harmonics*, 2nd rev. ed. (1948). There are also many works entirely devoted to one or another particular special function.

The reader interested in dynamical systems on manifolds can obtain some additional background on manifolds from SHLOMO STERNBERG, *Lectures on Differential Geometry* (1961); SERGE LANG, *Introduction to Differentiable Manifolds* (1962), a very basic book; and MICHAEL SPIVAK, *Calculus on Manifolds* (1965), an especially readable elementary work. For more information on ordinary differential equations, in addition to the works mentioned above, see WITOLD HUREWICZ, *Lectures on Ordinary Differential Equations* (1958), a highly recommended and less imposing book than most on this subject; and SOLOMON LEFSCHETZ, *Differential Equations: Geometric Theory* (1957), which discusses structural stability and the van der Pol equation. Some works on dynamical systems are STEPHEN SMALE, "What Is Global Analysis," *Am. Math. Mon.*, 76:4–9 (1969); and "Differentiable Dynamical Systems," *Bull. Am. Math. Soc.*, 73:747–817 (1967)—both of these include further references. For the mathematics of electrical circuits, see CHARLES A. DESOER and ERNEST S. KUHN, *Basic Circuit Theory* (1969). GERARD DEBREU, *Theory of Value* (1959), gives a good background in mathematical economics. An excellent standard text with a traditional view is HERBERT GOLDSIEIN, *Classical Mechanics* (1950); some modern approaches are in LYNN H. LOOMIS and SHLOMO STERNBERG, *Advanced Calculus* (1968), see especially ch. 13; RALPH ABRAHAM, *Foundations of Mechanics* (1967); V.I. ARNOLD and ANDRE AVEZ, *Problèmes ergodiques de la mécanique classique* (1967; Eng. trans., *Ergodic Problems of Classical Mechanics*, 1968); and STEPHEN SMALE, "Topology and Mechanics," 2 pt., *Inventiones Mathematicae*, 10:305–331 and 11:45–64 (1970).

Liouville's  
theorem

## Digestion, Disorders of

Generally speaking, digestion is the process whereby ingested food is converted into material suitable for absorption into, and assimilation by, the body. The digestive system includes the alimentary canal—from mouth to anus—in which this and related processes occur, and the various glands associated with it. This article is concerned with disturbed functions of the digestive system, rather than with the diseases of that system of which such disturbed functions are a reflection. Because many symptoms of these disorders may occur in the absence of demonstrable disease of the gastrointestinal tract or of its accessory glands—the liver, gallbladder, and pancreas—emphasis will be placed upon these symptoms, their causes, their effects, and, in many instances, their treatment.

Symptoms related to the mouth, pharynx, and esophagus. Sensation in the mouth may be affected by alterations in taste or smell, or by odours, either stemming from the mouth itself or derived from exhalations from the nasopharynx, oropharynx, or the stomach. Many disorders of this type are brought about by the effects of various drugs upon the nerve endings in this highly sensitive area of the body; others represent actual disturbances of the nervous elements themselves, either as a result of primary nervous system diseases or from various psychiatric disorders. Since the central representation of smell, taste, and spatial recognition occurs in different portions of the brain, diseases of that organ, such as tumours, inflammations, or impairment of the blood vessels, may cause persistent distortion of these perceptions.

Careful neurological and dental examinations are necessary to distinguish between central and local causes, although it is probable that most of the minor difficulties of this type do reflect local hygienic conditions of teeth and gums or are derived from chronic inflammation in the nasal sinuses. Persons who habitually use tobacco or other local irritants in large amounts may find their taste discrimination faulty; normalcy returns, however, after discontinuance of their use.

Many problems related to the cutting and grinding of food in the mouth, and its subsequent reduction to a mass capable of being easily swallowed, are of course directly related to the presence or absence of teeth and to alignment of the upper and lower jaws. Insufficient chewing can make for difficult, and sometimes painful, swallowing and may reduce the efficiency of digestion. In certain neurological disorders or local disease processes in the throat there is perhaps more impairment of swallowing than of chewing, but the individual so afflicted may complain primarily of difficulty in moving the food within the mouth into an area that provides the best position for cutting, chewing, or grinding. Reduction in amount or quality of salivary juices, or poor mobility of the joint between the jawbones and the skull—the temporomandibular joint—may account for difficulty in chewing.

In general, individuals are able to identify fairly sharply whether dysphagia, or difficulty in swallowing, is high (in the back of the throat or in the neck) or low (farther down under the breastbone where the chest and abdomen meet). The distinction is of importance, both in the methods used to investigate the two areas and in the kinds of, and outlook for recovery from, the various causes. For most persons localization of a sensation of swallowed food "sticking" in one of these two areas is rather precise. The sensation that there is "a lump in the throat," however, which in no way interferes with swallowing, is called globus hystericus, an important psychoneurotic entity with a usually favourable prognosis. Various neurological disorders may impair the function of the pharynx and the upper constrictor muscles of the esophagus, although this is usually transient in the case of a stroke. Some chronic neurologic disturbances cause failures of synchronization of the striated, or voluntary, muscles of the pharynx with the smooth, or involuntary, muscle of the esophagus, and this can be a serious problem. Such conditions can now be identified without dif-

ficulty by using combinations of cineradiography, or serial X-rays, and techniques of recording pressure within the interior, or lumen, of the tube.

Low dysphagia, as mentioned previously, refers to the sensation that food, after leaving the pharynx in a normal manner, sticks at a level below the breastbone or sternum. In younger persons the most common cause for this is either a spastic contraction of the esophageal muscle, resulting in difficult forward or downward propulsion for the swallowed food, or a primary failure of the esophageal muscle to provide sufficient pressure to drive the food along. The first of these conditions, known as diffuse esophageal spasm, seems to occur rather commonly, often brought on by rapid eating, emotional disorders, or in response to the reflux of gastric juice back into the lower esophagus. The second, known as achalasia, is brought about when a degenerative process in the nerves to the esophageal muscle causes the entire esophagus to dilate. In the swallowing process, in either case, pain is generated by ineffective attempts to push food along into the stomach through a lower esophageal barrier.

In older persons the sensation of food "sticking" in this area is more often caused by a disease process, frequently a tumour, involving the wall of the esophagus and providing a mechanical rather than a functional obstacle to the passage of food. In all disturbances of this sort, careful study of the esophagus by direct observation through the esophagoscope, by cineradiological and pressure techniques, and by the study of cells removed from the area, is of great help in diagnosis and treatment.

Between the esophagus and the stomach there exists a mechanism that not only opens to allow food to pass through but also closes to serve as a barrier against the reflux of the stomach contents back into the lower esophagus. The pressure exerted upon the gastric contents by stomach contractions is frequently augmented by the action of the abdominal muscles, as during defecation or sneezing, bending over and lifting, or suddenly assuming the horizontal position. Pressure in the chest can be abruptly lowered during forced inspiration. Thus the pressure gradient across the esophagogastric junction may be very great; when it is, it favours the flow of stomach contents back into the esophagus. Acid gastric juice produces abnormal motor behaviour of the esophagus and, often, a burning sensation that seems to travel from the tip of the breastbone up under it toward the neck. This moving sensation is called heartburn and is known medically as gastroesophageal reflux.

Although gastroesophageal reflux has been the subject of much research in recent years, all of its features are not yet completely understood, nor are details of the normal mechanisms that prevent it. Some of these mechanisms are: a normal pressure barrier exerted by the lower 2–3 centimetres of esophagus, an intra-abdominal segment of esophagus that is compressed by increased intra-abdominal pressures, an angle of entry (of the esophagus into the stomach) that permits the stomach mucous membrane to fold back over its opening as a kind of valve, and a normal gastric motor function that prevents the contents of the stomach from accumulating and distending its walls. When reflux does occur, and it is probable that nearly every normal person suffers from it occasionally, little harm is done if the esophagus contracts and pushes the refluxing juice back into the stomach quickly.

When reflux is frequent, however, and the esophagus cannot rid itself easily of the acid content—because of defects in its motor function or abnormalities such as herniation of the stomach through the diaphragm (hiatus hernia)—an abnormal state that may become chronic is produced. This abnormal state is called peptic esophagitis. The mucous membrane involved by peptic esophagitis is abnormally fragile and bleeds easily; the hiatus hernia (if present) frequently enlarges with the increasing age of the patient, and with obesity. The fat pad of the abdominal wall acts as a wedge elevating intragastric pressure when the patient strains or bends over. When medical treatment fails to control the factors making up this complex, surgery may be required.

heartburn

Peptic  
esophagitis

Disorders  
related to  
chewing

Symptoms related to the stomach. The stomach movements are in a rolling and wringing pattern, beginning about one-third of the way down the length of the organ, and propel the mixture of food and juices toward its outlet, the pylorus. Any disorder that affects the power or coordination of the stomach muscles is capable of producing symptoms ranging from those that are mildly unpleasant to others that are incompatible with life. The unpleasant sensations called anorexia and nausea seem to be mediated through the central nervous system, with reflex input from nerve endings in the stomach and duodenum. Sometimes the entire duration of a nausea-vomiting episode is so short that it appears to be vomiting alone, obscuring the presence of nausea. This is characteristically noted in persons with primary diseases of the brain, especially those with tumours or meningitis in which the cerebrospinal fluid is under increased pressure. In many diseases vomiting may not be preceded by nausea at all, and in others there may be a long time lag between nausea and vomiting. Seasickness is the paradigm of this relationship.

The stomach muscles are innervated by branches of the vagus nerve, travelling all the way down the esophagus from their point of emergence in the brainstem. Cutting these nerves, as is often done in surgical treatment of peptic ulcer, may produce temporary or more prolonged changes in the ability of the stomach to empty itself. Many drugs, particularly the anticholinergic medications, are often used in the treatment of peptic ulcer. Anticholinergic drugs exert an action comparable to that produced by cutting the vagus; *i.e.*, they block the impulses from nerves to muscles in the stomach wall, with resultant slowed gastric emptying, sometimes to the point of complete inability to empty. Certain diseases, in particular diabetes mellitus, are associated with degeneration of the nervous fibres in the stomach, and consequently with impairment of the stomach's emptying powers.

These conditions, as well as those diseases that actually produce obstruction to the outflow tract of the stomach, may all result in gastric retention. Thus ulcers of the antrum, or distal portion of the stomach, characteristically obstruct gastric emptying, as do tumours infiltrating the walls and duodenal ulcers just outside the pylorus or in the pyloric channel. In such circumstances the stomach fills up with fluid of its own production, as well as with partially digested food, and vomiting often occurs. The sequel of persistent vomiting is dehydration, and death ultimately will ensue if the condition is not corrected. Persons who vomit frequently lose not only water but also such electrolytes as potassium, deficit of which markedly interferes with the ability of muscles to contract and of the kidneys and heart to function normally. The ingestion of soluble alkali, or "antacid," drugs in this situation produces profound disturbances in the acid-base defenses of the body.

Secretory disturbances of the stomach by themselves rarely produce symptoms. Any human population may be classified into component groups by the relative ability of these components to secrete hydrochloric acid or pepsin. It cannot be stated categorically that those who produce the most acid have symptoms as a result, any more than the reverse can be implied. What can be stated, however, is that duodenal ulcer occurs more often in those who produce the higher amounts of acid, but such occurrence is not determined only by the quantity of acid produced. A substance called "intrinsic factor" is secreted by the gastric cells and is necessary for the absorption of vitamin B<sub>12</sub> from food, but only a tiny amount of this factor is needed to ensure such absorption. Some immunologic block to its action is usually found in those persons suffering from pernicious, or B<sub>12</sub> deficient, anemia. The stomach also secretes a hormone called gastrin, a powerful stimulus to the secretion of acid by the parietal cells of the gastric wall. The interaction of this hormone with histamine and acetylcholine, both found in the stomach wall, is a complex system for regulating the stopping, starting, and amounts of acid-peptic secretion.

The notion of "indigestion" and of its relationship to

foods, habits, or the daily problems of living is highly imprecise in most circumstances. In children specific reactions to certain nutrients may occur, and it is possible to demonstrate that such reactions may be due to allergy. Almost every adult knows that certain foods or beverages will give him some kind of digestive tract disturbance, usually not disabling, but nevertheless unpleasant. These offending agents, furthermore, usually will give him more trouble when he is tense, frightened, tired, or otherwise ill, than when he is well and relaxed. On occasion the unpleasant reaction may be explosive and potentially fatal, as with giant hives, bleeding into the gut, or acute swelling of the pharynx or larynx. Unpleasant gastrointestinal symptoms are the most common adverse reactions to therapeutic agents and, when they occur, seriously limit the usefulness of the drugs. The mechanism by which such reactions are produced is poorly understood, and it may be more dependent on characteristics of the user than upon the drug itself. The interaction between the brain and the gastrointestinal tract has been well demonstrated, and many disturbances of gut function are closely dependent upon the "set" of the central nervous system. Such rare but profound psychiatric disorders as anorexia nervosa (psychotic loss of appetite) can often kill patients through starvation and incessant vomiting.

For many individuals the presence of gas provokes great distress. In the stomach there is always some air as a result of swallowing. The constant passage of air from the mouth into the esophagus and the stomach (and the reverse) is a form of nervous tic in some highly neurotic persons, but occasional belching is engaged in by everyone. The drinking of carbonated beverages influences the ease with which gas can be belched, but the total volume of gas in the stomach, like the total volume of acid gastric juice, is not correlated with symptoms. Some persons carry large gastric air bubbles without discomfort; others have difficulty even when only a little is present.

The small intestine. This longest portion of the gastrointestinal tract is primarily responsible for the absorption of foodstuffs. It is exquisitely designed to advance the chyme received from the stomach, admix it with digestive enzymes from the pancreas and the constituents of the bile, and then keep this mixture churning in small squirt-like movements until the necessary nutrients have been extracted from it.

When the coordination of the inner circular and outer longitudinal muscular layers of the intestinal wall is impaired, there is usually an accumulation of excess contents in the lumen, with consequent distention of the wall. This distention may cause pain, and it usually results in hyperactive contractions of the normal segment next to the disturbed loop. Such contractions may be strenuous enough to produce severe pain, which is characteristically crampy; *i.e.*, occurring in cycles with relatively normal pain-free intervals interspersed among the painful ones. When a large portion of the gut is irritated by an infection—as in viral gastroenteritis—such crampy pain may be generalized throughout the abdomen, but usually small bowel pain tends to be "located" by the brain as in the midline, either at the level of the navel, or slightly above or below it. The brain does not "see" sensation from the small bowel as either left or right until some infection or adhesion of the peritoneal membrane makes the external covering of the organ fix itself to the abdominal wall, from which the somatic nerves can determine its position.

The most serious problems in the area of small intestinal motor disturbances arise from intestinal obstruction, which, in turn, can result from an actual encroachment on the bowel by an adhesive band, or an internal block produced by a tumour or gallstone. Just as profound an obstruction results when a portion of the intestine undergoes partial necrosis, or death, from failure of its blood supply. This necrotic section cannot pass peristaltic activity and, for all practical purposes, is serving as an obstruction. The death of the tissue, furthermore, results in the escape of highly toxic fluids from the intestinal contents, through the wall, producing peritonitis. Surgical

"Indigestion"

Motor disturbances

Secretory disturbances

correction of all these types of obstruction is usually necessary early in the course of the illness.

The speed with which material is passed along the small bowel is increased by many factors, including the swallowing of air, the nature of foods—which may be physically very cold or highly spiced—and most importantly by emotions. The upright position during physical activity, on the other hand, causes the small bowel to swing about on its mesenteric root, so that merely assuming the horizontal position will often markedly slow intestinal motor activity.

Absorptive  
distur-  
bances

For proper absorption of nutrients, coordination of motor and digestive activities is necessary. Of the mixture of fats, proteins, carbohydrates, minerals, and vitamins that are ingested, it appears that fat, generally, is most subject to malabsorption when conditions become unfavourable. Measurements of fat absorption, consequently, have been used for some time as an index of general intestinal malabsorption. The solubilizing of fats is prerequisite to their absorption and requires certain optimum conditions for the action of bile salts, phospholipids, and the enzyme lipase from the pancreas. Normal motor function must be present so that these materials can be aggressively and continuously mixed. The cells lining the intestine must be normal, and contact between them and the mixture to be absorbed must be long enough to permit the lipids to leave the intestine and be carried into the cells. Pathways leading from these cells into the lymph channels and blood vessels of the body must be unobstructed. Under normal circumstances a gross excess of fat can be ingested without appearing in the stool, but if any of the aforementioned necessary conditions cannot be met, it will show up in the stool, either as visible fat or in a form detectable only on chemical analysis, depending upon the amount of fat ingested.

A dramatic example of the interrelation of motor and absorptive defects is shown by persons who are deficient in lactase, the enzyme that splits lactose (milk sugar) into glucose and galactose, its two component hexoses. Shortly after drinking milk, lactase-deficient persons usually have severe intestinal cramping, followed later by watery diarrhea. What has happened is that the lactose in the milk is not broken down and stays in the gut, drawing water to it osmotically. This increased bulk of fluid and sugar distends the intestine, which then contracts actively. The rapid contractions become crampy, and the material is driven along the intestine into the colon, which cannot absorb all the water rapidly enough. The resulting watery, unformed stools are frequently acidic.

Diagnosis of disturbances of small intestinal function is made primarily from the patient's history, physical examination, X-ray films of the abdomen, and by the study of the stools under controlled dietary conditions. Some test substances can be administered and their recovery measured in the stools and in the blood. Instruments are available that can be passed into the intestine to secure sections of intestinal mucous membrane for biopsy. Special methods of studying this material have been most helpful in furthering the knowledge of disorders of absorption. Motor aspects of the intestine can be studied rather grossly by measuring "transit times" after giving X-ray contrast material, or more precisely by the use of pressure monitoring through intubing tubes. Recently, a new method for motor and pressure monitoring has been developed, involving the use of "radio pills"—tiny, encapsulated transmitters that, after being swallowed, send the information in the form of electronic signals. The capsules are ultimately eliminated in the stool.

**The large intestine.** The colon begins in the right lower quadrant of the abdomen, rises along the right side, crosses the entire abdomen, and descends along the left flank and hip bone into the pelvis, where it is called first the sigmoid (S-shaped) colon and then the rectum, or straight colon. It is a large organ with an extensive surface area and relatively sluggish muscular activity. Its functions are to absorb water from the material ejected into it by the small intestine and to prepare this material for excretion as feces. It has a nervous supply that is com-

plex but, unlike that of the small intestine, sufficiently extensive to allow the brain to perceive whether motor function disturbances are to the left or right, at midline, or in the pelvis. The brain becomes increasingly more precise in appreciating what is going on within the large intestine as the latter approaches its terminus at the anal skin. This is necessary if voluntary control over defecation (continence of feces) is to be learned. It may take small children a long time to acquire this degree of learned control, and disease can cause an adult to lose it in a short period of time.

The kinds of foods eaten and general habit patterns in toilet training may be responsible for rather wide variations in the frequency of stools passed, or "bowel movements." The frequency may range, for 95 percent of all healthy persons in the Western world, from three a day to three a week. Five percent of the population, on the other hand, have stool habits that may differ markedly from this, and they suffer no ill effects as a consequence. The average stool, of mixed Western diets, weighs under 150 grams and is about 70 percent water, although it appears solid. A slight increase in the water content may easily cause it to fragment into unformed fecal matter.

The frequent passage of unformed watery stools is referred to as diarrhea. Water is normally absorbed from the colonic content, principally in the ascending, or right, colon. Thus, any inflammatory, neoplastic, or vascular disturbance of that part of the colon will usually decrease the firmness of the stool, increase its 24-hour total weight, and often produce blood or other evidences of inflammation, apparent when the feces are examined under the microscope. Some parasites, in particular *Entamoeba histolytica*, invade the right colon, and their motile or cyst forms may be identified in the stools. Surgical removal of the right colon for various disorders usually results in loose stools for months, or even years, until some form of adaptive compensation by the colon assists the water-reabsorbing process.

The colon does not show regularly rhythmic progressive peristalsis as does the small intestine, but rather exhibits a series of stationary segmental contractions (haustra) as its principal motor pattern. The purpose of this segmentation is to keep the contents from passing along too rapidly. Within the individual closed compartments thus produced, the material is churned to facilitate the absorption of water from it. As the contents are passed slowly over to the left side of the colon, the segmenting waves become less frequent, and the material is sent by coordinated waves into the pelvic, or sigmoid, colon where it is held up just above the rectum by a strong musculature assemblage. This is the area of the pelvic floor that represents a convergence point of abdominal wall muscles, the muscles of the pelvic floor itself, and thickened muscles of the colon wall. It is in this area that the final molding and ejection of the stool into the upper rectum occurs. The upper rectum is the site for the initiation of the defecation reflex; distending it with a balloon, for example, will call forth many of the reflexes noted to occur in the passage of a normal stool. The reflexes necessary for the completion of the urge to defecate are localized in the upper rectum and extend into the lower spinal cord. Diseases of the nerves, or of the muscles, involved will diminish or abolish the reflex, so that the patient will not be aware of the fullness of his rectum. The very last stronghold for control of the defecatory urge or of continence is the external anal sphincter, a muscular circle just under the anal skin, which is under central (brain) control. A momentary contraction of this ring can serve to inhibit the propulsive force by which the stool enters the rectum, so that it slips back up into the pelvic colon. Damage to this sphincter muscle by disease or surgery obviously reduces its competence.

Gas in the colon normally has a volume of about 100 millilitres. Some is from swallowed air, but some also arises from bacterial action on various substrates present in the colonic lumen. In the dietary intake of a lactase-deficient patient, the unhydrolyzed lactose will enter the colon, where the lactose equivalent of that in a glass of

Diarrhea

milk will be capable of liberating, after bacterial fermentation, the equivalent of two cups (500 millilitres) of gas (hydrogen), about 15 percent of which diffuses back into the blood, and the rest passes as flatus. Although the small intestine normally digests and absorbs most short chain sugars, the longer complex sugars (*e.g.*, those found in beans and some other legumes) escape such action and in the colon are converted by bacteria into other products, with hydrogen gas given off in the process. Gas-fluid mixtures do not provide peristaltic pressure distribution as smoothly as do fluids alone. Gas is also subject to physical laws, and in the upright position it will diffuse to the most superior portions of the colon, at the right and left "corners." Here it can be compressed by contraction of adjacent segments, giving rise to pain that is localized either near the liver and gallbladder, or under the diaphragm and heart. Many a person has been thought to have diseases of these organs when the entire problem was caused by increased gas in the colon. Reduction of air intake by slowing down the rate of food ingestion, decreasing the intake of carbonated beverages and whipped desserts that contain air bubbles, and in avoiding certain gas-producing foods, such as most beans and nuts, usually helps to reduce flatulence.

The "irritable colon syndrome" is a term applied to periodic episodes of abdominal pain radiating from the colon, associated with the passage of small stools—sometimes loose or diarrheal but more often hard and pellet-like. The triggering mechanism for this disturbance appears to be an unrelaxed sigmoid colon. The pain can be very severe, and the disorder is primarily related to nervous tension, fatigue, or occasionally to a recent bacterial or viral infection of the intestine.

Constipation

Constipation, the undue delay in passage of feces, may result from failures at any point in the sequence of events described earlier. The most common forms of this disorder, which rarely occur in primitive civilizations, are the irritable colon syndrome, in which the rectum is usually free of feces, and various forms of sensory or motor failure in the colon-rectal segment. Some individuals' senses may be dulled by brain disease, metabolic failure, or by drugs—they simply do not appreciate the normal signals arriving in their brains to inform them that the lower colon is full of stool that needs expelling. Other persons, quite aware of the defecation urge, cannot mobilize the effective pressures needed to empty their colons, due to poor abdominal musculature or to a poor pelvic floor, sometimes the result of surgery or childbirth. Some persons are apathetic, eat irregularly and with no gusto, drink inadequate fluids, and do not observe regular times to defecate. Differentiation among these many causes can be achieved only by careful study, proper rearrangement of diet, habit patterns, emotional states, and by physical measures. Constant use of laxatives in the past has been a major cause of chronic constipation, but this practice is becoming less frequent.

**Liver, gallbladder, and pancreas.** These complex accessory glands provide essential digestive materials to the gut. Diseases of the liver characteristically produce nausea, and when bile flow is interfered with, the patient usually becomes jaundiced. In some forms of liver disease, itching and fever may be present in varying degrees, along with the jaundice. When bile flow is slowed or stopped under these conditions, the stools become lighter in colour—from light yellow to a silvery gray—and the urine becomes dark with bile. The gallbladder is a muscular hollow sac that normally contracts after a meal containing fat, so as to discharge concentrated bile into the upper intestine. If it is blocked by a gallstone the contractions become more intense and may be very painful. Such pains are called biliary colic. If the gallstone leaves the outlet of the gallbladder and moves into the common bile duct, it may obstruct this larger conduit from the liver and produce obstructive jaundice. Such an obstruction usually is associated with nausea and vomiting; behind the obstruction infection often occurs, accompanied by fever and chills.

The pancreas usually makes its disorders evident by

producing pain, often in the back, or by acute inflammation associated with nausea, vomiting, and sometimes collapse. The digestive functions of the pancreas may be perturbed by pancreatic disease, and this then results in an inadequate delivery of pancreatic enzymes into the intestine. Such pancreatic insufficiency results in the production of large bulky stools and by marked weight loss due to the maldigestion. Digestive enzymes from the pancreas are now available and can be used in substitution therapy for pancreatic insufficiency.

**BIBLIOGRAPHY.** H.W. DAVENPORT, *Physiology of the Digestive Tract*, 3rd ed. (1971), is a lucid, well-illustrated, and critical survey of the most important functions and disorders of the gastrointestinal tract, exclusive of the metabolic functions of the liver. The most complete treatment of the functions of the alimentary tract, including the pancreas, gallbladder, and liver, is the massive five-volume *Handbook of Physiology*, sect. 6, *Alimentary Canal*, ed. by C.F. CODE *et al.* (1966–68).

(A.I.M.)

## Digestion, Human

Digestion, in the human body, is the process of dissolving and chemically breaking down ingested food into simple compounds that are easily absorbed into the body. Digestion occurs chiefly through the actions of enzymes secreted into the alimentary canal and is aided by certain mechanical actions such as chewing and the motor action of the stomach, small intestine, and the large intestine. Thus, the ultimate aim of digestion is to reduce food to relatively simple chemical compounds that go into solution easily so that they can be absorbed by the mucous membrane that lines the alimentary canal.

The three primary activities of the alimentary canal of man are: secretion, motility, and absorption. These activities will be described, in the sections that follow, in some detail as they relate to the process of digestion. It is only after absorption that the various nutriment become available to the organism for assimilation into its own cells for such various metabolic activities as energy production, growth, repair, and conversion into other chemical compounds essential for life processes.

The alimentary canal begins at the mouth and ends at the anus. In between are the pharynx, esophagus, stomach, small intestine (comprised of the duodenum, jejunum, and ileum), large intestine (colon), and rectum (see DIGESTIVE SYSTEM, HUMAN). The contents of the alimentary canal are really external to the body, and it is only after transport across the epithelial lining of the alimentary canal that the chemical end products of digestion become available for use within the body.

In man, as in other animals, special enzymes are required for the digestion of the three principal food sources—carbohydrates, proteins, and fats. The digestion of each of these substances will be considered in the various parts of the alimentary canal of man. Minerals and vitamins, also essential for life, are absorbed directly in the form of soluble compounds.

### DIGESTION IN THE MOUTH

Little digestion of food takes place in the mouth. Important mechanical and other events, however, usually do occur, and these prepare food for transport through the upper alimentary canal and thus aid the digestive processes in the stomach and small intestine.

**Mechanical activities.** Mastication, or chewing, is the first mechanical process to which food is subjected in the mouth. Movements of the lower jaw in chewing are brought about by the muscles of mastication; these include the masseter, the temporal, the internal and external pterygoid, and the buccinator muscles. In chewing, the lower jaw or mandible may be moved in any one of several directions. A rotational movement of the jaw produces the grinding movements of the molar teeth. This kind of chewing is accomplished by the alternate contractions of the right and left pterygoid muscles.

The sensitivity of the periodontal membrane, rather than the power of the muscles of mastication, limits the force of the bite. In man the force between upper and lower

The alimentary canal

Mastication

molar teeth has been measured to be in excess of 250 pounds. The more sensitive teeth such as the incisors may exert a pressure of 30 to 50 pounds. The act of mastication may be voluntary, but for the most part it is a reflex act. Chewing movements can be elicited by electrical stimulation of appropriate areas of the cerebral cortex of the brain.

Mastication is not essential for adequate digestion and nutritional well-being. Chewing does aid digestion, however, by reducing food to small particles and mixing it with the saliva secreted by the salivary glands. The saliva lubricates and moistens dry food while the chewing distributes the saliva throughout the food mass. The lubrication of the food mass is primarily accomplished by the mucus, also secreted by the salivary glands.

The movements of the tongue against the hard palate and the cheeks help to form a bolus of the food by moistening and mixing the material with saliva. After this intra-oral preparation, the bolus is manoeuvred to a position at the back of the mouth on the upper surface of the tongue. This has been termed the "preparatory position," as the bolus is always manoeuvred to a constant position on the dorsal surface of the tongue just before swallowing.

The first stage of deglutition, or swallowing, consists of passage of material through the oral cavity into the pharynx. This stage of swallowing is initiated voluntarily. The front portion of the tongue is then retracted and depressed, mastication ceases, respiration is inhibited reflexly, and the back portion of the tongue is elevated and retracted against the hard palate. This action, produced by the strong muscles of the tongue, forces the bolus into the pharynx. It has been demonstrated that during the first stage of swallowing negative pressure changes occur in the anterior part of the mouth, near the incisor teeth. In the posterior part positive pressure changes occur, brought about by the forceful contraction of the tongue against the hard and soft palates. Pressures as great as 100 centimetres of water have been recorded in the posterior part of the oral cavity during swallowing.

**Chemical functions.** The composition of saliva is variable, but principally it contains water, the same inorganic ions commonly found in the blood plasma, and a number of organic constituents. The variability of the composition of saliva is accounted for by the fact that the different salivary glands contribute different constituents. In addition, the concentration of many of the common inorganic constituents depends upon the rate of salivary flow.

The amount of saliva secreted by an individual in 24 hours usually amounts to 1,000 to 1,500 millilitres, or, roughly, a quart. This amounts, on the average, to about one millilitre per minute. Although saliva is slightly acid in reaction, the bicarbonates and phosphates contained within it serve as buffers and maintain the pH, or hydrogen ion concentration, of saliva relatively constant under ordinary conditions.

Bicarbonate concentration in saliva rises with increased salivary flow. The concentration of bicarbonate also is directly influenced by the partial pressure of the carbon dioxide in the arterial blood. Thus, with an increased arterial partial pressure of carbon dioxide, concentration of bicarbonate in saliva is increased. The chloride concentration of saliva also shows considerable variation. The total chloride and bicarbonate ratio, however, tends to remain rather constant. Chloride concentration of saliva from different glands may show considerable variation and, in general, there is a direct relationship between the chloride concentration and flow rate. At all flow rates, however, the chloride concentration is below that in blood plasma. At low flow rates the chloride concentration may be as little as five milliequivalents per litre, whereas at high flow rates it may rise to 70 milliequivalents per litre. The salivary glands are capable of secreting bromide and iodide in a manner similar to that of chloride. Sodium concentration in saliva is highly dependent upon flow rate. At low flow rate the concentration may be less than five milliequivalents per litre, whereas at high flow rates it may exceed 100 milliequivalents per litre. The potassium concentration in saliva is

relatively high and exceeds that in the blood plasma. Ordinary mixed saliva usually contains from 8 to 20 milliequivalents per litre of potassium, which is  $1\frac{1}{2}$  to 4 times the concentration in plasma. The concentration of calcium in human saliva, like sodium, also increases with rate of flow. At high flow rates, a concentration of three to four milliequivalents of saliva per litre may be found.

Organic constituents of saliva consist of salivary proteins, free amino acids, lysozyme, specific blood group substances, and amylase. Glucose is normally absent from saliva even in individuals with diabetes. When saliva is subjected to electrophoretic analysis, the main protein band consists of salivary amylase. Amylase is the enzyme that digests starch, breaking it down into its sugar components, maltose and glucose. Digestion in the mouth consists primarily of the action of amylase on starch. There are no enzymes in saliva for the digestion of proteins and fats. The details of starch digestion by amylase, from both the salivary glands and the pancreas, will be described later.

The main functions of saliva are to initiate the digestion of starch and to provide a protective secretion in the mouth to keep the mucous membranes moist. Saliva has many other functions, however, including maintaining oral hygiene, which is accomplished by its solvent and cleansing action. The constant flow of saliva exerts a cleansing effect on the mouth and teeth and keeps the oral cavity and teeth comparatively free from food residues, sloughed epithelial cells, and foreign particles. By removing material that may serve as culture media, saliva inhibits the growth of bacteria. The lysozyme in saliva also serves a protective function, for it has the ability of lysing, or dissolving certain bacteria. Taste is mediated by chemical mechanisms, and in order to be tasted, substances must be in solution for the taste buds to be stimulated. Saliva provides the solvent for the solution of food materials.

The secretion of saliva also provides a mechanism whereby certain organic and inorganic substances can be excreted. A number of drugs and chemical substances are excreted in the saliva when introduced into the body. Examples of such substances include mercury, lead and potassium iodide, morphine, and certain antibiotics; e.g., penicillin, streptomycin, chlortetracycline. Ethyl alcohol is excreted by the salivary glands, and the recommendation has been made that the alcohol content in saliva be used for medicolegal purposes.

Saliva is not essential to life. Its absence, however, results in a number of inconveniences, including dryness of the oral mucous membrane, poor oral hygiene because of bacterial overgrowth, and a greatly diminished sense of taste.

#### DIGESTION IN THE PHARYNX AND ESOPHAGUS

The primary digestive function of the pharynx (throat) and esophagus is to transport swallowed materials from the mouth to the stomach. The pharynx and esophagus have no significant secretory or absorptive functions. Transport of swallowed material through the pharynx constitutes the second stage of deglutition, and transport through the esophagus constitutes the third stage of deglutition.
